Welcome! This is the documentation for IronPython 2.7.4a1, last updated May 10, 2013.

Parts of the documentation:

- What's new in Python 2.7.4? or all "What's new" documents since 2.0
- Tutorial start here
- Using Python how to use Python on different platforms
- Library Reference keep this under your pillow
- Language Reference describes syntax and language elements
- Python HOWTOs in-depth documents on specific topics
- Hosting IronPython hosting, embedding, .NET interop
- Extending IronPython adding new modules, Python specific extending
- Installing Python Modules information for installers & sys-admins
- Distributing Python Modules sharing modules with others
- Documenting Python guide for documentation authors
- FAQs frequently asked questions (with answers!)

Indices and tables:

</table>
handler for CGI scripts.

**chunk**
Module to read IFF chunks.

**cmath**
Mathematical functions for complex numbers.

**cmd**
Build line-oriented command interpreters.

**code**
Facilities to implement read-eval-print loops.

**codecs**
Encode and decode data and streams.

**codeop**
Compile (possibly incomplete) Python code.

**collections**
High-performance datatypes

**colorsys**
Conversion functions between RGB and other color systems.

**compileall**
Tools for byte-compiling all Python source files in a directory tree.

**compiler**
**Deprecated**: Python code compiler written in Python.

**compiler.ast**

**compiler.visitor**

**ConfigParser**
Configuration file parser.

**contextlib**
Utilities for with-statement contexts.

**Cookie**
Support for HTTP state management (cookies).

**cookielib**
Classes for automatic handling of HTTP cookies.

**copy**
Shallow and deep copy operations.

**copy_reg**
Register pickle support functions.

**cPickle**
Faster version of pickle, but not subclassable.
cProfile  
Python profiler

cStringIO  
Faster version of StringIO, but not subclassable.

csv  
Write and read tabular data to and from delimited files.

ctypes  
A foreign function library for Python.

curses (Unix)  
An interface to the curses library, providing portable terminal handling.

curses.ascii  
Constants and set-membership functions for ASCII characters.

curses.panel  
A panel stack extension that adds depth to curses windows.

curses.textpad  
Emacs-like input editing in a curses window.

curses.wrapper  
Terminal configuration wrapper for curses programs.

D

datetime  
Basic date and time types.

dbhash  
DBM-style interface to the BSD database library.

decimal  

difflib  
Helpers for computing differences between objects.

dircache  
Deprecated: Return directory listing, with cache mechanism.

dis  
Disassembler for Python bytecode.

distutils  
Support for building and installing Python modules into
distutils.archive_util Utilities functions for creating archive files (tarballs, zip files, ...)

distutils.bcppcompiler Abstract CCompiler class

distutils.ccompiler Abstract CCompiler class

distutils.cmd This module provides the abstract base class Command. This class is subclassed by the modules in the distutils.command subpackage.

distutils.command This subpackage contains one module for each standard Distutils command.

distutils.command.bdist Build a binary installer for a package

distutils.command.bdist_dumb Build a "dumb" installer - a simple archive of files

distutils.command.bdist_msi Build a binary distribution as a Windows MSI file

distutils.command.bdist_packager Abstract base class for packagers

Build a binary distribution as a Redhat RPM and SRPM

Build a Windows installer

Build all files of a package

Build any C libraries in a package

Build any extensions in a package

Build the .py/.pyc files of a package

Build the scripts of a package
distutils.command.clean  Clean a package build area
distutils.command.config  Perform package configuration
distutils.command.install  Install a package
distutils.command.install_data  Install data files from a package
distutils.command.install_headers  Install C/C++ header files from a package
distutils.command.install_lib  Install library files from a package
distutils.command.install_scripts  Install script files from a package
distutils.command.register  Register a module with the Python Package Index
distutils.command.sdist  Build a source distribution
distutils.core  The core Distutils functionality
distutils.cygwinccompiler  Provides the debug flag for distutils
distutils.dep_util  Utility functions for simple dependency checking
distutils.dir_util  Utility functions for operating on directories and directory trees
distutils.dist  Provides the Distribution class, which represents the module distribution being built/installed/distributed
distutils.emxccompiler  OS/2 EMX Compiler support
distutils.errors  Provides standard distutils exceptions
distutils.extension  Provides the Extension class, used to describe C/C++ extension modules in setup scripts
distutils.fancy_getopt  Additional getopt functionality
distutils.file_util  Utility functions for operating on single files

distutils.filelist  The FileList class, used for poking about the file system and building lists of files.

distutils.log  A simple logging mechanism, 282-style

distutils.msvc.compiler  Microsoft Compiler

distutils.spawn  Provides the spawn() function

distutils.sysconfig  Low-level access to configuration information of the Python interpreter.

distutils.text_file  provides the TextFile class, a simple interface to text files

distutils.unixccompiler  UNIX C Compiler

distutils.util  Miscellaneous other utility functions

distutils.version  implements classes that represent module version numbers.

doctest  Test pieces of code within docstrings.

DocXMLRPCServer  Self-documenting XML-RPC server implementation.

dumbdbm  Portable implementation of the simple DBM interface.

dummy_thread  Drop-in replacement for the thread module.

dummy_threading  Drop-in replacement for the threading module.

dummy_threading  Drop-in replacement for the threading module.

email  Package supporting the parsing, manipulating, and generating email messages, including MIME documents.

<td>Locate and run Python modules without importing them first.</td>
</tr>
</tbody>
</table>
sched
General purpose event scheduler.

select
Wait for I/O completion on multiple streams.

sets
Deprecated: Implementation of sets of unique elements.

sgmlib
Deprecated: Only as much of an SGML parser as needed to parse HTML.

sha
Deprecated: NIST's secure hash algorithm, SHA.

shelve
Python object persistence.

shlex
Simple lexical analysis for Unix shell-like languages.

shutil
High-level file operations, including copying.

signal
Set handlers for asynchronous events.

SimpleHTTPServer
This module provides a basic request handler for HTTP servers.

SimpleXMLRPCServer
Basic XML-RPC server implementation.

site
A standard way to reference site-specific modules.

smtpd
A SMTP server implementation in Python.

smtplib
SMTP protocol client (requires sockets).

sndhdr
Determine type of a sound file.

socket
Low-level networking interface.

SocketServer
A framework for network servers.

sqlite3
A DB-API 2.0 implementation using SQLite 3.x.
ssl
SSL wrapper for socket objects

stat
Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().

statvfs
Deprecated: Constants for interpreting the result of os.statvfs().

string
Common string operations.

StringIO
Read and write strings as if they were files.

stringprep
Deprecated: String preparation, as per RFC 3453

struct
Interpret strings as packed binary data.

subprocess
Subprocess management.

sunau
Provide an interface to the Sun AU sound format.

symbol
Constants representing internal nodes of the parse tree.

symtable
Interface to the compiler's internal symbol tables.

sys
Access system-specific parameters and functions.

sysconfig
Python's configuration information

T

tabnanny
Tool for detecting white space related problems in Python source files in a directory tree.

tarfile
Read and write tar-format archive files.

telnetlib
Telnet client class.

tempfile
Generate temporary files and
directories.
Regression tests package containing the testing suite for Python.
Support for Python regression tests.
Text wrapping and filling
Create multiple threads of control within one interpreter.
Higher-level threading interface.
Time access and conversions.
Measure the execution time of small code snippets.
Constants representing terminal nodes of the parse tree.
Lexical scanner for Python source code.
Trace or track Python statement execution.
Print or retrieve a stack traceback.
Tk themed widget set
Names for built-in types.

</tbody>
</table>
decompression routines compatible with gzip.
This article explains the new features in Python 2.7. Python 2.7 was released on July 7, 2010.

Numeric handling has been improved in many ways, for both floating-point numbers and for the `Decimal` class. There are some useful additions to the standard library, such as a greatly enhanced `unittest` module, the `argparse` module for parsing command-line options, convenient `OrderedDict` and `Counter` classes in the `collections` module, and many other improvements.

Python 2.7 is planned to be the last of the 2.x releases, so we worked on making it a good release for the long term. To help with porting to Python 3, several new features from the Python 3.x series have been included in 2.7.

This article doesn’t attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.7 at [http://docs.python.org](http://docs.python.org). If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature or the issue on [http://bugs.python.org](http://bugs.python.org) in which a change was discussed. Whenever possible, “What’s New in Python” links to the bug/patch item for each change.
The Future for Python 2.x

Python 2.7 is intended to be the last major release in the 2.x series. The Python maintainers are planning to focus their future efforts on the Python 3.x series.

This means that 2.7 will remain in place for a long time, running production systems that have not been ported to Python 3.x. Two consequences of the long-term significance of 2.7 are:

- It's very likely the 2.7 release will have a longer period of maintenance compared to earlier 2.x versions. Python 2.7 will continue to be maintained while the transition to 3.x continues, and the developers are planning to support Python 2.7 with bug-fix releases beyond the typical two years.

- A policy decision was made to silence warnings only of interest to developers. `DeprecationWarning` and its descendants are now ignored unless otherwise requested, preventing users from seeing warnings triggered by an application. This change was also made in the branch that will become Python 3.2. (Discussed on stdlib-sig and carried out in issue 7319.)

In previous releases, `DeprecationWarning` messages were enabled by default, providing Python developers with a clear indication of where their code may break in a future major version of Python.

However, there are increasingly many users of Python-based applications who are not directly involved in the development of those applications. `DeprecationWarning` messages are irrelevant to such users, making them worry about an application that's actually working correctly and burdening application developers with responding to these concerns.
You can re-enable display of `DeprecationWarning` messages by running Python with the `-Wdefault` (short form: `-Wd`) switch, or by setting the `PYTHONWARNINGS` environment variable to "default" (or "d") before running Python. Python code can also re-enable them by calling `warnings.simplefilter('default').`
Much as Python 2.6 incorporated features from Python 3.0, version 2.7 incorporates some of the new features in Python 3.1. The 2.x series continues to provide tools for migrating to the 3.x series.

A partial list of 3.1 features that were backported to 2.7:

- The syntax for set literals (`{1, 2, 3}` is a mutable set).
- Dictionary and set comprehensions (`{i: i*2 for i in range(3)}`).
- Multiple context managers in a single `with` statement.
- A new version of the `io` library, rewritten in C for performance.
- The ordered-dictionary type described in [PEP 372: Adding an Ordered Dictionary to collections](https://www.python.org/dev/peps/pep-0372/).
- The new `,` format specifier described in [PEP 378: Format Specifier for Thousands Separator](https://www.python.org/dev/peps/pep-0378/).
- The `memoryview` object.
- A small subset of the `importlib` module, described below.
- Float-to-string and string-to-float conversions now round their results more correctly, and `repr()` of a floating-point number `x` returns a result that’s guaranteed to round back to the same number when converted back to a string.
- The `PyCapsule` type, used to provide a C API for extension modules.
- The `PyLong_AsLongAndOverflow()` C API function.

Other new Python3-mode warnings include:

- `operator.isCallable()` and `operator.sequenceIncludes()`, which are not supported in 3.x, now trigger warnings.
- The `-3` switch now automatically enables the `-Qwarn` switch that
causes warnings about using classic division with integers and long integers.
PEP 372: Adding an Ordered Dictionary to collections

Regular Python dictionaries iterate over key/value pairs in arbitrary order. Over the years, a number of authors have written alternative implementations that remember the order that the keys were originally inserted. Based on the experiences from those implementations, 2.7 introduces a new `OrderedDict` class in the `collections` module.

The `OrderedDict` API provides the same interface as regular dictionaries but iterates over keys and values in a guaranteed order depending on when a key was first inserted:

```python
>>> from collections import OrderedDict
>>> d = OrderedDict([('first', 1), ...
...                   ('second', 2),
...                   ('third', 3)])
>>> d.items()
[('first', 1), ('second', 2), ('third', 3)]
```

If a new entry overwrites an existing entry, the original insertion position is left unchanged:

```python
>>> d['second'] = 4
>>> d.items()
[('first', 1), ('second', 4), ('third', 3)]
```

Deleting an entry and reinserting it will move it to the end:

```python
>>> del d['second']
>>> d['second'] = 5
>>> d.items()
[('first', 1), ('third', 3), ('second', 5)]
```

The `popitem()` method has an optional `last` argument that defaults to
True. If `last` is True, the most recently added key is returned and removed; if it's False, the oldest key is selected:

```python
>>> od = OrderedDict([(x,0) for x in range(20)])
>>> od.popitem()
(19, 0)
>>> od.popitem()
(18, 0)
>>> od.popitem(last=False)
(0, 0)
>>> od.popitem(last=False)
(1, 0)
```

Comparing two ordered dictionaries checks both the keys and values, and requires that the insertion order was the same:

```python
>>> od1 = OrderedDict([('first', 1), ...
...                     ('second', 2), ...
...                     ('third', 3)])
>>> od2 = OrderedDict([('third', 3), ...
...                     ('first', 1), ...
...                     ('second', 2)])
>>> od1 == od2
False
>>> # Move 'third' key to the end
>>> del od2['third']; od2['third'] = 3
>>> od1 == od2
True
```

Comparing an `OrderedDict` with a regular dictionary ignores the insertion order and just compares the keys and values.

How does the `OrderedDict` work? It maintains a doubly-linked list of keys, appending new keys to the list as they're inserted. A secondary dictionary maps keys to their corresponding list node, so deletion doesn't have to traverse the entire linked list and therefore remains O(1).

The standard library now supports use of ordered dictionaries in several modules.
The `ConfigParser` module uses them by default, meaning that configuration files can now read, modified, and then written back in their original order.

The `_asdict()` method for `collections.namedtuple()` now returns an ordered dictionary with the values appearing in the same order as the underlying tuple indices.

The `json` module's `JSONDecoder` class constructor was extended with an `object_pairs_hook` parameter to allow `OrderedDict` instances to be built by the decoder. Support was also added for third-party tools like `PyYAML`.

**PEP 372 - Adding an ordered dictionary to collections**

PEP written by Armin Ronacher and Raymond Hettinger; implemented by Raymond Hettinger.
To make program output more readable, it can be useful to add separators to large numbers, rendering them as 18,446,744,073,709,551,616 instead of 18446744073709551616.

The fully general solution for doing this is the `locale` module, which can use different separators (",” in North America, “.” in Europe) and different grouping sizes, but `locale` is complicated to use and unsuitable for multi-threaded applications where different threads are producing output for different locales.

Therefore, a simple comma-grouping mechanism has been added to the mini-language used by the `str.format()` method. When formatting a floating-point number, simply include a comma between the width and the precision:

```python
>>> '{:20,.2f}'.format(18446744073709551616.0)
'18,446,744,073,709,551,616.00'
```

When formatting an integer, include the comma after the width:

```python
>>> '{:20,d}'.format(18446744073709551616)
'18,446,744,073,709,551,616'
```

This mechanism is not adaptable at all; commas are always used as the separator and the grouping is always into three-digit groups. The comma-formatting mechanism isn't as general as the `locale` module, but it's easier to use.

See also:

**PEP 378 - Format Specifier for Thousands Separator**
PEP written by Raymond Hettinger; implemented by Eric Smith.
PEP 389: The argparse Module for Parsing Command Lines

The `argparse` module for parsing command-line arguments was added as a more powerful replacement for the `optparse` module.

This means Python now supports three different modules for parsing command-line arguments: `getopt`, `optparse`, and `argparse`. The `getopt` module closely resembles the C library's `getopt()` function, so it remains useful if you're writing a Python prototype that will eventually be rewritten in C. `optparse` becomes redundant, but there are no plans to remove it because there are many scripts still using it, and there's no automated way to update these scripts. (Making the `argparse` API consistent with `optparse`'s interface was discussed but rejected as too messy and difficult.)

In short, if you're writing a new script and don't need to worry about compatibility with earlier versions of Python, use `argparse` instead of `optparse`.

Here's an example:

```python
import argparse

parser = argparse.ArgumentParser(description='Command-line example.'

# Add optional switches
parser.add_argument('-v', action='store_true', dest='is_verbose', help='produce verbose output')
parser.add_argument('-o', action='store', dest='output', metavar='FILE', help='direct output to FILE instead of stdout')
parser.add_argument('-C', action='store', type=int, dest='context', metavar='NUM', default=0, help='display NUM lines of added context')
```
# Allow any number of additional arguments.
parser.add_argument(nargs='*', action='store', dest='inputs',
    help='input filenames (default is stdin)')

args = parser.parse_args()
print args.__dict__

Unless you override it, -h and --help switches are automatically added, and produce neatly formatted output:

-> ./python.exe argparse-example.py --help
usage: argparse-example.py [-h] [-v] [-o FILE] [-C NUM] [inputs

Command-line example.

positional arguments:
    inputs    input filenames (default is stdin)

optional arguments:
    -h, --help  show this help message and exit
    -v          produce verbose output
    -o FILE    direct output to FILE instead of stdout
    -C NUM     display NUM lines of added context

As with optparse, the command-line switches and arguments are returned as an object with attributes named by the dest parameters:

-> ./python.exe argparse-example.py -v
{'output': None,
 'is_verbose': True,
 'context': 0,
 'inputs': []}

-> ./python.exe argparse-example.py -v -o /tmp/output -C 4 file1 file2
{'output': '/tmp/output',
 'is_verbose': True,
 'context': 4,
 'inputs': ['file1', 'file2']}

argparse has much fancier validation than optparse; you can specify
an exact number of arguments as an integer, 0 or more arguments by passing '***', 1 or more by passing '+', or an optional argument with '?'. A top-level parser can contain sub-parsers to define subcommands that have different sets of switches, as in `svn commit`, `svn checkout`, etc. You can specify an argument's type as `FileType`, which will automatically open files for you and understands that '-' means standard input or output.

Upgrading optparse code
   Part of the Python documentation, describing how to convert code that uses optparse.

PEP 389 - argparse - New Command Line Parsing Module
   PEP written and implemented by Steven Bethard.
The `logging` module is very flexible; applications can define a tree of logging subsystems, and each logger in this tree can filter out certain messages, format them differently, and direct messages to a varying number of handlers.

All this flexibility can require a lot of configuration. You can write Python statements to create objects and set their properties, but a complex set-up requires verbose but boring code. `logging` also supports a `fileConfig()` function that parses a file, but the file format doesn't support configuring filters, and it's messier to generate programmatically.

Python 2.7 adds a `dictConfig()` function that uses a dictionary to configure logging. There are many ways to produce a dictionary from different sources: construct one with code; parse a file containing JSON; or use a YAML parsing library if one is installed. For more information see `Configuration functions`.

The following example configures two loggers, the root logger and a logger named “network”. Messages sent to the root logger will be sent to the system log using the syslog protocol, and messages to the “network” logger will be written to a `network.log` file that will be rotated once the log reaches 1MB.

```python
import logging
import logging.config

cfgdict = {
    'version': 1,  # Configuration schema in use; must be 1 for 'formatters': {
        'standard': {
            'format': ('%(asctime)s (%(name)-15s) %s
```
Three smaller enhancements to the `logging` module, all implemented by Vinay Sajip, are:

- The `SysLogHandler` class now supports syslogging over TCP. The constructor has a `socktype` parameter giving the type of socket to use, either `socket.SOCK_DGRAM` for UDP or `socket.SOCK_STREAM` for TCP. The default protocol remains UDP.
- `Logger` instances gained a `getChild()` method that retrieves a
descendant logger using a relative path. For example, once you retrieve a logger by doing `log = getLogger('app')`, calling `log.getChild('network.listen')` is equivalent to `getLogger('app.network.listen')`.

- The `LoggerAdapter` class gained a `isEnabledFor()` method that takes a `level` and returns whether the underlying logger would process a message of that level of importance.

See also:

**PEP 391 - Dictionary-Based Configuration For Logging**

PEP written and implemented by Vinay Sajip.
The dictionary methods `keys()`, `values()`, and `items()` are different in Python 3.x. They return an object called a view instead of a fully materialized list.

It's not possible to change the return values of `keys()`, `values()`, and `items()` in Python 2.7 because too much code would break. Instead the 3.x versions were added under the new names `viewkeys()`, `viewvalues()`, and `viewitems()`.

```python
>>> d = dict((i*10, chr(65+i)) for i in range(26))
>>> d
>>> d.viewkeys()
dict_keys([0, 130, 10, 140, 20, 150, 30, '... ', 250])
```

Views can be iterated over, but the key and item views also behave like sets. The `&` operator performs intersection, and `|` performs a union:

```python
>>> d1 = dict((i*10, chr(65+i)) for i in range(26))
>>> d2 = dict((i**.5, i) for i in range(1000))
>>> d1.viewkeys() & d2.viewkeys()
set([0.0, 10.0, 20.0, 30.0])
>>> d1.viewkeys() | range(0, 30)
set([0, 1, 130, 3, 4, 5, 6, '... ', 120, 250])
```

The view keeps track of the dictionary and its contents change as the dictionary is modified:

```python
>>> vk = d.viewkeys()
>>> vk
dict_keys([0, 130, 10, '... ', 250])
>>> d[260] = '&'
>>> vk
dict_keys([0, 130, 260, 10, '... ', 250])
```
However, note that you can’t add or remove keys while you’re iterating over the view:

```python
>>> for k in vk:
    ...    d[k*2] = k
... 
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
RuntimeError: dictionary changed size during iteration
```

You can use the view methods in Python 2.x code, and the 2to3 converter will change them to the standard `keys()`, `values()`, and `items()` methods.

**See also:**

**PEP 3106 - Revamping dict.keys(), .values() and .items()**

PEP written by Guido van Rossum. Backported to 2.7 by Alexandre Vassalotti; issue 1967.
The `memoryview` object provides a view of another object's memory content that matches the `bytes` type's interface.

```python
>>> import string
>>> m = memoryview(string.letters)
>>> m
<memory at 0x37f850>
>>> len(m)  # Returns length of underlying object
52
>>> m[0], m[25], m[26]  # Indexing returns one byte
('a', 'z', 'A')
>>> m2 = m[0:26]  # Slicing returns another memoryview
>>> m2
<memory at 0x37f080>
```

The content of the view can be converted to a string of bytes or a list of integers:

```python
>>> m2.tobytes()
'abcdefghijklmnopqrstuvwxyz'
>>> m2.tolist()
[97, 98, 99, 100, 101, 102, 103, ... 121, 122]
```

`memoryview` objects allow modifying the underlying object if it's a mutable object.

```python
>>> m2[0] = 75
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: cannot modify read-only memory
>>> b = bytearray(string.letters)  # Creating a mutable object
>>> b
bytearray(b'abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ')
>>> mb = memoryview(b)
>>> mb[0] = '*'  # Assign to view, changing the bytearray
>>> b[0:5]  # The bytearray has been changed.
bytearray(b'*bcde')
```
See also:

**PEP 3137 - Immutable Bytes and Mutable Buffer**

PEP written by Guido van Rossum. Implemented by Travis Oliphant, Antoine Pitrou and others. Backported to 2.7 by Antoine Pitrou; issue 2396.
Other Language Changes

Some smaller changes made to the core Python language are:

- The syntax for set literals has been backported from Python 3.x. Curly brackets are used to surround the contents of the resulting mutable set; set literals are distinguished from dictionaries by not containing colons and values. `{}` continues to represent an empty dictionary; use `set()` for an empty set.

```
>>> {1, 2, 3, 4, 5}
set([1, 2, 3, 4, 5])
>>> set()  # empty set
set([])
>>> {}  # empty dict
{}
```

Backported by Alexandre Vassalotti; issue 2335.

- Dictionary and set comprehensions are another feature backported from 3.x, generalizing list/generator comprehensions to use the literal syntax for sets and dictionaries.

```
>>> {x: x*x for x in range(6)}
{0: 0, 1: 1, 2: 4, 3: 9, 4: 16, 5: 25}
>>> {'a'*x for x in range(6)}
set(['', 'a', 'aa', 'aaa', 'aaaa', 'aaaaa'])
```

Backported by Alexandre Vassalotti; issue 2333.

- The `with` statement can now use multiple context managers in one statement. Context managers are processed from left to right and each one is treated as beginning a new `with` statement. This means that:

```
with A() as a, B() as b:
```
is equivalent to:

```python
with A() as a:
    with B() as b:
        ... suite of statements ...
```

The `contextlib.nested()` function provides a very similar function, so it’s no longer necessary and has been deprecated.

(Proposed in [http://codereview.appspot.com/53094](http://codereview.appspot.com/53094); implemented by Georg Brandl.)

- Conversions between floating-point numbers and strings are now correctly rounded on most platforms. These conversions occur in many different places: `str()` on floats and complex numbers; the `float` and `complex` constructors; numeric formatting; serializing and deserializing floats and complex numbers using the `marshal`, `pickle` and `json` modules; parsing of float and imaginary literals in Python code; and `Decimal`-to-float conversion.

Related to this, the `repr()` of a floating-point number \( x \) now returns a result based on the shortest decimal string that’s guaranteed to round back to \( x \) under correct rounding (with round-half-to-even rounding mode). Previously it gave a string based on rounding \( x \) to 17 decimal digits.

The rounding library responsible for this improvement works on Windows and on Unix platforms using the gcc, icc, or suncc compilers. There may be a small number of platforms where correct operation of this code cannot be guaranteed, so the code is not used on such systems. You can find out which code is being used by checking `sys.float_repr_style`, which will be
if the new code is in use and legacy if it isn’t.

Implemented by Eric Smith and Mark Dickinson, using David Gay’s dtoa.c library; issue 7117.

- Conversions from long integers and regular integers to floating point now round differently, returning the floating-point number closest to the number. This doesn't matter for small integers that can be converted exactly, but for large numbers that will unavoidably lose precision, Python 2.7 now approximates more closely. For example, Python 2.6 computed the following:

```python
>>> n = 295147905179352891391
>>> float(n)
2.9514790517935283e+20
>>> n - long(float(n))
65535L
```

Python 2.7’s floating-point result is larger, but much closer to the true value:

```python
>>> n = 295147905179352891391
>>> float(n)
2.9514790517935289e+20
>>> n - long(float(n))
-1L
```

(Implemented by Mark Dickinson; issue 3166.)

Integer division is also more accurate in its rounding behaviours. (Also implemented by Mark Dickinson; issue 1811.)

- Implicit coercion for complex numbers has been removed; the interpreter will no longer ever attempt to call a __coerce__() method on complex objects. (Removed by Meador Inge and Mark Dickinson; issue 5211.)

- The str.format() method now supports automatic numbering of
the replacement fields. This makes using \texttt{str.format()} more closely resemble using \texttt{\%s} formatting:

\begin{verbatim}
>>> '{}:{}'.format(2009, 04, 'Sunday')
'2009:4:Sunday'
>>> '{}:{}'.format(2009, 4, day='Sunday')
'2009:4:Sunday'
\end{verbatim}

The auto-numbering takes the fields from left to right, so the first \{...\} specifier will use the first argument to \texttt{str.format()}, the next specifier will use the next argument, and so on. You can’t mix auto-numbering and explicit numbering – either number all of your specifier fields or none of them – but you can mix auto-numbering and named fields, as in the second example above. (Contributed by Eric Smith; \texttt{issue 5237}.)

Complex numbers now correctly support usage with \texttt{format()}, and default to being right-aligned. Specifying a precision or comma-separation applies to both the real and imaginary parts of the number, but a specified field width and alignment is applied to the whole of the resulting 1.5\texttt{+3j} output. (Contributed by Eric Smith; \texttt{issue 1588} and \texttt{issue 7988}.)

The ‘F’ format code now always formats its output using uppercase characters, so it will now produce ‘INF’ and ‘NAN’. (Contributed by Eric Smith; \texttt{issue 3382}.)

A low-level change: the \texttt{object.__format__()} method now triggers a \texttt{PendingDeprecationWarning} if it’s passed a format string, because the \texttt{__format__()} method for \texttt{object} converts the object to a string representation and formats that. Previously the method silently applied the format string to the string representation, but that could hide mistakes in Python code. If you’re supplying formatting information such as an alignment or precision, presumably you’re expecting the formatting to be
applied in some object-specific way. (Fixed by Eric Smith; issue 7994.)

- The `int()` and `long()` types gained a `bit_length` method that returns the number of bits necessary to represent its argument in binary:

```python
>>> n = 37
>>> bin(n)
'0b100101'
>>> n.bit_length()
6
>>> n = 2**123-1
>>> n.bit_length()
123
>>> (n+1).bit_length()
124
```

(Contributed by Fredrik Johansson and Victor Stinner; issue 3439.)

- The `import` statement will no longer try a relative import if an absolute import (e.g. `from .os import sep`) fails. This fixes a bug, but could possibly break certain `import` statements that were only working by accident. (Fixed by Meador Inge; issue 7902.)

- It's now possible for a subclass of the built-in `unicode` type to override the `__unicode__()` method. (Implemented by Victor Stinner; issue 1583863.)

- The `bytearray` type's `translate()` method now accepts `None` as its first argument. (Fixed by Georg Brandl; issue 4759.)

- When using `@classmethod` and `@staticmethod` to wrap methods as class or static methods, the wrapper object now exposes the wrapped function as their `__func__` attribute. (Contributed by
Amaury Forgeot d'Arc, after a suggestion by George Sakkis; issue 5982.)

- When a restricted set of attributes were set using `__slots__`, deleting an unset attribute would not raise `AttributeError` as you would expect. Fixed by Benjamin Peterson; issue 7604.)

- Two new encodings are now supported: “cp720”, used primarily for Arabic text; and “cp858”, a variant of CP 850 that adds the euro symbol. (CP720 contributed by Alexander Belchenko and Amaury Forgeot d'Arc in issue 1616979; CP858 contributed by Tim Hatch in issue 8016.)

- The `file` object will now set the `filename` attribute on the `IOError` exception when trying to open a directory on POSIX platforms (noted by Jan Kaliszewski; issue 4764), and now explicitly checks for and forbids writing to read-only file objects instead of trusting the C library to catch and report the error (fixed by Stefan Krah; issue 5677).

- The Python tokenizer now translates line endings itself, so the `compile()` built-in function now accepts code using any line-ending convention. Additionally, it no longer requires that the code end in a newline.

- Extra parentheses in function definitions are illegal in Python 3.x, meaning that you get a syntax error from `def f((x)): pass`. In Python3-warning mode, Python 2.7 will now warn about this odd usage. (Noted by James Lingard; issue 7362.)

- It’s now possible to create weak references to old-style class objects. New-style classes were always weak-referenceable. (Fixed by Antoine Pitrou; issue 8268.)

- When a module object is garbage-collected, the module's
dictionary is now only cleared if no one else is holding a reference to the dictionary (issue 7140).

**Interpreter Changes**

A new environment variable, `PYTHONWARNINGS`, allows controlling warnings. It should be set to a string containing warning settings, equivalent to those used with the `-W` switch, separated by commas. (Contributed by Brian Curtin; issue 7301.)

For example, the following setting will print warnings every time they occur, but turn warnings from the `Cookie` module into an error. (The exact syntax for setting an environment variable varies across operating systems and shells.)

```bash
export PYTHONWARNINGS=all,error:::Cookie:0
```

**Optimizations**

Several performance enhancements have been added:

- A new opcode was added to perform the initial setup for `with` statements, looking up the `__enter__()` and `__exit__()` methods. (Contributed by Benjamin Peterson.)

- The garbage collector now performs better for one common usage pattern: when many objects are being allocated without deallocating any of them. This would previously take quadratic time for garbage collection, but now the number of full garbage collections is reduced as the number of objects on the heap grows. The new logic only performs a full garbage collection pass when the middle generation has been collected 10 times and when the number of survivor objects from the middle generation exceeds 10% of the number of objects in the oldest
The garbage collector tries to avoid tracking simple containers which can't be part of a cycle. In Python 2.7, this is now true for tuples and dicts containing atomic types (such as ints, strings, etc.). Transitively, a dict containing tuples of atomic types won't be tracked either. This helps reduce the cost of each garbage collection by decreasing the number of objects to be considered and traversed by the collector. (Contributed by Antoine Pitrou; issue 4688.)

Long integers are now stored internally either in base 2**15 or in base 2**30, the base being determined at build time. Previously, they were always stored in base 2**15. Using base 2**30 gives significant performance improvements on 64-bit machines, but benchmark results on 32-bit machines have been mixed. Therefore, the default is to use base 2**30 on 64-bit machines and base 2**15 on 32-bit machines; on Unix, there's a new configure option --enable-big-digits that can be used to override this default.

Apart from the performance improvements this change should be invisible to end users, with one exception: for testing and debugging purposes there's a new structseq sys.long_info that provides information about the internal format, giving the number of bits per digit and the size in bytes of the C type used to store each digit:

```python
>>> import sys
>>> sys.long_info
sys.long_info(bits_per_digit=30, sizeof_digit=4)
```

(Contributed by Mark Dickinson; issue 4258.)

Another set of changes made long objects a few bytes smaller:
2 bytes smaller on 32-bit systems and 6 bytes on 64-bit. (Contributed by Mark Dickinson; issue 5260.)

- The division algorithm for long integers has been made faster by tightening the inner loop, doing shifts instead of multiplications, and fixing an unnecessary extra iteration. Various benchmarks show speedups of between 50% and 150% for long integer divisions and modulo operations. (Contributed by Mark Dickinson; issue 5512.) Bitwise operations are also significantly faster (initial patch by Gregory Smith; issue 1087418).

- The implementation of % checks for the left-side operand being a Python string and special-cases it; this results in a 1-3% performance increase for applications that frequently use % with strings, such as templating libraries. (Implemented by Collin Winter; issue 5176.)

- List comprehensions with an if condition are compiled into faster bytecode. (Patch by Antoine Pitrou, back-ported to 2.7 by Jeffrey Yasskin; issue 4715.)

- Converting an integer or long integer to a decimal string was made faster by special-casing base 10 instead of using a generalized conversion function that supports arbitrary bases. (Patch by Gawain Bolton; issue 6713.)

- The split(), replace(), rindex(), rpartition(), and rsplit() methods of string-like types (strings, Unicode strings, and bytearray objects) now use a fast reverse-search algorithm instead of a character-by-character scan. This is sometimes faster by a factor of 10. (Added by Florent Xicluna; issue 7462 and issue 7622.)

- The pickle and cPickle modules now automatically intern the strings used for attribute names, reducing memory usage of the
objects resulting from unpickling. (Contributed by Jake McGuire; issue 5084.)

- The `cPickle` module now special-cases dictionaries, nearly halving the time required to pickle them. (Contributed by Collin Winter; issue 5670.)
New and Improved Modules

As in every release, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- The `bdb` module's base debugging class `Bdb` gained a feature for skipping modules. The constructor now takes an iterable containing glob-style patterns such as `django.*`; the debugger will not step into stack frames from a module that matches one of these patterns. (Contributed by Maru Newby after a suggestion by Senthil Kumaran; issue 5142.)

- The `binascii` module now supports the buffer API, so it can be used with `memoryview` instances and other similar buffer objects. (Backported from 3.x by Florent Xicluna; issue 7703.)

- Updated module: the `bsddb` module has been updated from 4.7.2devel9 to version 4.8.4 of the `pybsddb` package. The new version features better Python 3.x compatibility, various bug fixes, and adds several new BerkeleyDB flags and methods. (Updated by Jesús Cea Avión; issue 8156. The `pybsddb` changelog can be read at http://hg.jcea.es/pybsddb/file/tip/ChangeLog.)

- The `bz2` module's `BZ2File` now supports the context management protocol, so you can write `with bz2.BZ2File(...) as f:`. (Contributed by Hagen Fürstenau; issue 3860.)

- New class: the `Counter` class in the `collections` module is useful for tallying data. `Counter` instances behave mostly like
dictionaries but return zero for missing keys instead of raising a `KeyError`:

```python
>>> from collections import Counter
>>> c = Counter()
>>> for letter in 'here is a sample of english text':
...     c[letter] += 1
...  
>>> c
Counter({'	': 6, 'e': 5, 's': 3, 'a': 2, 'i': 2, 'h': 2, 'l': 2, 't': 2, 'g': 1, 'f': 1, 'm': 1, 'o': 1, 'n': 1, 'p': 1, 'r': 1, 'x': 1})
>>> c['e']
5
>>> c['z']
0
```

There are three additional `Counter` methods. `most_common()` returns the N most common elements and their counts. `elements()` returns an iterator over the contained elements, repeating each element as many times as its count. `subtract()` takes an iterable and subtracts one for each element instead of adding; if the argument is a dictionary or another `Counter`, the counts are subtracted.

```python
>>> c.most_common(5)
[(' ', 6), ('e', 5), ('s', 3), ('a', 2), ('i', 2)]
>>> c.elements() ->
'a', 'a', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ', 'e', 'e', 'e', 'e', 'e', 'g', 'f', 'i', 'i', 'h', 'h', 'm', 'l', 'l', 'o', 'n', 'p', 's', 's', 's', 'r', 't', 't', 'x'
>>> c['e']
5
>>> c.subtract('very heavy on the letter e')
>>> c['e']  # Count is now lower
-1
```

Contributed by Raymond Hettinger; issue 1696199.
New class: OrderedDict is described in the earlier section PEP 372: Adding an Ordered Dictionary to collections.

New method: The deque data type now has a count() method that returns the number of contained elements equal to the supplied argument \( x \), and a reverse() method that reverses the elements of the deque in-place. deque also exposes its maximum length as the read-only maxlen attribute. (Both features added by Raymond Hettinger.)

The namedtuple class now has an optional rename parameter. If rename is true, field names that are invalid because they've been repeated or aren't legal Python identifiers will be renamed to legal names that are derived from the field's position within the list of fields:

```python
>>> from collections import namedtuple
>>> T = namedtuple('T', ['field1', '$illegal', 'for', 'field2'], rename=True)
>>> T._fields
('field1', '_1', '_2', 'field2')
```

(Added by Raymond Hettinger; issue 1818.)

Finally, the Mapping abstract base class now raises a NotImplemented exception if a mapping is compared to another type that isn’t a Mapping. (Fixed by Daniel Stutzbach; issue 8729.)

- Constructors for the parsing classes in the ConfigParser module now take a allow_no_value parameter, defaulting to false; if true, options without values will be allowed. For example:

```python
>>> import ConfigParser, StringIO
>>> sample_config = ""
... [mysql]
```
...
user = mysql
pid-file = /var/run/mysqld/mysqld.pid
skip-bdb

>>> config = ConfigParser.RawConfigParser(allow_no_value=True)
>>> config.readfp(StringIO.StringIO(sample_config))
>>> config.get('mysqld', 'user')
'mysql'
>>> print config.get('mysqld', 'skip-bdb')
None
>>> print config.get('mysqld', 'unknown')
Traceback (most recent call last):
...
NoOptionError: No option 'unknown' in section: 'mysqld'

(Contributed by Mats Kindahl; issue 7005.)

- Deprecated function: `contextlib.nested()`, which allows handling more than one context manager with a single `with` statement, has been deprecated, because the `with` statement now supports multiple context managers.

- The `cookielib` module now ignores cookies that have an invalid version field, one that doesn’t contain an integer value. (Fixed by John J. Lee; issue 3924.)

- The `copy` module's `deepcopy()` function will now correctly copy bound instance methods. (Implemented by Robert Collins; issue 1515.)

- The `ctypes` module now always converts `None` to a C NULL pointer for arguments declared as pointers. (Changed by Thomas Heller; issue 4606.) The underlying `libffi library` has been updated to version 3.0.9, containing various fixes for different platforms. (Updated by Matthias Klose; issue 8142.)

- New method: the `datetime` module’s `timedelta` class gained a `total_seconds()` method that returns the number of seconds in
the duration. (Contributed by Brian Quinlan; issue 5788.)

- New method: the `Decimal` class gained a `from_float()` class method that performs an exact conversion of a floating-point number to a `Decimal`. This exact conversion strives for the closest decimal approximation to the floating-point representation’s value; the resulting decimal value will therefore still include the inaccuracy, if any. For example, `Decimal.from_float(0.1)` returns `Decimal('0.10000000000000000555111512312578270211815834045410')` (Implemented by Raymond Hettinger; issue 4796.)

Comparing instances of `Decimal` with floating-point numbers now produces sensible results based on the numeric values of the operands. Previously such comparisons would fall back to Python’s default rules for comparing objects, which produced arbitrary results based on their type. Note that you still cannot combine `Decimal` and floating-point in other operations such as addition, since you should be explicitly choosing how to convert between float and `Decimal`. (Fixed by Mark Dickinson; issue 2531.)

The constructor for `Decimal` now accepts floating-point numbers (added by Raymond Hettinger; issue 8257) and non-European Unicode characters such as Arabic-Indic digits (contributed by Mark Dickinson; issue 6595).

Most of the methods of the `Context` class now accept integers as well as `Decimal` instances; the only exceptions are the `canonical()` and `is_canonical()` methods. (Patch by Juan José Conti; issue 7633.)

When using `Decimal` instances with a string’s `format()` method, the default alignment was previously left-alignment. This has
been changed to right-alignment, which is more sensible for numeric types. (Changed by Mark Dickinson; issue 6857.)

Comparisons involving a signaling NaN value (or \texttt{SNAN}) now signal \texttt{InvalidOperation} instead of silently returning a true or false value depending on the comparison operator. Quiet NaN values (or \texttt{NaN}) are now hashable. (Fixed by Mark Dickinson; issue 7279.)

- The \texttt{difflib} module now produces output that is more compatible with modern \texttt{diff/patch} tools through one small change, using a tab character instead of spaces as a separator in the header giving the filename. (Fixed by Anatoly Techtonik; issue 7585.)

- The Distutils \texttt{sdist} command now always regenerates the \texttt{MANIFEST} file, since even if the \texttt{MANIFEST.in} or \texttt{setup.py} files haven’t been modified, the user might have created some new files that should be included. (Fixed by Tarek Ziadé; issue 8688.)

- The \texttt{doctest} module’s \texttt{IGNORE_EXCEPTION_DETAIL} flag will now ignore the name of the module containing the exception being tested. (Patch by Lennart Regebro; issue 7490.)

- The \texttt{email} module’s \texttt{Message} class will now accept a Unicode-valued payload, automatically converting the payload to the encoding specified by \texttt{output_charset}. (Added by R. David Murray; issue 1368247.)

- The \texttt{Fraction} class now accepts a single float or \texttt{Decimal} instance, or two rational numbers, as arguments to its constructor. (Implemented by Mark Dickinson; rationals added in issue 5812, and float/decimal in issue 8294.)
Ordering comparisons (<, <=, >, >=) between fractions and complex numbers now raise a **TypeError**. This fixes an oversight, making the **Fraction** match the other numeric types.

- **New class**: **FTP_TLS** in the **ftplib** module provides secure FTP connections using TLS encapsulation of authentication as well as subsequent control and data transfers. (Contributed by Giampaolo Rodola; issue 2054.)

  The **storbinary()** method for binary uploads can now restart uploads thanks to an added **rest** parameter (patch by Pablo Mouzo; issue 6845.)

- **New class decorator**: **total_ordering()** in the **functools** module takes a class that defines an **__eq__()** method and one of **__lt__()**, **__le__()**, **__gt__()**, or **__ge__()**, and generates the missing comparison methods. Since the **__cmp__()** method is being deprecated in Python 3.x, this decorator makes it easier to define ordered classes. (Added by Raymond Hettinger; issue 5479.)

  New function: **cmp_to_key()** will take an old-style comparison function that expects two arguments and return a new callable that can be used as the **key** parameter to functions such as **sorted()**, **min()** and **max()**, etc. The primary intended use is to help with making code compatible with Python 3.x. (Added by Raymond Hettinger.)

- **New function**: the **gc** module's **is_tracked()** returns true if a given instance is tracked by the garbage collector, false otherwise. (Contributed by Antoine Pitrou; issue 4688.)

- The **gzip** module’s **GzipFile** now supports the context management protocol, so you can write **with**
gzip.GzipFile(...) as f:  (contributed by Hagen Fürstenau; issue 3860), and it now implements the io.BufferedIOBase ABC, so you can wrap it with io.BufferedReader for faster processing (contributed by Nir Aides; issue 7471). It's also now possible to override the modification time recorded in a gzipped file by providing an optional timestamp to the constructor. (Contributed by Jacques Frechet; issue 4272.)

Files in gzip format can be padded with trailing zero bytes; the gzip module will now consume these trailing bytes. (Fixed by Tadek Pietraszek and Brian Curtin; issue 2846.)

- New attribute: the hashlib module now has an **algorithms** attribute containing a tuple naming the supported algorithms. In Python 2.7, hashlib.algorithms contains ('md5', 'sha1', 'sha224', 'sha256', 'sha384', 'sha512'). (Contributed by Carl Chenet; issue 7418.)

- The default HTTPResponse class used by the httplib module now supports buffering, resulting in much faster reading of HTTP responses. (Contributed by Kristján Valur Jónsson; issue 4879.)

The httpclient and HTTPSConnection classes now support a **source_address** parameter, a (host, port) 2-tuple giving the source address that will be used for the connection. (Contributed by Eldon Ziegler; issue 3972.)

- The ihooks module now supports relative imports. Note that ihooks is an older module for customizing imports, superseded by the imputil module added in Python 2.0. (Relative import support added by Neil Schemenauer.)

- The imaplib module now supports IPv6 addresses. (Contributed
New function: the `inspect` module’s `getcallargs()` takes a callable and its positional and keyword arguments, and figures out which of the callable’s parameters will receive each argument, returning a dictionary mapping argument names to their values. For example:

```python
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...    pass
>>> getcallargs(f, 1, 2, 3)
{'a': 1, 'b': 2, 'pos': (3,), 'named':{}}
>>> getcallargs(f, a=2, x=4)
{'a': 2, 'b': 1, 'pos': (), 'named': {'x': 4}}
>>> getcallargs(f)
Traceback (most recent call last):
...  TypeError: f() takes at least 1 argument (0 given)
```

Contributed by George Sakkis; issue 3135.

Updated module: The `io` library has been upgraded to the version shipped with Python 3.1. For 3.1, the I/O library was entirely rewritten in C and is 2 to 20 times faster depending on the task being performed. The original Python version was renamed to the `_pyio` module.

One minor resulting change: the `io.TextIOBase` class now has an `errors` attribute giving the error setting used for encoding and decoding errors (one of `'strict'`, `'replace'`, `'ignore'`).

The `io.FileIO` class now raises an `OSError` when passed an invalid file descriptor. (Implemented by Benjamin Peterson; issue 4991.) The `truncate()` method now preserves the file position; previously it would change the file position to the end of the new file. (Fixed by Pascal Chambon; issue 6939.)
• New function: `itertools.compress(data, selectors)` takes two iterators. Elements of `data` are returned if the corresponding value in `selectors` is true:

```python
itertools.compress('ABCDEF', [1,0,1,0,1,1]) =>
A, C, E, F
```

New function: `itertools.combinations_with_replacement(iter, r)` returns all the possible `r`-length combinations of elements from the iterable `iter`. Unlike `combinations()`, individual elements can be repeated in the generated combinations:

```python
itertools.combinations_with_replacement('abc', 2) =>
('a', 'a'), ('a', 'b'), ('a', 'c'),
('b', 'b'), ('b', 'c'), ('c', 'c')
```

Note that elements are treated as unique depending on their position in the input, not their actual values.

The `itertools.count()` function now has a `step` argument that allows incrementing by values other than 1. `count()` also now allows keyword arguments, and using non-integer values such as floats or `Decimal` instances. (Implemented by Raymond Hettinger; issue 5032.)

`itertools.combinations()` and `itertools.product()` previously raised `ValueError` for values of `r` larger than the input iterable. This was deemed a specification error, so they now return an empty iterator. (Fixed by Raymond Hettinger; issue 4816.)

• Updated module: The `json` module was upgraded to version 2.0.9 of the simplejson package, which includes a C extension that makes encoding and decoding faster. (Contributed by Bob Ippolito; issue 4136.)
To support the new `collections.OrderedDict` type, `json.load()` now has an optional `object_pairs_hook` parameter that will be called with any object literal that decodes to a list of pairs. (Contributed by Raymond Hettinger; issue 5381.)

- The `mailbox` module’s `Maildir` class now records the timestamp on the directories it reads, and only re-reads them if the modification time has subsequently changed. This improves performance by avoiding unneeded directory scans. (Fixed by A.M. Kuchling and Antoine Pitrou; issue 1607951, issue 6896.)

- New functions: the `math` module gained `erf()` and `erfc()` for the error function and the complementary error function, `expm1()` which computes $e^x - 1$ with more precision than using `exp()` and subtracting 1, `gamma()` for the Gamma function, and `lgamma()` for the natural log of the Gamma function. (Contributed by Mark Dickinson and nirinA raseliarison; issue 3366.)

- The `multiprocessing` module’s `Manager`* classes can now be passed a callable that will be called whenever a subprocess is started, along with a set of arguments that will be passed to the callable. (Contributed by lekma; issue 5585.)

The `Pool` class, which controls a pool of worker processes, now has an optional `maxtasksperchild` parameter. Worker processes will perform the specified number of tasks and then exit, causing the `Pool` to start a new worker. This is useful if tasks may leak memory or other resources, or if some tasks will cause the worker to become very large. (Contributed by Charles Cazabon; issue 6963.)

- The `nntplib` module now supports IPv6 addresses. (Contributed by Derek Morr; issue 1664.)
• New functions: the `os` module wraps the following POSIX system calls: `getresgid()` and `getresuid()`, which return the real, effective, and saved GIDs and UIDs; `setresgid()` and `setresuid()`, which set real, effective, and saved GIDs and UIDs to new values; `initgroups()`, which initialize the group access list for the current process. (GID/UID functions contributed by Travis H.; issue 6508. Support for initgroups added by Jean-Paul Calderone; issue 7333.)

The `os.fork()` function now re-initializes the import lock in the child process; this fixes problems on Solaris when `fork()` is called from a thread. (Fixed by Zsolt Cserna; issue 7242.)

• In the `os.path` module, the `normpath()` and `abspath()` functions now preserve Unicode; if their input path is a Unicode string, the return value is also a Unicode string. (`normpath()` fixed by Matt Giuca in issue 5827; `abspath()` fixed by Ezio Melotti in issue 3426.)

• The `pydoc` module now has help for the various symbols that Python uses. You can now do `help('<<')` or `help('@')`, for example. (Contributed by David Laban; issue 4739.)

• The `re` module's `split()`, `sub()`, and `subn()` now accept an optional `flags` argument, for consistency with the other functions in the module. (Added by Gregory P. Smith.)

• New function: `run_path()` in the `runpy` module will execute the code at a provided `path` argument. `path` can be the path of a Python source file (`example.py`), a compiled bytecode file (`example.pyc`), a directory (`./package/`), or a zip archive (`example.zip`). If a directory or zip path is provided, it will be added to the front of `sys.path` and the module `__main__` will be
imported. It's expected that the directory or zip contains a
`__main__.py`; if it doesn't, some other `__main__.py` might be
imported from a location later in `sys.path`. This makes more of
the machinery of runpy available to scripts that want to mimic
the way Python's command line processes an explicit path
name. (Added by Nick Coghlan; issue 6816.)

- New function: in the `shutil` module, `make_archive()` takes a
  filename, archive type (zip or tar-format), and a directory path,
  and creates an archive containing the directory's contents.
  (Added by Tarek Ziadé.)

  `shutil`'s `copyfile()` and `copytree()` functions now raise a
  `SpecialFileError` exception when asked to copy a named pipe.
  Previously the code would treat named pipes like a regular file
  by opening them for reading, and this would block indefinitely.
  (Fixed by Antoine Pitrou; issue 3002.)

- The `signal` module no longer re-installs the signal handler
  unless this is truly necessary, which fixes a bug that could make
  it impossible to catch the EINTR signal robustly. (Fixed by
  Charles-Francois Natali; issue 8354.)

- New functions: in the `site` module, three new functions return
  various site- and user-specific paths. `getsitepackages()` returns
  a list containing all global site-packages directories,
  `getusersitepackages()` returns the path of the user's site-
  packages directory, and `getuserbase()` returns the value of the
  `USER_BASE` environment variable, giving the path to a
directory that can be used to store data. (Contributed by Tarek
  Ziadé; issue 6693.)

  The `site` module now reports exceptions occurring when the
  `sitecustomize` module is imported, and will no longer catch and
swallow the *KeyboardInterrupt* exception. (Fixed by Victor Stinner; issue 3137.)

- The `create_connection()` function gained a `source_address` parameter, a `(host, port)` 2-tuple giving the source address that will be used for the connection. (Contributed by Eldon Ziegler; issue 3972.)

The `recv_into()` and `recvfrom_into()` methods will now write into objects that support the buffer API, most usefully the `bytearray` and `memoryview` objects. (Implemented by Antoine Pitrou; issue 8104.)

- The `SocketServer` module's `TCPServer` class now supports socket timeouts and disabling the Nagle algorithm. The `disable_nagle_algorithm` class attribute defaults to False; if overridden to be True, new request connections will have the `TCP_NODELAY` option set to prevent buffering many small sends into a single TCP packet. The `timeout` class attribute can hold a timeout in seconds that will be applied to the request socket; if no request is received within that time, `handle_timeout()` will be called and `handle_request()` will return. (Contributed by Kristján Valur Jónsson; issue 6192 and issue 6267.)

- Updated module: the `sqlite3` module has been updated to version 2.6.0 of the `pysqlite` package. Version 2.6.0 includes a number of bugfixes, and adds the ability to load SQLite extensions from shared libraries. Call the `enable_load_extension(True)` method to enable extensions, and then call `load_extension()` to load a particular shared library. (Updated by Gerhard Häring.)

- The `ssl` module's `SSLSocket` objects now support the buffer API,
which fixed a test suite failure (fix by Antoine Pitrou; issue 7133) and automatically set OpenSSL’s `SSL_MODE_AUTO_RETRY`, which will prevent an error code being returned from `recv()` operations that trigger an SSL renegotiation (fix by Antoine Pitrou; issue 8222).

The `ssl.wrap_socket()` constructor function now takes a *ciphers* argument that’s a string listing the encryption algorithms to be allowed; the format of the string is described in the OpenSSL documentation. (Added by Antoine Pitrou; issue 8322.)

Another change makes the extension load all of OpenSSL’s ciphers and digest algorithms so that they’re all available. Some SSL certificates couldn’t be verified, reporting an “unknown algorithm” error. (Reported by Beda Kosata, and fixed by Antoine Pitrou; issue 8484.)

The version of OpenSSL being used is now available as the module attributes `ssl.OPENSSL_VERSION` (a string), `ssl.OPENSSL_VERSION_INFO` (a 5-tuple), and `ssl.OPENSSL_VERSION_NUMBER` (an integer). (Added by Antoine Pitrou; issue 8321.)

- The *struct* module will no longer silently ignore overflow errors when a value is too large for a particular integer format code (one of `bBhHiIlLqQ`); it now always raises a `struct.error` exception. (Changed by Mark Dickinson; issue 1523.) The `pack()` function will also attempt to use `__index__()` to convert and pack non-integers before trying the `__int__()` method or reporting an error. (Changed by Mark Dickinson; issue 8300.)

- New function: the *subprocess* module’s `check_output()` runs a command with a specified set of arguments and returns the command’s output as a string when the command runs without
error, or raises a **CalledProcessError** exception otherwise.

```python
>>> subprocess.check_output(['df', '-h', '.'])
'Filesystem  Size  Used  Avail  Capacity  Mounted on
/dev/disk0s2  52G  49G  3.0G  94%  /
'
>>> subprocess.check_output(['df', '-h', '/bogus'])
... subprocess.CalledProcessError: Command ['df', '-h', '/bogus'] returned non-zero exit status 1
```

(Contributed by Gregory P. Smith.)

The **subprocess** module will now retry its internal system calls on receiving an **EINTR** signal. (Reported by several people; final patch by Gregory P. Smith in issue 1068268.)

- New function: **is_declared_global()** in the **symtable** module returns true for variables that are explicitly declared to be global, false for ones that are implicitly global. (Contributed by Jeremy Hylton.)

- The **syslog** module will now use the value of `sys.argv[0]` as the identifier instead of the previous default value of `'python'`. (Changed by Sean Reifschneider; issue 8451.)

- The **sys.version_info** value is now a named tuple, with attributes named **major**, **minor**, **micro**, **releaselevel**, and **serial**. (Contributed by Ross Light; issue 4285.)

  `sys.getwindowsversion()` also returns a named tuple, with attributes named **major**, **minor**, **build**, **platform**, **service_pack**, **service_pack_major**, **service_pack_minor**, **suite_mask**, and **product_type**. (Contributed by Brian Curtin; issue 7766.)

- The **tarfile** module's default error handling has changed, to no
longer suppress fatal errors. The default error level was previously 0, which meant that errors would only result in a message being written to the debug log, but because the debug log is not activated by default, these errors go unnoticed. The default error level is now 1, which raises an exception if there’s an error. (Changed by Lars Gustäbel; issue 7357.)

`tarfile` now supports filtering the `TarInfo` objects being added to a tar file. When you call `add()`, you may supply an optional `filter` argument that’s a callable. The `filter` callable will be passed the `TarInfo` for every file being added, and can modify and return it. If the callable returns `None`, the file will be excluded from the resulting archive. This is more powerful than the existing `exclude` argument, which has therefore been deprecated. (Added by Lars Gustäbel; issue 6856.) The `TarFile` class also now supports the context manager protocol. (Added by Lars Gustäbel; issue 7232.)

- The `wait()` method of the `threading.Event` class now returns the internal flag on exit. This means the method will usually return true because `wait()` is supposed to block until the internal flag becomes true. The return value will only be false if a timeout was provided and the operation timed out. (Contributed by Tim Lesher; issue 1674032.)

- The Unicode database provided by the `unicodedata` module is now used internally to determine which characters are numeric, whitespace, or represent line breaks. The database also includes information from the `Unihan.txt` data file (patch by Anders Chrigström and Amaury Forgeot d'Arc; issue 1571184) and has been updated to version 5.2.0 (updated by Florent Xicluna; issue 8024).

- The `urlparse` module’s `urlsplit()` now handles unknown URL
schemes in a fashion compliant with RFC 3986: if the URL is of the form "<something>://...", the text before the :// is treated as the scheme, even if it’s a made-up scheme that the module doesn’t know about. This change may break code that worked around the old behaviour. For example, Python 2.6.4 or 2.5 will return the following:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', '', '://host/filename?query', '', '')
```

Python 2.7 (and Python 2.6.5) will return:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', 'host', '/filename?query', '', '')
```

(Python 2.7 actually produces slightly different output, since it returns a named tuple instead of a standard tuple.)

The `urlparse` module also supports IPv6 literal addresses as defined by RFC 2732 (contributed by Senthil Kumaran; issue 2987).

```python
>>> urlparse.urlparse('http://[1080::8:800:200C:417A]/foo')
ParseResult(scheme='http', netloc='[1080::8:800:200C:417A]', path='/foo', params='', query='', fragment='')
```

- New class: the `WeakSet` class in the `weakref` module is a set that only holds weak references to its elements; elements will be removed once there are no references pointing to them. (Originally implemented in Python 3.0 by Raymond Hettinger, and backported to 2.7 by Michael Foord.)

- The ElementTree library, `xml.etree`, no longer escapes ampersands and angle brackets when outputting an XML
processing instruction (which looks like `<?xml-stylesheet href="#style1"?>`) or comment (which looks like <!-- comment -->). (Patch by Neil Muller; issue 2746.)

- The XML-RPC client and server, provided by the `xmlrpclib` and `SimpleXMLRPCServer` modules, have improved performance by supporting HTTP/1.1 keep-alive and by optionally using gzip encoding to compress the XML being exchanged. The gzip compression is controlled by the `encode_threshold` attribute of `SimpleXMLRPCRequestHandler`, which contains a size in bytes; responses larger than this will be compressed. (Contributed by Kristján Valur Jónsson; issue 6267.)

- The `zipfile` module's `ZipFile` now supports the context management protocol, so you can write with `zipfile.ZipFile(...) as f:`. (Contributed by Brian Curtin; issue 5511.)

  `zipfile` now also supports archiving empty directories and extracts them correctly. (Fixed by Kuba Wieczorek; issue 4710.)
  Reading files out of an archive is faster, and interleaving `read()` and `readline()` now works correctly. (Contributed by Nir Aides; issue 7610.)

  The `is_zipfile()` function now accepts a file object, in addition to the path names accepted in earlier versions. (Contributed by Gabriel Genellina; issue 4756.)

  The `writestr()` method now has an optional `compress_type` parameter that lets you override the default compression method specified in the `ZipFile` constructor. (Contributed by Ronald Oussoren; issue 6003.)
New module: importlib

Python 3.1 includes the importlib package, a re-implementation of the logic underlying Python's import statement. importlib is useful for implementors of Python interpreters and to users who wish to write new importers that can participate in the import process. Python 2.7 doesn’t contain the complete importlib package, but instead has a tiny subset that contains a single function, import_module().

import_module(name, package=None) imports a module. name is a string containing the module or package’s name. It's possible to do relative imports by providing a string that begins with a . character, such as ..utils.errors. For relative imports, the package argument must be provided and is the name of the package that will be used as the anchor for the relative import. import_module() both inserts the imported module into sys.modules and returns the module object.

Here are some examples:

```python
>>> from importlib import import_module
>>> anydbm = import_module('anydbm')  # Standard absolute import
>>> anydbm
<module 'anydbm' from '/p/python/Lib/anydbm.py'>
>>> # Relative import
>>> file_util = import_module('..file_util', 'distutils.command
>>> file_util
<module 'distutils.file_util' from '/python/Lib/distutils/file_
```

importlib was implemented by Brett Cannon and introduced in Python 3.1.

New module: sysconfig
The `sysconfig` module has been pulled out of the Distutils package, becoming a new top-level module in its own right. `sysconfig` provides functions for getting information about Python's build process: compiler switches, installation paths, the platform name, and whether Python is running from its source directory.

Some of the functions in the module are:

- `get_config_var()` returns variables from Python’s Makefile and the `pyconfig.h` file.
- `get_config_vars()` returns a dictionary containing all of the configuration variables.
- `get_path()` returns the configured path for a particular type of module: the standard library, site-specific modules, platform-specific modules, etc.
- `is_python_build()` returns true if you’re running a binary from a Python source tree, and false otherwise.

Consult the `sysconfig` documentation for more details and for a complete list of functions.

The Distutils package and `sysconfig` are now maintained by Tarek Ziadé, who has also started a Distutils2 package (source repository at [http://hg.python.org/distutils2/](http://hg.python.org/distutils2/)) for developing a next-generation version of Distutils.

**ttk: Themed Widgets for Tk**

Tcl/Tk 8.5 includes a set of themed widgets that re-implement basic Tk widgets but have a more customizable appearance and can therefore more closely resemble the native platform’s widgets. This widget set was originally called Tile, but was renamed to Ttk (for “themed Tk”) on being added to Tcl/Tk release 8.5.

The `ttk` module was written by Guilherme Polo and added in issue 2983. An alternate version called `Tile.py`, written by Martin Franklin and maintained by Kevin Walzer, was proposed for inclusion in issue 2618, but the authors argued that Guilherme Polo's work was more comprehensive.

**Updated module: unittest**

The `unittest` module was greatly enhanced; many new features were added. Most of these features were implemented by Michael Foord, unless otherwise noted. The enhanced version of the module is downloadable separately for use with Python versions 2.4 to 2.6, packaged as the `unittest2` package, from [http://pypi.python.org/pypi/unittest2](http://pypi.python.org/pypi/unittest2).

When used from the command line, the module can automatically discover tests. It's not as fancy as `py.test` or `nose`, but provides a simple way to run tests kept within a set of package directories. For example, the following command will search the `test/` subdirectory for any importable test files named `test*.py`:

```bash
python -m unittest discover -s test
```

Consult the `unittest` module documentation for more details. (Developed in issue 6001.)

The `main()` function supports some other new options:
- **-b or --buffer** will buffer the standard output and standard error streams during each test. If the test passes, any resulting output will be discarded; on failure, the buffered output will be displayed.

- **-c or --catch** will cause the control-C interrupt to be handled more gracefully. Instead of interrupting the test process immediately, the currently running test will be completed and then the partial results up to the interruption will be reported. If you’re impatient, a second press of control-C will cause an immediate interruption.

  This control-C handler tries to avoid causing problems when the code being tested or the tests being run have defined a signal handler of their own, by noticing that a signal handler was already set and calling it. If this doesn’t work for you, there’s a `removeHandler()` decorator that can be used to mark tests that should have the control-C handling disabled.

- **-f or --failfast** makes test execution stop immediately when a test fails instead of continuing to execute further tests. (Suggested by Cliff Dyer and implemented by Michael Foord; issue 8074.)

  The progress messages now show ‘x’ for expected failures and ‘u’ for unexpected successes when run in verbose mode. (Contributed by Benjamin Peterson.)

  Test cases can raise the `SkipTest` exception to skip a test (issue 1034053).

  The error messages for `assertEqual()`, `assertTrue()`, and `assertFalse()` failures now provide more information. If you set the `longMessage` attribute of your `TestCase` classes to True, both the standard error message and any additional message you provide will be printed for failures. (Added by Michael Foord; issue 5663.)
The `assertRaises()` method now returns a context handler when called without providing a callable object to run. For example, you can write this:

```python
with self.assertRaises(KeyError):
    {}['foo']
```

(Implemented by Antoine Pitrou; issue 4444.)

Module- and class-level setup and teardown fixtures are now supported. Modules can contain `setUpModule()` and `tearDownModule()` functions. Classes can have `setUpClass()` and `tearDownClass()` methods that must be defined as class methods (using `@classmethod` or equivalent). These functions and methods are invoked when the test runner switches to a test case in a different module or class.

The methods `addCleanup()` and `doCleanups()` were added. `addCleanup()` lets you add cleanup functions that will be called unconditionally (after `setUp()` if `setUp()` fails, otherwise after `tearDown()`). This allows for much simpler resource allocation and deallocation during tests (issue 5679).

A number of new methods were added that provide more specialized tests. Many of these methods were written by Google engineers for use in their test suites; Gregory P. Smith, Michael Foord, and GvR worked on merging them into Python's version of `unittest`.

- `assertIsNone()` and `assertIsNotNone()` take one expression and verify that the result is or is not `None`.
- `assertIs()` and `assertIsNot()` take two values and check whether the two values evaluate to the same object or not. (Added by Michael Foord; issue 2578.)
- `assertIsInstance()` and `assertNotIsInstance()` check whether
the resulting object is an instance of a particular class, or of one of a tuple of classes. (Added by Georg Brandl; issue 7031.)

- `assertGreater()`, `assertGreaterEqual()`, `assertLess()`, and `assertLessEqual()` compare two quantities.
- `assertMultilineEqual()` compares two strings, and if they're not equal, displays a helpful comparison that highlights the differences in the two strings. This comparison is now used by default when Unicode strings are compared with `assertEqual()`.
- `assertRegexpMatches()` and `assertNotRegexpMatches()` checks whether the first argument is a string matching or not matching the regular expression provided as the second argument (issue 8038).
- `assertRaisesRegexp()` checks whether a particular exception is raised, and then also checks that the string representation of the exception matches the provided regular expression.
- `assertIn()` and `assertNotIn()` tests whether first is or is not in second.
- `assertItemsEqual()` tests whether two provided sequences contain the same elements.
- `assertSetEqual()` compares whether two sets are equal, and only reports the differences between the sets in case of error.
- Similarly, `assertListEqual()` and `assertTupleEqual()` compare the specified types and explain any differences without necessarily printing their full values; these methods are now used by default when comparing lists and tuples using `assertEqual()`. More generally, `assertSequenceEqual()` compares two sequences and can optionally check whether both sequences are of a particular type.
- `assertDictEqual()` compares two dictionaries and reports the differences; it’s now used by default when you compare two dictionaries using `assertEqual()`. `assertDictContainsSubset()` checks whether all of the key/value pairs in first are found in second.
assertAlmostEqual() and assertNotAlmostEqual() test whether first and second are approximately equal. This method can either round their difference to an optionally-specified number of places (the default is 7) and compare it to zero, or require the difference to be smaller than a supplied delta value.

loadTestsFromName() properly honors the suiteClass attribute of the TestLoader. (Fixed by Mark Roddy; issue 6866.)

A new hook lets you extend the assertEqual() method to handle new data types. The addTypeEqualityFunc() method takes a type object and a function. The function will be used when both of the objects being compared are of the specified type. This function should compare the two objects and raise an exception if they don’t match; it’s a good idea for the function to provide additional information about why the two objects aren’t matching, much as the new sequence comparison methods do.

unittest.main() now takes an optional exit argument. If False, main() doesn’t call sys.exit(), allowing main() to be used from the interactive interpreter. (Contributed by J. Pablo Fernández; issue 3379.)

TestResult has new startTestRun() and stopTestRun() methods that are called immediately before and after a test run. (Contributed by Robert Collins; issue 5728.)

With all these changes, the unittest.py was becoming awkwardly large, so the module was turned into a package and the code split into several files (by Benjamin Peterson). This doesn’t affect how the module is imported or used.

Describes the new features, how to use them, and the rationale
Updated module: ElementTree 1.3

The version of the ElementTree library included with Python was updated to version 1.3. Some of the new features are:

- The various parsing functions now take a `parser` keyword argument giving an `XMLParser` instance that will be used. This makes it possible to override the file's internal encoding:

  ```python
  p = ET.XMLParser(encoding='utf-8')
  t = ET.XML(""""<root/>"""", parser=p)
  ```

  Errors in parsing XML now raise a `ParseError` exception, whose instances have a `position` attribute containing a `(line, column)` tuple giving the location of the problem.

- ElementTree’s code for converting trees to a string has been significantly reworked, making it roughly twice as fast in many cases. The `ElementTree write()` and `Element write()` methods now have a `method` parameter that can be “xml” (the default), “html”, or “text”. HTML mode will output empty elements as `<empty></empty>` instead of `<empty/>`, and text mode will skip over elements and only output the text chunks. If you set the `tag` attribute of an element to `None` but leave its children in place, the element will be omitted when the tree is written out, so you don’t need to do more extensive rearrangement to remove a single element.

  Namespace handling has also been improved. All `xmlns:<whatever>` declarations are now output on the root element, not scattered throughout the resulting XML. You can set the default
namespace for a tree by setting the `default_namespace` attribute and can register new prefixes with `register_namespace()`. In XML mode, you can use the true/false `xml_declaration` parameter to suppress the XML declaration.

- **New Element method:** `extend()` appends the items from a sequence to the element’s children. Elements themselves behave like sequences, so it’s easy to move children from one element to another:

```python
from xml.etree import ElementTree as ET

t = ET.XML("""<list>
   <item>1</item> <item>2</item> <item>3</item>
</list>""")
new = ET.XML('<root/>')
new.extend(t)

# Outputs <root><item>1</item>...</root>
print ET.tostring(new)
```

- **New Element method:** `iter()` yields the children of the element as a generator. It’s also possible to write `for child in elem:` to loop over an element’s children. The existing method `getiterator()` is now deprecated, as is `getchildren()` which constructs and returns a list of children.

- **New Element method:** `itertext()` yields all chunks of text that are descendants of the element. For example:

```python

t = ET.XML("""<list>
   <item>1</item> <item>2</item> <item>3</item>
</list>""")

# Outputs ['
 ', '1', ' ', '2', ' ', '3', '
']
print list(t.itertext())
```

- **Deprecated:** using an element as a Boolean (i.e., `if elem:`)
would return true if the element had any children, or false if there were no children. This behaviour is confusing – `None` is false, but so is a childless element? – so it will now trigger a `FutureWarning`. In your code, you should be explicit: write `len(elem) != 0` if you’re interested in the number of children, or `elem is not None`.

Fredrik Lundh develops ElementTree and produced the 1.3 version; you can read his article describing 1.3 at http://effbot.org/zone/elementtree-13-intro.htm. Florent Xicluna updated the version included with Python, after discussions on python-dev and in issue 6472.)
Build and C API Changes

Changes to Python's build process and to the C API include:

- The latest release of the GNU Debugger, GDB 7, can be scripted using Python. When you begin debugging an executable program P, GDB will look for a file named P-gdb.py and automatically read it. Dave Malcolm contributed a python-gdb.py that adds a number of commands useful when debugging Python itself. For example, py-up and py-down go up or down one Python stack frame, which usually corresponds to several C stack frames. py-print prints the value of a Python variable, and py-bt prints the Python stack trace. (Added as a result of issue 8032.)

- If you use the .gdbinit file provided with Python, the “pyo” macro in the 2.7 version now works correctly when the thread being debugged doesn’t hold the GIL; the macro now acquires it before printing. (Contributed by Victor Stinner; issue 3632.)

- Py_AddPendingCall() is now thread-safe, letting any worker thread submit notifications to the main Python thread. This is particularly useful for asynchronous IO operations. (Contributed by Kristján Valur Jónsson; issue 4293.)

- New function: PyCode_NewEmpty() creates an empty code object; only the filename, function name, and first line number are required. This is useful for extension modules that are attempting to construct a more useful traceback stack. Previously such extensions needed to call PyCode_New(), which had many more arguments. (Added by Jeffrey Yasskin.)

- New function: PyErr_NewExceptionWithDoc() creates a new
exception class, just as the existing `PyErr_NewException()` does, but takes an extra \texttt{char *} argument containing the docstring for the new exception class. (Added by ‘lekma’ on the Python bug tracker; [issue 7033](https://bugs.python.org/issue7033).)

- **New function:** `PyFrame_GetLineNumber()` takes a frame object and returns the line number that the frame is currently executing. Previously code would need to get the index of the bytecode instruction currently executing, and then look up the line number corresponding to that address. (Added by Jeffrey Yasskin.)

- **New functions:** `PyLong_AsLongAndOverflow()` and `PyLong_AsLongLongAndOverflow()` approximates a Python long integer as a C \texttt{long} or \texttt{long long}. If the number is too large to fit into the output type, an \texttt{overflow} flag is set and returned to the caller. (Contributed by Case Van Horsen; [issue 7528](https://bugs.python.org/issue7528) and [issue 7767](https://bugs.python.org/issue7767).)

- **New function:** stemming from the rewrite of string-to-float conversion, a new `PyOS_string_to_double()` function was added. The old `PyOS_ascii_strtod()` and `PyOS_ascii_atof()` functions are now deprecated.

- **New function:** `PySys_SetArgvEx()` sets the value of `sys.argv` and can optionally update `sys.path` to include the directory containing the script named by `sys.argv[0]` depending on the value of an `updatepath` parameter.

This function was added to close a security hole for applications that embed Python. The old function, `PySys_SetArgv()`, would always update `sys.path`, and sometimes it would add the current directory. This meant that, if you ran an application embedding Python in a directory controlled by someone else,
attackers could put a Trojan-horse module in the directory (say, a file named os.py) that your application would then import and run.

If you maintain a C/C++ application that embeds Python, check whether you’re calling PySys_SetArgv() and carefully consider whether the application should be using PySys_SetArgvEx() with updatepath set to false.

Security issue reported as CVE-2008-5983; discussed in issue 5753, and fixed by Antoine Pitrou.

- New macros: the Python header files now define the following macros: Py_ISALNUM, Py_ISALPHA, Py_ISDIGIT, Py_ISLOWER, Py_ISSPACE, Py_ISUPPER, Py_ISXDIGIT, Py_TOLOWER, and Py_TOUPPER. All of these functions are analogous to the C standard macros for classifying characters, but ignore the current locale setting, because in several places Python needs to analyze characters in a locale-independent way. (Added by Eric Smith; issue 5793.)

- Removed function: PyEval_CallObject is now only available as a macro. A function version was being kept around to preserve ABI linking compatibility, but that was in 1997; it can certainly be deleted by now. (Removed by Antoine Pitrou; issue 8276.)

- New format codes: the PyFormat_FromString(), PyFormat_FromStringV(), and PyErr_Format() functions now accept %lld and %llu format codes for displaying C’s long long types. (Contributed by Mark Dickinson; issue 7228.)

- The complicated interaction between threads and process forking has been changed. Previously, the child process created by os.fork() might fail because the child is created with only a
single thread running, the thread performing the `os.fork()`.
If other threads were holding a lock, such as Python's import lock,
when the fork was performed, the lock would still be marked as
“held” in the new process. But in the child process nothing would
ever release the lock, since the other threads weren't replicated,
and the child process would no longer be able to perform
imports.

Python 2.7 acquires the import lock before performing an
`os.fork()`, and will also clean up any locks created using the
`threading` module. C extension modules that have internal
locks, or that call `fork()` themselves, will not benefit from this
clean-up.

(Fixed by Thomas Wouters; issue 1590864.)

- The `Py_Finalize()` function now calls the internal
  `threading._shutdown()` function; this prevents some exceptions
  from being raised when an interpreter shuts down. (Patch by
  Adam Olsen; issue 1722344.)

- When using the `PyMemberDef` structure to define attributes of a
type, Python will no longer let you try to delete or set a
`T_STRING_INPLACE` attribute.

- Global symbols defined by the `ctypes` module are now prefixed
  with `Py`, or with `_ctypes`. (Implemented by Thomas Heller; issue
  3102.)

- New configure option: the `--with-system-expat` switch allows
  building the `pyexpat` module to use the system Expat library.
  (Contributed by Arfrever Frehtes Taifersar Arahesis; issue
  7609.)
New configure option: the --with-valgrind option will now disable the pymalloc allocator, which is difficult for the Valgrind memory-error detector to analyze correctly. Valgrind will therefore be better at detecting memory leaks and overruns. (Contributed by James Henstridge; issue 2422.)

New configure option: you can now supply an empty string to --with-dbmliborder= in order to disable all of the various DBM modules. (Added by Arfrever Frehtes Taifersar Arahesis; issue 6491.)

The configure script now checks for floating-point rounding bugs on certain 32-bit Intel chips and defines a X87_DOUBLE_ROUNDING preprocessor definition. No code currently uses this definition, but it’s available if anyone wishes to use it. (Added by Mark Dickinson; issue 2937.)

configure also now sets a LDCXXSHARED Makefile variable for supporting C++ linking. (Contributed by Arfrever Frehtes Taifersar Arahesis; issue 1222585.)

The build process now creates the necessary files for pkg-config support. (Contributed by Clinton Roy; issue 3585.)

The build process now supports Subversion 1.7. (Contributed by Arfrever Frehtes Taifersar Arahesis; issue 6094.)

Capsules

Python 3.1 adds a new C datatype, PyCapsule, for providing a C API to an extension module. A capsule is essentially the holder of a C void * pointer, and is made available as a module attribute; for example, the socket module’s API is exposed as socket.CAPI, and unicodedata exposes ucnhash_CAPI. Other extensions can import the module, access its dictionary to get the capsule object, and then get
the `void *` pointer, which will usually point to an array of pointers to the module's various API functions.

There is an existing data type already used for this, `PyObject`, but it doesn’t provide type safety. Evil code written in pure Python could cause a segmentation fault by taking a `PyObject` from module A and somehow substituting it for the `PyObject` in module B. Capsules know their own name, and getting the pointer requires providing the name:

```c
void *vtable;

if (!PyCapsule_IsValid(capsule, "mymodule.CAPI") {
    PyErr_SetString(PyExc_ValueError, "argument type invalid
    return NULL;
}

vtable = PyCapsule_GetPointer(capsule, "mymodule.CAPI");
```

You are assured that `vtable` points to whatever you’re expecting. If a different capsule was passed in, `PyCapsule_IsValid()` would detect the mismatched name and return false. Refer to `using-capsules` for more information on using these objects.

Python 2.7 now uses capsules internally to provide various extension-module APIs, but the `PyObject_AsVoidPtr()` was modified to handle capsules, preserving compile-time compatibility with the `CObject` interface. Use of `PyObject_AsVoidPtr()` will signal a `PendingDeprecationWarning`, which is silent by default.

Implemented in Python 3.1 and backported to 2.7 by Larry Hastings; discussed in issue 5630.

---

**Port-Specific Changes: Windows**
• The msvcrtn module now contains some constants from the crtassem.h header file: CRT_ASSEMBLY_VERSION, VC_ASSEMBLY_PUBLICKEYTOKEN, and LIBRARIES_ASSEMBLY_NAME_PREFIX. (Contributed by David Cournapeau; issue 4365.)

• The _winreg module for accessing the registry now implements the CreateKeyEx() and DeleteKeyEx() functions, extended versions of previously-supported functions that take several extra arguments. The DisableReflectionKey(), EnableReflectionKey(), and QueryReflectionKey() were also tested and documented. (Implemented by Brian Curtin: issue 7347.)

• The new _beginthreadex() API is used to start threads, and the native thread-local storage functions are now used. (Contributed by Kristján Valur Jónsson; issue 3582.)

• The os.kill() function now works on Windows. The signal value can be the constants CTRL_C_EVENT, CTRL_BREAK_EVENT, or any integer. The first two constants will send Control-C and Control-Break keystroke events to subprocesses; any other value will use the TerminateProcess() API. (Contributed by Miki Tebeka; issue 1220212.)

• The os.listdir() function now correctly fails for an empty path. (Fixed by Hirokazu Yamamoto; issue 5913.)

• The mimelib module will now read the MIME database from the Windows registry when initializing. (Patch by Gabriel Genellina; issue 4969.)

Port-Specific Changes: Mac OS X

• The path /Library/Python/2.7/site-packages is now appended to sys.path, in order to share added packages between the system installation and a user-installed copy of the same
Port-Specific Changes: FreeBSD

- FreeBSD 7.1's `SO_SETFIB` constant, used with `getsockopt()/setsockopt()` to select an alternate routing table, is now available in the `socket` module. (Added by Kyle VanderBeek; issue 8235.)
Other Changes and Fixes

- Two benchmark scripts, `iobench` and `ccbench`, were added to the `Tools` directory. `iobench` measures the speed of the built-in file I/O objects returned by `open()` while performing various operations, and `ccbench` is a concurrency benchmark that tries to measure computing throughput, thread switching latency, and IO processing bandwidth when performing several tasks using a varying number of threads.

- The `Tools/i18n/msgfmt.py` script now understands plural forms in `.po` files. (Fixed by Martin von Löwis; issue 5464.)

- When importing a module from a `.pyc` or `.pyo` file with an existing `.py` counterpart, the `co_filename` attributes of the resulting code objects are overwritten when the original filename is obsolete. This can happen if the file has been renamed, moved, or is accessed through different paths. (Patch by Ziga Seilnacht and Jean-Paul Calderone; issue 1180193.)

- The `regrtest.py` script now takes a `--randseed=` switch that takes an integer that will be used as the random seed for the `-r` option that executes tests in random order. The `-r` option also reports the seed that was used (Added by Collin Winter.)

- Another `regrtest.py` switch is `-j`, which takes an integer specifying how many tests run in parallel. This allows reducing the total runtime on multi-core machines. This option is compatible with several other options, including the `-R` switch which is known to produce long runtimes. (Added by Antoine Pitrou, issue 6152.) This can also be used with a new `-F` switch that runs selected tests in a loop until they fail. (Added by Antoine Pitrou; issue 7312.)

- When executed as a script, the `py_compile.py` module now accepts `'-` as an argument, which will read standard input for
the list of filenames to be compiled. (Contributed by Piotr Ożarowski; issue 8233.)
Porting to Python 2.7

This section lists previously described changes and other bug fixes that may require changes to your code:

- The `range()` function processes its arguments more consistently; it will now call `__int__()` on non-float, non-integer arguments that are supplied to it. (Fixed by Alexander Belopolsky; issue 1533.)
- The string `format()` method changed the default precision used for floating-point and complex numbers from 6 decimal places to 12, which matches the precision used by `str()`. (Changed by Eric Smith; issue 5920.)
- Because of an optimization for the `with` statement, the special methods `__enter__()` and `__exit__()` must belong to the object’s type, and cannot be directly attached to the object’s instance. This affects new-style classes (derived from `object`) and C extension types. (issue 6101.)
- Due to a bug in Python 2.6, the `exc_value` parameter to `__exit__()` methods was often the string representation of the exception, not an instance. This was fixed in 2.7, so `exc_value` will be an instance as expected. (Fixed by Florent Xicluna; issue 7853.)
- When a restricted set of attributes were set using `__slots__`, deleting an unset attribute would not raise `AttributeError` as you would expect. Fixed by Benjamin Peterson; issue 7604.)

In the standard library:

- Operations with `datetime` instances that resulted in a year falling outside the supported range didn’t always raise `OverflowError`. Such errors are now checked more carefully and will now raise
the exception. (Reported by Mark Leander, patch by Anand B. Pillai and Alexander Belopolsky; issue 7150.)

- When using `Decimal` instances with a string's `format()` method, the default alignment was previously left-alignment. This has been changed to right-alignment, which might change the output of your programs. (Changed by Mark Dickinson; issue 6857.)

Comparisons involving a signaling NaN value (or `sNaN`) now signal `InvalidOperation` instead of silently returning a true or false value depending on the comparison operator. Quiet NaN values (or `NaN`) are now hashable. (Fixed by Mark Dickinson; issue 7279.)

- The `ElementTree` library, `xml.etree`, no longer escapes ampersands and angle brackets when outputting an XML processing instruction (which looks like `<?xml-stylesheet href="#style1"?>`) or comment (which looks like `<!– comment – >`). (Patch by Neil Muller; issue 2746.)

- The `readline()` method of `StringIO` objects now does nothing when a negative length is requested, as other file-like objects do. (issue 7348).

- The `syslog` module will now use the value of `sys.argv[0]` as the identifier instead of the previous default value of `'python'`. (Changed by Sean Reifschneider; issue 8451.)

- The `tarfile` module’s default error handling has changed, to no longer suppress fatal errors. The default error level was previously 0, which meant that errors would only result in a message being written to the debug log, but because the debug log is not activated by default, these errors go unnoticed. The default error level is now 1, which raises an exception if there’s
an error. (Changed by Lars Gustäbel; issue 7357.)

- The `urlparse` module's `urlsplit()` now handles unknown URL schemes in a fashion compliant with RFC 3986: if the URL is of the form "<something>://...", the text before the `://` is treated as the scheme, even if it's a made-up scheme that the module doesn't know about. This change may break code that worked around the old behaviour. For example, Python 2.6.4 or 2.5 will return the following:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', '', '//host/filename?query', '', '')
```

Python 2.7 (and Python 2.6.5) will return:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', 'host', '/filename?query', '', '')
```

(Python 2.7 actually produces slightly different output, since it returns a named tuple instead of a standard tuple.)

For C extensions:

- C extensions that use integer format codes with the PyArg_Parse* family of functions will now raise a `TypeError` exception instead of triggering a `DeprecationWarning` (issue 5080).

  - Use the new `PyOS_string_to_double()` function instead of the old `PyOS_ascii_strtod()` and `PyOS_ascii_atof()` functions, which are now deprecated.

For applications that embed Python:

- The `PySys_SetArgvEx()` function was added, letting applications
close a security hole when the existing `PySys_SetArgv()` function was used. Check whether you're calling `PySys_SetArgv()` and carefully consider whether the application should be using `PySys_SetArgvEx()` with `updatepath` set to false.
Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Nick Coghlan, Philip Jenvey, Ryan Lovett, R. David Murray, Hugh Secker-Walker.
This article explains the new features in IronPython 2.6.

The major theme of IronPython 2.6 is preparing the migration path to Python 3.0, a major redesign of the language. Whenever possible, IronPython 2.6 incorporates new features and syntax from 3.0 while remaining compatible with existing code by not removing older features or syntax. When it's not possible to do that, IronPython 2.6 tries to do what it can, adding compatibility functions in a `future_builtins` module and a `-3` switch to warn about usages that will become unsupported in 3.0.

Some significant new packages have been added to the standard library, such as the `multiprocessing` and `json` modules, but there aren't many new features that aren't related to Python 3.0 in some way.

IronPython 2.6 also sees a number of improvements and bugfixes throughout the source. A search through the change logs finds there were 259 patches applied and 612 bugs fixed between Python 2.5 and 2.6. Both figures are likely to be underestimates.

This article doesn't attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for IronPython 2.6. If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature. Whenever possible, “What’s New in Python” links to the bug/patch item for each change.
Python 3.0

The development cycle for Python versions 2.6 and 3.0 was synchronized, with the alpha and beta releases for both versions being made on the same days. The development of 3.0 has influenced many features in 2.6.

Python 3.0 is a far-ranging redesign of Python that breaks compatibility with the 2.x series. This means that existing Python code will need some conversion in order to run on Python 3.0. However, not all the changes in 3.0 necessarily break compatibility. In cases where new features won’t cause existing code to break, they’ve been backported to 2.6 and are described in this document in the appropriate place. Some of the 3.0-derived features are:

- A `__complex__()` method for converting objects to a complex number.
- Alternate syntax for catching exceptions: `except TypeError as exc`.
- The addition of `functools.reduce()` as a synonym for the built-in `reduce()` function.

Python 3.0 adds several new built-in functions and changes the semantics of some existing builtins. Functions that are new in 3.0 such as `bin()` have simply been added to IronPython 2.6, but existing builtins haven’t been changed; instead, the `future_builtins` module has versions with the new 3.0 semantics. Code written to be compatible with 3.0 can do `from future_builtins import hex, map` as necessary.

A new command-line switch, `-3`, enables warnings about features that will be removed in Python 3.0. You can run code with this switch to see how much work will be necessary to port code to 3.0. The
value of this switch is available to Python code as the boolean variable `sys.py3kwarning`, and to C extension code as `Py_Py3kWarningFlag`.

**See also:** The 3xxx series of PEPs, which contains proposals for Python 3.0. [PEP 3000](https://www.python.org/dev/peps/pep-0300/) describes the development process for Python 3.0. ### New Documentation Format: reStructuredText Using Sphinx

The Python documentation was written using LaTeX since the project started around 1989. In the 1980s and early 1990s, most documentation was printed out for later study, not viewed online. LaTeX was widely used because it provided attractive printed output while remaining straightforward to write once the basic rules of the markup were learned.

Today LaTeX is still used for writing publications destined for printing, but the landscape for programming tools has shifted. We no longer print out reams of documentation; instead, we browse through it online and HTML has become the most important format to support. Unfortunately, converting LaTeX to HTML is fairly complicated and Fred L. Drake Jr., the long-time Python documentation editor, spent a lot of time maintaining the conversion process. Occasionally people would suggest converting the documentation into SGML and later XML, but performing a good conversion is a major task and no one ever committed the time required to finish the job.

During the 2.6 development cycle, Georg Brandl put a lot of effort into building a new toolchain for processing the documentation. The resulting package is called Sphinx, and is available from
Sphinx concentrates on HTML output, producing attractively styled and modern HTML; printed output is still supported through conversion to LaTeX. The input format is reStructuredText, a markup syntax supporting custom extensions and directives that is commonly used in the Python community.

Sphinx is a standalone package that can be used for writing, and almost two dozen other projects (listed on the Sphinx web site) have adopted Sphinx as their documentation tool.

PEP 343: The ‘with’ statement

The previous version, Python 2.5, added the ‘with’ statement as an optional feature, to be enabled by a `from __future__ import with_statement` directive. In 2.6 the statement no longer needs to be specially enabled; this means that `with` is now always a keyword. The rest of this section is a copy of the corresponding section from the “What’s New in Python 2.5” document; if you’re familiar with the ‘with’ statement from Python 2.5, you can skip this section.

The ‘with’ statement clarifies code that previously would use `try...finally` blocks to ensure that clean-up code is executed. In this section, I’ll discuss the statement as it will commonly be used. In the next section, I’ll examine the implementation details and show how to write objects for use with this statement.

The ‘with’ statement is a control-flow structure whose basic structure is:

```
with expression [as variable]:
    with-block
```

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has `__enter__()` and `__exit__()` methods).

The object's `__enter__()` is called before `with-block` is executed and therefore can run set-up code. It also may return a value that is bound to the name `variable`, if given. (Note carefully that `variable` is not assigned the result of expression.)

After execution of the `with-block` is finished, the object's `__exit__()` method is called, even if the block raised an exception, and can
therefore run clean-up code.

Some standard Python objects now support the context management protocol and can be used with the `with` statement. File objects are one example:

```python
with open('/etc/passwd', 'r') as f:
    for line in f:
        print line
    ... more processing code ...
```

After this statement has executed, the file object in `f` will have been automatically closed, even if the `for` loop raised an exception part-way through the block.

**Note:** In this case, `f` is the same object created by `open()`, because `file.__enter__()` returns `self`.

The `threading` module’s locks and condition variables also support the `with` statement:

```python
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for computations:

```python
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
```
print v.sqrt()

with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16 digits.
    # The original context is restored on exiting the block.
    print v.sqrt()

Writing Context Managers

Under the hood, the ‘with’ statement is fairly complicated. Most people will only use ‘with’ in company with existing objects and don’t need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have __enter__( ) and __exit__( ) methods.
- The context manager’s __enter__( ) method is called. The value returned is assigned to VAR. If no as VAR clause is present, the value is simply discarded.
- The code in BLOCK is executed.
- If BLOCK raises an exception, the context manager’s __exit__( ) method is called with three arguments, the exception details (type, value, traceback, the same values returned by sys.exc_info(), which can also be None if no exception occurred). The method’s return value controls whether an exception is re-raised: any false value re-raises the exception, and True will result in suppressing it. You’ll only rarely want to suppress the exception, because if you do the author of the code containing the ‘with’ statement will never realize anything went wrong.
- If BLOCK didn’t raise an exception, the __exit__( ) method is
still called, but type, value, and traceback are all None.

Let's think through an example. I won't present detailed code but will only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let's assume there's an object representing a database connection. Our goal will be to let the user write code like this:

```python
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there's an exception. Here's the basic interface for `DatabaseConnection` that I'll assume:

```python
class DatabaseConnection:
    # Database interface
    def cursor(self):
        "Returns a cursor object and starts a new transaction"
    def commit(self):
        "Commits current transaction"
    def rollback(self):
        "Rolls back current transaction"
```

The `__enter__()` method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add as
cursor to their 'with' statement to bind the cursor to a variable name.

```python
class DatabaseConnection:
    ...
    def __enter__(self):
        # Code to start a new transaction
        cursor = self.cursor()
        return cursor
```

The __exit__() method is the most complicated because it's where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of None. None is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a return statement at the marked location.

```python
class DatabaseConnection:
    ...
    def __exit__(self, type, value, tb):
        if tb is None:
            # No exception, so commit
            self.commit()
        else:
            # Exception occurred, so rollback.
            self.rollback()
            # return False
```

The contextlib module

The contextlib module provides some functions and a decorator that are useful when writing objects for use with the 'with' statement.

The decorator is called contextmanager(), and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the yield will be
executed as the \_enter\_() method, and the value yielded will be the method’s return value that will get bound to the variable in the ‘with’ statement’s as clause, if any. The code after the yield will be executed in the \_exit\_() method. Any exception raised in the block will be raised by the yield statement.

Using this decorator, our database example from the previous section could be written as:

```python
from contextlib import contextmanager

@contextmanager
def db_transaction(connection):
    cursor = connection.cursor()
    try:
        yield cursor
    except:
        connection.rollback()
        raise
    else:
        connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...
```

The contextlib module also has a nested(mgr1, mgr2, ...) function that combines a number of context managers so you don’t need to write nested ‘with’ statements. In this example, the single ‘with’ statement both starts a database transaction and acquires a thread lock:

```python
lock = threading.Lock()
with nested(db_transaction(db), lock) as (cursor, locked):
    ...
```

Finally, the closing() function returns its argument so that it can be bound to a variable, and calls the argument’s close() method at the end of the block.
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com')) as f:
    for line in f:
        sys.stdout.write(line)

**PEP 343 - The “with” statement**

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal Norwitz. The PEP shows the code generated for a `with` statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.
Python's `-m` switch allows running a module as a script. When you ran a module that was located inside a package, relative imports didn’t work correctly.

The fix for IronPython 2.6 adds a `__package__` attribute to modules. When this attribute is present, relative imports will be relative to the value of this attribute instead of the `__name__` attribute.

PEP 302-style importers can then set `__package__` as necessary. The `runpy` module that implements the `-m` switch now does this, so relative imports will now work correctly in scripts running from inside a package.
PEP 370: Per-user site-packages Directory

When you run Python, the module search path `sys.path` usually includes a directory whose path ends in "site-packages". This directory is intended to hold locally-installed packages available to all users using a machine or a particular site installation.

IronPython 2.6 introduces a convention for user-specific site directories. The directory varies depending on the platform:

- Unix and Mac OS X: `~/.local/`
- Windows: `%APPDATA%/Python`

Within this directory, there will be version-specific subdirectories, such as `lib/python2.6/site-packages` on Unix/Mac OS and `Python26/site-packages` on Windows.

If you don’t like the default directory, it can be overridden by an environment variable. `PYTHONUSERBASE` sets the root directory used for all Python versions supporting this feature. On Windows, the directory for application-specific data can be changed by setting the `APPDATA` environment variable. You can also modify the `site.py` file for your Python installation.

The feature can be disabled entirely by running Python with the `-s` option or setting the `PYTHONNOUSERSITE` environment variable.

PEP 370 - Per-user site-packages Directory
PEP written and implemented by Christian Heimes.
PEP 3101: Advanced String Formatting

In Python 3.0, the % operator is supplemented by a more powerful string formatting method, `format()`. Support for the `str.format()` method has been backported to IronPython 2.6.

In 2.6, both 8-bit and Unicode strings have a `.format()` method that treats the string as a template and takes the arguments to be formatted. The formatting template uses curly brackets `{, }` as special characters:

```python
>>> # Substitute positional argument 0 into the string.
>>> "User ID: {0}".format("root")
'User ID: root'
>>> # Use the named keyword arguments
>>> "User ID: {uid} Last seen: {last_login}".format(
...   uid="root",
...   last_login = "5 Mar 2008 07:20")
'User ID: root Last seen: 5 Mar 2008 07:20'
```

Curly brackets can be escaped by doubling them:

```python
>>> "Empty dict: {{{}}}".format()
"Empty dict: {}"
```

Field names can be integers indicating positional arguments, such as `{0}`, `{1}`, etc. or names of keyword arguments. You can also supply compound field names that read attributes or access dictionary keys:

```python
>>> import sys
>>> print 'Platform: {0.platform}\nPython version: {0.version}'
Platform: darwin
[GCC 4.0.1 (Apple Computer, Inc. build 5367)]

>>> import mimetypes
>>> 'Content-type: {0[.mp4]}'.format(mimetypes.types_map)
```
Note that when using dictionary-style notation such as `[.mp4]`, you don’t need to put any quotation marks around the string; it will look up the value using `.mp4` as the key. Strings beginning with a number will be converted to an integer. You can’t write more complicated expressions inside a format string.

So far we’ve shown how to specify which field to substitute into the resulting string. The precise formatting used is also controllable by adding a colon followed by a format specifier. For example:

```python
>>> # Field 0: left justify, pad to 15 characters
>>> # Field 1: right justify, pad to 6 characters
>>> fmt = '{0:15} ${1:>6}'
>>> fmt.format('Registration', 35)
'Registration $ 35'
>>> fmt.format('Tutorial', 50)
'Tutorial $ 50'
>>> fmt.format('Banquet', 125)
'Banquet $ 125'
```

Format specifiers can reference other fields through nesting:

```python
>>> fmt = '{0:{1}}'
>>> width = 15
>>> fmt.format('Invoice #1234', width)
'Invoice #1234  
>>> width = 35
>>> fmt.format('Invoice #1234', width)
'Invoice #1234   
```

The alignment of a field within the desired width can be specified:

<table>
<thead>
<tr>
<th>Character</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt; (default)</td>
<td>Left-align</td>
</tr>
<tr>
<td>&gt;</td>
<td>Right-align</td>
</tr>
<tr>
<td>^</td>
<td>Center</td>
</tr>
</tbody>
</table>
(For numeric types only) Pad after the sign.

Format specifiers can also include a presentation type, which controls how the value is formatted. For example, floating-point numbers can be formatted as a general number or in exponential notation:

```python
>>> '{0:g}'.format(3.75)
'3.75'
>>> '{0:e}'.format(3.75)
'3.750000e+00'
```

A variety of presentation types are available. Consult the 2.6 documentation for a complete list; here's a sample:

| b | Binary. Outputs the number in base 2. |
| c | Character. Converts the integer to the corresponding Unicode character before printing. |
| d | Decimal Integer. Outputs the number in base 10. |
| o | Octal format. Outputs the number in base 8. |
| x | Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9. |
| e | Exponent notation. Prints the number in scientific notation using the letter ‘e’ to indicate the exponent. |
| g | General format. This prints the number as a fixed-point number, unless the number is too large, in which case it switches to ‘e’ exponent notation. |
| n | Number. This is the same as ‘g’ (for floats) or ‘d’ (for integers), except that it uses the current locale setting to insert the appropriate number separator characters. |
| % | Percentage. Multiplies the number by 100 and displays in fixed ('f') format, followed by a percent sign. |

Classes and types can define a `__format__()` method to control how they're formatted. It receives a single argument, the format specifier:
```python
def __format__(self, format_spec):
    if isinstance(format_spec, unicode):
        return unicode(str(self))
    else:
        return str(self)
```

There's also a `format()` builtin that will format a single value. It calls
the type's `__format__()` method with the provided specifier:

```python
>>> format(75.6564, '.2f')
'75.66'
```

See also:

**Format String Syntax**

The reference documentation for format fields.

**PEP 3101 - Advanced String Formatting**

PEP written by Talin. Implemented by Eric Smith.
The `print` statement becomes the `print()` function in Python 3.0. Making `print()` a function makes it possible to replace the function by doing `def print(...)`, or importing a new function from somewhere else.

IronPython 2.6 has a `__future__` import that removes `print` as language syntax, letting you use the functional form instead. For example:

```python
>>> from __future__ import print_function
>>> print('# of entries', len(dictionary), file=sys.stderr)
```

The signature of the new function is:

```python
def print(*args, sep=' ', end='
', file=None)
```

The parameters are:

- `args`: positional arguments whose values will be printed out.
- `sep`: the separator, which will be printed between arguments.
- `end`: the ending text, which will be printed after all of the arguments have been output.
- `file`: the file object to which the output will be sent.

See also:

**PEP 3105 - Make print a function**

PEP written by Georg Brandl.
One error that Python programmers occasionally make is writing the following code:

```python
try:
    ...
except TypeError, ValueError:  # Wrong!
    ...
```

The author is probably trying to catch both `TypeError` and `ValueError` exceptions, but this code actually does something different: it will catch `TypeError` and bind the resulting exception object to the local name "ValueError". The `ValueError` exception will not be caught at all. The correct code specifies a tuple of exceptions:

```python
try:
    ...
except (TypeError, ValueError):
    ...
```

This error happens because the use of the comma here is ambiguous: does it indicate two different nodes in the parse tree, or a single node that’s a tuple?

Python 3.0 makes this unambiguous by replacing the comma with the word “as”. To catch an exception and store the exception object in the variable `exc`, you must write:

```python
try:
    ...
except TypeError as exc:
    ...
```

Python 3.0 will only support the use of “as”, and therefore interprets the first example as catching two different exceptions. IronPython 2.6
supports both the comma and “as”, so existing code will continue to work. We therefore suggest using “as” when writing new Python code that will only be executed with 2.6.

See also:

**PEP 3110 - Catching Exceptions in Python 3000**
PEP written and implemented by Collin Winter.
PEP 3112: Byte Literals

Python 3.0 adopts Unicode as the language's fundamental string type and denotes 8-bit literals differently, either as b'string' or using a bytes constructor. For future compatibility, IronPython 2.6 adds bytes as a synonym for the str type, and it also supports the b'' notation.

The 2.6 str differs from 3.0's bytes type in various ways; most notably, the constructor is completely different. In 3.0, bytes([65, 66, 67]) is 3 elements long, containing the bytes representing ABC; in 2.6, bytes([65, 66, 67]) returns the 12-byte string representing the str() of the list.

The primary use of bytes in 2.6 will be to write tests of object type such as isinstance(x, bytes). This will help the 2to3 converter, which can't tell whether 2.x code intends strings to contain either characters or 8-bit bytes; you can now use either bytes or str to represent your intention exactly, and the resulting code will also be correct in Python 3.0.

There's also a __future__ import that causes all string literals to become Unicode strings. This means that \u escape sequences can be used to include Unicode characters:

```python
from __future__ import unicode_literals
s = ('\u751f\u3080\u304e\u3000\u751f\u3054\n\u3081\u3000\u751f\u305f\u307e\u3054'
print len(s)  # 12 Unicode characters
```

At the C level, Python 3.0 will rename the existing 8-bit string type, called PyStringObject in Python 2.x, to PyBytesObject. IronPython
2.6 uses \#define to support using the names \texttt{PyBytesObject()}, \texttt{PyBytes_Check()}, \texttt{PyBytes_FromStringAndSize()}, and all the other functions and macros used with strings.

Instances of the \texttt{bytes} type are immutable just as strings are. A new \texttt{bytearray} type stores a mutable sequence of bytes:

\begin{verbatim}
>>> bytearray([65, 66, 67])
bytearray(b'ABC')
>>> b = bytearray(u'⇯㉄', 'utf-8')
>>> b
bytearray(b'\xe2\x87\xaf\xe3\x89\x84')
>>> b[0] = '\xe3'
>>> b
bytearray(b'\xe3\x87\xaf\xe3\x89\x84')
>>> unicode(str(b), 'utf-8')
u'\u31ef \u3244'
\end{verbatim}

Byte arrays support most of the methods of string types, such as \texttt{startswith()}/\texttt{endswith()}, \texttt{find()}/\texttt{rfind()}, and some of the methods of lists, such as \texttt{append()}, \texttt{pop()}, and \texttt{reverse()}.

\begin{verbatim}
>>> b = bytearray('ABC')
>>> b.append('d')
>>> b.append(ord('e'))
>>> b
bytearray(b'ABCde')
\end{verbatim}

\textbf{See also:}

\textbf{PEP 3112 - Bytes literals in Python 3000}

PEP written by Jason Orendorff; backported to 2.6 by Christian Heimes.
Python’s built-in file objects support a number of methods, but file-like objects don’t necessarily support all of them. Objects that imitate files usually support `read()` and `write()`, but they may not support `readline()`, for example. Python 3.0 introduces a layered I/O library in the `io` module that separates buffering and text-handling features from the fundamental read and write operations.

There are three levels of abstract base classes provided by the `io` module:

- **RawI0Base** defines raw I/O operations: `read()`, `readinto()`, `write()`, `seek()`, `tell()`, `truncate()`, and `close()`. Most of the methods of this class will often map to a single system call. There are also `readable()`, `writable()`, and `seekable()` methods for determining what operations a given object will allow.

  Python 3.0 has concrete implementations of this class for files and sockets, but IronPython 2.6 hasn’t restructured its file and socket objects in this way.

- **BufferedIOBase** is an abstract base class that buffers data in memory to reduce the number of system calls used, making I/O processing more efficient. It supports all of the methods of `RawI0Base`, and adds a `raw` attribute holding the underlying raw object.

  There are five concrete classes implementing this ABC. `BufferedWriter` and `BufferedReader` are for objects that support write-only or read-only usage that have a `seek()` method for random access. `BufferedRandom` objects support read and write
access upon the same underlying stream, and BufferedRWPair is for objects such as TTYs that have both read and write operations acting upon unconnected streams of data. The BytesIO class supports reading, writing, and seeking over an in-memory buffer.

- **TextIOBase**: Provides functions for reading and writing strings (remember, strings will be Unicode in Python 3.0), and supporting universal newlines. TextIOBase defines the readline() method and supports iteration upon objects.

There are two concrete implementations. TextIOWrapper wraps a buffered I/O object, supporting all of the methods for text I/O and adding a buffer attribute for access to the underlying object. StringIO simply buffers everything in memory without ever writing anything to disk.

(In IronPython 2.6, io.StringIO is implemented in pure Python, so it's pretty slow. You should therefore stick with the existing StringIO module or cStringIO for now. At some point Python 3.0’s io module will be rewritten into C for speed, and perhaps the C implementation will be backported to the 2.x releases.)

In IronPython 2.6, the underlying implementations haven’t been restructured to build on top of the io module’s classes. The module is being provided to make it easier to write code that’s forward-compatible with 3.0, and to save developers the effort of writing their own implementations of buffering and text I/O.

**PEP 3116 - New I/O**

PEP written by Daniel Stutzbach, Mike Verdone, and Guido van Rossum. Code by Guido van Rossum, Georg Brandl, Walter
Doerwald, Jeremy Hylton, Martin von Loewis, Tony Lownds, and others.
PEP 3119: Abstract Base Classes

Some object-oriented languages such as Java support interfaces, declaring that a class has a given set of methods or supports a given access protocol. Abstract Base Classes (or ABCs) are an equivalent feature for Python. The ABC support consists of an abc module containing a metaclass called ABCMeta, special handling of this metaclass by the isinstance() and issubclass() builtins, and a collection of basic ABCs that the Python developers think will be widely useful. Future versions of Python will probably add more ABCs.

Let’s say you have a particular class and wish to know whether it supports dictionary-style access. The phrase “dictionary-style” is vague, however. It probably means that accessing items with obj[1] works. Does it imply that setting items with obj[2] = value works? Or that the object will have keys(), values(), and items() methods? What about the iterative variants such as iterkeys()? copy() and update()? Iterating over the object with iter()? The IronPython 2.6 collections module includes a number of different ABCs that represent these distinctions. Iterable indicates that a class defines __iter__(), and Container means the class defines a __contains__() method and therefore supports x in y expressions. The basic dictionary interface of getting items, setting items, and keys(), values(), and items(), is defined by the MutableMapping ABC.

You can derive your own classes from a particular ABC to indicate they support that ABC’s interface:

```python
import collections
```
class Storage(collections.MutableMapping):
    ...

Alternatively, you could write the class without deriving from the desired ABC and instead register the class by calling the ABC's `register()` method:

```python
import collections
class Storage:
    ...
collections.MutableMapping.register(Storage)
```

For classes that you write, deriving from the ABC is probably clearer. The `register()` method is useful when you've written a new ABC that can describe an existing type or class, or if you want to declare that some third-party class implements an ABC. For example, if you defined a `PrintableType` ABC, it's legal to do:

```python
# Register Python's types
PrintableType.register(int)
PrintableType.register(float)
PrintableType.register(str)
```

Classes should obey the semantics specified by an ABC, but Python can't check this; it's up to the class author to understand the ABC's requirements and to implement the code accordingly.

To check whether an object supports a particular interface, you can now write:

```python
def func(d):
    if not isinstance(d, collections.MutableMapping):
        raise ValueError("Mapping object expected, not %r" % d)
```

Don’t feel that you must now begin writing lots of checks as in the
above example. Python has a strong tradition of duck-typing, where explicit type-checking is never done and code simply calls methods on an object, trusting that those methods will be there and raising an exception if they aren’t. Be judicious in checking for ABCs and only do it where it’s absolutely necessary.

You can write your own ABCs by using `abc.ABCMeta` as the metaclass in a class definition:

```python
from abc import ABCMeta, abstractmethod

class Drawable:
    __metaclass__ = ABCMeta

    @abstractmethod
    def draw(self, x, y, scale=1.0):
        pass

    def draw_doubled(self, x, y):
        self.draw(x, y, scale=2.0)

class Square(Drawable):
    def draw(self, x, y, scale):
        ...
```

In the `Drawable` ABC above, the `draw_doubled()` method renders the object at twice its size and can be implemented in terms of other methods described in `Drawable`. Classes implementing this ABC therefore don’t need to provide their own implementation of `draw_doubled()`, though they can do so. An implementation of `draw()` is necessary, though; the ABC can’t provide a useful generic implementation.

You can apply the `@abstractmethod` decorator to methods such as `draw()` that must be implemented; Python will then raise an exception for classes that don’t define the method. Note that the exception is only raised when you actually try to create an instance
of a subclass lacking the method:

```python
>>> class Circle(Drawable):
...     pass
...  
>>> c = Circle()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: Can't instantiate abstract class Circle with abstract
```

Abstract data attributes can be declared using the `@abstractproperty` decorator:

```python
from abc import abstractproperty
...

@abstractproperty
def readonly(self):
    return self._x
```

Subclasses must then define a `readonly()` property.

**See also:**

**PEP 3119 - Introducing Abstract Base Classes**

PEP written by Guido van Rossum and Talin. Implemented by Guido van Rossum. Backported to 2.6 by Benjamin Aranguren, with Alex Martelli.
PEP 3127: Integer Literal Support and Syntax

Python 3.0 changes the syntax for octal (base-8) integer literals, prefixing them with “0o” or “0O” instead of a leading zero, and adds support for binary (base-2) integer literals, signalled by a “0b” or “0B” prefix.

IronPython 2.6 doesn’t drop support for a leading 0 signalling an octal number, but it does add support for “0o” and “0b”:

```python
>>> 0o21, 2*8 + 1
(17, 17)
>>> 0b101111
47
```

The `oct()` builtin still returns numbers prefixed with a leading zero, and a new `bin()` builtin returns the binary representation for a number:

```python
>>> oct(42)
'052'
>>> future_builtins.oct(42)
'0052'
>>> bin(173)
'0b10101101'
```

The `int()` and `long()` builtins will now accept the “0o” and “0b” prefixes when base-8 or base-2 are requested, or when the `base` argument is zero (signalling that the base used should be determined from the string):

```python
>>> int('0o52', 0)
42
>>> int('1101', 2)
13
```
See also:

**PEP 3127 - Integer Literal Support and Syntax**
PEP written by Patrick Maupin; backported to 2.6 by Eric Smith.
Decorators have been extended from functions to classes. It's now legal to write:

```python
@foo
@bar
class A:
    pass
```

This is equivalent to:

```python
class A:
    pass
A = foo(bar(A))
```

See also:

**PEP 3129 - Class Decorators**

PEP written by Collin Winter.
Python 3.0 adds several abstract base classes for numeric types inspired by Scheme’s numeric tower. These classes were backported to 2.6 as the `numbers` module.

The most general ABC is `Number`. It defines no operations at all, and only exists to allow checking if an object is a number by doing `isinstance(obj, Number)`.

`Complex` is a subclass of `Number`. Complex numbers can undergo the basic operations of addition, subtraction, multiplication, division, and exponentiation, and you can retrieve the real and imaginary parts and obtain a number’s conjugate. Python’s built-in complex type is an implementation of `Complex`.

`Real` further derives from `Complex`, and adds operations that only work on real numbers: `floor()`, `trunc()`, rounding, taking the remainder mod N, floor division, and comparisons.

`Rational` numbers derive from `Real`, have `numerator` and `denominator` properties, and can be converted to floats. IronPython 2.6 adds a simple rational-number class, `Fraction`, in the `fractions` module. (It’s called `Fraction` instead of `Rational` to avoid a name clash with `numbers.Rational`.)

`Integral` numbers derive from `Rational`, and can be shifted left and right with `<<` and `>>`, combined using bitwise operations such as `&` and `|`, and can be used as array indexes and slice boundaries.

In Python 3.0, the PEP slightly redefines the existing builtins `round()`, `math.floor()`, `math.ceil()`, and adds a new one,
math.trunc(), that's been backported to IronPython 2.6. 

math.trunc() rounds toward zero, returning the closest Integral 
that's between the function's argument and zero.

See also:

**PEP 3141 - A Type Hierarchy for Numbers**
PEP written by Jeffrey Yasskin.

Scheme's numerical tower, from the Guile manual.

Scheme's number datatypes from the R5RS Scheme specification.

The fractions Module

To fill out the hierarchy of numeric types, the fractions module 
provides a rational-number class. Rational numbers store their 
values as a numerator and denominator forming a fraction, and can 
exactly represent numbers such as $\frac{2}{3}$ that floating-point numbers 
can only approximate.

The Fraction constructor takes two Integral values that will be the 
numerator and denominator of the resulting fraction.

```python
>>> from fractions import Fraction
>>> a = Fraction(2, 3)
>>> b = Fraction(2, 5)
>>> float(a), float(b)
(0.6666666666666666, 0.4000000000000002)
>>> a+b
Fraction(16, 15)
>>> a/b
Fraction(5, 3)
```

For converting floating-point numbers to rationals, the float type now 
has an `as_integer_ratio()` method that returns the numerator and
denominator for a fraction that evaluates to the same floating-point value:

```python
>>> (2.5) .as_integer_ratio()
(5, 2)
>>> (3.1415) .as_integer_ratio()
(7074029114692207L, 2251799813685248L)
>>> (1./3) .as_integer_ratio()
(6004799503160661L, 18014398509481984L)
```

Note that values that can only be approximated by floating-point numbers, such as 1./3, are not simplified to the number being approximated; the fraction attempts to match the floating-point value exactly.

The `fractions` module is based upon an implementation by Sjoerd Mullender that was in Python’s `Demo/classes/` directory for a long time. This implementation was significantly updated by Jeffrey Yasskin.
Other Language Changes

Some smaller changes made to the core Python language are:

- Directories and zip archives containing a `__main__.py` file can now be executed directly by passing their name to the interpreter. The directory or zip archive is automatically inserted as the first entry in `sys.path`. (Suggestion and initial patch by Andy Chu, subsequently revised by Phillip J. Eby and Nick Coghlan; issue 1739468.)

- The `hasattr()` function was catching and ignoring all errors, under the assumption that they meant a `__getattr__()` method was failing somehow and the return value of `hasattr()` would therefore be `False`. This logic shouldn't be applied to `KeyboardInterrupt` and `SystemExit`, however; IronPython 2.6 will no longer discard such exceptions when `hasattr()` encounters them. (Fixed by Benjamin Peterson; issue 2196.)

- When calling a function using the `**` syntax to provide keyword arguments, you are no longer required to use a Python dictionary; any mapping will now work:

```python
>>> def f(**kw):
...    print sorted(kw)
...  
>>> ud=UserDict.UserDict()
>>> ud['a'] = 1
>>> ud['b'] = 'string'
>>> f(**ud)
['a', 'b']
```

(Contributed by Alexander Belopolsky; issue 1686487.)

It’s also become legal to provide keyword arguments after a
*args argument to a function call.

```python
>>> def f(*args, **kw):
    ...     print args, kw
    ...
>>> f(1, 2, 3, *(4, 5, 6), keyword=13)
(1, 2, 3, 4, 5, 6) {'keyword': 13}
```

Previously this would have been a syntax error. (Contributed by Amaury Forgeot d'Arc; issue 3473.)

- A new builtin, `next(iterator, [default])` returns the next item from the specified iterator. If the `default` argument is supplied, it will be returned if `iterator` has been exhausted; otherwise, the `StopIteration` exception will be raised. (Backported in issue 2719.)

- Tuples now have `index()` and `count()` methods matching the list type's `index()` and `count()` methods:

  ```python
  >>> t = (0,1,2,3,4,0,1,2)
  >>> t.index(3)
  3
  >>> t.count(0)
  2
  ```

  (Contributed by Raymond Hettinger)

- The built-in types now have improved support for extended slicing syntax, accepting various combinations of `start, stop, step`. Previously, the support was partial and certain corner cases wouldn't work. (Implemented by Thomas Wouters.)

- Properties now have three attributes, `getter`, `setter` and `deleter`, that are decorators providing useful shortcuts for adding a getter, setter or deleter function to an existing property. You would use them like this:
class C(object):
    @property
    def x(self):
        return self._x

    @x.setter
    def x(self, value):
        self._x = value

    @x.deleter
    def x(self):
        del self._x

class D(C):
    @C.x.getter
    def x(self):
        return self._x * 2

    @x.setter
    def x(self, value):
        self._x = value / 2

- Several methods of the built-in set types now accept multiple iterables: `intersection()`, `intersection_update()`, `union()`, `update()`, `difference()` and `difference_update()`.

```python
>>> s=set('1234567890')
>>> s.intersection('abc123', 'cdf246')  # Intersection between all inputs
set(['2'])
>>> s.difference('246', '789')
set(['1', '0', '3', '5'])
```

(Contributed by Raymond Hettinger.)

- Many floating-point features were added. The `float()` function will now turn the string `nan` into an IEEE 754 Not A Number value, and `+inf` and `-inf` into positive or negative infinity. This works on any platform with IEEE 754 semantics. (Contributed by Christian Heimes; issue 1635.)
Other functions in the `math` module, `isinf()` and `isnan()`, return true if their floating-point argument is infinite or Not A Number. (issue 1640)

Conversion functions were added to convert floating-point numbers into hexadecimal strings (issue 3008). These functions convert floats to and from a string representation without introducing rounding errors from the conversion between decimal and binary. Floats have a `hex()` method that returns a string representation, and the `float.fromhex()` method converts a string back into a number:

```
>>> a = 3.75
>>> a.hex()
'0x1.e000000000000p+1'
>>> float.fromhex('0x1.e000000000000p+1')
3.75
>>> b=1./3
>>> b.hex()
'0x1.5555555555555p-2'
```

- A numerical nicety: when creating a complex number from two floats on systems that support signed zeros (-0 and +0), the `complex()` constructor will now preserve the sign of the zero. (Fixed by Mark T. Dickinson; issue 1507.)

- Classes that inherit a `__hash__()` method from a parent class can set `__hash__ = None` to indicate that the class isn’t hashable. This will make `hash(obj)` raise a `TypeError` and the class will not be indicated as implementing the `Hashable ABC`.

You should do this when you’ve defined a `__cmp__()` or `__eq__()` method that compares objects by their value rather than by identity. All objects have a default hash method that uses `id(obj)` as the hash value. There’s no tidy way to remove the `__hash__()` method inherited from a parent class, so assigning
None was implemented as an override. At the C level, extensions can set `tp_hash` to `PyObject_HashNotImplemented()`. (Fixed by Nick Coghlan and Amaury Forgeot d'Arc; issue 2235.)

- The `GeneratorExit` exception now subclasses `BaseException` instead of `Exception`. This means that an exception handler that does `except Exception:` will not inadvertently catch `GeneratorExit`. (Contributed by Chad Austin; issue 1537.)

- Generator objects now have a `gi_code` attribute that refers to the original code object backing the generator. (Contributed by Collin Winter; issue 1473257.)

- The `compile()` built-in function now accepts keyword arguments as well as positional parameters. (Contributed by Thomas Wouters; issue 1444529.)

- The `complex()` constructor now accepts strings containing parenthesized complex numbers, meaning that `complex(repr(cplx))` will now round-trip values. For example, `complex('(3+4j)')` now returns the value `(3+4j)`. (issue 1491866)

- The string `translate()` method now accepts `None` as the translation table parameter, which is treated as the identity transformation. This makes it easier to carry out operations that only delete characters. (Contributed by Bengt Richter and implemented by Raymond Hettinger; issue 1193128.)

- The built-in `dir()` function now checks for a `__dir__()` method on the objects it receives. This method must return a list of strings containing the names of valid attributes for the object, and lets the object control the value that `dir()` produces. Objects that have `__getattr__()` or `__getattribute__()`
methods can use this to advertise pseudo-attributes they will honor. (issue 1591665)

- Instance method objects have new attributes for the object and function comprising the method; the new synonym for \texttt{im\_self} is \texttt{__self__}, and \texttt{im\_func} is also available as \texttt{__func__}. The old names are still supported in IronPython 2.6, but are gone in 3.0.

- An obscure change: when you use the \texttt{locals()} function inside a \texttt{class} statement, the resulting dictionary no longer returns free variables. (Free variables, in this case, are variables referenced in the \texttt{class} statement that aren’t attributes of the class.)

\textbf{Optimizations}

- The \texttt{warnings} module has been rewritten in C. This makes it possible to invoke warnings from the parser, and may also make the interpreter’s startup faster. (Contributed by Neal Norwitz and Brett Cannon; issue 1631171.)

- Type objects now have a cache of methods that can reduce the work required to find the correct method implementation for a particular class; once cached, the interpreter doesn’t need to traverse base classes to figure out the right method to call. The cache is cleared if a base class or the class itself is modified, so the cache should remain correct even in the face of Python’s dynamic nature. (Original optimization implemented by Armin Rigo, updated for IronPython 2.6 by Kevin Jacobs; issue 1700288.)

By default, this change is only applied to types that are included with the Python core. Extension modules may not necessarily be compatible with this cache, so they must explicitly add \texttt{Py\_TPFLAGS\_HAVE\_VERSION\_TAG} to the module’s \texttt{tp\_flags} field to
enable the method cache. (To be compatible with the method cache, the extension module’s code must not directly access and modify the `tp_dict` member of any of the types it implements. Most modules don’t do this, but it’s impossible for the Python interpreter to determine that. See issue 1878 for some discussion.)

- Function calls that use keyword arguments are significantly faster by doing a quick pointer comparison, usually saving the time of a full string comparison. (Contributed by Raymond Hettinger, after an initial implementation by Antoine Pitrou; issue 1819.)

- All of the functions in the `struct` module have been rewritten in C, thanks to work at the Need For Speed sprint. (Contributed by Raymond Hettinger.)

- Some of the standard built-in types now set a bit in their type objects. This speeds up checking whether an object is a subclass of one of these types. (Contributed by Neal Norwitz.)

- Unicode strings now use faster code for detecting whitespace and line breaks; this speeds up the `split()` method by about 25% and `splitlines()` by 35%. (Contributed by Antoine Pitrou.) Memory usage is reduced by using pymalloc for the Unicode string's data.

- The `with` statement now stores the `_exit_()` method on the stack, producing a small speedup. (Implemented by Jeffrey Yasskin.)

- To reduce memory usage, the garbage collector will now clear internal free lists when garbage-collecting the highest generation of objects. This may return memory to the operating system sooner.
Two command-line options have been reserved for use by other Python implementations. The -J switch has been reserved for use by Jython for Jython-specific options, such as switches that are passed to the underlying JVM. -X has been reserved for options specific to a particular implementation of Python such as CPython, Jython, or IronPython. If either option is used with IronPython 2.6, the interpreter will report that the option isn’t currently used.

Python can now be prevented from writing .pyc or .pyo files by supplying the -B switch to the Python interpreter, or by setting the PYTHONDONTWRITEBYTECODE environment variable before running the interpreter. This setting is available to Python programs as the sys.dont_write_bytecode variable, and Python code can change the value to modify the interpreter’s behaviour. (Contributed by Neal Norwitz and Georg Brandl.)

The encoding used for standard input, output, and standard error can be specified by setting the PYTHONIOENCODING environment variable before running the interpreter. The value should be a string in the form <encoding> or <encoding>:<errorhandler>. The encoding part specifies the encoding’s name, e.g. utf-8 or latin-1; the optional errorhandler part specifies what to do with characters that can’t be handled by the encoding, and should be one of “error”, “ignore”, or “replace”. (Contributed by Martin von Loewis.)
New and Improved Modules

As in every release, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- The asyncore and asynchat modules are being actively maintained again, and a number of patches and bug fixes were applied. ( Maintained by Josiah Carlson; see issue 1736190 for one patch.)

- The bsddb module also has a new maintainer, Jesús Cea Avion, and the package is now available as a standalone package. The web page for the package is www.jcea.es/programacion/pybsddb.htm. The plan is to remove the package from the standard library in Python 3.0, because its pace of releases is much more frequent than Python's.

  The bsddb.dbshelve module now uses the highest pickling protocol available, instead of restricting itself to protocol 1. (Contributed by W. Barnes.)

- The cgi module will now read variables from the query string of an HTTP POST request. This makes it possible to use form actions with URLs that include query strings such as “/cgi-bin/add.py?category=1”. (Contributed by Alexandre Fiori and Nubis; issue 1817.)

  The parse_qs() and parse_qsl() functions have been relocated from the cgi module to the urlparse module. The versions still available in the cgi module will trigger
The `cmath` module underwent extensive revision, contributed by Mark Dickinson and Christian Heimes. Five new functions were added:

- `polar()` converts a complex number to polar form, returning the modulus and argument of the complex number.
- `rect()` does the opposite, turning a modulus, argument pair back into the corresponding complex number.
- `phase()` returns the argument (also called the angle) of a complex number.
- `isnan()` returns True if either the real or imaginary part of its argument is a NaN.
- `isinf()` returns True if either the real or imaginary part of its argument is infinite.

The revisions also improved the numerical soundness of the `cmath` module. For all functions, the real and imaginary parts of the results are accurate to within a few units of least precision (ulps) whenever possible. See issue 1381 for the details. The branch cuts for `asinh()`, `atanh()`, and `atan()` have also been corrected.

The tests for the module have been greatly expanded; nearly 2000 new test cases exercise the algebraic functions.

On IEEE 754 platforms, the `cmath` module now handles IEEE 754 special values and floating-point exceptions in a manner consistent with Annex ‘G’ of the C99 standard.

- A new data type in the `collections` module: `namedtuple(typename, fieldnames)` is a factory function that creates subclasses of the standard tuple whose fields are
accessible by name as well as index. For example:

```python
>>> var_type = collections.namedtuple('variable',
...     'id name type size')
>>> # Names are separated by spaces or commas.
>>> # 'id, name, type, size' would also work.
>>> var_type._fields
('id', 'name', 'type', 'size')

>>> var = var_type(1, 'frequency', 'int', 4)
>>> print var[0], var.id          # Equivalent
 1 1
>>> print var[2], var.type        # Equivalent
  int int
>>> var._asdict()
{'size': 4, 'type': 'int', 'id': 1, 'name': 'frequency'}
>>> v2 = var._replace(name='amplitude')
>>> v2
variable(id=1, name='amplitude', type='int', size=4)

Several places in the standard library that returned tuples have been modified to return `namedtuple` instances. For example, the `Decimal.as_tuple()` method now returns a named tuple with `sign`, `digits`, and `exponent` fields.

(Contributed by Raymond Hettinger.)

- Another change to the `collections` module is that the `deque` type now supports an optional `maxlen` parameter; if supplied, the deque’s size will be restricted to no more than `maxlen` items. Adding more items to a full deque causes old items to be discarded.

```python
>>> from collections import deque
>>> dq=deque(maxlen=3)
>>> dq
deque([], maxlen=3)
>>> dq.append(1) ; dq.append(2) ; dq.append(3)
>>> dq
deque([1, 2, 3], maxlen=3)
>>> dq.append(4)
```
>>> dq
deque([2, 3, 4], maxlen=3)

(Contributed by Raymond Hettinger.)

- The **Cookie** module’s **Morsel** objects now support an `httponly` attribute. In some browsers, cookies with this attribute set cannot be accessed or manipulated by JavaScript code. (Contributed by Arvin Schnell; issue 1638033.)

- A new window method in the **curses** module, `chgat()`, changes the display attributes for a certain number of characters on a single line. (Contributed by Fabian Kreutz.)

```python
# Boldface text starting at y=0, x=21
# and affecting the rest of the line.
stdscr.chgat(0, 21, curses.A_BOLD)
```

The **Textbox** class in the **curses.textpad** module now supports editing in insert mode as well as overwrite mode. Insert mode is enabled by supplying a true value for the `insert_mode` parameter when creating the **Textbox** instance.

- The **datetime** module’s `strftime()` methods now support a `%f` format code that expands to the number of microseconds in the object, zero-padded on the left to six places. (Contributed by Skip Montanaro; issue 1158.)

- The **decimal** module was updated to version 1.66 of the **General Decimal Specification**. New features include some methods for some basic mathematical functions such as `exp()` and `log10()`:

```python
>>> Decimal(1).exp()
Decimal("2.718281828459045235360287471")
>>> Decimal("2.7182818").ln()
Decimal("0.999999995305022877376682436")
>>> Decimal(1000).log10()
```
The `as_tuple()` method of `Decimal` objects now returns a named tuple with `sign`, `digits`, and `exponent` fields.

(Implemented by Facundo Batista and Mark Dickinson. Named tuple support added by Raymond Hettinger.)

- The `difflib` module’s `SequenceMatcher` class now returns named tuples representing matches, with `a`, `b`, and `size` attributes. (Contributed by Raymond Hettinger.)

- An optional `timeout` parameter, specifying a timeout measured in seconds, was added to the `ftplib.FTP` class constructor as well as the `connect()` method. (Added by Facundo Batista.) Also, the `FTP` class’s `storbinary()` and `storlines()` now take an optional `callback` parameter that will be called with each block of data after the data has been sent. (Contributed by Phil Schwartz; issue 1221598.)

- The `reduce()` built-in function is also available in the `functools` module. In Python 3.0, the `reduce()` built-in function has been dropped and `reduce()` is only available from `functools`; currently there are no plans to drop the built-in in the 2.x series. (Patched by Christian Heimes; issue 1739906.)

- When possible, the `getpass` module will now use `/dev/tty` to print a prompt message and read the password, falling back to standard error and standard input. If the password may be echoed to the terminal, a warning is printed before the prompt is displayed. (Contributed by Gregory P. Smith.)

- The `glob.glob()` function can now return Unicode filenames if a Unicode path was used and Unicode filenames are matched
within the directory. (issue 1001604)

- A new function in the `heapq` module, `merge(iter1, iter2, ...)`, takes any number of iterables returning data in sorted order, and returns a new generator that returns the contents of all the iterators, also in sorted order. For example:

```python
>>> list(heapq.merge([1, 3, 5, 9], [2, 8, 16]))
[1, 2, 3, 5, 8, 9, 16]
```

Another new function, `heappushpop(heap, item)`, pushes `item` onto `heap`, then pops off and returns the smallest item. This is more efficient than making a call to `heappush()` and then `heappop()`.

`heapq` is now implemented to only use less-than comparison, instead of the less-than-or-equal comparison it previously used. This makes `heapq`'s usage of a type match the `list.sort()` method. (Contributed by Raymond Hettinger.)

- An optional `timeout` parameter, specifying a timeout measured in seconds, was added to the `httplib.HTTPConnection` and `HTTPSCConnection` class constructors. (Added by Facundo Batista.)

- Most of the `inspect` module’s functions, such as `getmoduleinfo()` and `getargs()`, now return named tuples. In addition to behaving like tuples, the elements of the return value can also be accessed as attributes. (Contributed by Raymond Hettinger.)

Some new functions in the module include `isgenerator()`, `isgeneratorfunction()`, and `isabstract()`.
The `itertools` module gained several new functions.

`izip_longest(iter1, iter2, ...[, fillvalue])` makes tuples from each of the elements; if some of the iterables are shorter than others, the missing values are set to `fillvalue`. For example:

```python
>>> tuple(itertools.izip_longest([1,2,3], [1,2,3,4,5]))
((1, 1), (2, 2), (3, 3), (None, 4), (None, 5))
```

`product(iter1, iter2, ..., [repeat=N])` returns the Cartesian product of the supplied iterables, a set of tuples containing every possible combination of the elements returned from each iterable.

```python
>>> list(itertools.product([1,2,3], [4,5,6]))
[(1, 4), (1, 5), (1, 6),
 (2, 4), (2, 5), (2, 6),
 (3, 4), (3, 5), (3, 6)]
```

The optional `repeat` keyword argument is used for taking the product of an iterable or a set of iterables with themselves, repeated `N` times. With a single iterable argument, `N`-tuples are returned:

```python
>>> list(itertools.product([1,2], repeat=3))
[(1, 1, 1), (1, 1, 2), (1, 2, 1), (1, 2, 2),
 (2, 1, 1), (2, 1, 2), (2, 2, 1), (2, 2, 2)]
```

With two iterables, `2N`-tuples are returned.

```python
>>> list(itertools.product([1,2], [3,4], repeat=2))
[(1, 3, 1, 3), (1, 3, 1, 4), (1, 3, 2, 3), (1, 3, 2, 4),
 (1, 4, 1, 3), (1, 4, 1, 4), (1, 4, 2, 3), (1, 4, 2, 4),
 (2, 3, 1, 3), (2, 3, 1, 4), (2, 3, 2, 3), (2, 3, 2, 4),
 (2, 4, 1, 3), (2, 4, 1, 4), (2, 4, 2, 3), (2, 4, 2, 4)]
```

`combinations(iterable, r)` returns sub-sequences of length `r` from the elements of `iterable`. 
permutations(iter[, r]) returns all the permutations of length r of the iterable's elements. If r is not specified, it will default to the number of elements produced by the iterable.

itertools.chain(*iterables) is an existing function in itertools that gained a new constructor in IronPython 2.6. itertools.chain.from_iterable(iterable) takes a single iterable that should return other iterables. chain() will then return all the elements of the first iterable, then all the elements of the second, and so on.

(All contributed by Raymond Hettinger.)

- The logging module's FileHandler class and its subclasses WatchedFileHandler, RotatingFileHandler, and TimedRotatingFileHandler now have an optional delay parameter to their constructors. If delay is true, opening of the log file is deferred until the first emit() call is made. (Contributed by Vinay Sajip.)
TimedRotatingFileHandler also has a utc constructor parameter. If the argument is true, UTC time will be used in determining when midnight occurs and in generating filenames; otherwise local time will be used.

- Several new functions were added to the *math* module:
  - `isinf()` and `isnan()` determine whether a given float is a (positive or negative) infinity or a NaN (Not a Number), respectively.
  - `copysign()` copies the sign bit of an IEEE 754 number, returning the absolute value of x combined with the sign bit of y. For example, `math.copysign(1, -0.0)` returns -1.0. (Contributed by Christian Heimes.)
  - `factorial()` computes the factorial of a number. (Contributed by Raymond Hettinger; issue 2138.)
  - `fsum()` adds up the stream of numbers from an iterable, and is careful to avoid loss of precision through using partial sums. (Contributed by Jean Brouwers, Raymond Hettinger, and Mark Dickinson; issue 2819.)
  - `acosh()`, `asinh()` and `atanh()` compute the inverse hyperbolic functions.
  - `log1p()` returns the natural logarithm of 1+x (base e).
  - `trunc()` rounds a number toward zero, returning the closest Integral that's between the function's argument and zero. Added as part of the backport of PEP 3141’s type hierarchy for numbers.

- The *math* module has been improved to give more consistent behaviour across platforms, especially with respect to handling of floating-point exceptions and IEEE 754 special values.

Whenever possible, the module follows the recommendations of the C99 standard about 754’s special values. For example,
sqrt(-1.) should now give a \texttt{ValueError} across almost all platforms, while \texttt{sqrt(float('NaN'))} should return a NaN on all IEEE 754 platforms. Where Annex ‘F’ of the C99 standard recommends signaling ‘divide-by-zero’ or ‘invalid’, Python will raise \texttt{ValueError}. Where Annex ‘F’ of the C99 standard recommends signaling ‘overflow’, Python will raise \texttt{OverflowError}. (See \texttt{issue 711019} and \texttt{issue 1640}.)

(Contributed by Christian Heimes and Mark Dickinson.)

- \texttt{mmap} objects now have a \texttt{rfind()} method that searches for a substring beginning at the end of the string and searching backwards. The \texttt{find()} method also gained an \texttt{end} parameter giving an index at which to stop searching. (Contributed by John Lenton.)

- The \texttt{operator} module gained a \texttt{methodcaller()} function that takes a name and an optional set of arguments, returning a callable that will call the named function on any arguments passed to it. For example:

\begin{verbatim}
>>> # Equivalent to lambda s: s.replace('old', 'new')
>>> replacer = operator.methodcaller('replace', 'old', 'new')
>>> replacer('old wine in old bottles')
'new wine in new bottles'
\end{verbatim}

(Contributed by Georg Brandl, after a suggestion by Gregory Petrosyan.)

The \texttt{attrgetter()} function now accepts dotted names and performs the corresponding attribute lookups:

\begin{verbatim}
>>> inst_name = operator.attrgetter('...__class__.__name__')
>>> inst_name('')
'str'
\end{verbatim}
The os module now wraps several new system calls. `fchmod(fd, mode)` and `fchown(fd, uid, gid)` change the mode and ownership of an opened file, and `lchmod(path, mode)` changes the mode of a symlink. (Contributed by Georg Brandl and Christian Heimes.)

`chflags()` and `lchflags()` are wrappers for the corresponding system calls (where they're available), changing the flags set on a file. Constants for the flag values are defined in the `stat` module; some possible values include `UF_IMMUTABLE` to signal the file may not be changed and `UF_APPEND` to indicate that data can only be appended to the file. (Contributed by M. Levinson.)

`os.closerange(low, high)` efficiently closes all file descriptors from `low` to `high`, ignoring any errors and not including `high` itself. This function is now used by the `subprocess` module to make starting processes faster. (Contributed by Georg Brandl; issue 1663329.)

The `os.environ` object's `clear()` method will now unset the environment variables using `os.unsetenv()` in addition to clearing the object's keys. (Contributed by Martin Horcicka; issue 1181.)

The `os.walk()` function now has a `followlinks` parameter. If set to `True`, it will follow symlinks pointing to directories and visit the directory’s contents. For backward compatibility, the parameter’s default value is false. Note that the function can fall into an
infinite recursion if there's a symlink that points to a parent directory. (issue 1273829)

- In the `os.path` module, the `splitext()` function has been changed to not split on leading period characters. This produces better results when operating on Unix's dot-files. For example, `os.path.splitext('.ipython')` now returns `('.ipython', '')` instead of `('', '.ipython')`. (issue 1115886)

A new function, `os.path.relpath(path, start='.')`, returns a relative path from the `start` path, if it's supplied, or from the current working directory to the destination `path`. (Contributed by Richard Barran; issue 1339796.)

On Windows, `os.path.expandvars()` will now expand environment variables given in the form “%var%”, and “~user” will be expanded into the user's home directory path. (Contributed by Josiah Carlson; issue 957650.)

- The Python debugger provided by the `pdb` module gained a new command: “run” restarts the Python program being debugged and can optionally take new command-line arguments for the program. (Contributed by Rocky Bernstein; issue 1393667.)

- The `pdb.post_mortem()` function, used to begin debugging a traceback, will now use the traceback returned by `sys.exc_info()` if no traceback is supplied. (Contributed by Facundo Batista; issue 1106316.)

- The `pickletools` module now has an `optimize()` function that takes a string containing a pickle and removes some unused opcodes, returning a shorter pickle that contains the same data structure. (Contributed by Raymond Hettinger.)
• A `get_data()` function was added to the `pkgutil` module that returns the contents of resource files included with an installed Python package. For example:

```python
>>> import pkgutil
>>> print(pkgutil.get_data('test', 'exceptionHierarchy.txt'))
BaseException
  +-- SystemExit
  +-- KeyboardInterrupt
  +-- GeneratorExit
  +-- Exception
    +-- StopIteration
    +-- StandardError
...
```

(Contributed by Paul Moore; issue 2439.)

• The `pyexpat` module’s `Parser` objects now allow setting their `buffer_size` attribute to change the size of the buffer used to hold character data. (Contributed by Achim Gaedke; issue 1137.)

• The `Queue` module now provides queue variants that retrieve entries in different orders. The `PriorityQueue` class stores queued items in a heap and retrieves them in priority order, and `LifoQueue` retrieves the most recently added entries first, meaning that it behaves like a stack. (Contributed by Raymond Hettinger.)

• The `random` module’s `Random` objects can now be pickled on a 32-bit system and unpickled on a 64-bit system, and vice versa. Unfortunately, this change also means that IronPython 2.6’s `Random` objects can’t be unpickled correctly on earlier versions of Python. (Contributed by Shawn Ligocki; issue 1727780.)

The new `triangular(low, high, mode)` function returns random
numbers following a triangular distribution. The returned values are between low and high, not including high itself, and with mode as the most frequently occurring value in the distribution. (Contributed by Wladmir van der Laan and Raymond Hettinger; issue 1681432.)

- Long regular expression searches carried out by the re module will check for signals being delivered, so time-consuming searches can now be interrupted. (Contributed by Josh Hoyt and Ralf Schmitt; issue 846388.)

The regular expression module is implemented by compiling bytecodes for a tiny regex-specific virtual machine. Untrusted code could create malicious strings of bytecode directly and cause crashes, so IronPython 2.6 includes a verifier for the regex bytecode. (Contributed by Guido van Rossum from work for Google App Engine; issue 3487.)

- The rlcompleter module’s Completer.complete() method will now ignore exceptions triggered while evaluating a name. (Fixed by Lorenz Quack; issue 2250.)

- The sched module’s scheduler instances now have a read-only queue attribute that returns the contents of the scheduler’s queue, represented as a list of named tuples with the fields (time, priority, action, argument). (Contributed by Raymond Hettinger; issue 1861.)

- The select module now has wrapper functions for the Linux epoll() and BSD kqueue() system calls. modify() method was added to the existing poll objects; pollobj.modify(fd, eventmask) takes a file descriptor or file object and an event mask, modifying the recorded event mask for that file. (Contributed by Christian Heimes; issue 1657.)
The `shutil.copytree()` function now has an optional `ignore` argument that takes a callable object. This callable will receive each directory path and a list of the directory's contents, and returns a list of names that will be ignored, not copied.

The `shutil` module also provides an `ignore_patterns()` function for use with this new parameter. `ignore_patterns()` takes an arbitrary number of glob-style patterns and returns a callable that will ignore any files and directories that match any of these patterns. The following example copies a directory tree, but skips both `.svn` directories and Emacs backup files, which have names ending with ‘~’:

```python
shutil.copytree('Doc/library', '/tmp/library',
    ignore=shutil.ignore_patterns('*~', '.svn'))
```

(Contributed by Tarek Ziadé; issue 2663.)

Integrating signal handling with GUI handling event loops like those used by Tkinter or GTK+ has long been a problem; most software ends up polling, waking up every fraction of a second to check if any GUI events have occurred. The `signal` module can now make this more efficient. Calling `signal.set_wakeup_fd(fd)` sets a file descriptor to be used; when a signal is received, a byte is written to that file descriptor. There's also a C-level function, `PySignal_SetWakeupFd()`, for setting the descriptor.

Event loops will use this by opening a pipe to create two descriptors, one for reading and one for writing. The writable descriptor will be passed to `set_wakeup_fd()`, and the readable descriptor will be added to the list of descriptors monitored by the event loop via `select()` or `poll()`. On receiving a signal, a byte will be written and the main event loop will be woken up,
avoiding the need to poll.

(Contributed by Adam Olsen; issue 1583.)

The `siginterrupt()` function is now available from Python code, and allows changing whether signals can interrupt system calls or not. (Contributed by Ralf Schmitt.)

The `setitimer()` and `getitimer()` functions have also been added (where they're available). `setitimer()` allows setting interval timers that will cause a signal to be delivered to the process after a specified time, measured in wall-clock time, consumed process time, or combined process+system time. (Contributed by Guilherme Polo; issue 2240.)

- The `smtplib` module now supports SMTP over SSL thanks to the addition of the `SMTP_SSL` class. This class supports an interface identical to the existing `SMTP` class. (Contributed by Monty Taylor.) Both class constructors also have an optional `timeout` parameter that specifies a timeout for the initial connection attempt, measured in seconds. (Contributed by Facundo Batista.)

An implementation of the LMTP protocol (RFC 2033) was also added to the module. LMTP is used in place of SMTP when transferring e-mail between agents that don’t manage a mail queue. (LMTP implemented by Leif Hedstrom; issue 957003.)

`SMTP.starttls()` now complies with RFC 3207 and forgets any knowledge obtained from the server not obtained from the TLS negotiation itself. (Patch contributed by Bill Fenner; issue 829951.)

- The `socket` module now supports TIPC (http://tipc.sf.net), a high-performance non-IP-based protocol designed for use in
clustered environments. TIPC addresses are 4- or 5-tuples. (Contributed by Alberto Bertogli; issue 1646.)

A new function, `create_connection()`, takes an address and connects to it using an optional timeout value, returning the connected socket object. This function also looks up the address’s type and connects to it using IPv4 or IPv6 as appropriate. Changing your code to use `create_connection()` instead of `socket(socket.AF_INET, ...)` may be all that’s required to make your code work with IPv6.

- The base classes in the `SocketServer` module now support calling a `handle_timeout()` method after a span of inactivity specified by the server’s `timeout` attribute. (Contributed by Michael Pomraning.) The `serve_forever()` method now takes an optional poll interval measured in seconds, controlling how often the server will check for a shutdown request. (Contributed by Pedro Werneck and Jeffrey Yasskin; issue 742598, issue 1193577.)

- The `sqlite3` module, maintained by Gerhard Haering, has been updated from version 2.3.2 in Python 2.5 to version 2.4.1.

- The `struct` module now supports the C99 `_Bool` type, using the format character `'?'.` (Contributed by David Remahl.)

- The `Popen` objects provided by the `subprocess` module now have `terminate()`, `kill()`, and `send_signal()` methods. On Windows, `send_signal()` only supports the `SIGTERM` signal, and all these methods are aliases for the Win32 API function `TerminateProcess()`.(Contributed by Christian Heimes.)

- A new variable in the `sys` module, `float_info`, is an object containing information derived from the `float.h` file about the
platform's floating-point support. Attributes of this object include `mant_dig` (number of digits in the mantissa), `epsilon` (smallest difference between 1.0 and the next largest value representable), and several others. (Contributed by Christian Heimes; issue 1534.)

Another new variable, `dont_write_bytecode`, controls whether Python writes any `.pyc` or `.pyo` files on importing a module. If this variable is true, the compiled files are not written. The variable is initially set on start-up by supplying the `-B` switch to the Python interpreter, or by setting the `PYTHONDONOTWRITEBYTECODE` environment variable before running the interpreter. Python code can subsequently change the value of this variable to control whether bytecode files are written or not. (Contributed by Neal Norwitz and Georg Brandl.)

Information about the command-line arguments supplied to the Python interpreter is available by reading attributes of a named tuple available as `sys.flags`. For example, the `verbose` attribute is true if Python was executed in verbose mode, `debug` is true in debugging mode, etc. These attributes are all read-only. (Contributed by Christian Heimes.)

A new function, `getsizeof()`, takes a Python object and returns the amount of memory used by the object, measured in bytes. Built-in objects return correct results; third-party extensions may not, but can define a `__sizeof__()` method to return the object’s size. (Contributed by Robert Schuppenies; issue 2898.)

It's now possible to determine the current profiler and tracer functions by calling `sys.getprofile()` and `sys.gettrace()`. (Contributed by Georg Brandl; issue 1648.)

- The `tarfile` module now supports POSIX.1-2001 (pax) tarfiles
in addition to the POSIX.1-1988 (ustar) and GNU tar formats that were already supported. The default format is GNU tar; specify the `format` parameter to open a file using a different format:

```python
import tarfile

tar = tarfile.open("output.tar", "w",
                    format=tarfile.PAX_FORMAT)
```

The new `encoding` and `errors` parameters specify an encoding and an error handling scheme for character conversions. 'strict', 'ignore', and 'replace' are the three standard ways Python can handle errors.; 'utf-8' is a special value that replaces bad characters with their UTF-8 representation. (Character conversions occur because the PAX format supports Unicode filenames, defaulting to UTF-8 encoding.)

The `TarFile.add()` method now accepts an `exclude` argument that's a function that can be used to exclude certain filenames from an archive. The function must take a filename and return true if the file should be excluded or false if it should be archived. The function is applied to both the name initially passed to `add()` and to the names of files in recursively-added directories.

(All changes contributed by Lars Gustäbel).

- An optional `timeout` parameter was added to the `telnetlib.Telnet` class constructor, specifying a timeout measured in seconds. (Added by Facundo Batista.)

- The `tempfile.NamedTemporaryFile` class usually deletes the temporary file it created when the file is closed. This behaviour can now be changed by passing `delete=False` to the constructor. (Contributed by Damien Miller; issue 1537850.)
A new class, **SpooledTemporaryFile**, behaves like a temporary file but stores its data in memory until a maximum size is exceeded. On reaching that limit, the contents will be written to an on-disk temporary file. (Contributed by Dustin J. Mitchell.)

The **NamedTemporaryFile** and **SpooledTemporaryFile** classes both work as context managers, so you can write

```python
with tempfile.NamedTemporaryFile() as tmp: .... (Contributed by Alexander Belopolsky; issue 2021.)
```

- The **test.test_support** module gained a number of context managers useful for writing tests. **EnvironmentVarGuard()** is a context manager that temporarily changes environment variables and automatically restores them to their old values.

Another context manager, **TransientResource**, can surround calls to resources that may or may not be available; it will catch and ignore a specified list of exceptions. For example, a network test may ignore certain failures when connecting to an external web site:

```python
with test_support.TransientResource(IOError, errno=errno.ETIMEDOUT):
    f = urllib.urlopen('https://sf.net')
...  
```

Finally, **check_warnings()** resets the warning module’s warning filters and returns an object that will record all warning messages triggered (issue 3781):

```python
with test_support.check_warnings() as wrec:
    warnings.simplefilter("always")
    # ... code that triggers a warning ...
    assert str(wrec.message) == "function is outdated"
    assert len(wrec.warnings) == 1, "Multiple warnings rais
(Contributed by Brett Cannon.)

- The `textwrap` module can now preserve existing whitespace at the beginnings and ends of the newly-created lines by specifying `drop_whitespace=False` as an argument:

```python
>>> S = """This sentence has a bunch of ...
   extra whitespace."""
>>> print textwrap.fill(S, width=15)
This sentence
has a bunch
of extra
whitespace.
```

```python
>>> print textwrap.fill(S, drop_whitespace=False, width=15)
This sentence
has a bunch
of extra
whitespace.
```

(Contributed by Dwayne Bailey; issue 1581073.)

- The `threading` module API is being changed to use properties such as `daemon` instead of `setDaemon()` and `isDaemon()` methods, and some methods have been renamed to use underscores instead of camel-case; for example, the `activeCount()` method is renamed to `active_count()`. Both the 2.6 and 3.0 versions of the module support the same properties and renamed methods, but don’t remove the old methods. No date has been set for the deprecation of the old APIs in Python 3.x; the old APIs won’t be removed in any 2.x version. (Carried out by several people, most notably Benjamin Peterson.)

The `threading` module’s `Thread` objects gained an `ident` property that returns the thread’s identifier, a nonzero integer. (Contributed by Gregory P. Smith; issue 2871.)
- The `timeit` module now accepts callables as well as strings for the statement being timed and for the setup code. Two convenience functions were added for creating `Timer` instances: `repeat(stmt, setup, time, repeat, number)` and `timeit(stmt, setup, time, number)`. These create an instance and call the corresponding method. (Contributed by Erik Demaine; issue 1533909.)

- An optional `timeout` parameter was added to the `urllib.urlopen()` function and the `urllib.ftpwrapper` class constructor, as well as the `urllib2.urlopen()` function. The parameter specifies a timeout measured in seconds. For example:

  ```python
  >>> u = urllib2.urlopen("http://slow.example.com",
                        timeout=3)
  Traceback (most recent call last):
  ... 
  urllib2.URLError: <urlopen error timed out>
  >>>
  ```

  (Added by Facundo Batista.)

  - The `warnings` module’s `formatwarning()` and `showwarning()` gained an optional `line` argument that can be used to supply the line of source code. (Added as part of issue 1631171, which re-implemented part of the `warnings` module in C code.)

    A new function, `catch_warnings()`, is a context manager intended for testing purposes that lets you temporarily modify the warning filters and then restore their original values (issue 3781).

- The XML-RPC `SimpleXMLRPCServer` and `DocXMLRPCServer` classes can now be prevented from immediately opening and
binding to their socket by passing True as the `bind_and_activate` constructor parameter. This can be used to modify the instance’s `allow_reuse_address` attribute before calling the `server_bind()` and `server_activate()` methods to open the socket and begin listening for connections. (Contributed by Peter Parente; issue 1599845.)

**SimpleXMLRPCServer** also has a `_send_traceback_header` attribute; if true, the exception and formatted traceback are returned as HTTP headers “X-Exception” and “X-Traceback”. This feature is for debugging purposes only and should not be used on production servers because the tracebacks might reveal passwords or other sensitive information. (Contributed by Alan McIntyre as part of his project for Google’s Summer of Code 2007.)

- The `xmlrpclib` module no longer automatically converts `datetime.date` and `datetime.time` to the `xmlrpclib.DateTime` type; the conversion semantics were not necessarily correct for all applications. Code using `xmlrpclib` should convert `date` and `time` instances. (issue 1330538) The code can also handle dates before 1900 (contributed by Ralf Schmitt; issue 2014) and 64-bit integers represented by using `<i8>` in XML-RPC responses (contributed by Riku Lindblad; issue 2985).

- The `zipfile` module’s `ZipFile` class now has `extract()` and `extractall()` methods that will unpack a single file or all the files in the archive to the current directory, or to a specified directory:

```python
z = zipfile.ZipFile('python-251.zip')
# Unpack a single file, writing it relative
# to the /tmp directory.
z.extract('Python/sysmodule.c', '/tmp')
```
# Unpack all the files in the archive.
z.extractall()

(Contributed by Alan McIntyre; issue 467924.)

The `open()`, `read()` and `extract()` methods can now take either a filename or a `zipInfo` object. This is useful when an archive accidentally contains a duplicated filename. (Contributed by Graham Horler; issue 1775025.)

Finally, `zipfile` now supports using Unicode filenames for archived files. (Contributed by Alexey Borzenkov; issue 1734346.)

**The future_builtins module**

Python 3.0 makes many changes to the repertoire of built-in functions, and most of the changes can't be introduced in the Python 2.x series because they would break compatibility. The `future_builtins` module provides versions of these built-in functions that can be imported when writing 3.0-compatible code.

The functions in this module currently include:

- `ascii(obj)`: equivalent to `repr()`. In Python 3.0, `repr()` will return a Unicode string, while `ascii()` will return a pure ASCII bytestring.
- `filter(predicate, iterable), map(func, iterable1, ...)`: the 3.0 versions return iterators, unlike the 2.x `builtins` which return lists.
- `hex(value), oct(value)`: instead of calling the `__hex__() or __oct__()` methods, these versions will call the `__index__()` method and convert the result to hexadecimal or octal. `oct()` will
The new **json** module supports the encoding and decoding of Python types in JSON (Javascript Object Notation). JSON is a lightweight interchange format often used in web applications. For more information about JSON, see [http://www.json.org](http://www.json.org).

**json** comes with support for decoding and encoding most built-in Python types. The following example encodes and decodes a dictionary:

```python
>>> import json
>>> data = {"spam" : "foo", "parrot" : 42}
>>> in_json = json.dumps(data) # Encode the data
>>> in_json
'{"parrot": 42, "spam": "foo"}"
>>> json.loads(in_json) # Decode into a Python object
{"spam" : "foo", "parrot" : 42}
```

It’s also possible to write your own decoders and encoders to support more types. Pretty-printing of the JSON strings is also supported.

**json** (originally called simplejson) was written by Bob Ippolito.

The **plistlib** module: A Property-List Parser

The **.plist** format is commonly used on Mac OS X to store basic data types (numbers, strings, lists, and dictionaries) by serializing them into an XML-based format. It resembles the XML-RPC serialization of data types.

Despite being primarily used on Mac OS X, the format has nothing Mac-specific about it and the Python implementation works on any
platform that Python supports, so the `plistlib` module has been promoted to the standard library.

Using the module is simple:

```python
import sys
import plistlib
import datetime

# Create data structure
data_struct = dict(lastAccessed=datetime.datetime.now(),
                   version=1,
                   categories=('Personal','Shared','Private'))

# Create string containing XML.
plist_str = plistlib.writePlistToString(data_struct)
new_struct = plistlib.readPlistFromString(plist_str)
print data_struct
print new_struct

# Write data structure to a file and read it back.
plistlib.writePlist(data_struct, '/tmp/customizations.plist')
new_struct = plistlib.readPlist('/tmp/customizations.plist')

# read/writePlist accepts file-like objects as well as paths.
plistlib.writePlist(data_struct, sys.stdout)
```

c** ctypes Enhancements **

Thomas Heller continued to maintain and enhance the `ctypes` module.

`ctypes` now supports a `c_bool` datatype that represents the C99 `bool` type. (Contributed by David Remahl; issue 1649190.)

The `ctypes` string, buffer and array types have improved support for extended slicing syntax, where various combinations of `(start, stop, step)` are supplied. (Implemented by Thomas Wouters.)

All `ctypes` data types now support `from_buffer()` and
from_buffer_copy() methods that create a ctypes instance based on a provided buffer object. from_buffer_copy() copies the contents of the object, while from_buffer() will share the same memory area.

A new calling convention tells ctypes to clear the errno or Win32 LastError variables at the outset of each wrapped call. (Implemented by Thomas Heller; issue 1798.)

You can now retrieve the Unix errno variable after a function call. When creating a wrapped function, you can supply use_errno=True as a keyword parameter to the DLL() function and then call the module-level methods set_errno() and get_errno() to set and retrieve the error value.

The Win32 LastError variable is similarly supported by the DLL(), OleDLL(), and WinDLL() functions. You supply use_last_error=True as a keyword parameter and then call the module-level methods set_last_error() and get_last_error().

The byref() function, used to retrieve a pointer to a ctypes instance, now has an optional offset parameter that is a byte count that will be added to the returned pointer.

## Improved SSL Support

Bill Janssen made extensive improvements to IronPython 2.6's support for the Secure Sockets Layer by adding a new module, ssl, that's built atop the OpenSSL library. This new module provides more control over the protocol negotiated, the X.509 certificates used, and has better support for writing SSL servers (as opposed to clients) in Python. The existing SSL support in the socket module hasn’t been removed and continues to work, though it will be removed in Python 3.0.
To use the new module, you must first create a TCP connection in the usual way and then pass it to the `ssl.wrap_socket()` function. It's possible to specify whether a certificate is required, and to obtain certificate info by calling the `getpeercert()` method.

**See also:** The documentation for the `ssl` module.
Deprecations and Removals

- String exceptions have been removed. Attempting to use them raises a `TypeError`.

- Changes to the `Exception` interface as dictated by PEP 352 continue to be made. For 2.6, the `message` attribute is being deprecated in favor of the `args` attribute.

- (3.0-warning mode) Python 3.0 will feature a reorganized standard library that will drop many outdated modules and rename others. Python 2.6 running in 3.0-warning mode will warn about these modules when they are imported.

  The list of deprecated modules is: `audiodev`, `bgenlocations`, `buildtools`, `bundlebuilder`, `Canvas`, `compiler`, `dircache`, `dl`, `fpformat`, `gensuitemodule`, `ihooks`, `imageop`, `imgfile`, `linuxaudiodev`, `mhlib`, `mimetools`, `multifile`, `new`, `pure`, `statvfs`, `sunaudiodev`, `test.testall`, and `toaiff`.

- The `gopherlib` module has been removed.

- The `MimeWriter` module and `mimify` module have been deprecated; use the `email` package instead.

- The `md5` module has been deprecated; use the `hashlib` module instead.

- The `posixfile` module has been deprecated; `fcntl.lockf()` provides better locking.

- The `popen2` module has been deprecated; use the `subprocess` module.
The `rgbimg` module has been removed.

The `sets` module has been deprecated; it’s better to use the built-in `set` and `frozenset` types.

The `sha` module has been deprecated; use the `hashlib` module instead.

This section lists previously described changes and other bugfixes that may require changes to your code:

- Classes that aren’t supposed to be hashable should set `__hash__ = None` in their definitions to indicate the fact.

- String exceptions have been removed. Attempting to use them raises a `TypeError`.

- The `__init__()` method of `collections.deque` now clears any existing contents of the deque before adding elements from the iterable. This change makes the behavior match `list.__init__()`.

- `object.__init__()` previously accepted arbitrary arguments and keyword arguments, ignoring them. In IronPython 2.6, this is no longer allowed and will result in a `TypeError`. This will affect `__init__()` methods that end up calling the corresponding method on `object` (perhaps through using `super()`). See issue 1683368 for discussion.

- The `Decimal` constructor now accepts leading and trailing whitespace when passed a string. Previously it would raise an `InvalidOperation` exception. On the other hand, the `create_decimal()` method of `Context` objects now explicitly
disallows extra whitespace, raising a ConversionSyntax exception.

- Due to an implementation accident, if you passed a file path to the built-in `__import__()` function, it would actually import the specified file. This was never intended to work, however, and the implementation now explicitly checks for this case and raises an ImportError.

- The `socket` module exception `socket.error` now inherits from IOError. Previously it wasn't a subclass of StandardError but now it is, through IOError. (Implemented by Gregory P. Smith; issue 1706815.)

- The `xmlrpclib` module no longer automatically converts `datetime.date` and `datetime.time` to the `xmlrpclib.DateTime` type; the conversion semantics were not necessarily correct for all applications. Code using `xmlrpclib` should convert `date` and `time` instances. (issue 1330538)

- (3.0-warning mode) The Exception class now warns when accessed using slicing or index access; having Exception behave like a tuple is being phased out.

- (3.0-warning mode) Inequality comparisons between two dictionaries or two objects that don’t implement comparison methods are reported as warnings. `dict1 == dict2` still works, but `dict1 < dict2` is being phased out.

Comparisons between cells, which are an implementation detail of Python’s scoping rules, also cause warnings because such comparisons are forbidden entirely in 3.0.

What’s New in Python 2.5 (IronPython 2.0)

Author: A.M. Kuchling

This article explains the new features in IronPython 2.0.

The changes in IronPython 2.0 are an interesting mix of language and library improvements. The library enhancements will be more important to Python’s user community, I think, because several widely-useful packages were added. New modules include ElementTree for XML processing (xml.etree), the SQLite database module (sqlite), and the ctypes module for calling C functions.

The language changes are of middling significance. Some pleasant new features were added, but most of them aren’t features that you’ll use every day. Conditional expressions were finally added to the language using a novel syntax; see section PEP 308: Conditional Expressions. The new ‘with’ statement will make writing cleanup code easier (section PEP 343: The ‘with’ statement). Values can now be passed into generators (section PEP 342: New Generator Features). Imports are now visible as either absolute or relative (section PEP 328: Absolute and Relative Imports). Some corner cases of exception handling are handled better (section PEP 341: Unified try/except/finally). All these improvements are worthwhile, but they’re improvements to one specific language feature or another; none of them are broad modifications to Python’s semantics.

As well as the language and library additions, other improvements and bugfixes were made throughout the source tree. A search through the SVN change logs finds there were 353 patches applied and 458 bugs fixed between Python 2.4 and 2.5. (Both figures are likely to be underestimates.)
This article doesn’t try to be a complete specification of the new features; instead changes are briefly introduced using helpful examples. For full details, you should always refer to the documentation for IronPython 2.0 at http://docs.python.org. If you want to understand the complete implementation and design rationale, refer to the PEP for a particular new feature.

Comments, suggestions, and error reports for this document are welcome; please e-mail them to the author or open a bug in the Python bug tracker.
For a long time, people have been requesting a way to write conditional expressions, which are expressions that return value A or value B depending on whether a Boolean value is true or false. A conditional expression lets you write a single assignment statement that has the same effect as the following:

```python
if condition:
    x = true_value
else:
    x = false_value
```

There have been endless tedious discussions of syntax on both python-dev and comp.lang.python. A vote was even held that found the majority of voters wanted conditional expressions in some form, but there was no syntax that was preferred by a clear majority. Candidates included C’s `cond ? true_v : false_v`, `if cond then true_v else false_v`, and 16 other variations.

Guido van Rossum eventually chose a surprising syntax:

```python
x = true_value if condition else false_value
```

Evaluation is still lazy as in existing Boolean expressions, so the order of evaluation jumps around a bit. The `condition` expression in the middle is evaluated first, and the `true_value` expression is evaluated only if the condition was true. Similarly, the `false_value` expression is only evaluated when the condition is false.

This syntax may seem strange and backwards; why does the condition go in the `middle` of the expression, and not in the front as in C’s `c ? x : y`? The decision was checked by applying the new syntax to the modules in the standard library and seeing how the
resulting code read. In many cases where a conditional expression is used, one value seems to be the ‘common case’ and one value is an ‘exceptional case’, used only on rarer occasions when the condition isn’t met. The conditional syntax makes this pattern a bit more obvious:

```python
contents = ((doc + '\n') if doc else '')
```

I read the above statement as meaning “here contents is usually assigned a value of `doc+\n`; sometimes doc is empty, in which special case an empty string is returned.” I doubt I will use conditional expressions very often where there isn’t a clear common and uncommon case.

There was some discussion of whether the language should require surrounding conditional expressions with parentheses. The decision was made to not require parentheses in the Python language’s grammar, but as a matter of style I think you should always use them. Consider these two statements:

```python
# First version -- no parens
level = 1 if logging else 0

# Second version -- with parens
level = (1 if logging else 0)
```

In the first version, I think a reader’s eye might group the statement into ‘level = 1’, ‘if logging’, ‘else 0’, and think that the condition decides whether the assignment to `level` is performed. The second version reads better, in my opinion, because it makes it clear that the assignment is always performed and the choice is being made between two values.

Another reason for including the brackets: a few odd combinations of list comprehensions and lambdas could look like incorrect conditional expressions. See PEP 308 for some examples. If you put
parentheses around your conditional expressions, you won’t run into this case.

**PEP 308 - Conditional Expressions**
PEP written by Guido van Rossum and Raymond D. Hettinger; implemented by Thomas Wouters.
PEP 309: Partial Function Application

The `functools` module is intended to contain tools for functional-style programming.

One useful tool in this module is the `partial()` function. For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c);` you could create a new function `g(b, c)` that was equivalent to `f(1, b, c)`. This is called “partial function application”.

`partial()` takes the arguments `(function, arg1, arg2, ... kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```python
import functools

def log(message, subsystem):
    "Write the contents of 'message' to the specified subsystem"
    print '%s: %s' % (subsystem, message)
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

Here's another example, from a program that uses PyGTK. Here a context-sensitive pop-up menu is being constructed dynamically. The callback provided for the menu option is a partially applied version of the `open_item()` method, where the first argument has been provided.

```python
...
class Application:
    def open_item(self, path):
        ...
    def init(self):
        open_func = functools.partial(self.open_item, item_path)
popup_menu.append(('Open', open_func, 1))

Another function in the `functools` module is the `update_wrapper(wrapper, wrapped)` function that helps you write well-behaved decorators. `update_wrapper()` copies the name, module, and docstring attribute to a wrapper function so that tracebacks inside the wrapped function are easier to understand. For example, you might write:

def my_decorator(f):
    def wrapper(*args, **kwds):
        print 'Calling decorated function'
        return f(*args, **kwds)
    functools.update_wrapper(wrapper, f)
    return wrapper

`wraps()` is a decorator that can be used inside your own decorators to copy the wrapped function's information. An alternate version of the previous example would be:

def my_decorator(f):
    @functools.wraps(f)
    def wrapper(*args, **kwds):
        print 'Calling decorated function'
        return f(*args, **kwds)
    return wrapper

**PEP 309 - Partial Function Application**

PEP proposed and written by Peter Harris; implemented by Hye-Shik Chang and Nick Coghlan, with adaptations by Raymond Hettinger.
Some simple dependency support was added to Distutils. The `setup()` function now has `requires`, `provides`, and `obsoletes` keyword parameters. When you build a source distribution using the `sdist` command, the dependency information will be recorded in the `PKG-INFO` file.

Another new keyword parameter is `download_url`, which should be set to a URL for the package's source code. This means it's now possible to look up an entry in the package index, determine the dependencies for a package, and download the required packages.

```python
VERSION = '1.0'
ssetup(name='PyPackage',
    version=VERSION,
    requires=['numarray', 'zlib (>=1.1.4)'],
    obsoletes=['OldPackage'],
    download_url=('http://www.example.com/pypackage/dist/pkg-%
        % VERSION'),
)
```

Another new enhancement to the Python package index at [http://cheeseshop.python.org](http://cheeseshop.python.org) is storing source and binary archives for a package. The new `upload` Distutils command will upload a package to the repository.

Before a package can be uploaded, you must be able to build a distribution using the `sdist` Distutils command. Once that works, you can run `python setup.py upload` to add your package to the PyPI archive. Optionally you can GPG-sign the package by supplying the `-sign` and `--identity` options.
Package uploading was implemented by Martin von Löwis and Richard Jones.

**PEP 314 - Metadata for Python Software Packages v1.1**

PEP proposed and written by A.M. Kuchling, Richard Jones, and Fred Drake; implemented by Richard Jones and Fred Drake.
PEP 328: Absolute and Relative Imports

The simpler part of PEP 328 was implemented in Python 2.4: parentheses could now be used to enclose the names imported from a module using the `from ... import ...` statement, making it easier to import many different names.

The more complicated part has been implemented in IronPython 2.0: importing a module can be specified to use absolute or package-relative imports. The plan is to move toward making absolute imports the default in future versions of Python.

Let’s say you have a package directory like this:

```
pkg/
pkg/__init__.py
pkg/main.py
pkg/string.py
```

This defines a package named `pkg` containing the `pkg.main` and `pkg.string` submodules.

Consider the code in the `main.py` module. What happens if it executes the statement `import string`? In Python 2.4 and earlier, it will first look in the package’s directory to perform a relative import, finds `pkg/string.py`, imports the contents of that file as the `pkg.string` module, and that module is bound to the name `string` in the `pkg.main` module’s namespace.

That’s fine if `pkg.string` was what you wanted. But what if you wanted Python’s standard `string` module? There’s no clean way to ignore `pkg.string` and look for the standard module; generally you had to look at the contents of `sys.modules`, which is slightly unclean.
Holger Krekel’s `py.std` package provides a tidier way to perform imports from the standard library, `import py; py.std.string.join()`, but that package isn’t available on all Python installations.

Reading code which relies on relative imports is also less clear, because a reader may be confused about which module, `string` or `pkg.string`, is intended to be used. Python users soon learned not to duplicate the names of standard library modules in the names of their packages’ submodules, but you can’t protect against having your submodule’s name being used for a new module added in a future version of Python.

In IronPython 2.0, you can switch `import`'s behaviour to absolute imports using a `from __future__ import absolute_import` directive. This absolute-import behaviour will become the default in a future version (probably Python 2.7). Once absolute imports are the default, `import string` will always find the standard library’s version. It’s suggested that users should begin using absolute imports as much as possible, so it’s preferable to begin writing `from pkg import string` in your code.

Relative imports are still possible by adding a leading period to the module name when using the `from ... import` form:

```python
# Import names from pkg.string
from .string import name1, name2
# Import pkg.string
from . import string
```

This imports the `string` module relative to the current package, so in `pkg.main` this will import `name1` and `name2` from `pkg.string`. Additional leading periods perform the relative import starting from the parent of the current package. For example, code in the `A.B.C`
module can do:

```python
from . import D       # Imports A.B.D
from .. import E     # Imports A.E
from ..F import G    # Imports A.F.G
```

Leading periods cannot be used with the `import modname` form of the import statement, only the `from ... import` form.

The `py` library by Holger Krekel, which contains the `py.std` package.
PEP 338: Executing Modules as Scripts

The `-m` switch added in Python 2.4 to execute a module as a script gained a few more abilities. Instead of being implemented in C code inside the Python interpreter, the switch now uses an implementation in a new module, `runpy`.

The `runpy` module implements a more sophisticated import mechanism so that it's now possible to run modules in a package such as `pychecker.checker`. The module also supports alternative import mechanisms such as the `zipimport` module. This means you can add a .zip archive's path to `sys.path` and then use the `-m` switch to execute code from the archive.

See also:

**PEP 338 - Executing modules as scripts**

PEP written and implemented by Nick Coghlan.
Until IronPython 2.0, the `try` statement came in two flavours. You could use a `finally` block to ensure that code is always executed, or one or more `except` blocks to catch specific exceptions. You couldn't combine both `except` blocks and a `finally` block, because generating the right bytecode for the combined version was complicated and it wasn't clear what the semantics of the combined statement should be.

Guido van Rossum spent some time working with Java, which does support the equivalent of combining `except` blocks and a `finally` block, and this clarified what the statement should mean. In IronPython 2.0, you can now write:

```python
try:
    block-1 ...
except Exception1:
    handler-1 ...
except Exception2:
    handler-2 ...
else:
    else-block
finally:
    final-block
```

The code in `block-1` is executed. If the code raises an exception, the various `except` blocks are tested: if the exception is of class `Exception1`, `handler-1` is executed; otherwise if it's of class `Exception2`, `handler-2` is executed, and so forth. If no exception is raised, the `else-block` is executed.

No matter what happened previously, the `final-block` is executed once the code block is complete and any raised exceptions handled. Even if there's an error in an exception handler or the `else-block` and
a new exception is raised, the code in the *final-block* is still run.

**PEP 341 - Unifying try-except and try-finally**

PEP written by Georg Brandl; implementation by Thomas Lee.
IronPython 2.0 adds a simple way to pass values into a generator. As introduced in Python 2.3, generators only produce output; once a generator’s code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. Sometimes the ability to pass in some information would be useful. Hackish solutions to this include making the generator’s code look at a global variable and then changing the global variable’s value, or passing in some mutable object that callers then modify.

To refresh your memory of basic generators, here’s a simple example:

```python
def counter (maximum):
    i = 0
    while i < maximum:
        yield i
    i += 1
```

When you call `counter(10)`, the result is an iterator that returns the values from 0 up to 9. On encountering the `yield` statement, the iterator returns the provided value and suspends the function's execution, preserving the local variables. Execution resumes on the following call to the iterator's `next()` method, picking up after the `yield` statement.

In Python 2.3, `yield` was a statement; it didn’t return any value. In 2.5, `yield` is now an expression, returning a value that can be assigned to a variable or otherwise operated on:

```python
val = (yield i)
```
I recommend that you always put parentheses around a yield expression when you’re doing something with the returned value, as in the above example. The parentheses aren’t always necessary, but it’s easier to always add them instead of having to remember when they’re needed.

**PEP 342** explains the exact rules, which are that a yield-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there’s an operation, as in `val = (yield i) + 12`.

Values are sent into a generator by calling its `send(value)()` method. The generator’s code is then resumed and the yield expression returns the specified value. If the regular `next()` method is called, the yield returns `None`.

Here’s the previous example, modified to allow changing the value of the internal counter.

```python
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here’s an example of changing the counter:

```python
>>> it = counter(10)
>>> print it.next()
0
>>> print it.next()
1
>>> print it.send(8)
```
yield will usually return None, so you should always check for this case. Don’t just use its value in expressions unless you’re sure that the send() method will be the only method used to resume your generator function.

In addition to send(), there are two other new methods on generators:

- **throw(type, value=None, traceback=None)()** is used to raise an exception inside the generator; the exception is raised by the yield expression where the generator’s execution is paused.

- **close()** raises a new GeneratorExit exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise GeneratorExit or StopIteration. Catching the GeneratorExit exception and returning a value is illegal and will trigger a RuntimeError; if the function raises some other exception, that exception is propagated to the caller. close() will also be called by Python’s garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a GeneratorExit occurs, I suggest using a try: ... finally: suite instead of catching GeneratorExit.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and
consumers.

Generators also become *coroutines*, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements). We'll have to figure out patterns for using coroutines effectively in Python.

The addition of the `close()` method has one side effect that isn’t obvious. `close()` is called when a generator is garbage-collected, so this means the generator's code gets one last chance to run before the generator is destroyed. This last chance means that `try...finally` statements in generators can now be guaranteed to work; the `finally` clause will now always get a chance to run. The syntactic restriction that you couldn't mix `yield` statements with a `try...finally` suite has therefore been removed. This seems like a minor bit of language trivia, but using generators and `try...finally` is actually necessary in order to implement the `with` statement described by PEP 343. I'll look at this new statement in the following section.

Another even more esoteric effect of this change: previously, the `gi_frame` attribute of a generator was always a frame object. It's now possible for `gi_frame` to be `None` once the generator has been exhausted.

**PEP 342 - Coroutines via Enhanced Generators**

PEP written by Guido van Rossum and Phillip J. Eby; implemented by Phillip J. Eby. Includes examples of some fancier uses of generators as coroutines.
Earlier versions of these features were proposed in PEP 288 by Raymond Hettinger and PEP 325 by Samuele Pedroni.

   The Wikipedia entry for coroutines.

http://www.sidhe.org/~dan/blog/archives/000178.html
   An explanation of coroutines from a Perl point of view, written by Dan Sugalski.
The ‘with’ statement clarifies code that previously would use \texttt{try...finally} blocks to ensure that clean-up code is executed. In this section, I’ll discuss the statement as it will commonly be used. In the next section, I’ll examine the implementation details and show how to write objects for use with this statement.

The ‘with’ statement is a new control-flow structure whose basic structure is:

\begin{verbatim}
with expression [as variable]:
  with-block
\end{verbatim}

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has \texttt{__enter__()} and \texttt{__exit__()} methods.

The object’s \texttt{__enter__()} is called before \texttt{with-block} is executed and therefore can run set-up code. It also may return a value that is bound to the name \texttt{variable}, if given. (Note carefully that \texttt{variable} is not assigned the result of \texttt{expression}.)

After execution of the \texttt{with-block} is finished, the object’s \texttt{__exit__()} method is called, even if the block raised an exception, and can therefore run clean-up code.

To enable the statement in IronPython 2.0, you need to add the following directive to your module:

\begin{verbatim}
from __future__ import with_statement
\end{verbatim}

The statement will always be enabled in Python 2.6.
Some standard Python objects now support the context management protocol and can be used with the `with` statement. File objects are one example:

```python
with open('/etc/passwd', 'r') as f:
    for line in f:
        print line
        ... more processing code ...
```

After this statement has executed, the file object in `f` will have been automatically closed, even if the `for` loop raised an exception part-way through the block.

**Note:** In this case, `f` is the same object created by `open()`, because `file.__enter__()` returns `self`.

The `threading` module's locks and condition variables also support the `with` statement:

```python
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The new `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for computations:

```python
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
print v.sqrt()
```
```
with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16 digits.
    # The original context is restored on exiting the block.
    print v.sqrt()
```

**Writing Context Managers**

Under the hood, the `with` statement is fairly complicated. Most people will only use `with` in company with existing objects and don’t need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have `__enter__()` and `__exit__()` methods.
- The context manager’s `__enter__()` method is called. The value returned is assigned to `VAR`. If no `as VAR` clause is present, the value is simply discarded.
- The code in `BLOCK` is executed.
- If `BLOCK` raises an exception, the `__exit__(type, value, traceback)()` is called with the exception details, the same values returned by `sys.exc_info()`. The method’s return value controls whether the exception is re-raised: any false value re-raises the exception, and `True` will result in suppressing it. You’ll only rarely want to suppress the exception, because if you do the author of the code containing the `with` statement will never realize anything went wrong.
- If `BLOCK` didn’t raise an exception, the `__exit__()` method is still called, but `type`, `value`, and `traceback` are all `None`. 
Let’s think through an example. I won’t present detailed code but will only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let’s assume there’s an object representing a database connection. Our goal will be to let the user write code like this:

```python
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there’s an exception. Here’s the basic interface for `DatabaseConnection` that I’ll assume:

```python
class DatabaseConnection:
    # Database interface
    def cursor (self):
        "Returns a cursor object and starts a new transaction"
    def commit (self):
        "Commits current transaction"
    def rollback (self):
        "Rolls back current transaction"
```

The `__enter__()` method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add `as cursor` to their `with` statement to bind the cursor to a variable name.
class DatabaseConnection:
    ...
    def __enter__(self):
        # Code to start a new transaction
        cursor = self.cursor()
        return cursor

The __exit__() method is the most complicated because it’s where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of None. None is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a return statement at the marked location.

```python
class DatabaseConnection:
    ...
    def __exit__(self, type, value, tb):
        if tb is None:
            # No exception, so commit
            self.commit()
        else:
            # Exception occurred, so rollback.
            self.rollback()
            # return False
```

The contextlib module

The new contextlib module provides some functions and a decorator that are useful for writing objects for use with the ‘with’ statement.

The decorator is called contextmanager(), and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the yield will be
executed as the __enter__() method, and the value yielded will be the method’s return value that will get bound to the variable in the ‘with’ statement’s as clause, if any. The code after the yield will be executed in the __exit__() method. Any exception raised in the block will be raised by the yield statement.

Our database example from the previous section could be written using this decorator as:

```python
from contextlib import contextmanager

@contextmanager
def db_transaction(connection):
    cursor = connection.cursor()
    try:
        yield cursor
    except:
        connection.rollback()
        raise
    else:
        connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...
```

The contextlib module also has a nested(mgr1, mgr2, ...)() function that combines a number of context managers so you don’t need to write nested ‘with’ statements. In this example, the single ‘with’ statement both starts a database transaction and acquires a thread lock:

```python
lock = threading.Lock()
with nested (db_transaction(db), lock) as (cursor, locked):
    ...
```

Finally, the closing(object)() function returns object so that it can be bound to a variable, and calls object.close at the end of the
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com')) as f:
    for line in f:
        sys.stdout.write(line)

See also:

**PEP 343 - The “with” statement**

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal Norwitz. The PEP shows the code generated for a `with` statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.
Exception classes can now be new-style classes, not just classic classes, and the built-in Exception class and all the standard built-in exceptions (NameError, ValueError, etc.) are now new-style classes.

The inheritance hierarchy for exceptions has been rearranged a bit. In 2.5, the inheritance relationships are:

```
BaseException    # New in IronPython 2.0
    |-
    | KeyboardInterrupt
    |-
    | SystemExit
    |-
    | Exception
        |-
        | (all other current built-in exceptions)
```

This rearrangement was done because people often want to catch all exceptions that indicate program errors. KeyboardInterrupt and SystemExit aren’t errors, though, and usually represent an explicit action such as the user hitting Control-C or code calling sys.exit(). A bare except: will catch all exceptions, so you commonly need to list KeyboardInterrupt and SystemExit in order to re-raise them. The usual pattern is:

```
try:
    ...
except (KeyboardInterrupt, SystemExit):
    raise
except:
    # Log error...
    # Continue running program...
```

In IronPython 2.0, you can now write except Exception to achieve the same result, catching all the exceptions that usually indicate errors but leaving KeyboardInterrupt and SystemExit alone. As in previous versions, a bare except: still catches all exceptions.
The goal for Python 3.0 is to require any class raised as an exception to derive from `BaseException` or some descendant of `BaseException`, and future releases in the Python 2.x series may begin to enforce this constraint. Therefore, I suggest you begin making all your exception classes derive from `Exception` now. It's been suggested that the bare `except:` form should be removed in Python 3.0, but Guido van Rossum hasn’t decided whether to do this or not.

Raising of strings as exceptions, as in the statement `raise "Error occurred"`, is deprecated in IronPython 2.0 and will trigger a warning. The aim is to be able to remove the string-exception feature in a few releases.

See also:

**PEP 352 - Required Superclass for Exceptions**

PEP written by Brett Cannon and Guido van Rossum; implemented by Brett Cannon.
The NumPy developers had a problem that could only be solved by adding a new special method, `__index__()`. When using slice notation, as in `[start:stop:step]`, the values of the `start`, `stop`, and `step` indexes must all be either integers or long integers. NumPy defines a variety of specialized integer types corresponding to unsigned and signed integers of 8, 16, 32, and 64 bits, but there was no way to signal that these types could be used as slice indexes.

Slicing can’t just use the existing `__int__()` method because that method is also used to implement coercion to integers. If slicing used `__int__()`, floating-point numbers would also become legal slice indexes and that’s clearly an undesirable behaviour.

Instead, a new special method called `__index__()` was added. It takes no arguments and returns an integer giving the slice index to use. For example:

```python
class C:
    def __index__(self):
        return self.value
```

The return value must be either a Python integer or long integer. The interpreter will check that the type returned is correct, and raises a `TypeError` if this requirement isn’t met.

A corresponding `nb_index` slot was added to the C-level `PyNumberMethods` structure to let C extensions implement this protocol. `PyNumber_Index(obj)()` can be used in extension code to call the `__index__()` function and retrieve its result.

PEP 357 - Allowing Any Object to be Used for Slicing

PEP written and implemented by Travis Oliphant.
Other Language Changes

Here are all of the changes that IronPython 2.0 makes to the core Python language.

- The `dict` type has a new hook for letting subclasses provide a default value when a key isn’t contained in the dictionary. When a key isn’t found, the dictionary’s `__missing__(key)()` method will be called. This hook is used to implement the new `defaultdict` class in the `collections` module. The following example defines a dictionary that returns zero for any missing key:

```python
class zerodict (dict):
    def __missing__ (self, key):
        return 0

d = zerodict({1:1, 2:2})
print d[1], d[2]    # Prints 1, 2
print d[3], d[4]    # Prints 0, 0
```

- Both 8-bit and Unicode strings have new `partition(sep)()` and `rpartition(sep)()` methods that simplify a common use case.

The `find(S)()` method is often used to get an index which is then used to slice the string and obtain the pieces that are before and after the separator. `partition(sep)()` condenses this pattern into a single method call that returns a 3-tuple containing the substring before the separator, the separator itself, and the substring after the separator. If the separator isn’t found, the first element of the tuple is the entire string and the other two elements are empty. `rpartition(sep)()` also returns a 3-tuple but starts searching from the end of the string; the `r` stands for ‘reverse’.
Some examples:

```python
>>> ('http://www.python.org').partition('://')
('http', '//', 'www.python.org')
>>> ('file:/usr/share/doc/index.html').partition('://')
('file:/usr/share/doc/index.html', '', '')
>>> (u'Subject: a quick question').partition(':')
(u'Subject', u':', u'a quick question')
>>> 'www.python.org'.rpartition('.')
('www.python', '.', 'org')
>>> 'www.python.org'.rpartition(':')
('', '', 'www.python.org')
```

(Implemented by Fredrik Lundh following a suggestion by Raymond Hettinger.)

- The `startswith()` and `endswith()` methods of string types now accept tuples of strings to check for.

```python
def is_image_file (filename):
    return filename.endswith(('.gif', '.jpg', '.tiff'))
```

(Implemented by Georg Brandl following a suggestion by Tom Lynn.)

- The `min()` and `max()` built-in functions gained a `key` keyword parameter analogous to the `key` argument for `sort()`. This parameter supplies a function that takes a single argument and is called for every value in the list; `min()/max()` will return the element with the smallest/largest return value from this function. For example, to find the longest string in a list, you can do:

```
L = ['medium', 'longest', 'short']
# Prints 'longest'
print max(L, key=len)
# Prints 'short', because lexicographically 'short' has the
print max(L)
```
Two new built-in functions, `any()` and `all()`, evaluate whether an iterator contains any true or false values. `any()` returns `True` if any value returned by the iterator is true; otherwise it will return `False`. `all()` returns `True` only if all of the values returned by the iterator evaluate as true. (Suggested by Guido van Rossum, and implemented by Raymond Hettinger.)

The result of a class's `__hash__()` method can now be either a long integer or a regular integer. If a long integer is returned, the hash of that value is taken. In earlier versions the hash value was required to be a regular integer, but in 2.5 the `id()` built-in was changed to always return non-negative numbers, and users often seem to use `id(self)` in `__hash__()` methods (though this is discouraged).

ASCII is now the default encoding for modules. It’s now a syntax error if a module contains string literals with 8-bit characters but doesn’t have an encoding declaration. In Python 2.4 this triggered a warning, not a syntax error. See PEP 263 for how to declare a module’s encoding; for example, you might add a line like this near the top of the source file:

```
# -*- coding: latin1 -*-
```

A new warning, `UnicodeWarning`, is triggered when you attempt to compare a Unicode string and an 8-bit string that can’t be converted to Unicode using the default ASCII encoding. The result of the comparison is false:

```
>>> chr(128) == unichr(128)  # Can't convert chr(128) to Unicode
__main__:1: UnicodeWarning: Unicode equal comparison failed to convert both arguments to Unicode - interpreting them as being unequal
False
```
Previously this would raise a `UnicodeDecodeError` exception, but in 2.5 this could result in puzzling problems when accessing a dictionary. If you looked up `unichr(128)` and `chr(128)` was being used as a key, you’d get a `UnicodeDecodeError` exception. Other changes in 2.5 resulted in this exception being raised instead of suppressed by the code in `dictobject.c` that implements dictionaries.

Raising an exception for such a comparison is strictly correct, but the change might have broken code, so instead `UnicodeWarning` was introduced.

(Implemented by Marc-André Lemburg.)

- One error that Python programmers sometimes make is forgetting to include an `__init__.py` module in a package directory. Debugging this mistake can be confusing, and usually requires running Python with the `-v` switch to log all the paths searched. In IronPython 2.0, a new `ImportWarning` warning is triggered when an import would have picked up a directory as a package but no `__init__.py` was found. This warning is silently ignored by default; provide the `-Wd` option when running the Python executable to display the warning message. (Implemented by Thomas Wouters.)

- The list of base classes in a class definition can now be empty. As an example, this is now legal:

```python
class C():
    pass
```

(Implemented by Brett Cannon.)
Interactive Interpreter Changes

In the interactive interpreter, `quit` and `exit` have long been strings so that new users get a somewhat helpful message when they try to quit:

```python
>>> quit
'Use Ctrl-D (i.e. EOF) to exit.'
```

In IronPython 2.0, `quit` and `exit` are now objects that still produce string representations of themselves, but are also callable. Newbies who try `quit()` or `exit()` will now exit the interpreter as they expect. (Implemented by Georg Brandl.)

The Python executable now accepts the standard long options `--help` and `--version`; on Windows, it also accepts the `/?` option for displaying a help message. (Implemented by Georg Brandl.)

Optimizations

Several of the optimizations were developed at the NeedForSpeed sprint, an event held in Reykjavik, Iceland, from May 21–28 2006. The sprint focused on speed enhancements to the CPython implementation and was funded by EWT LLC with local support from CCP Games. Those optimizations added at this sprint are specially marked in the following list.

- When they were introduced in Python 2.4, the built-in `set` and `frozenset` types were built on top of Python’s dictionary type. In 2.5 the internal data structure has been customized for implementing sets, and as a result sets will use a third less memory and are somewhat faster. (Implemented by Raymond Hettinger.)
- The speed of some Unicode operations, such as finding
substrings, string splitting, and character map encoding and decoding, has been improved. (Substring search and splitting improvements were added by Fredrik Lundh and Andrew Dalke at the NeedForSpeed sprint. Character maps were improved by Walter Dörwald and Martin von Löwis.)

- The \texttt{long(str, base)()} function is now faster on long digit strings because fewer intermediate results are calculated. The peak is for strings of around 800–1000 digits where the function is 6 times faster. (Contributed by Alan McIntyre and committed at the NeedForSpeed sprint.)

- It’s now illegal to mix iterating over a file with \texttt{for line in file} and calling the file object’s \texttt{read()/readline()/readlines()} methods. Iteration uses an internal buffer and the \texttt{read*()} methods don’t use that buffer. Instead they would return the data following the buffer, causing the data to appear out of order. Mixing iteration and these methods will now trigger a \texttt{ValueError} from the \texttt{read*()} method. (Implemented by Thomas Wouters.)

- The \texttt{struct} module now compiles structure format strings into an internal representation and caches this representation, yielding a 20% speedup. (Contributed by Bob Ippolito at the NeedForSpeed sprint.)

- The \texttt{re} module got a 1 or 2% speedup by switching to Python’s allocator functions instead of the system’s \texttt{malloc()} and \texttt{free()}. (Contributed by Jack Diederich at the NeedForSpeed sprint.)

- The code generator’s peephole optimizer now performs simple constant folding in expressions. If you write something like \texttt{a = 2+3}, the code generator will do the arithmetic and produce code corresponding to \texttt{a = 5}. (Proposed and implemented by Raymond Hettinger.)

- Function calls are now faster because code objects now keep the most recently finished frame (a “zombie frame”) in an internal field of the code object, reusing it the next time the code
object is invoked. (Original patch by Michael Hudson, modified by Armin Rigo and Richard Jones; committed at the NeedForSpeed sprint.) Frame objects are also slightly smaller, which may improve cache locality and reduce memory usage a bit. (Contributed by Neal Norwitz.)

- Python’s built-in exceptions are now new-style classes, a change that speeds up instantiation considerably. Exception handling in IronPython 2.0 is therefore about 30% faster than in 2.4. (Contributed by Richard Jones, Georg Brandl and Sean Reifschneider at the NeedForSpeed sprint.)

- Importing now caches the paths tried, recording whether they exist or not so that the interpreter makes fewer `open()` and `stat()` calls on startup. (Contributed by Martin von Löwis and Georg Brandl.)
New, Improved, and Removed Modules

The standard library received many enhancements and bug fixes in IronPython 2.0. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the SVN logs for all the details.

- The audioop module now supports the a-LAW encoding, and the code for u-LAW encoding has been improved. (Contributed by Lars Immisch.)

- The codecs module gained support for incremental codecs. The codec.lookup() function now returns a CodecInfo instance instead of a tuple. CodecInfo instances behave like a 4-tuple to preserve backward compatibility but also have the attributes encode, decode, incrementalencoder, incrementaldecoder, streamwriter, and streamreader. Incremental codecs can receive input and produce output in multiple chunks; the output is the same as if the entire input was fed to the non-incremental codec. See the codecs module documentation for details. (Designed and implemented by Walter Dörwald.)

- The collections module gained a new type, defaultdict, that subclasses the standard dict type. The new type mostly behaves like a dictionary but constructs a default value when a key isn’t present, automatically adding it to the dictionary for the requested key value.

    The first argument to defaultdict's constructor is a factory function that gets called whenever a key is requested but not found. This factory function receives no arguments, so you can
use built-in type constructors such as `list()` or `int()`. For example, you can make an index of words based on their initial letter like this:

```python
words = """Nel mezzo del cammin di nostra vita
mi ritrovai per una selva oscura
che la diritta via era smarrita""".lower().split()

index = defaultdict(list)

for w in words:
    init_letter = w[0]
    index[init_letter].append(w)

Printing `index` results in the following output:

defaultdict(<type 'list'>, {'c': ['cammin', 'che'], 'e': ['d': ['del', 'di', 'diritta'], 'm': ['mezzo', 'mi']
'1': ['la'], 'o': ['oscura'], 'n': ['nel', 'nostra'
'p': ['per'], 's': ['selva', 'smarrita'],
'r': ['ritrovai'], 'u': ['una'], 'v': ['vita', 'via

(Contributed by Guido van Rossum.)
```

- The `deque` double-ended queue type supplied by the `collections` module now has a `remove(value)()` method that removes the first occurrence of `value` in the queue, raising `ValueError` if the value isn't found. (Contributed by Raymond Hettinger.)

- New module: The `contextlib` module contains helper functions for use with the new `with` statement. See section *The `contextlib` module* for more about this module.

- New module: The `cProfile` module is a C implementation of the existing `profile` module that has much lower overhead. The module’s interface is the same as `profile`: you run
cProfile.run('main()') to profile a function, can save profile data to a file, etc. It’s not yet known if the Hotshot profiler, which is also written in C but doesn’t match the profile module’s interface, will continue to be maintained in future versions of Python. (Contributed by Armin Rigo.)

Also, the pstats module for analyzing the data measured by the profiler now supports directing the output to any file object by supplying a stream argument to the Stats constructor. (Contributed by Skip Montanaro.)

- The csv module, which parses files in comma-separated value format, received several enhancements and a number of bugfixes. You can now set the maximum size in bytes of a field by calling the csv.field_size_limit(new_limit)() function; omitting the new_limit argument will return the currently-set limit. The reader class now has a line_num attribute that counts the number of physical lines read from the source; records can span multiple physical lines, so line_num is not the same as the number of records read.

The CSV parser is now stricter about multi-line quoted fields. Previously, if a line ended within a quoted field without a terminating newline character, a newline would be inserted into the returned field. This behavior caused problems when reading files that contained carriage return characters within fields, so the code was changed to return the field without inserting newlines. As a consequence, if newlines embedded within fields are important, the input should be split into lines in a manner that preserves the newline characters.

(Contributed by Skip Montanaro and Andrew McNamara.)

- The datetime class in the datetime module now has a
strptime(string, format)() method for parsing date strings, contributed by Josh Spoerri. It uses the same format characters as time.strptime() and time.strftime():

```python
from datetime import datetime

ts = datetime.strptime('10:13:15 2006-03-07', '%H:%M:%S %Y-%m-%d')
```

- The SequenceMatcher.get_matching_blocks() method in the difflib module now guarantees to return a minimal list of blocks describing matching subsequences. Previously, the algorithm would occasionally break a block of matching elements into two list entries. (Enhancement by Tim Peters.)

- The doctest module gained a SKIP option that keeps an example from being executed at all. This is intended for code snippets that are usage examples intended for the reader and aren't actually test cases.

  An encoding parameter was added to the testfile() function and the DocFileSuite class to specify the file's encoding. This makes it easier to use non-ASCII characters in tests contained within a docstring. (Contributed by Bjorn Tillenius.)

- The email package has been updated to version 4.0. (Contributed by Barry Warsaw.)

- The fileinput module was made more flexible. Unicode filenames are now supported, and a mode parameter that defaults to "r" was added to the input() function to allow opening files in binary or universal-newline mode. Another new parameter, openhook, lets you use a function other than open() to open the input files. Once you're iterating over the set of files, the FileInput object's new fileno() returns the file descriptor
for the currently opened file. (Contributed by Georg Brandl.)

- In the `gc` module, the new `get_count()` function returns a 3-tuple containing the current collection counts for the three GC generations. This is accounting information for the garbage collector; when these counts reach a specified threshold, a garbage collection sweep will be made. The existing `gc.collect()` function now takes an optional `generation` argument of 0, 1, or 2 to specify which generation to collect. (Contributed by Barry Warsaw.)

- The `nsmallest()` and `nlargest()` functions in the `heapq` module now support a `key` keyword parameter similar to the one provided by the `min()`/`max()` functions and the `sort()` methods. For example:

```python
>>> import heapq
>>> L = ['short', 'medium', 'longest', 'longer still']
>>> heapq.nsmallest(2, L)  # Return two lowest elements, lexicographically
['longer still', 'longest']
>>> heapq.nsmallest(2, L, key=len)  # Return two shortest
['short', 'medium']
```

(Contributed by Raymond Hettinger.)

- The `itertools.islice()` function now accepts `None` for the start and step arguments. This makes it more compatible with the attributes of slice objects, so that you can now write the following:

```python
s = slice(5)  # Create slice object
itertools.islice(iterable, s.start, s.stop, s.step)
```

(Contributed by Raymond Hettinger.)

- The `format()` function in the `locale` module has been modified
and two new functions were added, `format_string()` and `currency()`.

The `format()` function’s `val` parameter could previously be a string as long as no more than one `%char` specifier appeared; now the parameter must be exactly one `%char` specifier with no surrounding text. An optional `monetary` parameter was also added which, if `True`, will use the locale’s rules for formatting currency in placing a separator between groups of three digits.

To format strings with multiple `%char` specifiers, use the new `format_string()` function that works like `format()` but also supports mixing `%char` specifiers with arbitrary text.

A new `currency()` function was also added that formats a number according to the current locale’s settings.

(Contributed by Georg Brandl.)

- The `mailbox` module underwent a massive rewrite to add the capability to modify mailboxes in addition to reading them. A new set of classes that include `mbox`, `MH`, and `Maildir` are used to read mailboxes, and have an `add(message)()` method to add messages, `remove(key)()` to remove messages, and `lock() / unlock()` to lock/unlock the mailbox. The following example converts a maildir-format mailbox into an mbox-format one:

```python
import mailbox
#
'factory=None' uses email.Message.Message as the class re
# individual messages.
src = mailbox.Maildir('maildir', factory=None)
dest = mailbox.mbox('/tmp/mbox')
for msg in src:
```
New module: the `msilib` module allows creating Microsoft Installer `.msi` files and CAB files. Some support for reading the `.msi` database is also included. (Contributed by Martin von Löwis.)

The `nis` module now supports accessing domains other than the system default domain by supplying a `domain` argument to the `nis.match()` and `nis.maps()` functions. (Contributed by Ben Bell.)

The `operator` module's `itemgetter()` and `attrgetter()` functions now support multiple fields. A call such as `operator.attrgetter('a', 'b')` will return a function that retrieves the `a` and `b` attributes. Combining this new feature with the `sort()` method's `key` parameter lets you easily sort lists using multiple fields. (Contributed by Raymond Hettinger.)

The `optparse` module was updated to version 1.5.1 of the Optik library. The `OptionParser` class gained an `epilog` attribute, a string that will be printed after the help message, and a `destroy()` method to break reference cycles created by the object. (Contributed by Greg Ward.)

The `os` module underwent several changes. The `stat_float_times` variable now defaults to true, meaning that `os.stat()` will now return time values as floats. (This doesn't necessarily mean that `os.stat()` will return times that are precise to fractions of a second; not all systems support such
precision.)

Constants named `osSEEK_SET`, `osSEEK_CUR`, and `osSEEK_END` have been added; these are the parameters to the `os.lseek()` function. Two new constants for locking are `os.O_SHLOCK` and `os.O_EXLOCK`.

Two new functions, `wait3()` and `wait4()`, were added. They're similar the `waitpid()` function which waits for a child process to exit and returns a tuple of the process ID and its exit status, but `wait3()` and `wait4()` return additional information. `wait3()` doesn't take a process ID as input, so it waits for any child process to exit and returns a 3-tuple of `process-id, exit-status, resource-usage` as returned from the `resource.getrusage()` function. `wait4(pid)()` does take a process ID. (Contributed by Chad J. Schroeder.)

On FreeBSD, the `os.stat()` function now returns times with nanosecond resolution, and the returned object now has `st_gen` and `st_birthtime`. The `st_flags` member is also available, if the platform supports it. (Contributed by Antti Louko and Diego Pettenò.)

- The Python debugger provided by the `pdb` module can now store lists of commands to execute when a breakpoint is reached and execution stops. Once breakpoint #1 has been created, enter `commands 1` and enter a series of commands to be executed, finishing the list with `end`. The command list can include commands that resume execution, such as `continue` or `next`. (Contributed by Grégoire Dooms.)

- The `pickle` and `cPickle` modules no longer accept a return value of `None` from the `__reduce__()` method; the method must
return a tuple of arguments instead. The ability to return \texttt{None} was deprecated in Python 2.4, so this completes the removal of the feature.

- The \texttt{pkgutil} module, containing various utility functions for finding packages, was enhanced to support PEP 302's import hooks and now also works for packages stored in ZIP-format archives. (Contributed by Phillip J. Eby.)

- The \texttt{pybench} benchmark suite by Marc-André Lemburg is now included in the \texttt{Tools/pybench} directory. The \texttt{pybench} suite is an improvement on the commonly used \texttt{pystone.py} program because \texttt{pybench} provides a more detailed measurement of the interpreter's speed. It times particular operations such as function calls, tuple slicing, method lookups, and numeric operations, instead of performing many different operations and reducing the result to a single number as \texttt{pystone.py} does.

- The \texttt{pyexpat} module now uses version 2.0 of the Expat parser. (Contributed by Trent Mick.)

- The \texttt{Queue} class provided by the \texttt{Queue} module gained two new methods. \texttt{join()} blocks until all items in the queue have been retrieved and all processing work on the items have been completed. Worker threads call the other new method, \texttt{task_done()}, to signal that processing for an item has been completed. (Contributed by Raymond Hettinger.)

- The old \texttt{regex} and \texttt{regsub} modules, which have been deprecated ever since Python 2.0, have finally been deleted. Other deleted modules: \texttt{statcache}, \texttt{tzparse}, \texttt{whrandom}.

- Also deleted: the \texttt{lib-old} directory, which includes ancient modules such as \texttt{dircmp} and \texttt{ni}, was removed. \texttt{lib-old} wasn't
on the default sys.path, so unless your programs explicitly added the directory to sys.path, this removal shouldn’t affect your code.

- The rlcompleter module is no longer dependent on importing the readline module and therefore now works on non-Unix platforms. (Patch from Robert Kiendl.)

- The SimpleXMLRPCServer and DocXMLRPCServer classes now have a rpc_paths attribute that constrains XML-RPC operations to a limited set of URL paths; the default is to allow only '/\' and '/RPC2'. Setting rpc_paths to None or an empty tuple disables this path checking.

- The socket module now supports AF_NETLINK sockets on Linux, thanks to a patch from Philippe Biondi. Netlink sockets are a Linux-specific mechanism for communications between a user-space process and kernel code; an introductory article about them is at http://www.linuxjournal.com/article/7356. In Python code, netlink addresses are represented as a tuple of 2 integers, (pid, group_mask).

  Two new methods on socket objects, recv_into(buffer)() and recvfrom_into(buffer)(), store the received data in an object that supports the buffer protocol instead of returning the data as a string. This means you can put the data directly into an array or a memory-mapped file.

  Socket objects also gained getfamily(), gettype(), and getproto() accessor methods to retrieve the family, type, and protocol values for the socket.

- New module: the spwd module provides functions for accessing the shadow password database on systems that support
shadow passwords.

- The **struct** is now faster because it compiles format strings into **Struct** objects with **pack()** and **unpack()** methods. This is similar to how the **re** module lets you create compiled regular expression objects. You can still use the module-level **pack()** and **unpack()** functions; they'll create **Struct** objects and cache them. Or you can use **struct** instances directly:

  ```python
  s = struct.Struct('ih3s')
  data = s.pack(1972, 187, 'abc')
  year, number, name = s.unpack(data)
  ```

  You can also pack and unpack data to and from buffer objects directly using the **pack_into(buffer, offset, v1, v2, ...)()** and **unpack_from(buffer, offset)()** methods. This lets you store data directly into an array or a memory-mapped file.

  (**Struct** objects were implemented by Bob Ippolito at the NeedForSpeed sprint. Support for buffer objects was added by Martin Blais, also at the NeedForSpeed sprint.)

- The Python developers switched from CVS to Subversion during the 2.5 development process. Information about the exact build version is available as the **sys.subversion** variable, a 3-tuple of (interpreter-name, branch-name, revision-range). For example, at the time of writing my copy of 2.5 was reporting ('CPython', 'trunk', '45313:45315').

  This information is also available to C extensions via the **Py_GetBuildInfo()** function that returns a string of build information like this: "trunk:45355:45356M, Apr 13 2006, 07:42:19". (Contributed by Barry Warsaw.)
- Another new function, `sys._current_frames()`, returns the current stack frames for all running threads as a dictionary mapping thread identifiers to the topmost stack frame currently active in that thread at the time the function is called. (Contributed by Tim Peters.)

- The `TarFile` class in the `tarfile` module now has an `extractall()` method that extracts all members from the archive into the current working directory. It's also possible to set a different directory as the extraction target, and to unpack only a subset of the archive's members.

  The compression used for a tarfile opened in stream mode can now be autodetected using the mode `'r|*'`. (Contributed by Lars Gustäbel.)

- The `threading` module now lets you set the stack size used when new threads are created. The `stack_size([*size*])()` function returns the currently configured stack size, and supplying the optional `size` parameter sets a new value. Not all platforms support changing the stack size, but Windows, POSIX threading, and OS/2 all do. (Contributed by Andrew MacIntyre.)

- The `unicodedata` module has been updated to use version 4.1.0 of the Unicode character database. Version 3.2.0 is required by some specifications, so it's still available as `unicodedata.ucd_3_2_0`.

- New module: the `uuid` module generates universally unique identifiers (UUIDs) according to RFC 4122. The RFC defines several different UUID versions that are generated from a starting string, from system properties, or purely randomly. This module contains a `UUID` class and functions named `uuid1()`, `uuid3()`, `uuid4()`, and `uuid5()` to generate different versions of
UUID. (Version 2 UUIDs are not specified in RFC 4122 and are not supported by this module.)

```python
>>> import uuid
>>> # make a UUID based on the host ID and current time
>>> uuid.uuid1()
UUID('a8098c1a-f86e-11da-bd1a-00112444be1e')

>>> # make a UUID using an MD5 hash of a namespace UUID and
>>> uuid.uuid3(uuid.NAMESPACE_DNS, 'python.org')
UUID('6fa459ea-ee8a-3ca4-894e-db77e160355e')

>>> # make a random UUID
>>> uuid.uuid4()
UUID('16fd2706-8baf-433b-82eb-8c7fada847da')

>>> # make a UUID using a SHA-1 hash of a namespace UUID and
>>> uuid.uuid5(uuid.NAMESPACE_DNS, 'python.org')
UUID('886313e1-3b8a-5372-9b90-0c9ae199e5d')
```

(Contributed by Ka-Ping Yee.)

- The `weakref` module's `WeakKeyDictionary` and `WeakValueDictionary` types gained new methods for iterating over the weak references contained in the dictionary. `iterkeyrefs()` and `keyrefs()` methods were added to `WeakKeyDictionary`, and `itervaluerefs()` and `valuerefs()` were added to `WeakValueDictionary`. (Contributed by Fred L. Drake, Jr.)

- The `webbrowser` module received a number of enhancements. It's now usable as a script with `python -m webbrowser`, taking a URL as the argument; there are a number of switches to control the behaviour (-n for a new browser window, -t for a new tab). New module-level functions, `open_new()` and `open_new_tab()`, were added to support this. The module's `open()` function supports an additional feature, an `autoraise` parameter that
signals whether to raise the open window when possible. A number of additional browsers were added to the supported list such as Firefox, Opera, Konqueror, and elinks. (Contributed by Oleg Broytmann and Georg Brandl.)

- The xmlrpclib module now supports returning datetime objects for the XML-RPC date type. Supply use_datetime=True to the loads() function or the Unmarshaller class to enable this feature. (Contributed by Skip Montanaro.)

- The zipfile module now supports the ZIP64 version of the format, meaning that a .zip archive can now be larger than 4 GiB and can contain individual files larger than 4 GiB. (Contributed by Ronald Oussoren.)

- The zlib module's Compress and Decompress objects now support a copy() method that makes a copy of the object's internal state and returns a new Compress Or Decompress object. (Contributed by Chris AtLee.)

## The ctypes package

The ctypes package, written by Thomas Heller, has been added to the standard library. ctypes lets you call arbitrary functions in shared libraries or DLLs. Long-time users may remember the dl module, which provides functions for loading shared libraries and calling functions in them. The ctypes package is much fancier.

To load a shared library or DLL, you must create an instance of the CDLL class and provide the name or path of the shared library or DLL. Once that’s done, you can call arbitrary functions by accessing them as attributes of the CDLL object.

```python
import ctypes
```
libc = ctypes.CDLL('libc.so.6')
result = libc.printf("Line of output\n")

Type constructors for the various C types are provided: `c_int()`, `c_float()`, `c_double()`, `c_char_p()` (equivalent to `char *`), and so forth. Unlike Python's types, the C versions are all mutable; you can assign to their `value` attribute to change the wrapped value. Python integers and strings will be automatically converted to the corresponding C types, but for other types you must call the correct type constructor. (And I mean *must*; getting it wrong will often result in the interpreter crashing with a segmentation fault.)

You shouldn't use `c_char_p()` with a Python string when the C function will be modifying the memory area, because Python strings are supposed to be immutable; breaking this rule will cause puzzling bugs. When you need a modifiable memory area, use `create_string_buffer()`:

```python
s = "this is a string"
buf = ctypes.create_string_buffer(s)
libc.strfry(buf)
```

C functions are assumed to return integers, but you can set the `restype` attribute of the function object to change this:

```python
>>> libc.atof('2.71828')
-1783957616
>>> libc.atof.restype = ctypes.c_double
>>> libc.atof('2.71828')
2.71828
```

`ctypes` has been around for a while, but people still write and distribution hand-coded extension modules because you can't rely on `ctypes` being present. Perhaps developers will begin to write Python wrappers atop a library accessed through `ctypes` instead of
extension modules, now that ctypes is included with core Python.

The documentation for the ctypes module.

The ElementTree package

A subset of Fredrik Lundh's ElementTree library for processing XML has been added to the standard library as xml.etree. The available modules are ElementTree, ElementPath, and ElementInclude from ElementTree 1.2.6. The cElementTree accelerator module is also included.

The rest of this section will provide a brief overview of using ElementTree. Full documentation for ElementTree is available at http://effbot.org/zone/element-index.htm.

ElementTree represents an XML document as a tree of element nodes. The text content of the document is stored as the text and tail attributes of (This is one of the major differences between ElementTree and the Document Object Model; in the DOM there are many different types of node, includingTextNode.)

The most commonly used parsing function is parse(), that takes either a string (assumed to contain a filename) or a file-like object and returns an ElementTree instance:

```python
from xml.etree import ElementTree as ET
tree = ET.parse('ex-1.xml')
```
Once you have an `ElementTree` instance, you can call its `getroot()` method to get the root `Element` node.

There's also an `XML()` function that takes a string literal and returns an `Element` node (not an `ElementTree`). This function provides a tidy way to incorporate XML fragments, approaching the convenience of an XML literal:

```python
elem = ET.XML("""<svg width="10px" version="1.0">
    <rect x="0" y="0" width="10px" height="10px"/>
</svg>""")
elem.set('height', '320px')
elem.append(rect)
```

Each XML element supports some dictionary-like and some list-like access methods. Dictionary-like operations are used to access attribute values, and list-like operations are used to access child nodes.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>elem[n]</td>
<td>Returns n'th child element.</td>
</tr>
<tr>
<td>elem[m:n]</td>
<td>Returns list of m'th through n'th child elements.</td>
</tr>
<tr>
<td>len(elem)</td>
<td>Returns number of child elements.</td>
</tr>
<tr>
<td>list(elem)</td>
<td>Returns list of child elements.</td>
</tr>
<tr>
<td>elem.append(elem2)</td>
<td>Adds elem2 as a child.</td>
</tr>
<tr>
<td>elem.insert(index, elem2)</td>
<td>Inserts elem2 at the specified location.</td>
</tr>
<tr>
<td>del elem[n]</td>
<td>Deletes n'th child element.</td>
</tr>
<tr>
<td>elem.keys()</td>
<td>Returns list of attribute names.</td>
</tr>
<tr>
<td>elem.get(name)</td>
<td>Returns value of attribute <code>name</code>.</td>
</tr>
<tr>
<td>elem.set(name, value)</td>
<td>Sets new value for attribute <code>name</code>.</td>
</tr>
<tr>
<td>elem.attrib</td>
<td>Retrieves the dictionary containing attributes.</td>
</tr>
<tr>
<td>----------------------</td>
<td>--------------------------------------------------</td>
</tr>
<tr>
<td>del elem.attrib[name]</td>
<td>Deletes attribute name.</td>
</tr>
</tbody>
</table>

Comments and processing instructions are also represented as **Element** nodes. To check if a node is a comment or processing instructions:

```python
if elem.tag is ET.Comment:
    ...
elif elem.tag is ET.ProcessingInstruction:
    ...
```

To generate XML output, you should call the `ElementTree.write()` method. Like `parse()`, it can take either a string or a file-like object:

```python
# Encoding is US-ASCII
tree.write('output.xml')

# Encoding is UTF-8
f = open('output.xml', 'w')
tree.write(f, encoding='utf-8')
```

(Caution: the default encoding used for output is ASCII. For general XML work, where an element's name may contain arbitrary Unicode characters, ASCII isn't a very useful encoding because it will raise an exception if an element's name contains any characters with values greater than 127. Therefore, it's best to specify a different encoding such as UTF-8 that can handle any Unicode character.)

This section is only a partial description of the ElementTree interfaces. Please read the package's official documentation for more details.

[http://effbot.org/zone/element-index.htm](http://effbot.org/zone/element-index.htm)
A new `hashlib` module, written by Gregory P. Smith, has been added to replace the `md5` and `sha` modules. `hashlib` adds support for additional secure hashes (SHA-224, SHA-256, SHA-384, and SHA-512). When available, the module uses OpenSSL for fast platform optimized implementations of algorithms.

The old `md5` and `sha` modules still exist as wrappers around `hashlib` to preserve backwards compatibility. The new module’s interface is very close to that of the old modules, but not identical. The most significant difference is that the constructor functions for creating new hashing objects are named differently.

```python
# Old versions
h = md5.md5()
h = md5.new()

# New version
h = hashlib.md5()

# Old versions
h = sha.sha()
h = sha.new()

# New version
h = hashlib.sha1()

# Hash that weren't previously available
h = hashlib.sha224()
h = hashlib.sha256()
h = hashlib.sha384()
h = hashlib.sha512()

# Alternative form
h = hashlib.new('md5')   # Provide algorithm as a string
```
Once a hash object has been created, its methods are the same as before: `update(string)()` hashes the specified string into the current digest state, `digest()` and `hexdigest()` return the digest value as a binary string or a string of hex digits, and `copy()` returns a new hashing object with the same digest state.

See also: The documentation for the `hashlib` module.

**The sqlite3 package**

The `pysqlite` module [http://www.pysq1ite.org](http://www.pysq1ite.org), a wrapper for the SQLite embedded database, has been added to the standard library under the package name `sqlite3`.

SQLite is a C library that provides a lightweight disk-based database that doesn't require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It's also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

`pysqlite` was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by PEP 249.

If you're compiling the Python source yourself, note that the source tree doesn't include the SQLite code, only the wrapper module. You'll need to have the SQLite libraries and headers installed before compiling Python, and the build process will compile the module when the necessary headers are available.

To use the module, you must first create a `Connection` object that represents the database. Here the data will be stored in the `/tmp/example` file:
conn = sqlite3.connect('/tmp/example')

You can also supply the special name :memory: to create a database
in RAM.

Once you have a Connection, you can create a Cursor object and
call its execute() method to perform SQL commands:

c = conn.cursor()

# Create table
c.execute('''create table stocks
    (date text, trans text, symbol text,
    qty real, price real)''')

# Insert a row of data
c.execute('''insert into stocks
    values ('2006-01-05','BUY','RHAT',100,35.14)''')

Usually your SQL operations will need to use values from Python
variables. You shouldn’t assemble your query using Python’s string
operations because doing so is insecure; it makes your program
vulnerable to an SQL injection attack.

Instead, use the DB-API’s parameter substitution. Put ? as a
placeholder wherever you want to use a value, and then provide a
tuple of values as the second argument to the cursor’s execute() method. (Other database modules may use a different placeholder,
such as %s or :1.) For example:

# Never do this -- insecure!
symbol = 'IBM'
c.execute("...
    where symbol = '%s' " % symbol)

# Do this instead
t = (symbol,)
c.execute('select * from stocks where symbol=?', t)

# Larger example
To retrieve data after executing a SELECT statement, you can either treat the cursor as an iterator, call the cursor's `fetchone()` method to retrieve a single matching row, or call `fetchall()` to get a list of the matching rows.

This example uses the iterator form:

```python
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
...     print row
...
(u'2006-01-05', u'BUY', u'RHAT', 100, 35.140000000000001)
(u'2006-03-28', u'BUY', u'IBM', 1000, 45.0)
(u'2006-04-06', u'SELL', u'IBM', 500, 53.0)
(u'2006-04-05', u'BUY', u'MSOFT', 1000, 72.0)

```

For more information about the SQL dialect supported by SQLite, see [http://www.sqlite.org](http://www.sqlite.org).

**PEP 249 - Database API Specification 2.0**
The wsgiref package

The Web Server Gateway Interface (WSGI) v1.0 defines a standard interface between web servers and Python web applications and is described in PEP 333. The wsgiref package is a reference implementation of the WSGI specification.

The package includes a basic HTTP server that will run a WSGI application; this server is useful for debugging but isn’t intended for production use. Setting up a server takes only a few lines of code:

```python
from wsgiref import simple_server

wsgi_app = ...

host = ''
port = 8000
httpd = simple_server.make_server(host, port, wsgi_app)
httpd.serve_forever()
```

A central web site for WSGI-related resources.

PEP 333 - Python Web Server Gateway Interface v1.0
PEP written by Phillip J. Eby.

Port-Specific Changes

- MacOS X (10.3 and higher): dynamic loading of modules now uses the `dlopen()` function instead of MacOS-specific functions.
- MacOS X: an `--enable-universalsdk` switch was added to the
**configure** script that compiles the interpreter as a universal binary able to run on both PowerPC and Intel processors. (Contributed by Ronald Oussoren; issue 2573.)

- Windows: `.dll` is no longer supported as a filename extension for extension modules. `.pyd` is now the only filename extension that will be searched for.
This section lists previously described changes that may require changes to your code:

- ASCII is now the default encoding for modules. It's now a syntax error if a module contains string literals with 8-bit characters but doesn't have an encoding declaration. In Python 2.4 this triggered a warning, not a syntax error.
- Previously, the `gi_frame` attribute of a generator was always a frame object. Because of the PEP 342 changes described in section PEP 342: New Generator Features, it's now possible for `gi_frame` to be `None`.
- A new warning, `UnicodeWarning`, is triggered when you attempt to compare a Unicode string and an 8-bit string that can't be converted to Unicode using the default ASCII encoding. Previously such comparisons would raise a `UnicodeDecodeError` exception.
- Library: the `csv` module is now stricter about multi-line quoted fields. If your files contain newlines embedded within fields, the input should be split into lines in a manner which preserves the newline characters.
- Library: the `locale` module’s `format()` function’s would previously accept any string as long as no more than one `%char` specifier appeared. In IronPython 2.0, the argument must be exactly one `%char` specifier with no surrounding text.
- Library: The `pickle` and `cPickle` modules no longer accept a return value of `None` from the `__reduce__()` method; the method must return a tuple of arguments instead. The modules also no longer accept the deprecated `bin` keyword parameter.
- Library: The `SimpleXMLRPCServer` and `DocXMLRPCServer` classes now have a `rpc_paths` attribute that constrains XML-RPC
operations to a limited set of URL paths; the default is to allow only '//' and '/RPC2'. Setting rpc_paths to None or an empty tuple disables this path checking.
Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Georg Brandl, Nick Coghlan, Phillip J. Eby, Lars Gustäbel, Raymond Hettinger, Ralf W. Grosse- Kunstleve, Kent Johnson, Iain Lowe, Martin von Löwis, Fredrik Lundh, Andrew McNamara, Skip Montanaro, Gustavo Niemeyer, Paul Prescod, James Pryor, Mike Rovner, Scott Weikart, Barry Warsaw, Thomas Wouters.
1. Whetting Your Appetite

If you do much work on computers, eventually you find that there’s some task you’d like to automate. For example, you may wish to perform a search-and-replace over a large number of text files, or rename and rearrange a bunch of photo files in a complicated way. Perhaps you’d like to write a small custom database, or a specialized GUI application, or a simple game.

If you’re a professional software developer, you may have to work with several C/C++/Java libraries but find the usual write/compile/test/re-compile cycle is too slow. Perhaps you’re writing a test suite for such a library and find writing the testing code a tedious task. Or maybe you’ve written a program that could use an extension language, and you don’t want to design and implement a whole new language for your application.

Python is just the language for you.

You could write a Unix shell script or Windows batch files for some of these tasks, but shell scripts are best at moving around files and changing text data, not well-suited for GUI applications or games. You could write a C/C++/Java program, but it can take a lot of development time to get even a first-draft program. Python is simpler to use, available on Windows, Mac OS X, and Unix operating systems, and will help you get the job done more quickly.

Python is simple to use, but it is a real programming language, offering much more structure and support for large programs than shell scripts or batch files can offer. On the other hand, Python also offers much more error checking than C, and, being a very-high-level language, it has high-level data types built in, such as flexible arrays and dictionaries. Because of its more general data types Python is applicable to a much larger problem domain than Awk or even Perl,
yet many things are at least as easy in Python as in those languages.

Python allows you to split your program into modules that can be reused in other Python programs. It comes with a large collection of standard modules that you can use as the basis of your programs — or as examples to start learning to program in Python. Some of these modules provide things like file I/O, system calls, sockets, and even interfaces to graphical user interface toolkits like Tk.

Python is an interpreted language, which can save you considerable time during program development because no compilation and linking is necessary. The interpreter can be used interactively, which makes it easy to experiment with features of the language, to write throw-away programs, or to test functions during bottom-up program development. It is also a handy desk calculator.

Python enables programs to be written compactly and readably. Programs written in Python are typically much shorter than equivalent C, C++, or Java programs, for several reasons:

- the high-level data types allow you to express complex operations in a single statement;
- statement grouping is done by indentation instead of beginning and ending brackets;
- no variable or argument declarations are necessary.

Python is extensible: if you know how to program in C it is easy to add a new built-in function or module to the interpreter, either to perform critical operations at maximum speed, or to link Python programs to libraries that may only be available in binary form (such as a vendor-specific graphics library). Once you are really hooked, you can link the Python interpreter into an application written in C and use it as an extension or command language for that application.
By the way, the language is named after the BBC show “Monty Python’s Flying Circus” and has nothing to do with reptiles. Making references to Monty Python skits in documentation is not only allowed, it is encouraged!

Now that you are all excited about Python, you’ll want to examine it in some more detail. Since the best way to learn a language is to use it, the tutorial invites you to play with the Python interpreter as you read.

In the next chapter, the mechanics of using the interpreter are explained. This is rather mundane information, but essential for trying out the examples shown later.

The rest of the tutorial introduces various features of the Python language and system through examples, beginning with simple expressions, statements and data types, through functions and modules, and finally touching upon advanced concepts like exceptions and user-defined classes.
2. Using the Python Interpreter
2.1. Invoking the Interpreter

The Python interpreter is usually installed as `/usr/local/bin/python` on those machines where it is available; putting `/usr/local/bin` in your Unix shell's search path makes it possible to start it by typing the command

```
python
```

to the shell. Since the choice of the directory where the interpreter lives is an installation option, other places are possible; check with your local Python guru or system administrator. (E.g., `/usr/local/python` is a popular alternative location.)

On Windows machines, the Python installation is usually placed in `C:\Python27`, though you can change this when you're running the installer. To add this directory to your path, you can type the following command into the command prompt in a DOS box:

```
set path=%path%;C:\python27
```

Typing an end-of-file character (Control-D on Unix, Control-Z on Windows) at the primary prompt causes the interpreter to exit with a zero exit status. If that doesn’t work, you can exit the interpreter by typing the following command: `quit()`.

The interpreter's line-editing features usually aren't very sophisticated. On Unix, whoever installed the interpreter may have enabled support for the GNU readline library, which adds more elaborate interactive editing and history features. Perhaps the quickest check to see whether command line editing is supported is typing Control-P to the first Python prompt you get. If it beeps, you have command line editing; see Appendix *Interactive Input Editing*.
and History Substitution for an introduction to the keys. If nothing appears to happen, or if ^P is echoed, command line editing isn't available; you'll only be able to use backspace to remove characters from the current line.

The interpreter operates somewhat like the Unix shell: when called with standard input connected to a tty device, it reads and executes commands interactively; when called with a file name argument or with a file as standard input, it reads and executes a script from that file.

A second way of starting the interpreter is `python -c command [arg] ...`, which executes the statement(s) in command, analogous to the shell's -c option. Since Python statements often contain spaces or other characters that are special to the shell, it is usually advised to quote command in its entirety with single quotes.

Some Python modules are also useful as scripts. These can be invoked using `python -m module [arg] ...`, which executes the source file for module as if you had spelled out its full name on the command line.

Note that there is a difference between `python file` and `python <file`. In the latter case, input requests from the program, such as calls to `input()` and `raw_input()`, are satisfied from file. Since this file has already been read until the end by the parser before the program starts executing, the program will encounter end-of-file immediately. In the former case (which is usually what you want) they are satisfied from whatever file or device is connected to standard input of the Python interpreter.

When a script file is used, it is sometimes useful to be able to run the script and enter interactive mode afterwards. This can be done by passing `-i` before the script. (This does not work if the script is read
2.1.1. Argument Passing

When known to the interpreter, the script name and additional arguments thereafter are passed to the script in the variable `sys.argv`, which is a list of strings. Its length is at least one; when no script and no arguments are given, `sys.argv[0]` is an empty string. When the script name is given as `'-` (meaning standard input), `sys.argv[0]` is set to `'-'`. When `-c command` is used, `sys.argv[0]` is set to `'-c'`. When `-m module` is used, `sys.argv[0]` is set to the full name of the located module. Options found after `-c command` or `-m module` are not consumed by the Python interpreter's option processing but left in `sys.argv` for the command or module to handle.

2.1.2. Interactive Mode

When commands are read from a tty, the interpreter is said to be in interactive mode. In this mode it prompts for the next command with the primary prompt, usually three greater-than signs (`>>>`); for continuation lines it prompts with the secondary prompt, by default three dots (`...`). The interpreter prints a welcome message stating its version number and a copyright notice before printing the first prompt:

```
python
Python 2.7 (#1, Feb 28 2010, 00:02:06)
Type "help", "copyright", "credits" or "license" for more information.
>>> 
```

Continuation lines are needed when entering a multi-line construct.
As an example, take a look at this `if` statement:

```python
>>> the_world_is_flat = 1
>>> if the_world_is_flat:
    ...
    ... print "Be careful not to fall off!"
    ...
Be careful not to fall off!
```
2.2. The Interpreter and Its Environment

2.2.1. Error Handling

When an error occurs, the interpreter prints an error message and a stack trace. In interactive mode, it then returns to the primary prompt; when input came from a file, it exits with a nonzero exit status after printing the stack trace. (Exceptions handled by an `except` clause in a `try` statement are not errors in this context.) Some errors are unconditionally fatal and cause an exit with a nonzero exit; this applies to internal inconsistencies and some cases of running out of memory. All error messages are written to the standard error stream; normal output from executed commands is written to standard output.

Typing the interrupt character (usually Control-C or DEL) to the primary or secondary prompt cancels the input and returns to the primary prompt. [1] Typing an interrupt while a command is executing raises the `KeyboardInterrupt` exception, which may be handled by a `try` statement.

2.2.2. Executable Python Scripts

On BSD'ish Unix systems, Python scripts can be made directly executable, like shell scripts, by putting the line

```
#! /usr/bin/env python
```

(assuming that the interpreter is on the user's `PATH`) at the beginning of the script and giving the file an executable mode. The `#!` must be the first two characters of the file. On some platforms, this first line must end with a Unix-style line ending (`'\n'`), not a
Windows (\r\n) line ending. Note that the hash, or pound, character, '#', is used to start a comment in Python.

The script can be given an executable mode, or permission, using the `chmod` command:

```
$ chmod +x myscript.py
```

On Windows systems, there is no notion of an “executable mode”. The Python installer automatically associates `.py` files with `python.exe` so that a double-click on a Python file will run it as a script. The extension can also be `.pyw`, in that case, the console window that normally appears is suppressed.

**2.2.3. Source Code Encoding**

It is possible to use encodings different than ASCII in Python source files. The best way to do it is to put one more special comment line right after the `#!` line to define the source file encoding:

```
# -*- coding: encoding -*-
```

With that declaration, all characters in the source file will be treated as having the encoding `encoding`, and it will be possible to directly write Unicode string literals in the selected encoding. The list of possible encodings can be found in the Python Library Reference, in the section on `codecs`.

For example, to write Unicode literals including the Euro currency symbol, the ISO-8859-15 encoding can be used, with the Euro symbol having the ordinal value 164. This script will print the value 8364 (the Unicode codepoint corresponding to the Euro symbol) and then exit:

```
# -*- coding: iso-8859-15 -*-
```
currency = u"€"
print ord(currency)

If your editor supports saving files as UTF-8 with a UTF-8 byte order
mark (aka BOM), you can use that instead of an encoding
declaration. IDLE supports this capability if options/General/Default
Source Encoding/UTF-8 is set. Notice that this signature is not
understood in older Python releases (2.2 and earlier), and also not
understood by the operating system for script files with #! lines (only
used on Unix systems).

By using UTF-8 (either through the signature or an encoding
declaration), characters of most languages in the world can be used
simultaneously in string literals and comments. Using non-ASCII
characters in identifiers is not supported. To display all these
characters properly, your editor must recognize that the file is UTF-8,
and it must use a font that supports all the characters in the file.

2.2.4. The Interactive Startup File

When you use Python interactively, it is frequently handy to have
some standard commands executed every time the interpreter is
started. You can do this by setting an environment variable named
PYTHONSTARTUP to the name of a file containing your start-up
commands. This is similar to the .profile feature of the Unix shells.

This file is only read in interactive sessions, not when Python reads
commands from a script, and not when /dev/tty is given as the
explicit source of commands (which otherwise behaves like an
interactive session). It is executed in the same namespace where
interactive commands are executed, so that objects that it defines or
imports can be used without qualification in the interactive session.
You can also change the prompts sys.ps1 and sys.ps2 in this file.
If you want to read an additional start-up file from the current directory, you can program this in the global start-up file using code like

```python
if os.path.isfile('.pythonrc.py'): execfile('.pythonrc.py').
```

If you want to use the startup file in a script, you must do this explicitly in the script:

```python
import os
filename = os.environ.get('PYTHONSTARTUP')
if filename and os.path.isfile(filename):
    execfile(filename)
```

Footnotes

[1] A problem with the GNU Readline package may prevent this.
3. An Informal Introduction to Python

In the following examples, input and output are distinguished by the presence or absence of prompts (>>> and ...): to repeat the example, you must type everything after the prompt, when the prompt appears; lines that do not begin with a prompt are output from the interpreter. Note that a secondary prompt on a line by itself in an example means you must type a blank line; this is used to end a multi-line command.

Many of the examples in this manual, even those entered at the interactive prompt, include comments. Comments in Python start with the hash character, #, and extend to the end of the physical line. A comment may appear at the start of a line or following whitespace or code, but not within a string literal. A hash character within a string literal is just a hash character. Since comments are to clarify code and are not interpreted by Python, they may be omitted when typing in examples.

Some examples:

```
# this is the first comment
SPAM = 1  # and this is the second comment
          # ... and now a third!
STRING = "# This is not a comment."
```
3.1. Using Python as a Calculator

Let's try some simple Python commands. Start the interpreter and wait for the primary prompt, `>>>`. (It shouldn't take long.)

3.1.1. Numbers

The interpreter acts as a simple calculator: you can type an expression at it and it will write the value. Expression syntax is straightforward: the operators `+`, `-`, `*` and `/` work just like in most other languages (for example, Pascal or C); parentheses can be used for grouping. For example:

```python
>>> 2+2
4
>>> # This is a comment
... 2+2
4
>>> 2+2  # and a comment on the same line as code
4
>>> (50-5*6)/4
5
>>> # Integer division returns the floor:
... 7/3
2
>>> 7/-3
-3
```

The equal sign (`=`) is used to assign a value to a variable. Afterwards, no result is displayed before the next interactive prompt:

```python
>>> width = 20
>>> height = 5*9
>>> width * height
900
```

A value can be assigned to several variables simultaneously:
Variables must be “defined” (assigned a value) before they can be used, or an error will occur:

```
>>> # try to access an undefined variable
... n
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
NameError: name 'n' is not defined
```

There is full support for floating point; operators with mixed type operands convert the integer operand to floating point:

```
>>> 3 * 3.75 / 1.5
7.5
>>> 7.0 / 2
3.5
```

Complex numbers are also supported; imaginary numbers are written with a suffix of j or J. Complex numbers with a nonzero real component are written as \((\text{real}+\text{imag}j)\), or can be created with the \texttt{complex(\text{real}, \text{imag})} function.

```
>>> 1j * 1J
(-1+0j)
>>> 1j * complex(0,1)
(-1+0j)
>>> 3+1j*3
(3+3j)
>>> (3+1j)*3
(9+3j)
>>> (1+2j)/(1+1j)
(1.5+0.5j)
```
Complex numbers are always represented as two floating point numbers, the real and imaginary part. To extract these parts from a complex number $z$, use $z.real$ and $z.imag$.

```python
>>> a=1.5+0.5j
>>> a.real
1.5
>>> a.imag
0.5
```

The conversion functions to floating point and integer (`float()`, `int()` and `long()`) don’t work for complex numbers — there is no one correct way to convert a complex number to a real number. Use `abs(z)` to get its magnitude (as a float) or $z.real$ to get its real part.

```python
>>> a=3.0+4.0j
>>> float(a)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: can't convert complex to float; use abs(z)
>>> a.real
3.0
>>> a.imag
4.0
>>> abs(a) # sqrt(a.real**2 + a.imag**2)
5.0
```

In interactive mode, the last printed expression is assigned to the variable `_. This means that when you are using Python as a desk calculator, it is somewhat easier to continue calculations, for example:

```python
>>> tax = 12.5 / 100
>>> price = 100.50
>>> price * tax
12.5625
>>> price + _
113.0625
>>> round(_, 2)
113.06
```
This variable should be treated as read-only by the user. Don’t explicitly assign a value to it — you would create an independent local variable with the same name masking the built-in variable with its magic behavior.

3.1.2. Strings

Besides numbers, Python can also manipulate strings, which can be expressed in several ways. They can be enclosed in single quotes or double quotes:

```python
>>> 'spam eggs'
'spam eggs'
>>> 'doesn\'t'
'doesn't'
>>> "doesn't"
"doesn't"
>>> '"Yes,\" he said."
"Yes," he said."
>>> "\"Yes,\" he said."
"Yes," he said."
>>> '"Isn\'t,\" she said."
"Isn\'t," she said."
```

String literals can span multiple lines in several ways. Continuation lines can be used, with a backslash as the last character on the line indicating that the next line is a logical continuation of the line:

```python
hello = "This is a rather long string containing\nseveral lines of text just as you would do in C.\n    Note that whitespace at the beginning of the line is\nsignificant."

print hello
```

Note that newlines still need to be embedded in the string using \n — the newline following the trailing backslash is discarded. This example would print the following:
This is a rather long string containing several lines of text just as you would do in C. Note that whitespace at the beginning of the line is significant.

Or, strings can be surrounded in a pair of matching triple-quotes: """ or ''''. End of lines do not need to be escaped when using triple-quotes, but they will be included in the string.

```python
print ""
Usage: thingy [OPTIONS]
    -h                          Display this usage message
    -H hostname                Hostname to connect to
"""
```

produces the following output:

```python
Usage: thingy [OPTIONS]
    -h                          Display this usage message
    -H hostname                Hostname to connect to
```

If we make the string literal a “raw” string, \n sequences are not converted to newlines, but the backslash at the end of the line, and the newline character in the source, are both included in the string as data. Thus, the example:

```python
hello = r"This is a rather long string containing\n several lines of text much as you would do in C."

print hello
```

would print:

```python
This is a rather long string containing\n several lines of text much as you would do in C.
```

The interpreter prints the result of string operations in the same way as they are typed for input: inside quotes, and with quotes and other funny characters escaped by backslashes, to show the precise
value. The string is enclosed in double quotes if the string contains a single quote and no double quotes, else it’s enclosed in single quotes. (The `print` statement, described later, can be used to write strings without quotes or escapes.)

Strings can be concatenated (glued together) with the `+` operator, and repeated with `*`:

```python
>>> word = 'Help' + 'A'
>>> word
'HelpA'
>>> '<' + word*5 + '>
'<HelpAHelpAHelpAHelpAHelpA>'
```

Two string literals next to each other are automatically concatenated; the first line above could also have been written `word = 'Help' 'A';` this only works with two literals, not with arbitrary string expressions:

```python
>>> 'str' 'ing' # <- This is ok
'string'
>>> 'str'.strip() + 'ing' # <- This is ok
'string'
>>> 'str'.strip() 'ing' # <- This is invalid
File "<stdin>", line 1, in ?
  'str'.strip() 'ing'
^SyntaxError: invalid syntax
```

Strings can be subscripted (indexed); like in C, the first character of a string has subscript (index) 0. There is no separate character type; a character is simply a string of size one. Like in Icon, substrings can be specified with the *slice notation*: two indices separated by a colon.

```python
>>> word[4]
'A'
>>> word[0:2]
'He'
>>> word[2:4]
'lp'
```
Slice indices have useful defaults; an omitted first index defaults to zero, an omitted second index defaults to the size of the string being sliced.

```
>>> word[:2]       # The first two characters
'He'
>>> word[2:]       # Everything except the first two characters
'lpA'
```

Unlike a C string, Python strings cannot be changed. Assigning to an indexed position in the string results in an error:

```
>>> word[0] = 'x'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object does not support item assignment
>>> word[1] = 'Splat'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object does not support slice assignment
```

However, creating a new string with the combined content is easy and efficient:

```
>>> 'x' + word[1:]
'xelpA'
>>> 'Splat' + word[4]
'SplatA'
```

Here's a useful invariant of slice operations: \$s[:i] + s[i:]\$ equals \$s\$.

```
>>> word[:2] + word[2:]
'HelpA'
>>> word[:3] + word[3:]
'HelpA'
```

Degenerate slice indices are handled gracefully: an index that is too large is replaced by the string size, an upper bound smaller than the lower bound returns an empty string.
Indices may be negative numbers, to start counting from the right. For example:

```python
>>> word[1:100]  # The last character
'elpA'
>>> word[10:]    # The last-but-one character
''
>>> word[2:1]   # The last two characters
''
```

But note that -0 is really the same as 0, so it does not count from the right!

```python
>>> word[-0]    # (since -0 equals 0)
'H'
```

Out-of-range negative slice indices are truncated, but don’t try this for single-element (non-slice) indices:

```python
>>> word[-100:]  # HelpA'
>>> word[-10]    # error
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
IndexError: string index out of range
```

One way to remember how slices work is to think of the indices as pointing between characters, with the left edge of the first character numbered 0. Then the right edge of the last character of a string of \( n \) characters has index \( n \), for example:
The first row of numbers gives the position of the indices 0...5 in the string; the second row gives the corresponding negative indices. The slice from $i$ to $j$ consists of all characters between the edges labeled $i$ and $j$, respectively.

For non-negative indices, the length of a slice is the difference of the indices, if both are within bounds. For example, the length of `word[1:3]` is 2.

The built-in function `len()` returns the length of a string:

```python
code>> s = 'supercalifragilisticexpialidocious'
code>> len(s)
code 34
code```

The old formatting operations invoked when strings and
3.1.3. Unicode Strings

Starting with Python 2.0 a new data type for storing text data is available to the programmer: the Unicode object. It can be used to store and manipulate Unicode data (see http://www.unicode.org/) and integrates well with the existing string objects, providing auto-conversions where necessary.

Unicode has the advantage of providing one ordinal for every character in every script used in modern and ancient texts. Previously, there were only 256 possible ordinals for script characters. Texts were typically bound to a code page which mapped the ordinals to script characters. This lead to very much confusion especially with respect to internationalization (usually written as i18n — 'i' + 18 characters + 'n') of software. Unicode solves these problems by defining one code page for all scripts.

Creating Unicode strings in Python is just as simple as creating normal strings:

```python
>>> u'Hello World !'
'u'Hello World !'
```

The small 'u' in front of the quote indicates that a Unicode string is supposed to be created. If you want to include special characters in the string, you can do so by using the Python Unicode-Escape encoding. The following example shows how:

```python
>>> u'Hello\u0020World !'
'u'Hello World !'
```
The escape sequence \u0020 indicates to insert the Unicode character with the ordinal value 0x0020 (the space character) at the given position.

Other characters are interpreted by using their respective ordinal values directly as Unicode ordinals. If you have literal strings in the standard Latin-1 encoding that is used in many Western countries, you will find it convenient that the lower 256 characters of Unicode are the same as the 256 characters of Latin-1.

For experts, there is also a raw mode just like the one for normal strings. You have to prefix the opening quote with ‘ur’ to have Python use the Raw-Unicode-Escape encoding. It will only apply the above conversion if there is an uneven number of backslashes in front of the small ‘u’.

```
>>> ur'Hello\u0020World !'
u'Hello World !'
>>> ur'Hello\\u0020World !'
u'Hello\\u0020World !'
```

The raw mode is most useful when you have to enter lots of backslashes, as can be necessary in regular expressions.

Apart from these standard encodings, Python provides a whole set of other ways of creating Unicode strings on the basis of a known encoding.

The built-in function `unicode()` provides access to all registered Unicode codecs (COders and DE Coders). Some of the more well-known encodings which these codecs can convert are Latin-1, ASCII, UTF-8, and UTF-16. The latter two are variable-length encodings that store each Unicode character in one or more bytes. The default encoding is normally set to ASCII, which passes through characters in the range 0 to 127 and rejects any other characters with an error. When a Unicode string is printed, written to a file, or
converted with \texttt{str()}, conversion takes place using this default encoding.

\begin{verbatim}
>>> u"abc"
  u'abc'
>>> str(u"abc")
  'abc'
>>> u"äöü"
  u'\xe4\xf6\xfc'
>>> str(u"äöü")
  Traceback (most recent call last):
    File "<stdin>", line 1, in ?
  UnicodeEncodeError: 'ascii' codec can't encode characters in position 0-2: ordinal not in range(128)
\end{verbatim}

To convert a Unicode string into an 8-bit string using a specific encoding, Unicode objects provide an \texttt{encode()} method that takes one argument, the name of the encoding. Lowercase names for encodings are preferred.

\begin{verbatim}
>>> u"äöü".encode('utf-8')
  '\xc3\xa4\xc3\xb6\xc3\xbfc'
\end{verbatim}

If you have data in a specific encoding and want to produce a corresponding Unicode string from it, you can use the \texttt{unicode()} function with the encoding name as the second argument.

\begin{verbatim}
>>> unicode('\xc3\xa4\xc3\xb6\xc3\xbfc', 'utf-8')
  u'\xe4\xf6\xfc'
\end{verbatim}

3.1.4. Lists

Python knows a number of \textit{compound} data types, used to group together other values. The most versatile is the \texttt{list}, which can be written as a list of comma-separated values (\texttt{items}) between square brackets. List items need not all have the same type.

\begin{verbatim}
>>> a = ['spam', 'eggs', 100, 1234]
\end{verbatim}
Like string indices, list indices start at 0, and lists can be sliced, concatenated and so on:

```python
>>> a
['spam', 'eggs', 100, 1234]
```

```python
>>> a[0]
'spam'
>>> a[3]
1234
>>> a[-2]
100
>>> a[1:-1]
['eggs', 100]
>>> a[:2] + ['bacon', 2*2]
['spam', 'eggs', 'bacon', 4]
>>> 3*a[:3] + ['Boo!']
['spam', 'eggs', 100, 'spam', 'eggs', 100, 'spam', 'eggs', 100, 'Boo!']
```

All slice operations return a new list containing the requested elements. This means that the following slice returns a shallow copy of the list `a`:

```python
>>> a[:]
['spam', 'eggs', 100, 1234]
```

Unlike strings, which are immutable, it is possible to change individual elements of a list:

```python
>>> a
['spam', 'eggs', 100, 1234]
>>> a
['spam', 'eggs', 123, 1234]
```

Assignment to slices is also possible, and this can even change the size of the list or clear it entirely:

```python
>>> # Replace some items:
... a[0:2] = [1, 12]
```
The built-in function `len()` also applies to lists:

```python
>>> a = ['a', 'b', 'c', 'd']
>>> len(a)
4
```

It is possible to nest lists (create lists containing other lists), for example:

```python
>>> q = [2, 3]
>>> p = [1, q, 4]
>>> len(p)
3
>>> p[1]
[2, 3]
>>> p[1][0]
2
>>> p[1].append('xtra')  # See section 5.1
>>> p
[1, [2, 3, 'xtra'], 4]
>>> q
[2, 3, 'xtra']
```

Note that in the last example, `p[1]` and `q` really refer to the same
object! We’ll come back to *object semantics* later.
3.2. First Steps Towards Programming

Of course, we can use Python for more complicated tasks than adding two and two together. For instance, we can write an initial sub-sequence of the Fibonacci series as follows:

```python
>>> # Fibonacci series:
... # the sum of two elements defines the next
... a, b = 0, 1
>>> while b < 10:
...     print b
...     a, b = b, a+b
...
1
1
2
3
5
8
```

This example introduces several new features.

- The first line contains a *multiple assignment*: the variables `a` and `b` simultaneously get the new values 0 and 1. On the last line this is used again, demonstrating that the expressions on the right-hand side are all evaluated first before any of the assignments take place. The right-hand side expressions are evaluated from the left to the right.

- The `while` loop executes as long as the condition (here: `b < 10`) remains true. In Python, like in C, any non-zero integer value is true; zero is false. The condition may also be a string or list value, in fact any sequence; anything with a non-zero length is true, empty sequences are false. The test used in the example is a simple comparison. The standard comparison operators are written the same as in C: `<` (less than), `>` (greater than), `==`
(equal to), <= (less than or equal to), >= (greater than or equal to) and != (not equal to).

- The body of the loop is indented: indentation is Python’s way of grouping statements. Python does not (yet!) provide an intelligent input line editing facility, so you have to type a tab or space(s) for each indented line. In practice you will prepare more complicated input for Python with a text editor; most text editors have an auto-indent facility. When a compound statement is entered interactively, it must be followed by a blank line to indicate completion (since the parser cannot guess when you have typed the last line). Note that each line within a basic block must be indented by the same amount.

- The print statement writes the value of the expression(s) it is given. It differs from just writing the expression you want to write (as we did earlier in the calculator examples) in the way it handles multiple expressions and strings. Strings are printed without quotes, and a space is inserted between items, so you can format things nicely, like this:

```python
>>> i = 256*256
>>> print 'The value of i is', i
The value of i is 65536
```

A trailing comma avoids the newline after the output:

```python
>>> a, b = 0, 1
>>> while b < 1000:
...     print b,
...     a, b = b, a+b
...
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
```

Note that the interpreter inserts a newline before it prints the next prompt if the last line was not completed.
4. More Control Flow Tools

Besides the `while` statement just introduced, Python knows the usual control flow statements known from other languages, with some twists.
4.1. if Statements

Perhaps the most well-known statement type is the if statement. For example:

```
>>> x = int(raw_input("Please enter an integer: "))
Please enter an integer: 42
>>> if x < 0:
...     x = 0
...     print 'Negative changed to zero'
... elif x == 0:
...     print 'Zero'
... elif x == 1:
...     print 'Single'
... else:
...     print 'More'
More
```

There can be zero or more elif parts, and the else part is optional. The keyword ‘elif’ is short for ‘else if’, and is useful to avoid excessive indentation. An if ... elif ... elif ... sequence is a substitute for the switch or case statements found in other languages.
4.2. for Statements

The `for` statement in Python differs a bit from what you may be used to in C or Pascal. Rather than always iterating over an arithmetic progression of numbers (like in Pascal), or giving the user the ability to define both the iteration step and halting condition (as C), Python's `for` statement iterates over the items of any sequence (a list or a string), in the order that they appear in the sequence. For example (no pun intended):

```python
>>> # Measure some strings:
... a = ['cat', 'window', 'defenestrate']
>>> for x in a:
...     print(x, len(x))
...# make a slice copy of the entire list
... if len(x) > 6: a.insert(0, x)
...# make a slice copy of the entire list
>>> a
['defenestrate', 'cat', 'window', 'defenestrate']
```

It is not safe to modify the sequence being iterated over in the loop (this can only happen for mutable sequence types, such as lists). If you need to modify the list you are iterating over (for example, to duplicate selected items) you must iterate over a copy. The slice notation makes this particularly convenient:

```python
>>> for x in a[:]: # make a slice copy of the entire list
...     if len(x) > 6: a.insert(0, x)
...# make a slice copy of the entire list
>>> a
['defenestrate', 'cat', 'window', 'defenestrate']
```
4.3. The range() Function

If you do need to iterate over a sequence of numbers, the built-in function `range()` comes in handy. It generates lists containing arithmetic progressions:

```
>>> range(10)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
```

The given end point is never part of the generated list; `range(10)` generates a list of 10 values, the legal indices for items of a sequence of length 10. It is possible to let the range start at another number, or to specify a different increment (even negative; sometimes this is called the ‘step’):

```
>>> range(5, 10)
[5, 6, 7, 8, 9]
>>> range(0, 10, 3)
[0, 3, 6, 9]
>>> range(-10, -100, -30)
[-10, -40, -70]
```

To iterate over the indices of a sequence, you can combine `range()` and `len()` as follows:

```
>>> a = ['Mary', 'had', 'a', 'little', 'lamb']
>>> for i in range(len(a)):
...    print i, a[i]
...
0 Mary
1 had
2 a
3 little
4 lamb
```

In most such cases, however, it is convenient to use the `enumerate()` function, see Looping Techniques.
4.4. **break** and **continue** Statements, and **else** Clauses on Loops

The **break** statement, like in C, breaks out of the smallest enclosing **for** or **while** loop.

The **continue** statement, also borrowed from C, continues with the next iteration of the loop.

Loop statements may have an **else** clause; it is executed when the loop terminates through exhaustion of the list (with **for**) or when the condition becomes false (with **while**), but not when the loop is terminated by a **break** statement. This is exemplified by the following loop, which searches for prime numbers:

```python
>>> for n in range(2, 10):
...    for x in range(2, n):
...        if n % x == 0:
...            print n, 'equals', x, '*', n/x
...            break
...    else:
...        # loop fell through without finding a factor
...        print n, 'is a prime number'
...
2 is a prime number
3 is a prime number
4 equals 2 * 2
5 is a prime number
6 equals 2 * 3
7 is a prime number
8 equals 2 * 4
9 equals 3 * 3
```
4.5. `pass` Statements

The `pass` statement does nothing. It can be used when a statement is required syntactically but the program requires no action. For example:

```python
>>> while True:
...    pass  # Busy-wait for keyboard interrupt (Ctrl+C)
...
```

This is commonly used for creating minimal classes:

```python
>>> class MyEmptyClass:
...    pass
...
```

Another place `pass` can be used is as a place-holder for a function or conditional body when you are working on new code, allowing you to keep thinking at a more abstract level. The `pass` is silently ignored:

```python
>>> def initlog(*args):
...    pass  # Remember to implement this!
...
```
4.6. Defining Functions

We can create a function that writes the Fibonacci series to an arbitrary boundary:

```python
>>> def fib(n):    # write Fibonacci series up to n
...    """Print a Fibonacci series up to n."""
...    a, b = 0, 1
...    while a < n:
...        print a,
...        a, b = b, a+b
...    # Now call the function we just defined:
...    fib(2000)
0 1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987 1597
```

The keyword `def` introduces a function *definition*. It must be followed by the function name and the parenthesized list of formal parameters. The statements that form the body of the function start at the next line, and must be indented.

The first statement of the function body can optionally be a string literal; this string literal is the function’s documentation string, or *docstring*. (More about docstrings can be found in the section *Documentation Strings.*) There are tools which use docstrings to automatically produce online or printed documentation, or to let the user interactively browse through code; it’s good practice to include docstrings in code that you write, so make a habit of it.

The *execution* of a function introduces a new symbol table used for the local variables of the function. More precisely, all variable assignments in a function store the value in the local symbol table; whereas variable references first look in the local symbol table, then in the local symbol tables of enclosing functions, then in the global symbol table, and finally in the table of built-in names. Thus, global variables cannot be directly assigned a value within a function.
(unless named in a \texttt{global} statement), although they may be referenced.

The actual parameters (arguments) to a function call are introduced in the local symbol table of the called function when it is called; thus, arguments are passed using \textit{call by value} (where the value is always an object \textit{reference}, not the value of the object). [1] When a function calls another function, a new local symbol table is created for that call.

A function definition introduces the function name in the current symbol table. The value of the function name has a type that is recognized by the interpreter as a user-defined function. This value can be assigned to another name which can then also be used as a function. This serves as a general renaming mechanism:

```python
>>> fib
<function fib at 10042ed0>
>>> f = fib
>>> f(100)
0 1 1 2 3 5 8 13 21 34 55 89
```

Coming from other languages, you might object that \texttt{fib} is not a function but a procedure since it doesn’t return a value. In fact, even functions without a \texttt{return} statement do return a value, albeit a rather boring one. This value is called \texttt{None} (it’s a built-in name). Writing the value \texttt{None} is normally suppressed by the interpreter if it would be the only value written. You can see it if you really want to using \texttt{print}:

```python
>>> fib(0)
>>> print fib(0)
None
```

It is simple to write a function that returns a list of the numbers of the Fibonacci series, instead of printing it:
This example, as usual, demonstrates some new Python features:

- The `return` statement returns with a value from a function. `return` without an expression argument returns `None`. Falling off the end of a function also returns `None`.

- The statement `result.append(a)` calls a `method` of the list object `result`. A method is a function that ‘belongs’ to an object and is named `obj.methodname`, where `obj` is some object (this may be an expression), and `methodname` is the name of a method that is defined by the object's type. Different types define different methods. Methods of different types may have the same name without causing ambiguity. (It is possible to define your own object types and methods, using `classes`, see `Classes`) The method `append()` shown in the example is defined for list objects; it adds a new element at the end of the list. In this example it is equivalent to `result = result + [a]`, but more efficient.
4.7. More on Defining Functions

It is also possible to define functions with a variable number of arguments. There are three forms, which can be combined.

4.7.1. Default Argument Values

The most useful form is to specify a default value for one or more arguments. This creates a function that can be called with fewer arguments than it is defined to allow. For example:

```python
def ask_ok(prompt, retries=4, complaint='Yes or no, please!'):
    while True:
        ok = raw_input(prompt)
        if ok in ('y', 'ye', 'yes'):
            return True
        if ok in ('n', 'no', 'nop', 'nope'):
            return False
        retries = retries - 1
        if retries < 0:
            raise IOError('refusenik user
print complaint
```

This function can be called in several ways:

- giving only the mandatory argument: `ask_ok('Do you really want to quit?')`
- giving one of the optional arguments: `ask_ok('OK to overwrite the file?', 2)`
- or even giving all arguments: `ask_ok('OK to overwrite the file?', 2, 'Come on, only yes or no!')`

This example also introduces the `in` keyword. This tests whether or not a sequence contains a certain value.

The default values are evaluated at the point of function definition in
the *defining* scope, so that

```python
i = 5
def f(arg=i):
    print arg
i = 6
f()
```

will print 5.

**Important warning:** The default value is evaluated only once. This makes a difference when the default is a mutable object such as a list, dictionary, or instances of most classes. For example, the following function accumulates the arguments passed to it on subsequent calls:

```python
def f(a, L=[]):
    L.append(a)
    return L
```

```python
print f(1)
print f(2)
print f(3)
```

This will print

```
[1]
[1, 2]
[1, 2, 3]
```

If you don’t want the default to be shared between subsequent calls, you can write the function like this instead:

```python
def f(a, L=None):
    if L is None:
        L = []
    L.append(a)
    return L
```
4.7.2. Keyword Arguments

Functions can also be called using keyword arguments of the form keyword = value. For instance, the following function:

```python
def parrot(voltage, state='a stiff', action='voom', type='Norwegian Blue'):
    print ''-- This parrot wouldn't', action,
    print ''if you put'', voltage, ''volts through it.''
    print ''-- Lovely plumage, the'', type
    print ''-- It's'', state, ''!''
```

could be called in any of the following ways:

```python
parrot(1000)
parrot(action = 'VOO000OM', voltage = 1000000)
parrot('a thousand', state = 'pushing up the daisies')
parrot('a million', 'bereft of life', 'jump')
```

but the following calls would all be invalid:

```python
parrot() # required argument missing
parrot(voltage=5.0, 'dead') # non-keyword argument following k
parrot(110, voltage=220) # duplicate value for argument
parrot(actor='John Cleese') # unknown keyword
```

In general, an argument list must have any positional arguments followed by any keyword arguments, where the keywords must be chosen from the formal parameter names. It's not important whether a formal parameter has a default value or not. No argument may receive a value more than once — formal parameter names corresponding to positional arguments cannot be used as keywords in the same calls. Here's an example that fails due to this restriction:

```python
>>> def function(a):
...     pass
...     ...
...     ...
>>> function(0, a=0)
```
When a final formal parameter of the form `**name` is present, it receives a dictionary (see *Mapping Types — dict*) containing all keyword arguments except for those corresponding to a formal parameter. This may be combined with a formal parameter of the form `*name` (described in the next subsection) which receives a tuple containing the positional arguments beyond the formal parameter list. (*name must occur before **name.*) For example, if we define a function like this:

```python
def cheeseshop(kind, *arguments, **keywords):
    print "-- Do you have any", kind, "?"
    print "-- I'm sorry, we're all out of", kind
    for arg in arguments: print arg
    print "-" * 40
    keys = keywords.keys()
    keys.sort()
    for kw in keys: print kw, ":", keywords[kw]
```

It could be called like this:

```python
cheeseshop("Limburger", "It's very runny, sir.",
            "It's really very, VERY runny, sir.",
            shopkeeper='Michael Palin',
            client="John Cleese",
            sketch="Cheese Shop Sketch")
```

and of course it would print:

```plaintext
-- Do you have any Limburger ?
-- I'm sorry, we're all out of Limburger
It's very runny, sir.
It's really very, VERY runny, sir.
----------------------------------------
client : John Cleese
shopkeeper : Michael Palin
sketch : Cheese Shop Sketch
```
Note that the `sort()` method of the list of keyword argument names is called before printing the contents of the `keywords` dictionary; if this is not done, the order in which the arguments are printed is undefined.

### 4.7.3. Arbitrary Argument Lists

Finally, the least frequently used option is to specify that a function can be called with an arbitrary number of arguments. These arguments will be wrapped up in a tuple (see *Tuples and Sequences*). Before the variable number of arguments, zero or more normal arguments may occur.

```python
def write_multiple_items(file, separator, *args):
    file.write(separator.join(args))
```

### 4.7.4. Unpacking Argument Lists

The reverse situation occurs when the arguments are already in a list or tuple but need to be unpacked for a function call requiring separate positional arguments. For instance, the built-in `range()` function expects separate `start` and `stop` arguments. If they are not available separately, write the function call with the `*`-operator to unpack the arguments out of a list or tuple:

```python
>>> range(3, 6)  # normal call with separate arguments
[3, 4, 5]
>>> args = [3, 6]
>>> range(*args)  # call with arguments unpacked from list
[3, 4, 5]
```

In the same fashion, dictionaries can deliver keyword arguments with the `**`-operator:
def parrot(voltage, state='a stiff', action='voom'):
...	print "-- This parrot wouldn't", action,
...	print "if you put", voltage, "volts through it."
...	print "E's", state, "!
...
>>> d = {"voltage": "four million", "state": "bleedin' demised"
>>> parrot(**d)
-- This parrot wouldn't VOOM if you put four million volts through it.
E's bleedin' demised!

4.7.5. Lambda Forms

By popular demand, a few features commonly found in functional programming languages like Lisp have been added to Python. With the lambda keyword, small anonymous functions can be created. Here's a function that returns the sum of its two arguments: lambda a, b: a+b. Lambda forms can be used wherever function objects are required. They are syntactically restricted to a single expression. Semantically, they are just syntactic sugar for a normal function definition. Like nested function definitions, lambda forms can reference variables from the containing scope:

>>> def make_incrementor(n):
...    return lambda x: x + n
...  
>>> f = make_incrementor(42)
>>> f(0)
42
>>> f(1)
43

4.7.6. Documentation Strings

There are emerging conventions about the content and formatting of documentation strings.

The first line should always be a short, concise summary of the object's purpose. For brevity, it should not explicitly state the object's
name or type, since these are available by other means (except if the name happens to be a verb describing a function's operation). This line should begin with a capital letter and end with a period.

If there are more lines in the documentation string, the second line should be blank, visually separating the summary from the rest of the description. The following lines should be one or more paragraphs describing the object’s calling conventions, its side effects, etc.

The Python parser does not strip indentation from multi-line string literals in Python, so tools that process documentation have to strip indentation if desired. This is done using the following convention. The first non-blank line after the first line of the string determines the amount of indentation for the entire documentation string. (We can’t use the first line since it is generally adjacent to the string’s opening quotes so its indentation is not apparent in the string literal.) Whitespace “equivalent” to this indentation is then stripped from the start of all lines of the string. Lines that are indented less should not occur, but if they occur all their leading whitespace should be stripped. Equivalence of whitespace should be tested after expansion of tabs (to 8 spaces, normally).

Here is an example of a multi-line docstring:

```python
>>> def my_function():
...     """Do nothing, but document it."
...     No, really, it doesn't do anything.
...     ""
...     pass
... >>> print my_function.__doc__
Do nothing, but document it.
    No, really, it doesn't do anything.
```
Now that you are about to write longer, more complex pieces of Python, it is a good time to talk about coding style. Most languages can be written (or more concise, formatted) in different styles; some are more readable than others. Making it easy for others to read your code is always a good idea, and adopting a nice coding style helps tremendously for that.

For Python, PEP 8 has emerged as the style guide that most projects adhere to; it promotes a very readable and eye-pleasing coding style. Every Python developer should read it at some point; here are the most important points extracted for you:

- Use 4-space indentation, and no tabs. 4 spaces are a good compromise between small indentation (allows greater nesting depth) and large indentation (easier to read). Tabs introduce confusion, and are best left out.

- Wrap lines so that they don’t exceed 79 characters. This helps users with small displays and makes it possible to have several code files side-by-side on larger displays.

- Use blank lines to separate functions and classes, and larger blocks of code inside functions.

- When possible, put comments on a line of their own.

- Use docstrings.

- Use spaces around operators and after commas, but not directly inside bracketing constructs: \( a = f(1, 2) + g(3, 4) \).
• Name your classes and functions consistently; the convention is to use `CamelCase` for classes and `lower_case_with_underscores` for functions and methods. Always use `self` as the name for the first method argument (see *A First Look at Classes* for more on classes and methods).

• Don’t use fancy encodings if your code is meant to be used in international environments. Plain ASCII works best in any case.

**Footnotes**

[1] Actually, *call by object reference* would be a better description, since if a mutable object is passed, the caller will see any changes the callee makes to it (items inserted into a list).
5. Data Structures

This chapter describes some things you’ve learned about already in more detail, and adds some new things as well.
5.1. More on Lists

The list data type has some more methods. Here are all of the methods of list objects:

- **list.append(x)**
  Add an item to the end of the list; equivalent to \(a[\text{len}(a):] = [x]\).

- **list.extend(L)**
  Extend the list by appending all the items in the given list; equivalent to \(a[\text{len}(a):] = L\).

- **list.insert(i, x)**
  Insert an item at a given position. The first argument is the index of the element before which to insert, so \(a.\text{insert}(0, x)\) inserts at the front of the list, and \(a.\text{insert}([\text{len}(a)], x)\) is equivalent to \(a.\text{append}(x)\).

- **list.remove(x)**
  Remove the first item from the list whose value is \(x\). It is an error if there is no such item.

- **list.pop([i])**
  Remove the item at the given position in the list, and return it. If no index is specified, \(a.\text{pop}()\) removes and returns the last item in the list. (The square brackets around the \(i\) in the method signature denote that the parameter is optional, not that you should type square brackets at that position. You will see this notation frequently in the Python Library Reference.)

- **list.index(x)**
  Return the index in the list of the first item whose value is \(x\). It is
an error if there is no such item.

`list.count(x)`
Return the number of times x appears in the list.

`list.sort()`
Sort the items of the list, in place.

`list.reverse()`
Reverse the elements of the list, in place.

An example that uses most of the list methods:

```python
>>> a = [66.25, 333, 333, 1, 1234.5]
>>> print a.count(333), a.count(66.25), a.count('x')
2 1 0
>>> a.insert(2, -1)
>>> a.append(333)
>>> a
[66.25, 333, -1, 333, 1, 1234.5, 333]
>>> a.index(333)
1
>>> a.remove(333)
>>> a
[66.25, -1, 333, 1, 1234.5, 333]
>>> a.reverse()
>>> a
[333, 1234.5, 1, 333, -1, 66.25]
>>> a.sort()
>>> a
[-1, 1, 66.25, 333, 333, 1234.5]
```

### 5.1.1. Using Lists as Stacks

The list methods make it very easy to use a list as a stack, where the last element added is the first element retrieved (“last-in, first-out”). To add an item to the top of the stack, use `append()`. To retrieve an item from the top of the stack, use `pop()` without an explicit index. For example:
5.1.2. Using Lists as Queues

It is also possible to use a list as a queue, where the first element added is the first element retrieved ("first-in, first-out"); however, lists are not efficient for this purpose. While appends and pops from the end of list are fast, doing inserts or pops from the beginning of a list is slow (because all of the other elements have to be shifted by one).

To implement a queue, use `collections.deque` which was designed to have fast appends and pops from both ends. For example:

```python
>>> from collections import deque
>>> queue = deque(['Eric', 'John', 'Michael'])
>>> queue.append('Terry')  # Terry arrives
>>> queue.append('Graham')  # Graham arrives
>>> queue.popleft()  # The first to arrive now leaves
'Eric'
>>> queue.popleft()  # The second to arrive now leaves
'John'
>>> queue  # Remaining queue in order
deque(['Michael', 'Terry', 'Graham'])
```
There are three built-in functions that are very useful when used with lists: `filter()`, `map()`, and `reduce()`.

`filter(function, sequence)` returns a sequence consisting of those items from the sequence for which `function(item)` is true. If `sequence` is a string or tuple, the result will be of the same type; otherwise, it is always a list. For example, to compute some primes:

```python
def f(x):
    return x % 2 != 0 and x % 3 != 0
...
>> filter(f, range(2, 25))
[5, 7, 11, 13, 17, 19, 23]
```

`map(function, sequence)` calls `function(item)` for each of the sequence's items and returns a list of the return values. For example, to compute some cubes:

```python
def cube(x):
    return x*x*x
...
>> map(cube, range(1, 11))
[1, 8, 27, 64, 125, 216, 343, 512, 729, 1000]
```

More than one sequence may be passed; the function must then have as many arguments as there are sequences and is called with the corresponding item from each sequence (or `None` if some sequence is shorter than another). For example:

```python
def add(x, y):
    return x+y
...
>> map(add, seq, seq)
[0, 2, 4, 6, 8, 10, 12, 14]
```

`reduce(function, sequence)` returns a single value constructed by calling the binary function `function` on the first two items of the sequence, then on the result and the next item, and so on. For
example, to compute the sum of the numbers 1 through 10:

```python
>>> def add(x,y): return x+y
... reduce(add, range(1, 11))
55
```

If there's only one item in the sequence, its value is returned; if the sequence is empty, an exception is raised.

A third argument can be passed to indicate the starting value. In this case the starting value is returned for an empty sequence, and the function is first applied to the starting value and the first sequence item, then to the result and the next item, and so on. For example,

```python
>>> def sum(seq):
...     def add(x,y): return x+y
...     return reduce(add, seq, 0)
... sum(range(1, 11))
55
>>> sum([])
0
```

Don’t use this example’s definition of `sum()`: since summing numbers is such a common need, a built-in function `sum(sequence)` is already provided, and works exactly like this.

*New in version 2.3.*

### 5.1.4. List Comprehensions

List comprehensions provide a concise way to create lists without resorting to use of `map()`, `filter()` and/or `lambda`. The resulting list definition tends often to be clearer than lists built using those constructs. Each list comprehension consists of an expression followed by a `for` clause, then zero or more `for` or `if` clauses. The
result will be a list resulting from evaluating the expression in the context of the `for` and `if` clauses which follow it. If the expression would evaluate to a tuple, it must be parenthesized.

```python
>>> freshfruit = ['banana', 'loganberry', 'passion fruit
>>> [weapon.strip() for weapon in freshfruit]
['banana', 'loganberry', 'passion fruit'
>>> vec = [2, 4, 6]
>>> [3*x for x in vec]
[6, 12, 18]
>>> [3*x for x in vec if x > 3]
[12, 18]
>>> [3*x for x in vec if x < 2]
[]
>>> [[x, x**2] for x in vec]
[[2, 4], [4, 16], [6, 36]]
>>> [x, x**2 for x in vec]  # error - parens required for tuple
  File "<stdin>", line 1, in ?
    [x, x**2 for x in vec]
    ^
SyntaxError: invalid syntax
>>> [(x, x**2) for x in vec]
[(2, 4), (4, 16), (6, 36)]
```

List comprehensions are much more flexible than `map()` and can be applied to complex expressions and nested functions:

```python
>>> [str(round(355/113.0, i)) for i in range(1,6)]
['3.1', '3.14', '3.142', '3.1416', '3.14159']
```

5.1.5. Nested List Comprehensions

If you've got the stomach for it, list comprehensions can be nested.
They are a powerful tool but – like all powerful tools – they need to be used carefully, if at all.

Consider the following example of a 3x3 matrix held as a list containing three lists, one list per row:

```python
>>> mat = [
...     [1, 2, 3],
...     [4, 5, 6],
...     [7, 8, 9],
... ]
```

Now, if you wanted to swap rows and columns, you could use a list comprehension:

```python
>>> print ([[row[i] for row in mat] for i in [0, 1, 2]])
[[1, 4, 7], [2, 5, 8], [3, 6, 9]]
```

Special care has to be taken for the nested list comprehension:

To avoid apprehension when nesting list comprehensions, read from right to left.

A more verbose version of this snippet shows the flow explicitly:

```python
for i in [0, 1, 2]:
    for row in mat:
        print row[i],
    print
```

In real world, you should prefer built-in functions to complex flow statements. The `zip()` function would do a great job for this use case:

```python
>>> zip(*mat)
[(1, 4, 7), (2, 5, 8), (3, 6, 9)]
```

See *Unpacking Argument Lists* for details on the asterisk in this line.
5.2. The \texttt{del} statement

There is a way to remove an item from a list given its index instead of its value: the \texttt{del} statement. This differs from the \texttt{pop()} method which returns a value. The \texttt{del} statement can also be used to remove slices from a list or clear the entire list (which we did earlier by assignment of an empty list to the slice). For example:

```python
>>> a = [-1, 1, 66.25, 333, 333, 1234.5]
>>> del a[0]
>>> a
[1, 66.25, 333, 333, 1234.5]
>>> del a[2:4]
>>> a
[1, 66.25, 1234.5]
>>> del a[:]
>>> a
[]
```

\texttt{del} can also be used to delete entire variables:

```python
>>> del a
```

Referencing the name \texttt{a} hereafter is an error (at least until another value is assigned to it). We’ll find other uses for \texttt{del} later.
5.3. Tuples and Sequences

We saw that lists and strings have many common properties, such as indexing and slicing operations. They are two examples of sequence data types (see Sequence Types — str, unicode, list, tuple, buffer, xrange). Since Python is an evolving language, other sequence data types may be added. There is also another standard sequence data type: the tuple.

A tuple consists of a number of values separated by commas, for instance:

```python
>>> t = 12345, 54321, 'hello!
>>> t[0]
12345
>>> t
(12345, 54321, 'hello!')
>>> # Tuples may be nested:
... u = t, (1, 2, 3, 4, 5)
>>> u
((12345, 54321, 'hello!'), (1, 2, 3, 4, 5))
```

As you see, on output tuples are always enclosed in parentheses, so that nested tuples are interpreted correctly; they may be input with or without surrounding parentheses, although often parentheses are necessary anyway (if the tuple is part of a larger expression).

Tuples have many uses. For example: (x, y) coordinate pairs, employee records from a database, etc. Tuples, like strings, are immutable: it is not possible to assign to the individual items of a tuple (you can simulate much of the same effect with slicing and concatenation, though). It is also possible to create tuples which contain mutable objects, such as lists.

A special problem is the construction of tuples containing 0 or 1 items: the syntax has some extra quirks to accommodate these.
Empty tuples are constructed by an empty pair of parentheses; a tuple with one item is constructed by following a value with a comma (it is not sufficient to enclose a single value in parentheses). Ugly, but effective. For example:

```python
>>> empty = ()
>>> singleton = 'hello',  # <-- note trailing comma
>>> len(empty)
0
>>> len(singleton)
1
>>> singleton
('hello',)
```

The statement `t = 12345, 54321, 'hello!'` is an example of tuple packing: the values `12345`, `54321` and `'hello!'` are packed together in a tuple. The reverse operation is also possible:

```python
>>> x, y, z = t
```

This is called, appropriately enough, sequence unpacking and works for any sequence on the right-hand side. Sequence unpacking requires the list of variables on the left to have the same number of elements as the length of the sequence. Note that multiple assignment is really just a combination of tuple packing and sequence unpacking.
5.4. Sets

Python also includes a data type for sets. A set is an unordered collection with no duplicate elements. Basic uses include membership testing and eliminating duplicate entries. Set objects also support mathematical operations like union, intersection, difference, and symmetric difference.

Here is a brief demonstration:

```python
>>> basket = ['apple', 'orange', 'apple', 'pear', 'orange', 'banana']
>>> fruit = set(basket)   # create a set without duplicates
>>> fruit
set(['orange', 'pear', 'apple', 'banana'])
>>> 'orange' in fruit    # fast membership testing
True
>>> 'crabgrass' in fruit
False

>>> # Demonstrate set operations on unique letters from two words...
>>> a = set('abracadabra')
>>> b = set('alacazam')
>>> a                # unique letters in a
set(['a', 'r', 'b', 'c', 'd'])
>>> a - b            # letters in a but not in b
set(['r', 'd', 'b'])
>>> a | b            # letters in either a or b
set(['a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'])
>>> a & b            # letters in both a and b
set(['a', 'c'])
>>> a ^ b            # letters in a or b but not both
set(['r', 'd', 'b', 'm', 'z', 'l'])
```
5.5. Dictionaries

Another useful data type built into Python is the *dictionary* (see *Mapping Types — dict*). Dictionaries are sometimes found in other languages as “associative memories” or “associative arrays”. Unlike sequences, which are indexed by a range of numbers, dictionaries are indexed by *keys*, which can be any immutable type; strings and numbers can always be keys. Tuples can be used as keys if they contain only strings, numbers, or tuples; if a tuple contains any mutable object either directly or indirectly, it cannot be used as a key. You can’t use lists as keys, since lists can be modified in place using index assignments, slice assignments, or methods like *append()* and *extend()*.

It is best to think of a dictionary as an unordered set of *key: value* pairs, with the requirement that the keys are unique (within one dictionary). A pair of braces creates an empty dictionary: `{}`. Placing a comma-separated list of key:value pairs within the braces adds initial key:value pairs to the dictionary; this is also the way dictionaries are written on output.

The main operations on a dictionary are storing a value with some key and extracting the value given the key. It is also possible to delete a key:value pair with *del*. If you store using a key that is already in use, the old value associated with that key is forgotten. It is an error to extract a value using a non-existent key.

The *keys()* method of a dictionary object returns a list of all the keys used in the dictionary, in arbitrary order (if you want it sorted, just apply the *sort()* method to the list of keys). To check whether a single key is in the dictionary, use the *in* keyword.

Here is a small example using a dictionary:
The `dict()` constructor builds dictionaries directly from lists of key-value pairs stored as tuples. When the pairs form a pattern, list comprehensions can compactly specify the key-value list.

```python
>>> dict([('sape', 4139), ('guido', 4127), ('jack', 4098)])
{'sape': 4139, 'jack': 4098, 'guido': 4127}
>>> dict([(x, x**2) for x in (2, 4, 6)])  # use a list comprehension
{2: 4, 4: 16, 6: 36}
```

Later in the tutorial, we will learn about Generator Expressions which are even better suited for the task of supplying key-values pairs to the `dict()` constructor.

When the keys are simple strings, it is sometimes easier to specify pairs using keyword arguments:

```python
>>> dict(sape=4139, guido=4127, jack=4098)
{'sape': 4139, 'jack': 4098, 'guido': 4127}
```
5.6. Looping Techniques

When looping through dictionaries, the key and corresponding value can be retrieved at the same time using the `iteritems()` method.

```python
>>> knights = {'gallahad': 'the pure', 'robin': 'the brave'}
>>> for k, v in knights.iteritems():
...     print k, v
...
gallahad the pure
robin the brave
```

When looping through a sequence, the position index and corresponding value can be retrieved at the same time using the `enumerate()` function.

```python
>>> for i, v in enumerate(['tic', 'tac', 'toe']):
...     print i, v
...
0 tic
1 tac
2 toe
```

To loop over two or more sequences at the same time, the entries can be paired with the `zip()` function.

```python
>>> questions = ['name', 'quest', 'favorite color']
>>> answers = ['lancelot', 'the holy grail', 'blue']
>>> for q, a in zip(questions, answers):
...     print 'What is your {0}? It is {1}.'.format(q, a)
...
What is your name? It is lancelot.
What is your quest? It is the holy grail.
What is your favorite color? It is blue.
```

To loop over a sequence in reverse, first specify the sequence in a forward direction and then call the `reversed()` function.
To loop over a sequence in sorted order, use the `sorted()` function which returns a new sorted list while leaving the source unaltered.
5.7. More on Conditions

The conditions used in `while` and `if` statements can contain any operators, not just comparisons.

The comparison operators `in` and `not in` check whether a value occurs (does not occur) in a sequence. The operators `is` and `is not` compare whether two objects are really the same object; this only matters for mutable objects like lists. All comparison operators have the same priority, which is lower than that of all numerical operators.

Comparisons can be chained. For example, `a < b == c` tests whether `a` is less than `b` and moreover `b` equals `c`.

Comparisons may be combined using the Boolean operators `and` and `or`, and the outcome of a comparison (or of any other Boolean expression) may be negated with `not`. These have lower priorities than comparison operators; between them, `not` has the highest priority and `or` the lowest, so that `A and not B or C` is equivalent to `(A and (not B)) or C`. As always, parentheses can be used to express the desired composition.

The Boolean operators `and` and `or` are so-called short-circuit operators: their arguments are evaluated from left to right, and evaluation stops as soon as the outcome is determined. For example, if `A` and `C` are true but `B` is false, `A and B and C` does not evaluate the expression `C`. When used as a general value and not as a Boolean, the return value of a short-circuit operator is the last evaluated argument.

It is possible to assign the result of a comparison or other Boolean expression to a variable. For example,
Note that in Python, unlike C, assignment cannot occur inside expressions. C programmers may grumble about this, but it avoids a common class of problems encountered in C programs: typing `=` in an expression when `==` was intended.
5.8. Comparing Sequences and Other Types

Sequence objects may be compared to other objects with the same sequence type. The comparison uses lexicographical ordering: first the first two items are compared, and if they differ this determines the outcome of the comparison; if they are equal, the next two items are compared, and so on, until either sequence is exhausted. If two items to be compared are themselves sequences of the same type, the lexicographical comparison is carried out recursively. If all items of two sequences compare equal, the sequences are considered equal. If one sequence is an initial sub-sequence of the other, the shorter sequence is the smaller (lesser) one. Lexicographical ordering for strings uses the ASCII ordering for individual characters. Some examples of comparisons between sequences of the same type:

\[
\begin{align*}
(1, 2, 3) & < (1, 2, 4) \\
[1, 2, 3] & < [1, 2, 4] \\
'ABC' & < 'C' < 'Pascal' < 'Python' \\
(1, 2, 3, 4) & < (1, 2, 4) \\
(1, 2) & < (1, 2, -1) \\
(1, 2, 3) & == (1.0, 2.0, 3.0) \\
(1, 2, ('aa', 'ab')) & < (1, 2, ('abc', 'a'), 4)
\end{align*}
\]

Note that comparing objects of different types is legal. The outcome is deterministic but arbitrary: the types are ordered by their name. Thus, a list is always smaller than a string, a string is always smaller than a tuple, etc. [1] Mixed numeric types are compared according to their numeric value, so 0 equals 0.0, etc.

Footnotes

The rules for comparing objects of different types should not be
[1] relied upon; they may change in a future version of the language.
6. Modules

If you quit from the Python interpreter and enter it again, the definitions you have made (functions and variables) are lost. Therefore, if you want to write a somewhat longer program, you are better off using a text editor to prepare the input for the interpreter and running it with that file as input instead. This is known as creating a script. As your program gets longer, you may want to split it into several files for easier maintenance. You may also want to use a handy function that you’ve written in several programs without copying its definition into each program.

To support this, Python has a way to put definitions in a file and use them in a script or in an interactive instance of the interpreter. Such a file is called a module; definitions from a module can be imported into other modules or into the main module (the collection of variables that you have access to in a script executed at the top level and in calculator mode).

A module is a file containing Python definitions and statements. The file name is the module name with the suffix .py appended. Within a module, the module’s name (as a string) is available as the value of the global variable __name__. For instance, use your favorite text editor to create a file called fibo.py in the current directory with the following contents:

```python
# Fibonacci numbers module

def fib(n):  # write Fibonacci series up to n
    a, b = 0, 1
    while b < n:
        print b,
        a, b = b, a+b

def fib2(n): # return Fibonacci series up to n
    result = []
```
a, b = 0, 1
while b < n:
    result.append(b)
    a, b = b, a+b
return result

Now enter the Python interpreter and import this module with the following command:

```python
>>> import fibo
```

This does not enter the names of the functions defined in `fibo` directly in the current symbol table; it only enters the module name `fibo` there. Using the module name you can access the functions:

```python
>>> fibo.fib(1000)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
>>> fibo.fib2(100)
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
>>> fibo.__name__
'fibo'
```

If you intend to use a function often you can assign it to a local name:

```python
>>> fib = fibo.fib
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```
6.1. More on Modules

A module can contain executable statements as well as function definitions. These statements are intended to initialize the module. They are executed only the first time the module is imported somewhere. [1]

Each module has its own private symbol table, which is used as the global symbol table by all functions defined in the module. Thus, the author of a module can use global variables in the module without worrying about accidental clashes with a user’s global variables. On the other hand, if you know what you are doing you can touch a module’s global variables with the same notation used to refer to its functions, \texttt{modname.itemname}.

Modules can import other modules. It is customary but not required to place all \texttt{import} statements at the beginning of a module (or script, for that matter). The imported module names are placed in the importing module’s global symbol table.

There is a variant of the \texttt{import} statement that imports names from a module directly into the importing module’s symbol table. For example:

```python
>>> from fibo import fib, fib2
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

This does not introduce the module name from which the imports are taken in the local symbol table (so in the example, \texttt{fibo} is not defined).

There is even a variant to import all names that a module defines:
This imports all names except those beginning with an underscore (_).

Note that in general the practice of importing * from a module or package is frowned upon, since it often causes poorly readable code. However, it is okay to use it to save typing in interactive sessions.

**Note:** For efficiency reasons, each module is only imported once per interpreter session. Therefore, if you change your modules, you must restart the interpreter – or, if it's just one module you want to test interactively, use `reload()`, e.g. `reload(modulename)`.

### 6.1.1. Executing modules as scripts

When you run a Python module with

```bash
python fibo.py <arguments>
```

the code in the module will be executed, just as if you imported it, but with the `__name__` set to "__main__". That means that by adding this code at the end of your module:

```python
if __name__ == "__main__":
    import sys
    fib(int(sys.argv[1]))
```

you can make the file usable as a script as well as an importable module, because the code that parses the command line only runs if the module is executed as the “main” file:
If the module is imported, the code is not run:

```python
>>> import fibo
```

This is often used either to provide a convenient user interface to a module, or for testing purposes (running the module as a script executes a test suite).

### 6.1.2. The Module Search Path

When a module named `spam` is imported, the interpreter searches for a file named `spam.py` in the current directory, and then in the list of directories specified by the environment variable `PYTHONPATH`. This has the same syntax as the shell variable `PATH`, that is, a list of directory names. When `PYTHONPATH` is not set, or when the file is not found there, the search continues in an installation-dependent default path; on Unix, this is usually `./usr/local/lib/python`.

Actually, modules are searched in the list of directories given by the variable `sys.path` which is initialized from the directory containing the input script (or the current directory), `PYTHONPATH` and the installation-dependent default. This allows Python programs that know what they're doing to modify or replace the module search path. Note that because the directory containing the script being run is on the search path, it is important that the script not have the same name as a standard module, or Python will attempt to load the script as a module when that module is imported. This will generally be an error. See section *Standard Modules* for more information.

### 6.1.3. “Compiled” Python files
As an important speed-up of the start-up time for short programs that use a lot of standard modules, if a file called spam.pyc exists in the directory where spam.py is found, this is assumed to contain an already-“byte-compiled” version of the module spam. The modification time of the version of spam.py used to create spam.pyc is recorded in spam.pyc, and the .pyc file is ignored if these don’t match.

Normally, you don’t need to do anything to create the spam.pyc file. Whenever spam.py is successfully compiled, an attempt is made to write the compiled version to spam.pyc. It is not an error if this attempt fails; if for any reason the file is not written completely, the resulting spam.pyc file will be recognized as invalid and thus ignored later. The contents of the spam.pyc file are platform independent, so a Python module directory can be shared by machines of different architectures.

Some tips for experts:

- When the Python interpreter is invoked with the -O flag, optimized code is generated and stored in .pyo files. The optimizer currently doesn’t help much; it only removes assert statements. When -O is used, all bytecode is optimized; .pyc files are ignored and .py files are compiled to optimized bytecode.

- Passing two -O flags to the Python interpreter (-OO) will cause the bytecode compiler to perform optimizations that could in some rare cases result in malfunctioning programs. Currently only __doc__ strings are removed from the bytecode, resulting in more compact .pyo files. Since some programs may rely on having these available, you should only use this option if you know what you’re doing.
• A program doesn't run any faster when it is read from a .pyc or .pyo file than when it is read from a .py file; the only thing that's faster about .pyc or .pyo files is the speed with which they are loaded.

• When a script is run by giving its name on the command line, the bytecode for the script is never written to a .pyc or .pyo file. Thus, the startup time of a script may be reduced by moving most of its code to a module and having a small bootstrap script that imports that module. It is also possible to name a .pyc or .pyo file directly on the command line.

• It is possible to have a file called spam.pyc (or spam.pyo when -O is used) without a file spam.py for the same module. This can be used to distribute a library of Python code in a form that is moderately hard to reverse engineer.

• The module compileall can create .pyc files (or .pyo files when -O is used) for all modules in a directory.
6.2. Standard Modules

Python comes with a library of standard modules, described in a separate document, the Python Library Reference ("Library Reference" hereafter). Some modules are built into the interpreter; these provide access to operations that are not part of the core of the language but are nevertheless built in, either for efficiency or to provide access to operating system primitives such as system calls. The set of such modules is a configuration option which also depends on the underlying platform. For example, the \texttt{winreg} module is only provided on Windows systems. One particular module deserves some attention: \texttt{sys}, which is built into every Python interpreter. The variables \texttt{sys.ps1} and \texttt{sys.ps2} define the strings used as primary and secondary prompts:

```python
>>> import sys
>>> sys.ps1
'>>>'
>>> sys.ps2
'...
>>> sys.ps1 = 'C> '
C> print 'Yuck!'
Yuck!
C>
```

These two variables are only defined if the interpreter is in interactive mode.

The variable \texttt{sys.path} is a list of strings that determines the interpreter’s search path for modules. It is initialized to a default path taken from the environment variable \texttt{PYTHONPATH}, or from a built-in default if \texttt{PYTHONPATH} is not set. You can modify it using standard list operations:

```python
>>> import sys
>>> sys.path.append('/ufs/guido/lib/python')
```
6.3. The dir() Function

The built-in function **dir()** is used to find out which names a module defines. It returns a sorted list of strings:

```python
>>> import fibo, sys
>>> dir(fibo)
['__name__', 'fib', 'fib2']
```

```python
>>> dir(sys)
['__displayhook__', '__doc__', '__excepthook__', '__name__', '_
'__stdin__', '__stdout__', '_getframe', 'api_version', 'argv',
'builtin_module_names', 'byteorder', 'callstats', 'copyright',
'displayhook', 'exc_clear', 'exc_info', 'exec_type', 'excepthoo
'exec_prefix', 'executable', 'exit', 'getdefaultencoding', 'ge
'getrecursionlimit', 'getrefcount', 'hexversion', 'maxint', 'm
'meta_path', 'modules', 'path', 'path_hooks', 'path_importer_c
'platform', 'prefix', 'ps1', 'ps2', 'setcheckinterval', 'setd1
'setprofile', 'setrecursionlimit', 'settrace', 'stderr', 'stdi
'version', 'version_info', 'warnoptions']
```

Without arguments, **dir()** lists the names you have defined currently:

```python
>>> a = [1, 2, 3, 4, 5]
>>> import fibo
>>> fib = fibo.fib
>>> dir()
['__builtin__', '__doc__', '__file__', '__name__', 'a', 'fib',
'
Note that it lists all types of names: variables, modules, functions, etc.

**dir()** does not list the names of built-in functions and variables. If you want a list of those, they are defined in the standard module **__builtin__**:

```python
>>> import __builtin__
```
>>> dir(__builtin__)
6.4. Packages

Packages are a way of structuring Python’s module namespace by using “dotted module names”. For example, the module name `A.B` designates a submodule named `B` in a package named `A`. Just like the use of modules saves the authors of different modules from having to worry about each other’s global variable names, the use of dotted module names saves the authors of multi-module packages like NumPy or the Python Imaging Library from having to worry about each other’s module names.

Suppose you want to design a collection of modules (a “package”) for the uniform handling of sound files and sound data. There are many different sound file formats (usually recognized by their extension, for example: `.wav`, `.aiff`, `.au`), so you may need to create and maintain a growing collection of modules for the conversion between the various file formats. There are also many different operations you might want to perform on sound data (such as mixing, adding echo, applying an equalizer function, creating an artificial stereo effect), so in addition you will be writing a never-ending stream of modules to perform these operations. Here’s a possible structure for your package (expressed in terms of a hierarchical filesystem):

```
sound/
  __init__.py
  formats/
    __init__.py
    wavread.py
    wavwrite.py
    aiffread.py
    aiffwrite.py
    auread.py
    auwrite.py
    ...
  effects/
```

Top-level package
Initialize the sound package
Subpackage for file format conversion
Subpackage for sound effects
When importing the package, Python searches through the directories on `sys.path` looking for the package subdirectory.

The `__init__.py` files are required to make Python treat the directories as containing packages; this is done to prevent directories with a common name, such as `string`, from unintentionally hiding valid modules that occur later on the module search path. In the simplest case, `__init__.py` can just be an empty file, but it can also execute initialization code for the package or set the `__all__` variable, described later.

Users of the package can import individual modules from the package, for example:

```python
import sound.effects.echo
```

This loads the submodule `sound.effects.echo`. It must be referenced with its full name.

```python
sound.effects.echo.echofilter(input, output, delay=0.7, atten=4)
```

An alternative way of importing the submodule is:

```python
from sound.effects import echo
```
This also loads the submodule `echo`, and makes it available without its package prefix, so it can be used as follows:

```python
echo.echofilter(input, output, delay=0.7, atten=4)
```

Yet another variation is to import the desired function or variable directly:

```python
from sound.effects.echo import echofilter
```

Again, this loads the submodule `echo`, but this makes its function `echofilter()` directly available:

```python
echofilter(input, output, delay=0.7, atten=4)
```

Note that when using `from package import item`, the item can be either a submodule (or subpackage) of the package, or some other name defined in the package, like a function, class or variable. The `import` statement first tests whether the item is defined in the package; if not, it assumes it is a module and attempts to load it. If it fails to find it, an `ImportError` exception is raised.

Contrarily, when using syntax like `import item.subitem.subsubitem`, each item except for the last must be a package; the last item can be a module or a package but can’t be a class or function or variable defined in the previous item.

### 6.4.1. Importing * From a Package

Now what happens when the user writes `from sound.effects import *`? Ideally, one would hope that this somehow goes out to the filesystem, finds which submodules are present in the package, and imports them all. This could take a long time and importing sub-modules might have unwanted side-effects that should only happen
when the sub-module is explicitly imported.

The only solution is for the package author to provide an explicit index of the package. The import statement uses the following convention: if a package's __init__.py code defines a list named __all__, it is taken to be the list of module names that should be imported when from package import * is encountered. It is up to the package author to keep this list up-to-date when a new version of the package is released. Package authors may also decide not to support it, if they don't see a use for importing * from their package. For example, the file sounds/effects/__init__.py could contain the following code:

```python
__all__ = ['echo', 'surround', 'reverse']
```

This would mean that from sound.effects import * would import the three named submodules of the sound package.

If __all__ is not defined, the statement from sound.effects import * does not import all submodules from the package sound.effects into the current namespace; it only ensures that the package sound.effects has been imported (possibly running any initialization code in __init__.py) and then imports whatever names are defined in the package. This includes any names defined (and submodules explicitly loaded) by __init__.py. It also includes any submodules of the package that were explicitly loaded by previous import statements. Consider this code:

```python
import sound.effects.echo
import sound.effects.surround
from sound.effects import *
```

In this example, the echo and surround modules are imported in the current namespace because they are defined in the sound.effects
package when the \texttt{from}...\texttt{import} statement is executed. (This also works when \texttt{__all__} is defined.)

Although certain modules are designed to export only names that follow certain patterns when you use \texttt{import *}, it is still considered bad practise in production code.

Remember, there is nothing wrong with using \texttt{from Package import specific\_submodule!} In fact, this is the recommended notation unless the importing module needs to use submodules with the same name from different packages.

6.4.2. Intra-package References

The submodules often need to refer to each other. For example, the \texttt{surround} module might use the \texttt{echo} module. In fact, such references are so common that the \texttt{import} statement first looks in the containing package before looking in the standard module search path. Thus, the \texttt{surround} module can simply use \texttt{import echo} or \texttt{from echo import echofilter}. If the imported module is not found in the current package (the package of which the current module is a submodule), the \texttt{import} statement looks for a top-level module with the given name.

When packages are structured into subpackages (as with the \texttt{sound} package in the example), you can use absolute imports to refer to submodules of siblings packages. For example, if the module \texttt{sound\_filters\_vocoder} needs to use the \texttt{echo} module in the \texttt{sound\_effects} package, it can use \texttt{from sound\_effects import echo}.

Starting with Python 2.5, in addition to the implicit relative imports described above, you can write explicit relative imports with the \texttt{from module import name} form of import statement. These explicit relative
imports use leading dots to indicate the current and parent packages involved in the relative import. From the `surround` module for example, you might use:

```python
from . import echo
from .. import formats
from ..filters import equalizer
```

Note that both explicit and implicit relative imports are based on the name of the current module. Since the name of the main module is always "__main__", modules intended for use as the main module of a Python application should always use absolute imports.

### 6.4.3. Packages in Multiple Directories

Packages support one more special attribute, `__path__`. This is initialized to be a list containing the name of the directory holding the package's `__init__.py` before the code in that file is executed. This variable can be modified; doing so affects future searches for modules and subpackages contained in the package.

While this feature is not often needed, it can be used to extend the set of modules found in a package.

**Footnotes**

In fact function definitions are also ‘statements’ that are executed; the execution of a module-level function enters the function name in the module’s global symbol table.

[1]
7. Input and Output

There are several ways to present the output of a program; data can be printed in a human-readable form, or written to a file for future use. This chapter will discuss some of the possibilities.
7.1. Fancier Output Formatting

So far we've encountered two ways of writing values: *expression statements* and the `print` statement. (A third way is using the `write()` method of file objects; the standard output file can be referenced as `sys.stdout`. See the Library Reference for more information on this.)

Often you’ll want more control over the formatting of your output than simply printing space-separated values. There are two ways to format your output; the first way is to do all the string handling yourself; using string slicing and concatenation operations you can create any layout you can imagine. The standard module `string` contains some useful operations for padding strings to a given column width; these will be discussed shortly. The second way is to use the `str.format()` method.

One question remains, of course: how do you convert values to strings? Luckily, Python has ways to convert any value to a string: pass it to the `repr()` or `str()` functions.

The `str()` function is meant to return representations of values which are fairly human-readable, while `repr()` is meant to generate representations which can be read by the interpreter (or will force a `SyntaxError` if there is not equivalent syntax). For objects which don’t have a particular representation for human consumption, `str()` will return the same value as `repr()`. Many values, such as numbers or structures like lists and dictionaries, have the same representation using either function. Strings and floating point numbers, in particular, have two distinct representations.

Some examples:
>>> s = 'Hello, world.'
>>> str(s)
'Hello, world.'
>>> repr(s)
"'Hello, world.'"
>>> str(1.0/7.0)
'0.142857142857'
>>> repr(1.0/7.0)
'0.14285714285714285'
>>> x = 10 * 3.25
>>> y = 200 * 200
>>> s = 'The value of x is ' + repr(x) + ', and y is ' + repr(y)
>>> print s
The value of x is 32.5, and y is 40000...
>>> # The repr() of a string adds string quotes and backslashes
... hello = 'hello, world\n'
>>> hellos = repr(hello)
>>> print hellos
'hello, world\n'
>>> # The argument to repr() may be any Python object:
... repr((x, y, ('spam', 'eggs')))
'(32.5, 40000, ('spam', 'eggs'))'

Here are two ways to write a table of squares and cubes:

```python
>>> for x in range(1, 11):
...     print repr(x).rjust(2), repr(x*x).rjust(3),
...     # Note trailing comma on previous line
...     print repr(x*x*x).rjust(4)
...
  1  1  1
  2  4  8
  3  9 27
  4 16 64
  5 25 125
  6 36 216
  7 49 343
  8 64 512
  9 81 729
 10 100 1000
```
(Note that in the first example, one space between each column was added by the way print works: it always adds spaces between its arguments.)

This example demonstrates the rjust() method of string objects, which right-justifies a string in a field of a given width by padding it with spaces on the left. There are similar methods ljust() and center(). These methods do not write anything, they just return a new string. If the input string is too long, they don’t truncate it, but return it unchanged; this will mess up your column lay-out but that’s usually better than the alternative, which would be lying about a value. (If you really want truncation you can always add a slice operation, as in x.ljust(n)[:-n].)

There is another method, zfill(), which pads a numeric string on the left with zeros. It understands about plus and minus signs:

```
>>> '12'.zfill(5)
'00012'
>>> '-3.14'.zfill(7)
'-003.14'
>>> '3.14159265359'.zfill(5)
'3.14159265359'
```

Basic usage of the str.format() method looks like this:

```
>>> print 'We are the {} who say "{}!"'.format('knights', 'Ni')
We are the knights who say "Ni!"
```
The brackets and characters within them (called format fields) are replaced with the objects passed into the `format()` method. A number in the brackets refers to the position of the object passed into the `format()` method.

```python
>>> print '{0} and {1}'.format('spam', 'eggs')
spam and eggs
>>> print '{1} and {0}'.format('spam', 'eggs')
eggs and spam
```

If keyword arguments are used in the `format()` method, their values are referred to by using the name of the argument.

```python
>>> print 'This {food} is {adjective}.'.format(food='spam', adjective='absolutely horrible')
This spam is absolutely horrible.
```

Positional and keyword arguments can be arbitrarily combined:

```python
>>> print 'The story of {0}, {1}, and {other}.'.format('Bill', 'Manfred', other='Georg')
The story of Bill, Manfred, and Georg.
```

`!s` (apply `str()`) and `!r` (apply `repr()`) can be used to convert the value before it is formatted.

```python
>>> import math
>>> print 'The value of PI is approximately {}'.format(math.pi)
The value of PI is approximately 3.14159265359.
>>> print 'The value of PI is approximately {!r}'.format(math.pi)
The value of PI is approximately 3.141592653589793.
```

An optional `:` and format specifier can follow the field name. This allows greater control over how the value is formatted. The following example truncates Pi to three places after the decimal.
### Code Snippets

```python
>>> import math
>>> print 'The value of PI is approximately {0:.3f}.'.format(math.pi)
The value of PI is approximately 3.142.
```

Passing an integer after the ': ' will cause that field to be a minimum number of characters wide. This is useful for making tables pretty.

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 7678}
>>> for name, phone in table.items():
...    print '{0:10} ==> {1:10d}'.format(name, phone)
... Jack ==> 4098
... Dcab ==> 7678
... Sjoerd ==> 4127
```

If you have a really long format string that you don’t want to split up, it would be nice if you could reference the variables to be formatted by name instead of by position. This can be done by simply passing the dict and using square brackets `[]` to access the keys

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
>>> print ('Jack: {0[Jack]:d}; Sjoerd: {0[Sjoerd]:d}; ' + 'Dcab: {0[Dcab]:d}').format(table)
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This could also be done by passing the table as keyword arguments with the ‘**’ notation.

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This is particularly useful in combination with the new built-in `vars()` function, which returns a dictionary containing all local variables.

For a complete overview of string formatting with `str.format()`, see `Format String Syntax`. 
7.1.1. Old string formatting

The % operator can also be used for string formatting. It interprets the left argument much like a sprintf()-style format string to be applied to the right argument, and returns the string resulting from this formatting operation. For example:

>>> import math
>>> print 'The value of PI is approximately %5.3f.' % math.pi
The value of PI is approximately 3.142.

Since str.format() is quite new, a lot of Python code still uses the % operator. However, because this old style of formatting will eventually be removed from the language, str.format() should generally be used.

More information can be found in the String Formatting Operations section.
7.2. Reading and Writing Files

`open()` returns a file object, and is most commonly used with two arguments: `open(filename, mode)`.

```python
>>> f = open('/tmp/workfile', 'w')
>>> print f
<open file '/tmp/workfile', mode 'w' at 80a0960>
```

The first argument is a string containing the filename. The second argument is another string containing a few characters describing the way in which the file will be used. `mode` can be `'r'` when the file will only be read, `'w'` for only writing (an existing file with the same name will be erased), and `'a'` opens the file for appending; any data written to the file is automatically added to the end. `'r+'` opens the file for both reading and writing. The `mode` argument is optional; `'r'` will be assumed if it's omitted.

On Windows, `'b'` appended to the mode opens the file in binary mode, so there are also modes like `'rb'`, `'wb'`, and `'r+b'`. Python on Windows makes a distinction between text and binary files; the end-of-line characters in text files are automatically altered slightly when data is read or written. This behind-the-scenes modification to file data is fine for ASCII text files, but it'll corrupt binary data like that in JPEG or EXE files. Be very careful to use binary mode when reading and writing such files. On Unix, it doesn't hurt to append a `'b'` to the mode, so you can use it platform-independently for all binary files.

7.2.1. Methods of File Objects

The rest of the examples in this section will assume that a file object called `f` has already been created.
To read a file’s contents, call \texttt{f.read(size)}, which reads some quantity of data and returns it as a string. \texttt{size} is an optional numeric argument. When \texttt{size} is omitted or negative, the entire contents of the file will be read and returned; it’s your problem if the file is twice as large as your machine’s memory. Otherwise, at most \texttt{size} bytes are read and returned. If the end of the file has been reached, \texttt{f.read()} will return an empty string ("").

\begin{verbatim}
>>> f.read()
'This is the entire file.\n'
>>> f.read()
'
\end{verbatim}

\texttt{f.readline()} reads a single line from the file; a newline character (\texttt{\textbackslash n}) is left at the end of the string, and is only omitted on the last line of the file if the file doesn't end in a newline. This makes the return value unambiguous; if \texttt{f.readline()} returns an empty string, the end of the file has been reached, while a blank line is represented by '\texttt{\textbackslash n}', a string containing only a single newline.

\begin{verbatim}
>>> f.readline()
'This is the first line of the file.\n'
>>> f.readline()
'Second line of the file\n'
>>> f.readline()
'
\end{verbatim}

\texttt{f.readlines()} returns a list containing all the lines of data in the file. If given an optional parameter \texttt{sizehint}, it reads that many bytes from the file and enough more to complete a line, and returns the lines from that. This is often used to allow efficient reading of a large file by lines, but without having to load the entire file in memory. Only complete lines will be returned.

\begin{verbatim}
>>> f.readlines()
['This is the first line of the file.\n', 'Second line of the file\n', 'Third line of the file\n']
\end{verbatim}
An alternative approach to reading lines is to loop over the file object. This is memory efficient, fast, and leads to simpler code:

```python
>>> for line in f:
    print line,
This is the first line of the file.
Second line of the file
```

The alternative approach is simpler but does not provide as fine-grained control. Since the two approaches manage line buffering differently, they should not be mixed.

`f.write(string)` writes the contents of `string` to the file, returning `None`.

```python
>>> f.write('This is a test\n')
```

To write something other than a string, it needs to be converted to a string first:

```python
>>> value = ('the answer', 42)
>>> s = str(value)
>>> f.write(s)
```

`f.tell()` returns an integer giving the file object's current position in the file, measured in bytes from the beginning of the file. To change the file object's position, use `f.seek(offset, from_what)`. The position is computed from adding `offset` to a reference point; the reference point is selected by the `from_what` argument. A `from_what` value of 0 measures from the beginning of the file, 1 uses the current file position, and 2 uses the end of the file as the reference point. `from_what` can be omitted and defaults to 0, using the beginning of the file as the reference point.

```python
>>> f = open('/tmp/workfile', 'r+')
>>> f.write('0123456789abcdef')
```
When you're done with a file, call `f.close()` to close it and free up any system resources taken up by the open file. After calling `f.close()`, attempts to use the file object will automatically fail.

```python
>>> f.close()
>>> f.read()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: I/O operation on closed file
```

It is good practice to use the `with` keyword when dealing with file objects. This has the advantage that the file is properly closed after its suite finishes, even if an exception is raised on the way. It is also much shorter than writing equivalent `try-finally` blocks:

```python
>>> with open('/tmp/workfile', 'r') as f:
...     read_data = f.read()
>>> f.closed
True
```

File objects have some additional methods, such as `isatty()` and `truncate()` which are less frequently used; consult the Library Reference for a complete guide to file objects.

### 7.2.2. The `pickle` Module

Strings can easily be written to and read from a file. Numbers take a bit more effort, since the `read()` method only returns strings, which will have to be passed to a function like `int()`, which takes a string like `'123'` and returns its numeric value 123. However, when you
want to save more complex data types like lists, dictionaries, or class instances, things get a lot more complicated.

Rather than have users be constantly writing and debugging code to save complicated data types, Python provides a standard module called pickle. This is an amazing module that can take almost any Python object (even some forms of Python code!), and convert it to a string representation; this process is called pickling. Reconstructing the object from the string representation is called unpickling. Between pickling and unpickling, the string representing the object may have been stored in a file or data, or sent over a network connection to some distant machine.

If you have an object \( x \), and a file object \( f \) that's been opened for writing, the simplest way to pickle the object takes only one line of code:

```python
pickle.dump(x, f)
```

To unpickle the object again, if \( f \) is a file object which has been opened for reading:

```python
x = pickle.load(f)
```

(There are other variants of this, used when pickling many objects or when you don’t want to write the pickled data to a file; consult the complete documentation for pickle in the Python Library Reference.)

pickle is the standard way to make Python objects which can be stored and reused by other programs or by a future invocation of the same program; the technical term for this is a persistent object. Because pickle is so widely used, many authors who write Python extensions take care to ensure that new data types such as matrices can be properly pickled and unpickled.
8. Errors and Exceptions

Until now error messages haven’t been more than mentioned, but if you have tried out the examples you have probably seen some. There are (at least) two distinguishable kinds of errors: syntax errors and exceptions.
8.1. Syntax Errors

Syntax errors, also known as parsing errors, are perhaps the most common kind of complaint you get while you are still learning Python:

```python
>>> while True print 'Hello world'
  File "<stdin>", line 1, in ?
    while True print 'Hello world'
^  
SyntaxError: invalid syntax
```

The parser repeats the offending line and displays a little ‘arrow’ pointing at the earliest point in the line where the error was detected. The error is caused by (or at least detected at) the token preceding the arrow: in the example, the error is detected at the keyword `print`, since a colon (`:`) is missing before it. File name and line number are printed so you know where to look in case the input came from a script.
8.2. Exceptions

Even if a statement or expression is syntactically correct, it may cause an error when an attempt is made to execute it. Errors detected during execution are called exceptions and are not unconditionally fatal: you will soon learn how to handle them in Python programs. Most exceptions are not handled by programs, however, and result in error messages as shown here:

```python
>>> 10 * (1/0)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ZeroDivisionError: integer division or modulo by zero
>>> 4 + spam*3
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: name 'spam' is not defined
>>> '2' + 2
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: cannot concatenate 'str' and 'int' objects
```

The last line of the error message indicates what happened. Exceptions come in different types, and the type is printed as part of the message: the types in the example are `ZeroDivisionError`, `NameError` and `TypeError`. The string printed as the exception type is the name of the built-in exception that occurred. This is true for all built-in exceptions, but need not be true for user-defined exceptions (although it is a useful convention). Standard exception names are built-in identifiers (not reserved keywords).

The rest of the line provides detail based on the type of exception and what caused it.

The preceding part of the error message shows the context where the exception happened, in the form of a stack traceback. In general
it contains a stack traceback listing source lines; however, it will not display lines read from standard input.

*Built-in Exceptions* lists the built-in exceptions and their meanings.
It is possible to write programs that handle selected exceptions. Look at the following example, which asks the user for input until a valid integer has been entered, but allows the user to interrupt the program (using `Control-C` or whatever the operating system supports); note that a user-generated interruption is signalled by raising the `KeyboardInterrupt` exception.

```python
>>> while True:
...     try:
...         x = int(raw_input("Please enter a number: "))
...         break
...     except ValueError:
...         print "Oops! That was no valid number. Try again."
...```

The `try` statement works as follows.

- First, the `try clause` (the statement(s) between the `try` and `except` keywords) is executed.
- If no exception occurs, the `except clause` is skipped and execution of the `try` statement is finished.
- If an exception occurs during execution of the `try` clause, the rest of the clause is skipped. Then if its type matches the exception named after the `except` keyword, the `except` clause is executed, and then execution continues after the `try` statement.
- If an exception occurs which does not match the exception named in the `except` clause, it is passed on to outer `try` statements; if no handler is found, it is an `unhandled exception` and execution stops with a message as shown above.

A `try` statement may have more than one except clause, to specify
handlers for different exceptions. At most one handler will be executed. Handlers only handle exceptions that occur in the corresponding try clause, not in other handlers of the same try statement. An except clause may name multiple exceptions as a parenthesized tuple, for example:

```python
... except (RuntimeError, TypeError, NameError):
    pass
```

The last except clause may omit the exception name(s), to serve as a wildcard. Use this with extreme caution, since it is easy to mask a real programming error in this way! It can also be used to print an error message and then re-raise the exception (allowing a caller to handle the exception as well):

```python
import sys

try:
    f = open('myfile.txt')
    s = f.readline()
    i = int(s.strip())
except IOError as (errno, strerror):
    print "I/O error({0}):{1}".format(errno, strerror)
except ValueError:
    print "Could not convert data to an integer."
except:
    print "Unexpected error:", sys.exc_info()[0]
    raise
```

The try ... except statement has an optional else clause, which, when present, must follow all except clauses. It is useful for code that must be executed if the try clause does not raise an exception. For example:

```python
for arg in sys.argv[1:]:
    try:
        f = open(arg, 'r')
    except IOError:
        print 'cannot open', arg
    else:
```
The use of the `else` clause is better than adding additional code to the `try` clause because it avoids accidentally catching an exception that wasn’t raised by the code being protected by the `try ... except` statement.

When an exception occurs, it may have an associated value, also known as the exception's `argument`. The presence and type of the argument depend on the exception type.

The `except` clause may specify a variable after the exception name (or tuple). The variable is bound to an exception instance with the arguments stored in `instance.args`. For convenience, the exception instance defines `__str__()` so the arguments can be printed directly without having to reference `.args`.

One may also instantiate an exception first before raising it and add any attributes to it as desired.

```python
>>> try:
...     raise Exception('spam', 'eggs')
... except Exception as inst:
...     print type(inst) # the exception instance
...     print inst.args # arguments stored in .args
...     print inst # __str__ allows args to printed directly
...     x, y = inst # __getitem__ allows args to be unpacked directly
...     print 'x =', x
...     print 'y =', y
...
<type 'exceptions.Exception'>
('spam', 'eggs')
('spam', 'eggs')
x = spam
y = eggs
```

If an exception has an argument, it is printed as the last part ('detail')
of the message for unhandled exceptions.

Exception handlers don’t just handle exceptions if they occur immediately in the try clause, but also if they occur inside functions that are called (even indirectly) in the try clause. For example:

```python
>>> def this_fails():
    ...     x = 1/0
    ...
>>> try:
    ...     this_fails()
    ... except ZeroDivisionError as detail:
    ...     print 'Handling run-time error:', detail
    ...
Handling run-time error: integer division or modulo by zero
```
8.4. Raising Exceptions

The `raise` statement allows the programmer to force a specified exception to occur. For example:

```python
>>> raise NameError('HiThere')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: HiThere
```

The sole argument to `raise` indicates the exception to be raised. This must be either an exception instance or an exception class (a class that derives from `Exception`).

If you need to determine whether an exception was raised but don’t intend to handle it, a simpler form of the `raise` statement allows you to re-raise the exception:

```python
>>> try:
...     raise NameError('HiThere')
... except NameError:
...     print 'An exception flew by!'
...     raise
...
An exception flew by!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
NameError: HiThere
```
8.5. User-defined Exceptions

Programs may name their own exceptions by creating a new exception class (see *Classes* for more about Python classes). Exceptions should typically be derived from the *Exception* class, either directly or indirectly. For example:

```python
>>> class MyError(Exception):
...     def __init__(self, value):
...         self.value = value
...     def __str__(self):
...         return repr(self.value)
...
>>> try:
...     raise MyError(2*2)
... except MyError as e:
...     print 'My exception occurred, value:', e.value
...
My exception occurred, value: 4
>>> raise MyError('oops!')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
__main__.MyError: 'oops!'
```

In this example, the default *__init__() of *Exception* has been overridden. The new behavior simply creates the *value* attribute. This replaces the default behavior of creating the *args* attribute.

Exception classes can be defined which do anything any other class can do, but are usually kept simple, often only offering a number of attributes that allow information about the error to be extracted by handlers for the exception. When creating a module that can raise several distinct errors, a common practice is to create a base class for exceptions defined by that module, and subclass that to create specific exception classes for different error conditions:

```python
class Error(Exception):
    """Base class for exceptions in this module."""
```
Most exceptions are defined with names that end in “Error,” similar to the naming of the standard exceptions.

Many standard modules define their own exceptions to report errors that may occur in functions they define. More information on classes is presented in chapter *Classes*.
8.6. Defining Clean-up Actions

The `try` statement has another optional clause which is intended to define clean-up actions that must be executed under all circumstances. For example:

```python
>>> try:
...    raise KeyboardInterrupt
... finally:
...    print 'Goodbye, world!
... Goodbye, world!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
KeyboardInterrupt
```

A `finally` clause is always executed before leaving the `try` statement, whether an exception has occurred or not. When an exception has occurred in the `try` clause and has not been handled by an `except` clause (or it has occurred in a `except` or `else` clause), it is re-raised after the `finally` clause has been executed. The `finally` clause is also executed “on the way out” when any other clause of the `try` statement is left via a `break`, `continue` or `return` statement. A more complicated example (having `except` and `finally` clauses in the same `try` statement works as of Python 2.5):

```python
>>> def divide(x, y):
...    try:
...        result = x / y
...    except ZeroDivisionError:
...        print "division by zero!"
...    else:
...        print "result is", result
... finally:
...    print "executing finally clause"
... >>> divide(2, 1)
```
As you can see, the `finally` clause is executed in any event. The `TypeError` raised by dividing two strings is not handled by the `except` clause and therefore re-raised after the `finally` clause has been executed.

In real world applications, the `finally` clause is useful for releasing external resources (such as files or network connections), regardless of whether the use of the resource was successful.
8.7. Predefined Clean-up Actions

Some objects define standard clean-up actions to be undertaken when the object is no longer needed, regardless of whether or not the operation using the object succeeded or failed. Look at the following example, which tries to open a file and print its contents to the screen.

```python
for line in open("myfile.txt"):
    print line
```

The problem with this code is that it leaves the file open for an indeterminate amount of time after the code has finished executing. This is not an issue in simple scripts, but can be a problem for larger applications. The `with` statement allows objects like files to be used in a way that ensures they are always cleaned up promptly and correctly.

```python
with open("myfile.txt") as f:
    for line in f:
        print line
```

After the statement is executed, the file `f` is always closed, even if a problem was encountered while processing the lines. Other objects which provide predefined clean-up actions will indicate this in their documentation.
9. Classes

Python’s class mechanism adds classes to the language with a minimum of new syntax and semantics. It is a mixture of the class mechanisms found in C++ and Modula-3. As is true for modules, classes in Python do not put an absolute barrier between definition and user, but rather rely on the politeness of the user not to “break into the definition.” The most important features of classes are retained with full power, however: the class inheritance mechanism allows multiple base classes, a derived class can override any methods of its base class or classes, and a method can call the method of a base class with the same name. Objects can contain an arbitrary amount of data.

In C++ terminology, all class members (including the data members) are public, and all member functions are virtual. As in Modula-3, there are no shorthands for referencing the object’s members from its methods: the method function is declared with an explicit first argument representing the object, which is provided implicitly by the call. As in Smalltalk, classes themselves are objects. This provides semantics for importing and renaming. Unlike C++ and Modula-3, built-in types can be used as base classes for extension by the user. Also, like in C++, most built-in operators with special syntax (arithmetic operators, subscripting etc.) can be redefined for class instances.

(Lacking universally accepted terminology to talk about classes, I will make occasional use of Smalltalk and C++ terms. I would use Modula-3 terms, since its object-oriented semantics are closer to those of Python than C++, but I expect that few readers have heard of it.)
9.1. A Word About Names and Objects

Objects have individuality, and multiple names (in multiple scopes) can be bound to the same object. This is known as aliasing in other languages. This is usually not appreciated on a first glance at Python, and can be safely ignored when dealing with immutable basic types (numbers, strings, tuples). However, aliasing has a possibly surprising effect on the semantics of Python code involving mutable objects such as lists, dictionaries, and most other types. This is usually used to the benefit of the program, since aliases behave like pointers in some respects. For example, passing an object is cheap since only a pointer is passed by the implementation; and if a function modifies an object passed as an argument, the caller will see the change — this eliminates the need for two different argument passing mechanisms as in Pascal.
Before introducing classes, I first have to tell you something about Python's scope rules. Class definitions play some neat tricks with namespaces, and you need to know how scopes and namespaces work to fully understand what's going on. Incidentally, knowledge about this subject is useful for any advanced Python programmer.

Let's begin with some definitions.

A **namespace** is a mapping from names to objects. Most namespaces are currently implemented as Python dictionaries, but that's normally not noticeable in any way (except for performance), and it may change in the future. Examples of namespaces are: the set of built-in names (functions such as `abs()`, and built-in exception names); the global names in a module; and the local names in a function invocation. In a sense the set of attributes of an object also form a namespace. The important thing to know about namespaces is that there is absolutely no relation between names in different namespaces; for instance, two different modules may both define a function `maximize` without confusion — users of the modules must prefix it with the module name.

By the way, I use the word **attribute** for any name following a dot — for example, in the expression `z.real`, `real` is an attribute of the object `z`. Strictly speaking, references to names in modules are attribute references: in the expression `modname.funcname`, `modname` is a module object and `funcname` is an attribute of it. In this case there happens to be a straightforward mapping between the module's attributes and the global names defined in the module: they share the same namespace! [1]

Attributes may be read-only or writable. In the latter case,
assignment to attributes is possible. Module attributes are writable: you can write `modname.the_answer = 42`. Writable attributes may also be deleted with the `del` statement. For example, `del modname.the_answer` will remove the attribute `the_answer` from the object named by `modname`.

Namespaces are created at different moments and have different lifetimes. The namespace containing the built-in names is created when the Python interpreter starts up, and is never deleted. The global namespace for a module is created when the module definition is read in; normally, module namespaces also last until the interpreter quits. The statements executed by the top-level invocation of the interpreter, either read from a script file or interactively, are considered part of a module called `__main__`, so they have their own global namespace. (The built-in names actually also live in a module; this is called `__builtin__`.)

The local namespace for a function is created when the function is called, and deleted when the function returns or raises an exception that is not handled within the function. (Actually, forgetting would be a better way to describe what actually happens.) Of course, recursive invocations each have their own local namespace.

A scope is a textual region of a Python program where a namespace is directly accessible. “Directly accessible” here means that an unqualified reference to a name attempts to find the name in the namespace.

Although scopes are determined statically, they are used dynamically. At any time during execution, there are at least three nested scopes whose namespaces are directly accessible:

- the innermost scope, which is searched first, contains the local names
- the scopes of any enclosing functions, which are searched
starting with the nearest enclosing scope, contains non-local, but also non-global names
• the next-to-last scope contains the current module’s global names
• the outermost scope (searched last) is the namespace containing built-in names

If a name is declared global, then all references and assignments go directly to the middle scope containing the module’s global names. Otherwise, all variables found outside of the innermost scope are read-only (an attempt to write to such a variable will simply create a new local variable in the innermost scope, leaving the identically named outer variable unchanged).

Usually, the local scope references the local names of the (textually) current function. Outside functions, the local scope references the same namespace as the global scope: the module’s namespace. Class definitions place yet another namespace in the local scope.

It is important to realize that scopes are determined textually: the global scope of a function defined in a module is that module’s namespace, no matter from where or by what alias the function is called. On the other hand, the actual search for names is done dynamically, at run time — however, the language definition is evolving towards static name resolution, at “compile” time, so don’t rely on dynamic name resolution! (In fact, local variables are already determined statically.)

A special quirk of Python is that — if no global statement is in effect — assignments to names always go into the innermost scope. Assignments do not copy data — they just bind names to objects. The same is true for deletions: the statement del x removes the binding of x from the namespace referenced by the local scope. In fact, all operations that introduce new names use the local scope: in particular, import statements and function definitions bind the
module or function name in the local scope. (The `global` statement can be used to indicate that particular variables live in the global scope.)
9.3. A First Look at Classes

Classes introduce a little bit of new syntax, three new object types, and some new semantics.

9.3.1. Class Definition Syntax

The simplest form of class definition looks like this:

```python
class Classname:
    <statement-1>
    .
    .
    .
    <statement-N>
```

Class definitions, like function definitions (def statements) must be executed before they have any effect. (You could conceivably place a class definition in a branch of an if statement, or inside a function.)

In practice, the statements inside a class definition will usually be function definitions, but other statements are allowed, and sometimes useful — we’ll come back to this later. The function definitions inside a class normally have a peculiar form of argument list, dictated by the calling conventions for methods — again, this is explained later.

When a class definition is entered, a new namespace is created, and used as the local scope — thus, all assignments to local variables go into this new namespace. In particular, function definitions bind the name of the new function here.

When a class definition is left normally (via the end), a class object is created. This is basically a wrapper around the contents of the
namespaces created by the class definition; we'll learn more about class objects in the next section. The original local scope (the one in effect just before the class definition was entered) is reinstated, and the class object is bound here to the class name given in the class definition header (ClassName in the example).

### 9.3.2. Class Objects

Class objects support two kinds of operations: attribute references and instantiation.

*Attribute references* use the standard syntax used for all attribute references in Python: `obj.name`. Valid attribute names are all the names that were in the class's namespace when the class object was created. So, if the class definition looked like this:

```python
class MyClass:
    """A simple example class""
    i = 12345
    def f(self):
        return 'hello world'
```

then `MyClass.i` and `MyClass.f` are valid attribute references, returning an integer and a function object, respectively. Class attributes can also be assigned to, so you can change the value of `MyClass.i` by assignment. `__doc__` is also a valid attribute, returning the docstring belonging to the class: "A simple example class".

Class *instantiation* uses function notation. Just pretend that the class object is a parameterless function that returns a new instance of the class. For example (assuming the above class):

```python
x = MyClass()
```

creates a new *instance* of the class and assigns this object to the
local variable \( x \).

The instantiation operation ("calling" a class object) creates an empty object. Many classes like to create objects with instances customized to a specific initial state. Therefore a class may define a special method named \_
\_
init\_
\_
, like this:

```python
def __init__(self):
    self.data = []
```

When a class defines an \_
\_
init\_
\_
 method, class instantiation automatically invokes \_
\_
init\_
\_
 for the newly-created class instance. So in this example, a new, initialized instance can be obtained by:

```python
x = MyClass()
```

Of course, the \_
\_
init\_
\_
 method may have arguments for greater flexibility. In that case, arguments given to the class instantiation operator are passed on to \_
\_
init\_
\_
. For example,

```python
>>> class Complex:
...     def __init__(self, realpart, imagpart):
...         self.r = realpart
...         self.i = imagpart
... >>> x = Complex(3.0, -4.5)
>>> x.r, x.i
(3.0, -4.5)
```

### 9.3.3. Instance Objects

Now what can we do with instance objects? The only operations understood by instance objects are attribute references. There are two kinds of valid attribute names, data attributes and methods.

*data attributes* correspond to "instance variables" in Smalltalk, and to
“data members” in C++. Data attributes need not be declared; like local variables, they spring into existence when they are first assigned to. For example, if \( x \) is the instance of \( \text{MyClass} \) created above, the following piece of code will print the value 16, without leaving a trace:

```python
x.counter = 1
while x.counter < 10:
    x.counter = x.counter * 2
print x.counter
del x.counter
```

The other kind of instance attribute reference is a \textit{method}. A method is a function that “belongs to” an object. (In Python, the term method is not unique to class instances; other object types can have methods as well. For example, list objects have methods called \texttt{append}, \texttt{insert}, \texttt{remove}, \texttt{sort}, and so on. However, in the following discussion, we’ll use the term method exclusively to mean methods of class instance objects, unless explicitly stated otherwise.)

Valid method names of an instance object depend on its class. By definition, all attributes of a class that are function objects define corresponding methods of its instances. So in our example, \( x.f \) is a valid method reference, since \( \text{MyClass.f} \) is a function, but \( x.i \) is not, since \( \text{MyClass.i} \) is not. But \( x.f \) is not the same thing as \( \text{MyClass.f} \) — it is a \textit{method object}, not a function object.

### 9.3.4. Method Objects

Usually, a method is called right after it is bound:

```python
x.f()
```

In the \texttt{MyClass} example, this will return the string ‘hello world’. However, it is not necessary to call a method right away: \( x.f \) is a
method object, and can be stored away and called at a later time. For example:

```
x = x.f  
while True:  
    print x.f()  
```

will continue to print `hello world` until the end of time.

What exactly happens when a method is called? You may have noticed that `x.f()` was called without an argument above, even though the function definition for `f()` specified an argument. What happened to the argument? Surely Python raises an exception when a function that requires an argument is called without any — even if the argument isn’t actually used...

Actually, you may have guessed the answer: the special thing about methods is that the object is passed as the first argument of the function. In our example, the call `x.f()` is exactly equivalent to `MyClass.f(x)`. In general, calling a method with a list of `n` arguments is equivalent to calling the corresponding function with an argument list that is created by inserting the method’s object before the first argument.

If you still don’t understand how methods work, a look at the implementation can perhaps clarify matters. When an instance attribute is referenced that isn’t a data attribute, its class is searched. If the name denotes a valid class attribute that is a function object, a method object is created by packing (pointers to) the instance object and the function object just found together in an abstract object: this is the method object. When the method object is called with an argument list, a new argument list is constructed from the instance object and the argument list, and the function object is called with this new argument list.
Data attributes override method attributes with the same name; to avoid accidental name conflicts, which may cause hard-to-find bugs in large programs, it is wise to use some kind of convention that minimizes the chance of conflicts. Possible conventions include capitalizing method names, prefixing data attribute names with a small unique string (perhaps just an underscore), or using verbs for methods and nouns for data attributes.

Data attributes may be referenced by methods as well as by ordinary users ("clients") of an object. In other words, classes are not usable to implement pure abstract data types. In fact, nothing in Python makes it possible to enforce data hiding — it is all based upon convention. (On the other hand, the Python implementation, written in C, can completely hide implementation details and control access to an object if necessary; this can be used by extensions to Python written in C.)

Clients should use data attributes with care — clients may mess up invariants maintained by the methods by stamping on their data attributes. Note that clients may add data attributes of their own to an instance object without affecting the validity of the methods, as long as name conflicts are avoided — again, a naming convention can save a lot of headaches here.

There is no shorthand for referencing data attributes (or other methods!) from within methods. I find that this actually increases the readability of methods: there is no chance of confusing local variables and instance variables when glancing through a method.

Often, the first argument of a method is called `self`. This is nothing more than a convention: the name `self` has absolutely no special meaning to Python. Note, however, that by not following the
convention your code may be less readable to other Python programmers, and it is also conceivable that a class browser program might be written that relies upon such a convention.

Any function object that is a class attribute defines a method for instances of that class. It is not necessary that the function definition is textually enclosed in the class definition: assigning a function object to a local variable in the class is also ok. For example:

```python
# Function defined outside the class
def f1(self, x, y):
    return min(x, x+y)

class C:
    f = f1
    def g(self):
        return 'hello world'
    h = g
```

Now f, g and h are all attributes of class C that refer to function objects, and consequently they are all methods of instances of C — h being exactly equivalent to g. Note that this practice usually only serves to confuse the reader of a program.

Methods may call other methods by using method attributes of the self argument:

```python
class Bag:
    def __init__(self):
        self.data = []
    def add(self, x):
        self.data.append(x)
    def addtwice(self, x):
        self.add(x)
        self.add(x)
```

Methods may reference global names in the same way as ordinary functions. The global scope associated with a method is the module containing the class definition. (The class itself is never used as a
global scope.) While one rarely encounters a good reason for using global data in a method, there are many legitimate uses of the global scope: for one thing, functions and modules imported into the global scope can be used by methods, as well as functions and classes defined in it. Usually, the class containing the method is itself defined in this global scope, and in the next section we'll find some good reasons why a method would want to reference its own class.

Each value is an object, and therefore has a class (also called its type). It is stored as `object.__class__`. 
9.5. Inheritance

Of course, a language feature would not be worthy of the name “class” without supporting inheritance. The syntax for a derived class definition looks like this:

```python
class DerivedClassName(BaseClassName):
    <statement-1>
    .
    .
    .
    <statement-N>
```

The name `BaseClassName` must be defined in a scope containing the derived class definition. In place of a base class name, other arbitrary expressions are also allowed. This can be useful, for example, when the base class is defined in another module:

```python
class DerivedClassName(modname.BaseClassName):
```

Execution of a derived class definition proceeds the same as for a base class. When the class object is constructed, the base class is remembered. This is used for resolving attribute references: if a requested attribute is not found in the class, the search proceeds to look in the base class. This rule is applied recursively if the base class itself is derived from some other class.

There's nothing special about instantiation of derived classes: `DerivedClassName()` creates a new instance of the class. Method references are resolved as follows: the corresponding class attribute is searched, descending down the chain of base classes if necessary, and the method reference is valid if this yields a function object.

Derived classes may override methods of their base classes.
Because methods have no special privileges when calling other methods of the same object, a method of a base class that calls another method defined in the same base class may end up calling a method of a derived class that overrides it. (For C++ programmers: all methods in Python are effectively virtual.)

An overriding method in a derived class may in fact want to extend rather than simply replace the base class method of the same name. There is a simple way to call the base class method directly: just call BaseClassName.methodname(self, arguments). This is occasionally useful to clients as well. (Note that this only works if the base class is accessible as BaseClassName in the global scope.)

Python has two built-in functions that work with inheritance:

- Use `isinstance()` to check an instance's type: `isinstance(obj, int)` will be True only if `obj.__class__` is `int` or some class derived from `int`.
- Use `issubclass()` to check class inheritance: `issubclass(bool, int)` is True since `bool` is a subclass of `int`. However, `issubclass(unicode, str)` is False since `unicode` is not a subclass of `str` (they only share a common ancestor, `basestring`).

### 9.5.1. Multiple Inheritance

Python supports a limited form of multiple inheritance as well. A class definition with multiple base classes looks like this:

```python
class DerivedClassName(Base1, Base2, Base3):
    <statement-1>
    .
    .
    .
    <statement-N>
```
For old-style classes, the only rule is depth-first, left-to-right. Thus, if an attribute is not found in DerivedClassName, it is searched in Base1, then (recursively) in the base classes of Base1, and only if it is not found there, it is searched in Base2, and so on.

(To some people breadth first — searching Base2 and Base3 before the base classes of Base1 — looks more natural. However, this would require you to know whether a particular attribute of Base1 is actually defined in Base1 or in one of its base classes before you can figure out the consequences of a name conflict with an attribute of Base2. The depth-first rule makes no differences between direct and inherited attributes of Base1.)

For new-style classes, the method resolution order changes dynamically to support cooperative calls to super(). This approach is known in some other multiple-inheritance languages as call-next-method and is more powerful than the super call found in single-inheritance languages.

With new-style classes, dynamic ordering is necessary because all cases of multiple inheritance exhibit one or more diamond relationships (where one at least one of the parent classes can be accessed through multiple paths from the bottommost class). For example, all new-style classes inherit from object, so any case of multiple inheritance provides more than one path to reach object. To keep the base classes from being accessed more than once, the dynamic algorithm linearizes the search order in a way that preserves the left-to-right ordering specified in each class, that calls each parent only once, and that is monotonic (meaning that a class can be subclassed without affecting the precedence order of its parents). Taken together, these properties make it possible to design reliable and extensible classes with multiple inheritance. For more detail, see http://www.python.org/download/releases/2.3/mro/.
9.6. Private Variables

“Private” instance variables that cannot be accessed except from inside an object don’t exist in Python. However, there is a convention that is followed by most Python code: a name prefixed with an underscore (e.g. `_spam`) should be treated as a non-public part of the API (whether it is a function, a method or a data member). It should be considered an implementation detail and subject to change without notice.

Since there is a valid use-case for class-private members (namely to avoid name clashes of names with names defined by subclasses), there is limited support for such a mechanism, called name mangling. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `__classname__spam`, where `classname` is the current class name with leading underscore(s) stripped. This mangling is done without regard to the syntactic position of the identifier, as long as it occurs within the definition of a class.

Note that the mangling rules are designed mostly to avoid accidents; it still is possible to access or modify a variable that is considered private. This can even be useful in special circumstances, such as in the debugger.

Notice that code passed to `exec`, `eval()` or `execfile()` does not consider the classname of the invoking class to be the current class; this is similar to the effect of the `global` statement, the effect of which is likewise restricted to code that is byte-compiled together. The same restriction applies to `getattr()`, `setattr()` and `delattr()`, as well as when referencing `__dict__` directly.
9.7. Odds and Ends

Sometimes it is useful to have a data type similar to the Pascal “record” or C “struct”, bundling together a few named data items. An empty class definition will do nicely:

```python
class Employee:
    pass

john = Employee() # Create an empty employee record

# Fill the fields of the record
john.name = 'John Doe'
john.dept = 'computer lab'
john.salary = 1000
```

A piece of Python code that expects a particular abstract data type can often be passed a class that emulates the methods of that data type instead. For instance, if you have a function that formats some data from a file object, you can define a class with methods `read()` and `readline()` that get the data from a string buffer instead, and pass it as an argument.

Instance method objects have attributes, too: `m.im_self` is the instance object with the method `m()`, and `m.im_func` is the function object corresponding to the method.
9.8. Exceptions Are Classes Too

User-defined exceptions are identified by classes as well. Using this mechanism it is possible to create extensible hierarchies of exceptions.

There are two new valid (semantic) forms for the `raise` statement:

```
raise Class, instance
raise instance
```

In the first form, `instance` must be an instance of `class` or of a class derived from it. The second form is a shorthand for:

```
raise instance.__class__, instance
```

A class in an `except` clause is compatible with an exception if it is the same class or a base class thereof (but not the other way around — an except clause listing a derived class is not compatible with a base class). For example, the following code will print B, C, D in that order:

```python
class B:
    pass
class C(B):
    pass
class D(C):
    pass
for c in [B, C, D]:
    try:
        raise c()
    except D:
        print "D"
    except C:
        print "C"
    except B:
```
print "B"

Note that if the except clauses were reversed (with `except B` first), it would have printed B, B, B — the first matching except clause is triggered.

When an error message is printed for an unhandled exception, the exception's class name is printed, then a colon and a space, and finally the instance converted to a string using the built-in function `str()`.
9.9. Iterators

By now you have probably noticed that most container objects can be looped over using a `for` statement:

```python
for element in [1, 2, 3]:
    print element
for element in (1, 2, 3):
    print element
for key in {'one':1, 'two':2}:
    print key
for char in "123":
    print char
for line in open("myfile.txt"):
    print line
```

This style of access is clear, concise, and convenient. The use of iterators pervades and unifies Python. Behind the scenes, the `for` statement calls `iter()` on the container object. The function returns an iterator object that defines the method `next()` which accesses elements in the container one at a time. When there are no more elements, `next()` raises a `StopIteration` exception which tells the `for` loop to terminate. This example shows how it all works:

```python
>>> s = 'abc'
>>> it = iter(s)
>>> it
<iterator object at 0x00A1DB50>
>>> it.next()
'a'
>>> it.next()
'b'
>>> it.next()
'c'
>>> it.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
    it.next()
```
Having seen the mechanics behind the iterator protocol, it is easy to add iterator behavior to your classes. Define a `__iter__()` method which returns an object with a `next()` method. If the class defines `next()`, then `__iter__()` can just return `self`:

```python
class Reverse:
    "Iterator for looping over a sequence backwards"
    def __init__(self, data):
        self.data = data
        self.index = len(data)
    def __iter__(self):
        return self
    def next(self):
        if self.index == 0:
            raise StopIteration
        self.index = self.index - 1
        return self.data[self.index]

>>> for char in Reverse('spam'):
...    print char
...
mapsp
```
9.10. Generators

Generators are a simple and powerful tool for creating iterators. They are written like regular functions but use the `yield` statement whenever they want to return data. Each time `next()` is called, the generator resumes where it left-off (it remembers all the data values and which statement was last executed). An example shows that generators can be trivially easy to create:

```python
def reverse(data):
    for index in range(len(data)-1, -1, -1):
        yield data[index]

>>> for char in reverse('golf'):
    ...       print char
    ...       
    ...       f
    ...       l
    ...       o
    ...       g
```

Anything that can be done with generators can also be done with class based iterators as described in the previous section. What makes generators so compact is that the `__iter__()` and `next()` methods are created automatically.

Another key feature is that the local variables and execution state are automatically saved between calls. This made the function easier to write and much more clear than an approach using instance variables like `self.index` and `self.data`.

In addition to automatic method creation and saving program state, when generators terminate, they automatically raise `StopIteration`. In combination, these features make it easy to create iterators with no more effort than writing a regular function.
9.11. Generator Expressions

Some simple generators can be coded succinctly as expressions using a syntax similar to list comprehensions but with parentheses instead of brackets. These expressions are designed for situations where the generator is used right away by an enclosing function. Generator expressions are more compact but less versatile than full generator definitions and tend to be more memory friendly than equivalent list comprehensions.

Examples:

```python
>>> sum(i*i for i in range(10))  # sum of squares
285

>>> xvec = [10, 20, 30]
>>> yvec = [7, 5, 3]
>>> sum(x*y for x, y in zip(xvec, yvec))  # dot product
260

>>> from math import pi, sin
>>> sine_table = dict((x, sin(x*pi/180)) for x in range(0, 91))

>>> unique_words = set(word for line in page for word in line.split())

>>> valedictorian = max((student.gpa, student.name) for student in graduates)

>>> data = 'golf'
>>> list(data[i] for i in range(len(data)-1,-1,-1))
['f', 'l', 'o', 'g']
```

Footnotes

[1] Except for one thing. Module objects have a secret read-only attribute called `__dict__` which returns the dictionary used to implement the module’s namespace; the name `__dict__` is an attribute but not a global name. Obviously, using this violates the abstraction of namespace implementation, and should be
restricted to things like post-mortem debuggers.
10. Brief Tour of the Standard Library
10.1. Operating System Interface

The `os` module provides dozens of functions for interacting with the operating system:

```python
>>> import os
>>> os.system('time 0:02')
0
>>> os.getcwd()  # Return the current working directory
'C:\Python26'
>>> os.chdir('/server/accesslogs')
```

Be sure to use the `import os` style instead of `from os import *`. This will keep `os.open()` from shadowing the built-in `open()` function which operates much differently.

The built-in `dir()` and `help()` functions are useful as interactive aids for working with large modules like `os`:

```python
>>> import os
>>> dir(os)
<returns a list of all module functions>
>>> help(os)
<returns an extensive manual page created from the module's doc>
```

For daily file and directory management tasks, the `shutil` module provides a higher level interface that is easier to use:

```python
>>> import shutil
>>> shutil.copyfile('data.db', 'archive.db')
>>> shutil.move('/build/executables', 'installdir')
```
10.2. File Wildcards

The `glob` module provides a function for making file lists from directory wildcard searches:

```python
>>> import glob
>>> glob.glob('*.py')
['primes.py', 'random.py', 'quote.py']
```
Common utility scripts often need to process command line arguments. These arguments are stored in the `sys` module's `argv` attribute as a list. For instance the following output results from running `python demo.py one two three` at the command line:

```python
>>> import sys
>>> print sys.argv
['demo.py', 'one', 'two', 'three']
```

The `getopt` module processes `sys.argv` using the conventions of the Unix `getopt()` function. More powerful and flexible command line processing is provided by the `argparse` module.
10.4. Error Output Redirection and Program Termination

The `sys` module also has attributes for `stdin`, `stdout`, and `stderr`. The latter is useful for emitting warnings and error messages to make them visible even when `stdout` has been redirected:

```python
>>> sys.stderr.write('Warning, log file not found starting a new one

Warning, log file not found starting a new one
```

The most direct way to terminate a script is to use `sys.exit()`.
The `re` module provides regular expression tools for advanced string processing. For complex matching and manipulation, regular expressions offer succinct, optimized solutions:

```python
>>> import re
>>> re.findall(r'^[a-z]*', 'which foot or hand fell fastest')
['foot', 'fell', 'fastest']
>>> re.sub(r'\b[a-z]+\1', r'\1', 'cat in the the the hat')
'cat in the hat'
```

When only simple capabilities are needed, string methods are preferred because they are easier to read and debug:

```python
>>> 'tea for too'.replace('too', 'two')
'tea for two'
```
10.6. Mathematics

The **math** module gives access to the underlying C library functions for floating point math:

```python
>>> import math
>>> math.cos(math.pi / 4.0)
0.70710678118654757
>>> math.log(1024, 2)
10.0
```

The **random** module provides tools for making random selections:

```python
>>> import random
>>> random.choice(['apple', 'pear', 'banana'])
'apple'
>>> random.sample(xrange(100), 10)  # sampling without replacement
[30, 83, 16, 4, 8, 81, 41, 50, 18, 33]
>>> random.random()  # random float
0.17970987693706186
>>> random.randrange(6)  # random integer chosen from range(6)
4
```
10.7. Internet Access

There are a number of modules for accessing the internet and processing internet protocols. Two of the simplest are `urllib2` for retrieving data from urls and `smtplib` for sending mail:

```python
>>> import urllib2
>>> for line in urllib2.urlopen('http://tycho.usno.navy.mil/cgi
...					if 'EST' in line or 'EDT' in line: # look for Eastern
...									print line

<BR>Nov. 25, 09:43:32 PM EST

>>> import smtplib
>>> server = smtplib.SMTP('localhost')
>>> server.sendmail('soothsayer@example.org', 'jcaesar@example.org',
...									"To: jcaesar@example.org
...									From: soothsayer@example.org
...									Beware the Ides of March.
...								"")
>>> server.quit()
```

(Note that the second example needs a mailserver running on localhost.)
10.8. Dates and Times

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. The module also supports objects that are timezone aware.

```python
>>> # dates are easily constructed and formatted
>>> from datetime import date
>>> now = date.today()
>>> now
datetime.date(2003, 12, 2)
>>> now.strftime("%m-%d-%y. %d %b %Y is a %A on the %d day of %
'12-02-03. 02 Dec 2003 is a Tuesday on the 02 day of December."

>>> # dates support calendar arithmetic
>>> birthday = date(1964, 7, 31)
>>> age = now - birthday
>>> age.days
14368
```
10.9. Data Compression

Common data archiving and compression formats are directly supported by modules including: `zlib`, `gzip`, `bz2`, `zipfile` and `tarfile`.

```python
>>> import zlib
>>> s = 'which widow has which widows wrist watch'
>>> len(s)
40
>>> t = zlib.compress(s)
>>> len(t)
37
>>> zlib.decompress(t)
'which widow has which widows wrist watch'
>>> zlib.crc32(s)
99618090
```
10.10. Performance Measurement

Some Python users develop a deep interest in knowing the relative performance of different approaches to the same problem. Python provides a measurement tool that answers those questions immediately.

For example, it may be tempting to use the tuple packing and unpacking feature instead of the traditional approach to swapping arguments. The `timeit` module quickly demonstrates a modest performance advantage:

```python
>>> from timeit import Timer
timeit('t=a; a=b; b=t', 'a=1; b=2')
0.57535828626024577
>>> Timer('a,b = b,a', 'a=1; b=2').timeit()
0.54962537085770791
```

In contrast to `timeit`'s fine level of granularity, the `profile` and `pstats` modules provide tools for identifying time critical sections in larger blocks of code.
10.11. Quality Control

One approach for developing high quality software is to write tests for each function as it is developed and to run those tests frequently during the development process.

The doctest module provides a tool for scanning a module and validating tests embedded in a program’s docstrings. Test construction is as simple as cutting-and-pasting a typical call along with its results into the docstring. This improves the documentation by providing the user with an example and it allows the doctest module to make sure the code remains true to the documentation:

```python
def average(values):
    """Computes the arithmetic mean of a list of numbers."
    >>> print average([20, 30, 70])
    40.0
    """
    return sum(values, 0.0) / len(values)
import doctest
doctest.testmod() # automatically validate the embedded tests
```

The unittest module is not as effortless as the doctest module, but it allows a more comprehensive set of tests to be maintained in a separate file:

```python
import unittest
class TestStatisticalFunctions(unittest.TestCase):
    def test_average(self):
        self.assertEqual(average([20, 30, 70]), 40.0)
        self.assertEqual(round(average([1, 5, 7]), 1), 4.3)
        self.assertRaises(ZeroDivisionError, average, [])
        self.assertRaises(TypeError, average, 20, 30, 70)
```
unittest.main() # Calling from the command line invokes all tests
10.12. Batteries Included

Python has a “batteries included” philosophy. This is best seen through the sophisticated and robust capabilities of its larger packages. For example:

- The xmlrpclib and SimpleXMLRPCServer modules make implementing remote procedure calls into an almost trivial task. Despite the modules names, no direct knowledge or handling of XML is needed.
- The email package is a library for managing email messages, including MIME and other RFC 2822-based message documents. Unlike smtplib and poplib which actually send and receive messages, the email package has a complete toolset for building or decoding complex message structures (including attachments) and for implementing internet encoding and header protocols.
- The xml.dom and xml.sax packages provide robust support for parsing this popular data interchange format. Likewise, the csv module supports direct reads and writes in a common database format. Together, these modules and packages greatly simplify data interchange between Python applications and other tools.
- Internationalization is supported by a number of modules including gettext, locale, and the codecs package.
11. Brief Tour of the Standard Library – Part II

This second tour covers more advanced modules that support professional programming needs. These modules rarely occur in small scripts.
11.1. Output Formatting

The `repr` module provides a version of `repr()` customized for abbreviated displays of large or deeply nested containers:

```python
>>> import repr
>>> repr.repr(set('supercalifragilisticexpialidocious'))
"set(['a', 'c', 'd', 'e', 'f', 'g', ...])"
```

The `pprint` module offers more sophisticated control over printing both built-in and user defined objects in a way that is readable by the interpreter. When the result is longer than one line, the “pretty printer” adds line breaks and indentation to more clearly reveal data structure:

```python
>>> import pprint
>>> t = [[[['black', 'cyan'], 'white', ['green', 'red']], [['ma...
...   'yellow'], 'blue']]]
... >>> pprint.pprint(t, width=30)
[[[['black', 'cyan'],
   'white',
   ['green', 'red']],
  [['magenta', 'yellow'],
   'blue']]]
```

The `textwrap` module formats paragraphs of text to fit a given screen width:

```python
>>> import textwrap
>>> doc = """The wrap() method is just like fill() except that ...
... a list of strings instead of one big string with newlines t...
... the wrapped lines."""
... >>> print textwrap.fill(doc, width=40)
The wrap() method is just like fill()
except that it returns a list of strings
instead of one big string with newlines
```
The `locale` module accesses a database of culture specific data formats. The grouping attribute of locale's format function provides a direct way of formatting numbers with group separators:

```python
>>> import locale
>>> locale.setlocale(locale.LC_ALL, 'English_United States.1252')
'English_United States.1252'
>>> conv = locale.localeconv()  # get a mapping of conv
>>> x = 1234567.8
>>> locale.format("%d", x, grouping=True)
'1,234,567'
>>> locale.format_string("%s%.f", (conv['currency_symbol'], conv['frac_digits'], x), grouping=True)
'$1,234,567.80'
```
11.2. Templating

The string module includes a versatile Template class with a simplified syntax suitable for editing by end-users. This allows users to customize their applications without having to alter the application.

The format uses placeholder names formed by $ with valid Python identifiers (alphanumeric characters and underscores). Surrounding the placeholder with braces allows it to be followed by more alphanumeric letters with no intervening spaces. Writing $$ creates a single escaped $:

```python
>>> from string import Template
>>> t = Template('${village}folk send $$10 to $cause.')
>>> t.substitute(village='Nottingham', cause='the ditch fund')
'Nottinghamfolk send $10 to the ditch fund.'
```

The substitute() method raises a KeyError when a placeholder is not supplied in a dictionary or a keyword argument. For mail-merge style applications, user supplied data may be incomplete and the safe_substitute() method may be more appropriate — it will leave placeholders unchanged if data is missing:

```python
>>> t = Template('Return the $item to $owner.')
>>> d = dict(item='unladen swallow')
>>> t.substitute(d)
Traceback (most recent call last):
  ... KeyError: 'owner'
>>> t.safe_substitute(d)
'Return the unladen swallow to $owner.'
```

Template subclasses can specify a custom delimiter. For example, a batch renaming utility for a photo browser may elect to use percent signs for placeholders such as the current date, image sequence number, or file format:
Another application for templating is separating program logic from the details of multiple output formats. This makes it possible to substitute custom templates for XML files, plain text reports, and HTML web reports.
11.3. Working with Binary Data Record Layouts

The `struct` module provides `pack()` and `unpack()` functions for working with variable length binary record formats. The following example shows how to loop through header information in a ZIP file without using the `zipfile` module. Pack codes "H" and "I" represent two and four byte unsigned numbers respectively. The "<" indicates that they are standard size and in little-endian byte order:

```python
import struct

data = open('myfile.zip', 'rb').read()
start = 0
for i in range(3):  # show the first 3 file
    start += 14
    fields = struct.unpack('<IIIHH', data[start:start+16])
    crc32, comp_size, uncomp_size, filenamesize, extra_size = fields

    start += 16
    filename = data[start:start+filenamesize]
    start += filenamesize
    extra = data[start:start+extra_size]
    print filename, hex(crc32), comp_size, uncomp_size

start += extra_size + comp_size  # skip to the next header
```
11.4. Multi-threading

Threading is a technique for decoupling tasks which are not sequentially dependent. Threads can be used to improve the responsiveness of applications that accept user input while other tasks run in the background. A related use case is running I/O in parallel with computations in another thread.

The following code shows how the high level `threading` module can run tasks in background while the main program continues to run:

```python
import threading, zipfile

class AsyncZip(threading.Thread):
    def __init__(self, infile, outfile):
        threading.Thread.__init__(self)
        self.infile = infile
        self.outfile = outfile
    def run(self):
        f = zipfile.ZipFile(self.outfile, 'w', zipfile.ZIP_DEFLATED)
        f.write(self.infile)
        f.close()
        print 'Finished background zip of: ', self.infile

background = AsyncZip('mydata.txt', 'myarchive.zip')
background.start()
print 'The main program continues to run in foreground.'

background.join()  # Wait for the background task to finish
print 'Main program waited until background was done.'
```

The principal challenge of multi-threaded applications is coordinating threads that share data or other resources. To that end, the threading module provides a number of synchronization primitives including locks, events, condition variables, and semaphores.

While those tools are powerful, minor design errors can result in problems that are difficult to reproduce. So, the preferred approach
to task coordination is to concentrate all access to a resource in a single thread and then use the `Queue` module to feed that thread with requests from other threads. Applications using `Queue.Queue` objects for inter-thread communication and coordination are easier to design, more readable, and more reliable.
11.5. Logging

The `logging` module offers a full featured and flexible logging system. At its simplest, log messages are sent to a file or to `sys.stderr`:

```python
import logging
logging.debug('Debugging information')
logging.info('Informational message')
logging.warning('Warning: config file %s not found', 'server.conf')
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')
```

This produces the following output:

```
WARNING:root:Warning: config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root:Critical error -- shutting down
```

By default, informational and debugging messages are suppressed and the output is sent to standard error. Other output options include routing messages through email, datagrams, sockets, or to an HTTP Server. New filters can select different routing based on message priority: `DEBUG`, `INFO`, `WARNING`, `ERROR`, and `CRITICAL`.

The logging system can be configured directly from Python or can be loaded from a user editable configuration file for customized logging without altering the application.
11.6. Weak References

Python does automatic memory management (reference counting for most objects and garbage collection to eliminate cycles). The memory is freed shortly after the last reference to it has been eliminated.

This approach works fine for most applications but occasionally there is a need to track objects only as long as they are being used by something else. Unfortunately, just tracking them creates a reference that makes them permanent. The weakref module provides tools for tracking objects without creating a reference. When the object is no longer needed, it is automatically removed from a weakref table and a callback is triggered for weakref objects. Typical applications include caching objects that are expensive to create:

```python
>>> import weakref, gc
>>> class A:
...     def __init__(self, value):
...         self.value = value
...     def __repr__(self):
...         return str(self.value)
...
>>> a = A(10)  # create a reference
>>> d = weakref.WeakValueDictionary()
>>> d['primary'] = a  # does not create a reference
>>> d['primary']  # fetch the object if it is still
10
>>> del a  # remove the one reference
>>> gc.collect()  # run garbage collection right away
0
>>> d['primary']  # entry was automatically removed
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
    d['primary']  # entry was automatically removed
  File "C:/python26/lib/weakref.py", line 46, in __getitem__
    o = self.data[key]()
KeyError: 'primary'
```
Many data structure needs can be met with the built-in list type. However, sometimes there is a need for alternative implementations with different performance trade-offs.

The `array` module provides an `array()` object that is like a list that stores only homogeneous data and stores it more compactly. The following example shows an array of numbers stored as two byte unsigned binary numbers (typecode "H") rather than the usual 16 bytes per entry for regular lists of Python int objects:

```python
>>> from array import array
>>> a = array('H', [4000, 10, 700, 22222])
>>> sum(a)
26932
>>> a[1:3]
array('H', [10, 700])
```

The `collections` module provides a `deque()` object that is like a list with faster appends and pops from the left side but slower lookups in the middle. These objects are well suited for implementing queues and breadth first tree searches:

```python
>>> from collections import deque
>>> d = deque(['task1', 'task2', 'task3'])
>>> d.append('task4')
>>> print "Handling", d.popleft()
Handling task1
```

```python
def breadth_first_search(unsearched):
    node = unsearched.popleft()
    for m in gen_moves(node):
        if is_goal(m):
            return m
    unsearched.append(m)
```
In addition to alternative list implementations, the library also offers other tools such as the `bisect` module with functions for manipulating sorted lists:

```python
>>> import bisect
>>> scores = [(100, 'perl'), (200, 'tcl'), (400, 'lua'), (500, 'python')]
>>> bisect.insort(scores, (300, 'ruby'))
>>> scores
[(100, 'perl'), (200, 'tcl'), (300, 'ruby'), (400, 'lua'), (500, 'python')]
```

The `heapq` module provides functions for implementing heaps based on regular lists. The lowest valued entry is always kept at position zero. This is useful for applications which repeatedly access the smallest element but do not want to run a full list sort:

```python
>>> from heapq import heapify, heappop, heappush
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> heapify(data)  # rearrange the list into heap order
>>> heappush(data, -5)  # add a new entry
>>> [heappop(data) for i in range(3)]  # fetch the three smallest entries
[-5, 0, 1]
```
The `decimal` module offers a `Decimal` datatype for decimal floating point arithmetic. Compared to the built-in `float` implementation of binary floating point, the class is especially helpful for

- financial applications and other uses which require exact decimal representation,
- control over precision,
- control over rounding to meet legal or regulatory requirements,
- tracking of significant decimal places, or
- applications where the user expects the results to match calculations done by hand.

For example, calculating a 5% tax on a 70 cent phone charge gives different results in decimal floating point and binary floating point. The difference becomes significant if the results are rounded to the nearest cent:

```
>>> from decimal import *
>>> x = Decimal('0.70') * Decimal('1.05')
>>> x
Decimal('0.7350')
>>> x.quantize(Decimal('0.01'))  # round to nearest cent
Decimal('0.74')
>>> round(.70 * 1.05, 2)  # same calculation with floats
0.73
```

The `Decimal` result keeps a trailing zero, automatically inferring four place significance from multiplicands with two place significance. Decimal reproduces mathematics as done by hand and avoids issues that can arise when binary floating point cannot exactly represent decimal quantities.

Exact representation enables the `Decimal` class to perform modulo
calculations and equality tests that are unsuitable for binary floating point:

```python
>>> Decimal('1.00') % Decimal('.10')
Decimal('0.00')
>>> 1.00 % 0.10
0.09999999999999995
```

```python
>>> sum([Decimal('0.1')]*10) == Decimal('1.0')
True
>>> sum([0.1]*10) == 1.0
False
```

The `decimal` module provides arithmetic with as much precision as needed:

```python
>>> getcontext().prec = 36
>>> Decimal(1) / Decimal(7)
Decimal('0.14285714285714285714285714285714285714285714285')
```
12. What Now?

Reading this tutorial has probably reinforced your interest in using Python — you should be eager to apply Python to solving your real-world problems. Where should you go to learn more?

This tutorial is part of Python’s documentation set. Some other documents in the set are:

- **The Python Standard Library**: You should browse through this manual, which gives complete (though terse) reference material about types, functions, and the modules in the standard library. The standard Python distribution includes a lot of additional code. There are modules to read Unix mailboxes, retrieve documents via HTTP, generate random numbers, parse command-line options, write CGI programs, compress data, and many other tasks. Skimming through the Library Reference will give you an idea of what's available.

- **Installing Python Modules** explains how to install external modules written by other Python users.

- **The Python Language Reference**: A detailed explanation of Python’s syntax and semantics. It’s heavy reading, but is useful as a complete guide to the language itself.

More Python resources:

- [http://www.python.org](http://www.python.org): The major Python Web site. It contains code, documentation, and pointers to Python-related pages around the Web. This Web site is mirrored in various places around the world, such as Europe, Japan, and Australia; a mirror may be faster than the main site, depending on your
geographical location.

- [http://docs.python.org](http://docs.python.org): Fast access to Python’s documentation.
- [http://pypi.python.org](http://pypi.python.org): The Python Package Index, previously also nicknamed the Cheese Shop, is an index of user-created Python modules that are available for download. Once you begin releasing code, you can register it here so that others can find it.

For Python-related questions and problem reports, you can post to the newsgroup comp.lang.python, or send them to the mailing list at python-list@python.org. The newsgroup and mailing list are gatewayed, so messages posted to one will automatically be forwarded to the other. There are around 120 postings a day (with peaks up to several hundred), asking (and answering) questions, suggesting new features, and announcing new modules. Before posting, be sure to check the list of Frequently Asked Questions (also called the FAQ), or look for it in the Misc/ directory of the Python source distribution. Mailing list archives are available at [http://mail.python.org/pipermail/](http://mail.python.org/pipermail/). The FAQ answers many of the questions that come up again and again, and may already contain the solution for your problem.
13. Interactive Input Editing and History Substitution

Some versions of the Python interpreter support editing of the current input line and history substitution, similar to facilities found in the Korn shell and the GNU Bash shell. This is implemented using the GNU Readline library, which supports Emacs-style and vi-style editing. This library has its own documentation which I won’t duplicate here; however, the basics are easily explained. The interactive editing and history described here are optionally available in the Unix and Cygwin versions of the interpreter.

This chapter does not document the editing facilities of Mark Hammond’s PythonWin package or the Tk-based environment, IDLE, distributed with Python. The command line history recall which operates within DOS boxes on NT and some other DOS and Windows flavors is yet another beast.
13.1. Line Editing

If supported, input line editing is active whenever the interpreter prints a primary or secondary prompt. The current line can be edited using the conventional Emacs control characters. The most important of these are: \texttt{c-A} (Control-A) moves the cursor to the beginning of the line, \texttt{c-E} to the end, \texttt{c-B} moves it one position to the left, \texttt{c-F} to the right. Backspace erases the character to the left of the cursor, \texttt{c-D} the character to its right. \texttt{c-K} kills (erases) the rest of the line to the right of the cursor, \texttt{c-Y} yanks back the last killed string. \texttt{c-underscore} undoes the last change you made; it can be repeated for cumulative effect.
13.2. History Substitution

History substitution works as follows. All non-empty input lines issued are saved in a history buffer, and when a new prompt is given you are positioned on a new line at the bottom of this buffer. **C-P** moves one line up (back) in the history buffer, **C-N** moves one down. Any line in the history buffer can be edited; an asterisk appears in front of the prompt to mark a line as modified. Pressing the **Return** key passes the current line to the interpreter. **C-R** starts an incremental reverse search; **C-S** starts a forward search.
13.3. Key Bindings

The key bindings and some other parameters of the Readline library can be customized by placing commands in an initialization file called ~/.inputrc. Key bindings have the form

\[
\text{key-name: function-name}
\]

or

\[
"\text{string}": \text{function-name}
\]

and options can be set with

\[
\text{set option-name value}
\]

For example:

\[
\begin{align*}
\# \text{I prefer vi-style editing:} \\
\text{set editing-mode vi}
\end{align*}
\]

\[
\begin{align*}
\# \text{Edit using a single line:} \\
\text{set horizontal-scroll-mode On}
\end{align*}
\]

\[
\begin{align*}
\# \text{Rebind some keys:} \\
\text{Meta-h: backward-kill-word} \\
"\text{C-u}": \text{universal-argument} \\
"\text{C-x}\text{C-r}": \text{re-read-init-file}
\end{align*}
\]

Note that the default binding for Tab in Python is to insert a Tab character instead of Readline's default filename completion function. If you insist, you can override this by putting

\[
\text{Tab: complete}
\]

in your ~/.inputrc. (Of course, this makes it harder to type indented
continuation lines if you’re accustomed to using Tab for that purpose.)

Automatic completion of variable and module names is optionally available. To enable it in the interpreter’s interactive mode, add the following to your startup file: [1]

```python
import rlcompleter, readline
readline.parse_and_bind('tab: complete')
```

This binds the Tab key to the completion function, so hitting the Tab key twice suggests completions; it looks at Python statement names, the current local variables, and the available module names. For dotted expressions such as `string.a`, it will evaluate the expression up to the final `'.'` and then suggest completions from the attributes of the resulting object. Note that this may execute application-defined code if an object with a `__getattr__()` method is part of the expression.

A more capable startup file might look like this example. Note that this deletes the names it creates once they are no longer needed; this is done since the startup file is executed in the same namespace as the interactive commands, and removing the names avoids creating side effects in the interactive environment. You may find it convenient to keep some of the imported modules, such as `os`, which turn out to be needed in most sessions with the interpreter.

```bash
# Add auto-completion and a stored history file of commands to
# interactive interpreter. Requires Python 2.0+, readline. Auto
# bound to the Esc key by default (you can change it - see read
#
# Store the file in ~/.pystartup, and set an environment variab
# to it: "export PYTHONSTARTUP=/home/user/.pystartup" in bash.
#
# Note that PYTHONSTARTUP does *not* expand "~", so you have to
# full path to your home directory.
```
import atexit
import os
import readline
import rlcompleter

historyPath = os.path.expanduser("~/.pyhistory")

def save_history(historyPath=historyPath):
    import readline
    readline.write_history_file(historyPath)

if os.path.exists(historyPath):
    readline.read_history_file(historyPath)

atexit.register(save_history)

del os, atexit, readline, rlcompleter, save_history, historyPath
13.4. Alternatives to the Interactive Interpreter

This facility is an enormous step forward compared to earlier versions of the interpreter; however, some wishes are left: It would be nice if the proper indentation were suggested on continuation lines (the parser knows if an indent token is required next). The completion mechanism might use the interpreter’s symbol table. A command to check (or even suggest) matching parentheses, quotes, etc., would also be useful.

One alternative enhanced interactive interpreter that has been around for quite some time is IPython, which features tab completion, object exploration and advanced history management. It can also be thoroughly customized and embedded into other applications. Another similar enhanced interactive environment is bpython.

Footnotes

[1] Python will execute the contents of a file identified by the \PYTONSTARTUP environment variable when you start an interactive interpreter.
14. Floating Point Arithmetic: Issues and Limitations

Floating-point numbers are represented in computer hardware as base 2 (binary) fractions. For example, the decimal fraction

\[ 0.125 \]

has value 1/10 + 2/100 + 5/1000, and in the same way the binary fraction

\[ 0.001 \]

has value 0/2 + 0/4 + 1/8. These two fractions have identical values, the only real difference being that the first is written in base 10 fractional notation, and the second in base 2.

Unfortunately, most decimal fractions cannot be represented exactly as binary fractions. A consequence is that, in general, the decimal floating-point numbers you enter are only approximated by the binary floating-point numbers actually stored in the machine.

The problem is easier to understand at first in base 10. Consider the fraction 1/3. You can approximate that as a base 10 fraction:

\[ 0.3 \]

or, better,

\[ 0.33 \]

or, better,

\[ 0.333 \]
and so on. No matter how many digits you're willing to write down, the result will never be exactly 1/3, but will be an increasingly better approximation of 1/3.

In the same way, no matter how many base 2 digits you're willing to use, the decimal value 0.1 cannot be represented exactly as a base 2 fraction. In base 2, 1/10 is the infinitely repeating fraction

\[ 0.00011001100110011001100110011001100110011001100110011\ldots \]

Stop at any finite number of bits, and you get an approximation. This is why you see things like:

```python
>>> 0.1
0.10000000000000001
```

On most machines today, that is what you'll see if you enter 0.1 at a Python prompt. You may not, though, because the number of bits used by the hardware to store floating-point values can vary across machines, and Python only prints a decimal approximation to the true decimal value of the binary approximation stored by the machine. On most machines, if Python were to print the true decimal value of the binary approximation stored for 0.1, it would have to display

```python
>>> 0.1
0.1000000000000000055511151231257827021181583404541015625
```

instead! The Python prompt uses the built-in `repr()` function to obtain a string version of everything it displays. For floats, `repr(float)` rounds the true decimal value to 17 significant digits, giving

```python
0.1000000000000001
```

`repr(float)` produces 17 significant digits because it turns out that's
enough (on most machines) so that \texttt{eval(repr(x)) == x} exactly for all finite floats \( x \), but rounding to 16 digits is not enough to make that true.

Note that this is in the very nature of binary floating-point: this is not a bug in Python, and it is not a bug in your code either. You'll see the same kind of thing in all languages that support your hardware's floating-point arithmetic (although some languages may not \textit{display} the difference by default, or in all output modes).

Python's built-in \texttt{str()} function produces only 12 significant digits, and you may wish to use that instead. It's unusual for \texttt{eval(str(x))} to reproduce \( x \), but the output may be more pleasant to look at:

\begin{verbatim}
>>> print str(0.1)
0.1
\end{verbatim}

It's important to realize that this is, in a real sense, an illusion: the value in the machine is not exactly \( 1/10 \), you're simply rounding the \textit{display} of the true machine value.

Other surprises follow from this one. For example, after seeing

\begin{verbatim}
>>> 0.1
0.10000000000000001
\end{verbatim}

you may be tempted to use the \texttt{round()} function to chop it back to the single digit you expect. But that makes no difference:

\begin{verbatim}
>>> round(0.1, 1)
0.10000000000000001
\end{verbatim}

The problem is that the binary floating-point value stored for “0.1” was already the best possible binary approximation to 1/10, so trying to round it again can’t make it better: it was already as good as it gets.
Another consequence is that since 0.1 is not exactly 1/10, summing ten values of 0.1 may not yield exactly 1.0, either:

```python
>>> sum = 0.0
>>> for i in range(10):
...    sum += 0.1
...  
>>> sum
0.9999999999999999
```

Binary floating-point arithmetic holds many surprises like this. The problem with “0.1” is explained in precise detail below, in the “Representation Error” section. See The Perils of Floating Point for a more complete account of other common surprises.

As that says near the end, “there are no easy answers.” Still, don’t be unduly wary of floating-point! The errors in Python float operations are inherited from the floating-point hardware, and on most machines are on the order of no more than 1 part in $2^{53}$ per operation. That’s more than adequate for most tasks, but you do need to keep in mind that it’s not decimal arithmetic, and that every float operation can suffer a new rounding error.

While pathological cases do exist, for most casual use of floating-point arithmetic you’ll see the result you expect in the end if you simply round the display of your final results to the number of decimal digits you expect. `str()` usually suffices, and for finer control see the `str.format()` method’s format specifiers in Format String Syntax.
14.1. Representation Error

This section explains the “0.1” example in detail, and shows how you can perform an exact analysis of cases like this yourself. Basic familiarity with binary floating-point representation is assumed.

*Representation error* refers to the fact that some (most, actually) decimal fractions cannot be represented exactly as binary (base 2) fractions. This is the chief reason why Python (or Perl, C, C++, Java, Fortran, and many others) often won't display the exact decimal number you expect:

```python
>>> 0.1
0.10000000000000001
```

Why is that? 1/10 is not exactly representable as a binary fraction. Almost all machines today (November 2000) use IEEE-754 floating point arithmetic, and almost all platforms map Python floats to IEEE-754 “double precision”. 754 doubles contain 53 bits of precision, so on input the computer strives to convert 0.1 to the closest fraction it can of the form \(J/2^{**N}\) where \(J\) is an integer containing exactly 53 bits. Rewriting

\[
1 / 10 \approx J / (2^{**N})
\]

as

\[
J \approx 2^{**N} / 10
\]

and recalling that \(J\) has exactly 53 bits (is \(\geq 2^{**52}\) but \(< 2^{**53}\), the best value for \(N\) is 56:

```text
>>> 2**52
4503599627370496L
>>> 2**53
```

That is, 56 is the only value for \( N \) that leaves \( J \) with exactly 53 bits. The best possible value for \( J \) is then that quotient rounded:

```python
>>> q, r = divmod(2**56, 10)
>>> r
6L
```

Since the remainder is more than half of 10, the best approximation is obtained by rounding up:

```python
>>> q + 1
7205759403792794L
```

Therefore the best possible approximation to 1/10 in 754 double precision is that over 2**56, or

```python
7205759403792794 / 72057594037927936
```

Note that since we rounded up, this is actually a little bit larger than 1/10; if we had not rounded up, the quotient would have been a little bit smaller than 1/10. But in no case can it be exactly 1/10!

So the computer never “sees” 1/10: what it sees is the exact fraction given above, the best 754 double approximation it can get:

```python
>>> .1 * 2**56
7205759403792794.0
```

If we multiply that fraction by 10**30, we can see the (truncated) value of its 30 most significant decimal digits:

```python
>>> 7205759403792794 * 10**30 / 2**56
100000000000000005551115123125L
```
meaning that the exact number stored in the computer is approximately equal to the decimal value 0.100000000000000005551115123125. Rounding that to 17 significant digits gives the 0.10000000000000001 that Python displays (well, will display on any 754-conforming platform that does best-possible input and output conversions in its C library — yours may not!).
1. Command line and environment

The CPython interpreter scans the command line and the environment for various settings.

**CPython implementation detail:** Other implementations’ command line schemes may differ. See *Alternate Implementations* for further resources.
1.1. Command line

When invoking Python, you may specify any of these options:

```
python [-BdEiOQsTuVwX3?] [-c command | -m module-name | script | -] [args]
```

The most common use case is, of course, a simple invocation of a script:

```
python myscript.py
```

1.1.1. Interface options

The interpreter interface resembles that of the UNIX shell, but provides some additional methods of invocation:

- When called with standard input connected to a tty device, it prompts for commands and executes them until an EOF (an end-of-file character, you can produce that with `Ctrl-D` on UNIX or `Ctrl-Z, Enter` on Windows) is read.
- When called with a file name argument or with a file as standard input, it reads and executes a script from that file.
- When called with a directory name argument, it reads and executes an appropriately named script from that directory.
- When called with `-c command`, it executes the Python statement(s) given as `command`. Here `command` may contain multiple statements separated by newlines. Leading whitespace is significant in Python statements!
- When called with `-m module-name`, the given module is located on the Python module path and executed as a script.

In non-interactive mode, the entire input is parsed before it is executed.
An interface option terminates the list of options consumed by the interpreter, all consecutive arguments will end up in `sys.argv` – note that the first element, subscript zero (\texttt{sys.argv[0]}), is a string reflecting the program’s source.

\textbf{-c} \texttt{<command>}

Execute the Python code in \texttt{command}. \texttt{command} can be one or more statements separated by newlines, with significant leading whitespace as in normal module code.

If this option is given, the first element of \texttt{sys.argv} will be \texttt{"-c"} and the current directory will be added to the start of \texttt{sys.path} (allowing modules in that directory to be imported as top level modules).

\textbf{-m} \texttt{<module-name>}

Search \texttt{sys.path} for the named module and execute its contents as the \texttt{__main__} module.

Since the argument is a \textit{module} name, you must not give a file extension (\texttt{.py}). The \texttt{module-name} should be a valid Python module name, but the implementation may not always enforce this (e.g. it may allow you to use a name that includes a hyphen).

Package names are also permitted. When a package name is supplied instead of a normal module, the interpreter will execute \texttt{<pkg>.__main__} as the main module. This behaviour is deliberately similar to the handling of directories and zipfiles that are passed to the interpreter as the script argument.

\textbf{Note:} This option cannot be used with built-in modules and extension modules written in C, since they do not have Python module files. However, it can still be used for precompiled modules, even if the original source file is not available.
If this option is given, the first element of `sys.argv` will be the full path to the module file. As with the `-c` option, the current directory will be added to the start of `sys.path`.

Many standard library modules contain code that is invoked on their execution as a script. An example is the `timeit` module:

```bash
python -mtimeit -s 'setup here' 'benchmarked code here'
python -mtimeit -h # for details
```

See also: `runpy.run_module()` Equivalent functionality directly available to Python code

**PEP 338** – Executing modules as scripts

New in version 2.4.

*Changed in version 2.5:* The named module can now be located inside a package.

*Changed in version 2.7:* Supply the package name to run a `__main__` submodule. `sys.argv[0]` is now set to "-m" while searching for the module (it was previously incorrectly set to "-c")

- Read commands from standard input (`sys.stdin`). If standard input is a terminal, `-i` is implied.

If this option is given, the first element of `sys.argv` will be "-m" and the current directory will be added to the start of `sys.path`.

```python
<script>
Execute the Python code contained in `script`, which must be a filesystem path (absolute or relative) referring to either a Python
file, a directory containing a __main__.py file, or a zipfile containing a __main__.py file.

If this option is given, the first element of sys.argv will be the script name as given on the command line.

If the script name refers directly to a Python file, the directory containing that file is added to the start of sys.path, and the file is executed as the __main__ module.

If the script name refers to a directory or zipfile, the script name is added to the start of sys.path and the __main__.py file in that location is executed as the __main__ module.

*Changed in version 2.5:* Directories and zipfiles containing a __main__.py file at the top level are now considered valid Python scripts.

If no interface option is given, -i is implied, sys.argv[0] is an empty string (""") and the current directory will be added to the start of sys.path.

**See also:** Invoking the Interpreter

### 1.1.2. Generic options

- ?
- h
  --help
    Print a short description of all command line options.

*Changed in version 2.5:* The --help variant.

- V
  --version
Print the Python version number and exit. Example output could be:

```
Python 2.5.1
```

*Changed in version 2.5:* The `--version` variant.

### 1.1.3. Miscellaneous options

**-B**

If given, Python won’t try to write `.pyc` or `.pyo` files on the import of source modules. See also [PYTHONDON'TWRITEBYTECODE](#).

*New in version 2.6.*

**-d**

Turn on parser debugging output (for wizards only, depending on compilation options). See also [PYTHONDEBUG](#).

**-E**

Ignore all PYTHON* environment variables, e.g. [PYTHONPATH](#) and [PYTHONHOME](#), that might be set.

*New in version 2.2.*

**-i**

When a script is passed as first argument or the `-c` option is used, enter interactive mode after executing the script or the command, even when `sys.stdin` does not appear to be a terminal. The [PYTHONSTARTUP](#) file is not read.

This can be useful to inspect global variables or a stack trace when a script raises an exception. See also [PYTHONINSPECT](#).

**-O**

Turn on basic optimizations. This changes the filename extension
for compiled *(bytecode)* files from *.pyc* to *.pyo*. See also `PYTHONOPTIMIZE`.

- **-00**  
  Discard docstrings in addition to the `-O` optimizations.

- **-Q <arg>**  
  Division control. The argument must be one of the following:

  - **old**  
    division of int/int and long/long return an int or long *(default)*
  
  - **new**  
    new division semantics, i.e. division of int/int and long/long returns a float

  - **warn**  
    old division semantics with a warning for int/int and long/long

  - **warnall**  
    old division semantics with a warning for all uses of the division operator

  [See also: Tools/scripts/fixdiv.py for a use of `warnall`]

PEP 238 – Changing the division operator

- **-s**  
  Don't add user site directory to sys.path

*New in version 2.6.*

[See also: PEP 370 – Per user site-packages directory]

- **-S**  
  Disable the import of the module `site` and the site-dependent
manipulations of \texttt{sys.path} that it entails.

\textbf{-t}

Issue a warning when a source file mixes tabs and spaces for indentation in a way that makes it depend on the worth of a tab expressed in spaces. Issue an error when the option is given twice (-tt).

\textbf{-u}

Force stdin, stdout and stderr to be totally unbuffered. On systems where it matters, also put stdin, stdout and stderr in binary mode.

Note that there is internal buffering in \texttt{file.readlines()} and \texttt{File Objects} (for line in \texttt{sys.stdin}) which is not influenced by this option. To work around this, you will want to use \texttt{file.readline()} inside a \texttt{while 1:} loop.

See also \texttt{PYTHONUNBUFFERED}.

\textbf{-v}

Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. When given twice (-vv), print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit. See also \texttt{PYTHONVERBOSE}.

\textbf{-W arg}

Warning control. Python’s warning machinery by default prints warning messages to \texttt{sys.stderr}. A typical warning message has the following form:

\texttt{file:line: category: message}

By default, each warning is printed once for each source line where it occurs. This option controls how often warnings are
Multiple \texttt{-W} options may be given; when a warning matches more than one option, the action for the last matching option is performed. Invalid \texttt{-W} options are ignored (though, a warning message is printed about invalid options when the first warning is issued).

Starting from Python 2.7, \texttt{DeprecationWarning} and its descendants are ignored by default. The \texttt{-Wd} option can be used to re-enable them.

Warnings can also be controlled from within a Python program using the \texttt{warnings} module.

The simplest form of argument is one of the following action strings (or a unique abbreviation) by themselves:

\texttt{ignore}

Ignore all warnings.

\texttt{default}

Explicitly request the default behavior (printing each warning once per source line).

\texttt{all}

Print a warning each time it occurs (this may generate many messages if a warning is triggered repeatedly for the same source line, such as inside a loop).

\texttt{module}

Print each warning only the first time it occurs in each module.

\texttt{once}

Print each warning only the first time it occurs in the program.
Raise an exception instead of printing a warning message.

The full form of argument is:

```
action:message:category:module:line
```

Here, `action` is as explained above but only applies to messages that match the remaining fields. Empty fields match all values; trailing empty fields may be omitted. The `message` field matches the start of the warning message printed; this match is case-insensitive. The `category` field matches the warning category. This must be a class name; the match tests whether the actual warning category of the message is a subclass of the specified warning category. The full class name must be given. The `module` field matches the (fully-qualified) module name; this match is case-sensitive. The `line` field matches the line number, where zero matches all line numbers and is thus equivalent to an omitted line number.

See also: `warnings` – the warnings module
PEP 230 – Warning framework
PYTHONWARNINGS

-x

Skip the first line of the source, allowing use of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Note: The line numbers in error messages will be off by one.

-3

Warn about Python 3.x incompatibilities which cannot be fixed trivially by `2to3`. Among these are:
• `dict.has_key()`
• `apply()`
• `callable()`
• `coerce()`
• `execfile()`
• `reduce()`
• `reload()`

Using these will emit a `DeprecationWarning`.

*New in version 2.6.*

### 1.1.4. Options you shouldn’t use

**-J**
Reserved for use by *Jython*.

**-U**
Turns all string literals into unicodes globally. Do not be tempted to use this option as it will probably break your world. It also produces `.pyc` files with a different magic number than normal. Instead, you can enable unicode literals on a per-module basis by using:

```python
from __future__ import unicode_literals
```

at the top of the file. See `__future__` for details.

**-X**
Reserved for alternative implementations of Python to use for their own purposes.
1.2. Environment variables

These environment variables influence Python’s behavior.

**PYTHONHOME**

Change the location of the standard Python libraries. By default, the libraries are searched in `prefix/lib/pythonversion` and `exec_prefix/lib/pythonversion`, where `prefix` and `exec_prefix` are installation-dependent directories, both defaulting to `/usr/local`.

When **PYTHONHOME** is set to a single directory, its value replaces both `prefix` and `exec_prefix`. To specify different values for these, set **PYTHONHOME** to `prefix:exec_prefix`.

**PYTHONPATH**

Augment the default search path for module files. The format is the same as the shell’s **PATH**: one or more directory pathnames separated by `os.pathsep` (e.g. colons on Unix or semicolons on Windows). Non-existent directories are silently ignored.

In addition to normal directories, individual **PYTHONPATH** entries may refer to zipfiles containing pure Python modules (in either source or compiled form). Extension modules cannot be imported from zipfiles.

The default search path is installation dependent, but generally begins with `prefix/lib/pythonversion` (see **PYTHONHOME** above). It is always appended to **PYTHONPATH**.

An additional directory will be inserted in the search path in front of **PYTHONPATH** as described above under *Interface options*. The search path can be manipulated from within a Python
program as the variable `sys.path`.

**PYTHONSTARTUP**
If this is the name of a readable file, the Python commands in that file are executed before the first prompt is displayed in interactive mode. The file is executed in the same namespace where interactive commands are executed so that objects defined or imported in it can be used without qualification in the interactive session. You can also change the prompts `sys.ps1` and `sys.ps2` in this file.

**PYTHONY2K**
Set this to a non-empty string to cause the `time` module to require dates specified as strings to include 4-digit years, otherwise 2-digit years are converted based on rules described in the `time` module documentation.

**PYTHONOPTIMIZE**
If this is set to a non-empty string it is equivalent to specifying the `-O` option. If set to an integer, it is equivalent to specifying `-O` multiple times.

**PYTHONDEBUG**
If this is set to a non-empty string it is equivalent to specifying the `-d` option. If set to an integer, it is equivalent to specifying `-d` multiple times.

**PYTHONINSPECT**
If this is set to a non-empty string it is equivalent to specifying the `-i` option.

This variable can also be modified by Python code using `os.environ` to force inspect mode on program termination.

**PYTHONUNBUFFERED**
If this is set to a non-empty string it is equivalent to specifying the
-u option.

**PYTHONVERBOSE**
If this is set to a non-empty string it is equivalent to specifying the -v option. If set to an integer, it is equivalent to specifying -v multiple times.

**PYTHONCASEOK**
If this is set, Python ignores case in import statements. This only works on Windows.

**PYTHONDONTWRITEBYTECODE**
If this is set, Python won’t try to write .pyc or .pyo files on the import of source modules.

*New in version 2.6.*

**PYTHONIOENCODING**
Overrrides the encoding used for stdin/stdout/stderr, in the syntax encodingname:errrorhandler. The :errorhandler part is optional and has the same meaning as in str.encode().

*New in version 2.6.*

**PYTHONNOUSERSITE**
If this is set, Python won’t add the user site directory to sys.path

*New in version 2.6.*

**PYTHONUSERBASE**
Sets the base directory for the user site directory

*New in version 2.6.*

See also: PEP 370 – Per user site-packages directory
See also: PEP 370 – Per user site-packages directory

**PYTHONEXECUTABLE**

If this environment variable is set, `sys.argv[0]` will be set to its value instead of the value got through the C runtime. Only works on Mac OS X.

**PYTHONWARNINGS**

This is equivalent to the `-W` option. If set to a comma separated string, it is equivalent to specifying `-W` multiple times.

### 1.2.1. Debug-mode variables

Setting these variables only has an effect in a debug build of Python, that is, if Python was configured with the `--with-pydebug` build option.

**PYTHONTREADDEBUG**

If set, Python will print threading debug info.

*Changed in version 2.6:* Previously, this variable was called THREADDEBUG.

**PYTHONDUMPREFS**

If set, Python will dump objects and reference counts still alive after shutting down the interpreter.

**PYTHONMALLOCSTATS**

If set, Python will print memory allocation statistics every time a new object arena is created, and on shutdown.
1. Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time — or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document — the implementation may change, and other implementations of the same language may work differently. On the other hand, there is currently only one Python implementation in widespread use (although alternate implementations exist), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you’ll find short “implementation notes” sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are documented in *The Python Standard Library*. A few built-in modules are mentioned when they interact in a significant way with the language definition.
1.1. Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

CPython
This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

Jython
Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at the Jython website.

Python for .NET
This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. It was created by Brian Lloyd. For more information, see the Python for .NET home page.

IronPython
An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see the IronPython website.

PyPy
An implementation of Python written completely in Python. It supports several advanced features not found in other
implementations like stackless support and a Just in Time compiler. One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python). Additional information is available on the PyPy project's home page.

Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what's covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you're using.
1.2. Notation

The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```
name ::= lc_letter (lc_letter | ")")*
lc_letter ::= "a"..."z"
```

The first line says that a name is an lc_letter followed by a sequence of zero or more lc_letters and underscores. An lc_letter in turn is any of the single characters 'a' through 'z'. (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and ::=. A vertical bar (|) is used to separate alternatives; it is the least binding operator in this notation. A star (*) means zero or more repetitions of the preceding item; likewise, a plus (+) means one or more repetitions, and a phrase enclosed in square brackets ([ ] ) means zero or one occurrences (in other words, the enclosed phrase is optional). The * and + operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of ASCII characters. A phrase between angular brackets (<...>) gives an informal description of the symbol defined; e.g., this could be used to describe the notion of ‘control character’ if needed.
Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter ("Lexical Analysis") are lexical definitions; uses in subsequent chapters are syntactic definitions.
A Python program is read by a parser. Input to the parser is a stream of tokens, generated by the lexical analyzer. This chapter describes how the lexical analyzer breaks a file into tokens.

Python uses the 7-bit ASCII character set for program text.

New in version 2.3: An encoding declaration can be used to indicate that string literals and comments use an encoding different from ASCII.

For compatibility with older versions, Python only warns if it finds 8-bit characters; those warnings should be corrected by either declaring an explicit encoding, or using escape sequences if those bytes are binary data, instead of characters.

The run-time character set depends on the I/O devices connected to the program but is generally a superset of ASCII.

Future compatibility note: It may be tempting to assume that the character set for 8-bit characters is ISO Latin-1 (an ASCII superset that covers most western languages that use the Latin alphabet), but it is possible that in the future Unicode text editors will become common. These generally use the UTF-8 encoding, which is also an ASCII superset, but with very different use for the characters with ordinals 128-255. While there is no consensus on this subject yet, it is unwise to assume either Latin-1 or UTF-8, even though the current implementation appears to favor Latin-1. This applies both to the source character set and the run-time character set.
2.1. Line structure

A Python program is divided into a number of logical lines.

2.1.1. Logical lines

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more physical lines by following the explicit or implicit line joining rules.

2.1.2. Physical lines

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files, any of the standard platform line termination sequences can be used - the Unix form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the old Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the \n character, representing ASCII LF, is the line terminator).

2.1.3. Comments

A comment starts with a hash character (#) that is not part of a string literal, and ends at the end of the physical line. A comment signifies the end of the logical line unless the implicit line joining rules are
invoked. Comments are ignored by the syntax; they are not tokens.

## 2.1.4. Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[:=]s*([-\w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The recommended forms of this expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar’s VIM. In addition, if the first bytes of the file are the UTF-8 byte-order mark (`\xef\xbb\xbf`), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft’s notepad).

If an encoding is declared, the encoding name must be recognized by Python. The encoding is used for all lexical analysis, in particular to find the end of a string, and to interpret the contents of Unicode literals. String literals are converted to Unicode for syntactical analysis, then converted back to their original encoding before interpretation starts. The encoding declaration must appear on a line of its own.

## 2.1.5. Explicit line joining

Two or more physical lines may be joined into logical lines using backslash characters (\), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined
with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```python
if 1900 < year < 2100 and 1 <= month <= 12 \
    and 1 <= day <= 31 and 0 <= hour < 24 \
    and 0 <= minute < 60 and 0 <= second < 60:  # Looks like a valid date
    return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.

### 2.1.6. Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```python
month_names = ['Januari', 'Februari', 'Maart', 'April', 'Mei', 'Juni', 'Juli', 'Augustus', 'September', 'Oktober', 'November', 'December']  # These are Dutch names for the months of the year
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.

### 2.1.7. Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated).
During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-eval-print loop. In the standard implementation, an entirely blank logical line (i.e. one containing not even whitespace or a comment) terminates a multi-line statement.

### 2.1.8. Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

First, tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by Unix). The total number of spaces preceding the first non-blank character then determines the line’s indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

**Cross-platform compatibility note:** because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.
Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it must be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python code:

```python
def perm(l):
    # Compute the list of all permutations of l
    if len(l) <= 1:
        return [l]
    r = []
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(s)
        for x in p:
            r.append(l[i:i+1] + x)
    return r
```

The following example shows various indentation errors:

```python
def perm(l):
    # error: first line indented
    for i in range(len(l)):
        # error: not indented
        s = l[:i] + l[i+1:]
        p = perm(l[:i] + l[i+1:])
        # error: unexpected indent
        for x in p:
            r.append(l[i:i+1] + x)
        return r
        # error: inconsistent dedent
```

(Actually, the first three errors are detected by the parser; only the
last error is found by the lexical analyzer — the indentation of `\texttt{return}` does not match a level popped off the stack.)

2.1.9. **Whitespace between tokens**

Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., `ab` is one token, but `a b` is two tokens).
2.2. Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: identifiers, keywords, literals, operators, and delimiters. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.
2.3. Identifiers and keywords

Identifiers (also referred to as *names*) are described by the following lexical definitions:

| identifier ::= (letter|"_") (letter | digit | "_")* |
| letter ::= lowercase | uppercase |
| lowercase ::= "a"..."z" |
| uppercase ::= "A"..."Z" |
| digit ::= "0"..."9" |

Identifiers are unlimited in length. Case is significant.

2.3.1. Keywords

The following identifiers are used as reserved words, or *keywords* of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

| and | del | from | not | while |
| as | elif | global | or | with |
| assert | else | if | pass | yield |
| break | except | import | print |
| class | exec | in | raise |
| continue | finally | is | return |
| def | for | lambda | try |

*Changed in version 2.4:* None became a constant and is now recognized by the compiler as a name for the built-in object None. Although it is not a keyword, you cannot assign a different object to it.

*Changed in version 2.5:* Both as and with are only recognized when the `with_statement` future feature has been enabled. It will always be enabled in Python 2.6. See section *The with statement* for details. Note that using as and with as identifiers will always issue a
warning, even when the `with_statement` future directive is not in effect.

2.3.2. Reserved classes of identifiers

Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

`_*`

Not imported by `from module import *`. The special identifier `_` is used in the interactive interpreter to store the result of the last evaluation; it is stored in the `__builtin__` module. When not in interactive mode, `_` has no special meaning and is not defined. See section *The import statement*.

**Note:** The name `_` is often used in conjunction with internationalization; refer to the documentation for the `gettext` module for more information on this convention.

`__*__`

System-defined names. These names are defined by the interpreter and its implementation (including the standard library); applications should not expect to define additional names using this convention. The set of names of this class defined by Python may be extended in future versions. See section *Special method names*.

`__*__`

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between “private” attributes of base and derived classes. See section *Identifiers (Names)*.
2.4. Literals

Literals are notations for constant values of some built-in types.

2.4.1. String literals

String literals are described by the following lexical definitions:

```
stringliteral ::= [stringprefix](shortstring | longstring)
stringprefix ::= "r" | "u" | "ur" | "R" | "U" | "UR" | "Ur"
shortstring ::= "'" shortstringitem* "'" | "'
longstring ::= "'''" longstringitem* "'''" | "" longstringitem* "" longstringchar | escapeseq
shortstringitem ::= shortstringchar | escapeseq
longstringitem ::= longstringchar | escapeseq
shortstringchar ::= <any source character except "\" or newlin
longstringchar ::= <any source character except "\”
escapeseq ::= "\" <any ASCII character>
```

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the `stringprefix` and the rest of the string literal. The source character set is defined by the encoding declaration; it is ASCII if no encoding declaration is given in the source file; see section Encoding declarations.

In plain English: String literals can be enclosed in matching single quotes (') or double quotes ("). They can also be enclosed in matching groups of three single or double quotes (these are generally referred to as triple-quoted strings). The backslash (\) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character. String literals may optionally be prefixed with a letter 'r' or 'R'; such strings are called raw strings and use different rules for interpreting backslash escape sequences. A prefix of 'u' or 'U' makes the string a Unicode string. Unicode strings use the Unicode
character set as defined by the Unicode Consortium and ISO 10646. Some additional escape sequences, described below, are available in Unicode strings. The two prefix characters may be combined; in this case, 'u' must appear before 'r'.

In triple-quoted strings, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the string. (A “quote” is the character used to open the string, i.e. either ' or ".)

Unless an 'r' or 'R' prefix is present, escape sequences in strings are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

<table>
<thead>
<tr>
<th>Escape Sequence</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>\newline</td>
<td>Ignored</td>
<td></td>
</tr>
<tr>
<td>\</td>
<td>Backslash ()</td>
<td></td>
</tr>
<tr>
<td>'</td>
<td>Single quote (‘)</td>
<td></td>
</tr>
<tr>
<td>&quot;</td>
<td>Double quote (&quot;)</td>
<td></td>
</tr>
<tr>
<td>\a</td>
<td>ASCII Bell (BEL)</td>
<td></td>
</tr>
<tr>
<td>\b</td>
<td>ASCII Backspace (BS)</td>
<td></td>
</tr>
<tr>
<td>\f</td>
<td>ASCII Formfeed (FF)</td>
<td></td>
</tr>
<tr>
<td>\n</td>
<td>ASCII Linefeed (LF)</td>
<td></td>
</tr>
<tr>
<td>\N{name}</td>
<td>Character named name in the Unicode database (Unicode only)</td>
<td></td>
</tr>
<tr>
<td>\r</td>
<td>ASCII Carriage Return (CR)</td>
<td></td>
</tr>
<tr>
<td>\t</td>
<td>ASCII Horizontal Tab (TAB)</td>
<td></td>
</tr>
<tr>
<td>\uxxxxx</td>
<td>Character with 16-bit hex value xxxx (Unicode only)</td>
<td>(1)</td>
</tr>
<tr>
<td>\Uxxxxxxxxxxxx</td>
<td>Character with 32-bit hex value xxxxxxxxxx (Unicode only)</td>
<td>(2)</td>
</tr>
<tr>
<td>\v</td>
<td>ASCII Vertical Tab (VT)</td>
<td></td>
</tr>
<tr>
<td>\ooo</td>
<td>Character with octal value ooo</td>
<td>(3,5)</td>
</tr>
<tr>
<td>\xhh</td>
<td>Character with hex value hh</td>
<td>(4,5)</td>
</tr>
</tbody>
</table>
Notes:

1. Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.
2. Any Unicode character can be encoded this way, but characters outside the Basic Multilingual Plane (BMP) will be encoded using a surrogate pair if Python is compiled to use 16-bit code units (the default). Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.
3. As in Standard C, up to three octal digits are accepted.
4. Unlike in Standard C, exactly two hex digits are required.
5. In a string literal, hexadecimal and octal escapes denote the byte with the given value; it is not necessary that the byte encodes a character in the source character set. In a Unicode literal, these escapes denote a Unicode character with the given value.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., *the backslash is left in the string*. (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences marked as “(Unicode only)” in the table above fall into the category of unrecognized escapes for non-Unicode string literals.

When an 'r' or 'R' prefix is present, a character following a backslash is included in the string without change, and *all backslashes are left in the string*. For example, the string literal \r"\n" consists of two characters: a backslash and a lowercase 'n'. String quotes can be escaped with a backslash, but the backslash remains in the string; for example, \r"\" is a valid string literal consisting of two characters: a backslash and a double quote; \r"\" is not a valid string literal (even a raw string cannot end in an odd number of
backslashes). Specifically, *a raw string cannot end in a single backslash* (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the string, *not* as a line continuation.

When an 'r' or 'R' prefix is used in conjunction with a 'u' or 'U' prefix, then the \uXXXX and \uXXXXXXX escape sequences are processed while *all other backslashes are left in the string*. For example, the string literal ur"\u0062\n" consists of three Unicode characters: ‘LATIN SMALL LETTER B’, ‘REVERSE SOLIDUS’, and ‘LATIN SMALL LETTER N’. Backslashes can be escaped with a preceding backslash; however, both remain in the string. As a result, \uXXXX escape sequences are only recognized when there are an odd number of backslashes.

### 2.4.2. String literal concatenation

Multiple adjacent string literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, "hello" 'world' is equivalent to "helloworld". This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```python
re.compile("[A-Za-z_]"   # letter or underscore
    "[A-Za-z0-9_]*"   # letter, digit or underscore
)
```

Note that this feature is defined at the syntactical level, but implemented at compile time. The '+' operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component
(even mixing raw strings and triple quoted strings).

### 2.4.3. Numeric literals

There are four types of numeric literals: plain integers, long integers, floating point numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator `-` and the literal `1`.

### 2.4.4. Integer and long integer literals

Integer and long integer literals are described by the following lexical definitions:

```
longinteger ::= integer ("l" | "L")
integer ::= decimalinteger | octinteger | hexinteger | bininteger
decimalinteger ::= nonzerodigit digit* | "0"
octinteger ::= "0" ("0" | "0") octdigit+ | "0" octdigit+
hexinteger ::= "0" ("x" | "X") hexdigit+
bininteger ::= "0" ("b" | "B") bindigit+
nonzerodigit ::= "1"..."9"
bindigit ::= "0" | "1"
hexdigit ::= digit | "a"..."f" | "A"..."F"
```

Although both lower case `l` and upper case `L` are allowed as suffix for long integers, it is strongly recommended to always use `L`, since the letter `l` looks too much like the digit `1`.

Plain integer literals that are above the largest representable plain integer (e.g., 2147483647 when using 32-bit arithmetic) are accepted as if they were long integers instead. [1] There is no limit
for long integer literals apart from what can be stored in available memory.

Some examples of plain integer literals (first row) and long integer literals (second and third rows):

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>7</td>
<td>2147483647</td>
<td>0177</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3L</td>
<td>79228162514264337593543950336L</td>
<td>0377L</td>
<td>0x100000000L</td>
<td></td>
</tr>
<tr>
<td>79228162514264337593543950336</td>
<td>0xdeadbeef</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

### 2.4.5. Floating point literals

Floating point literals are described by the following lexical definitions:

```
floatnumber ::= pointfloat | exponentfloat
pointfloat ::= [intpart] fraction | intpart "."
exponentfloat ::= (intpart | pointfloat) exponent
intpart ::= digit+
fraction ::= "." digit+
exponent ::= ("e" | "E") ["+" | "]" digit+
```

Note that the integer and exponent parts of floating point numbers can look like octal integers, but are interpreted using radix 10. For example, `077e010` is legal, and denotes the same number as `77e10`. The allowed range of floating point literals is implementation-dependent. Some examples of floating point literals:

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>3.14</td>
<td>10.</td>
<td>.001</td>
<td>1e100</td>
<td>3.14e-10</td>
</tr>
</tbody>
</table>

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator `-` and the literal `1`.

### 2.4.6. Imaginary literals
Imaginary literals are described by the following lexical definitions:

\[
\text{imagnumber} ::= \text{floatnumber} \mid \text{intpart} \ ("j" \mid "J")
\]

An imaginary literal yields a complex number with a real part of 0.0. Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., \((3+4j)\). Some examples of imaginary literals:

\[
3.14j \quad 10.j \quad 10j \quad .001j \quad 1e100j \quad 3.14e-10j
\]
2.5. Operators

The following tokens are operators:

<table>
<thead>
<tr>
<th>+</th>
<th>-</th>
<th>*</th>
<th>**</th>
<th>/</th>
<th>//</th>
<th>%</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;&lt;=</td>
<td>&gt;&gt;</td>
<td>&amp;</td>
<td></td>
<td>^</td>
<td>~</td>
<td></td>
</tr>
<tr>
<td>&lt;</td>
<td>&gt;</td>
<td>&lt;=</td>
<td>&gt;=</td>
<td>==</td>
<td>!=</td>
<td>&lt;&gt;</td>
</tr>
</tbody>
</table>

The comparison operators <= and != are alternate spellings of the same operator. != is the preferred spelling; <> is obsolescent.
2.6. Delimiters

The following tokens serve as delimiters in the grammar:

| (   ) | [   ] | {   } | @   |
| :   : | .   : | `   = | ;   |
| +=  - = | *=  /= | /=  %= |
| &=  | |=  ^= | >>= | <<= | **= |

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis in slices. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical analyzer:

| '   " | #   \ |

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

| $   ? |

Footnotes

[1] In versions of Python prior to 2.4, octal and hexadecimal literals in the range just above the largest representable plain integer but below the largest unsigned 32-bit number (on a machine using 32-bit arithmetic), 4294967296, were taken as the negative plain integer obtained by subtracting 4294967296 from their unsigned value.
3. Data model
3.1. Objects, values and types

*Objects* are Python’s abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann's model of a “stored program computer,” code is also represented by objects.)

Every object has an identity, a type and a value. An object’s *identity* never changes once it has been created; you may think of it as the object’s address in memory. The ‘*is*’ operator compares the identity of two objects; the *id()* function returns an integer representing its identity (currently implemented as its address). An object’s *type* is also unchangeable. [1] An object’s type determines the operations that the object supports (e.g., “does it have a length?”) and also defines the possible values for objects of that type. The *type()* function returns an object’s type (which is an object itself). The *value* of some objects can change. Objects whose value can change are said to be *mutable*; objects whose value is unchangeable once they are created are called *immutable*. (The value of an immutable container object that contains a reference to a mutable object can change when the latter’s value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object’s mutability is determined by its type; for instance, numbers, strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether — it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable.
**CPython implementation detail:** CPython currently uses a reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the documentation of the `gc` module for information on controlling the collection of cyclic garbage. Other implementations act differently and CPython may change.

Note that the use of the implementation’s tracing or debugging facilities may keep objects alive that would normally be collectable. Also note that catching an exception with a `try...except` statement may keep objects alive.

Some objects contain references to “external” resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a `close()` method. Programs are strongly recommended to explicitly close such objects. The `try...finally` statement provides a convenient way to do this.

Some objects contain references to other objects; these are called *containers*. Examples of containers are tuples, lists and dictionaries. The references are part of a container’s value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.
Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and value, while for mutable objects this is not allowed. E.g., after `a = 1; b = 1`, `a` and `b` may or may not refer to the same object with the value one, depending on the implementation, but after `c = []; d = []`, `c` and `d` are guaranteed to refer to two different, unique, newly created empty lists. (Note that `c = d = []` assigns the same object to both `c` and `d`.)
3.2. The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.).

Some of the type descriptions below contain a paragraph listing ‘special attributes.’ These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `None`. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don’t explicitly return anything. Its truth value is false.

NotImplemented

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `NotImplemented`. Numeric methods and rich comparison methods may return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback, depending on the operator.) Its truth value is true.

Ellipsis

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `Ellipsis`. It is used to indicate the presence of the `...` syntax in
a slice. Its truth value is true.

`numbers.Number`

These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.

Python distinguishes between integers, floating point numbers, and complex numbers:

`numbers.Integral`

These represent elements from the mathematical set of integers (positive and negative).

There are three types of integers:

**Plain integers**

These represent numbers in the range -2147483648 through 2147483647. (The range may be larger on machines with a larger natural word size, but not smaller.) When the result of an operation would fall outside this range, the result is normally returned as a long integer (in some cases, the exception `OverflowError` is raised instead). For the purpose of shift and mask operations, integers are assumed to have a binary, 2’s complement notation using 32 or more bits, and hiding no bits from the user (i.e., all 4294967296 different bit patterns correspond to different values).

**Long integers**

These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift
and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2’s complement which gives the illusion of an infinite string of sign bits extending to the left.

Booleans
These represent the truth values False and True. The two objects representing the values False and True are the only Boolean objects. The Boolean type is a subtype of plain integers, and Boolean values behave like the values 0 and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings "False" or "True" are returned, respectively.

The rules for integer representation are intended to give the most meaningful interpretation of shift and mask operations involving negative integers and the least surprises when switching between the plain and long integer domains. Any operation, if it yields a result in the plain integer domain, will yield the same result in the long integer domain or when using mixed operands. The switch between domains is transparent to the programmer.

numbers.Real (float)
These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these is dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.
numbers.Complex

These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number \( z \) can be retrieved through the read-only attributes \( z.real \) and \( z.imag \).

Sequences

These represent finite ordered sets indexed by non-negative numbers. The built-in function \( \text{len()} \) returns the number of items of a sequence. When the length of a sequence is \( n \), the index set contains the numbers 0, 1, ..., \( n-1 \). Item \( i \) of sequence \( a \) is selected by \( a[i] \).

Sequences also support slicing: \( a[i:j] \) selects all items with index \( k \) such that \( i \leq k < j \). When used as an expression, a slice is a sequence of the same type. This implies that the index set is renumbered so that it starts at 0.

Some sequences also support “extended slicing” with a third “step” parameter: \( a[i:j:k] \) selects all items of \( a \) with index \( x \) where \( x = i + n*k, n \geq 0 \) and \( i \leq x < j \).

Sequences are distinguished according to their mutability:

Immutable sequences

An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

Strings
The items of a string are characters. There is no separate character type; a character is represented by a string of one item. Characters represent (at least) 8-bit bytes. The built-in functions \texttt{chr()} and \texttt{ord()} convert between characters and nonnegative integers representing the byte values. Bytes with the values 0-127 usually represent the corresponding ASCII values, but the interpretation of values is up to the program. The string data type is also used to represent arrays of bytes, e.g., to hold data read from a file.

(On systems whose native character set is not ASCII, strings may use EBCDIC in their internal representation, provided the functions \texttt{chr()} and \texttt{ord()} implement a mapping between ASCII and EBCDIC, and string comparison preserves the ASCII order. Or perhaps someone can propose a better rule?)

Unicode

The items of a Unicode object are Unicode code units. A Unicode code unit is represented by a Unicode object of one item and can hold either a 16-bit or 32-bit value representing a Unicode ordinal (the maximum value for the ordinal is given in \texttt{sys.maxunicode}, and depends on how Python is configured at compile time). Surrogate pairs may be present in the Unicode object, and will be reported as two separate items. The built-in functions \texttt{unichr()} and \texttt{ord()} convert between code units and nonnegative integers representing the Unicode ordinals as defined in the Unicode Standard 3.0. Conversion from and to other encodings are possible through the Unicode method \texttt{encode()} and the built-in function \texttt{unicode()}.  

Tuples
The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of expressions. A tuple of one item (a ‘singleton’) can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

Mutable sequences
Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and \texttt{del} (delete) statements.

There are currently two intrinsic mutable sequence types:

Lists
The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

Byte Arrays
A bytearray object is a mutable array. They are created by the built-in \texttt{bytearray()} constructor. Aside from being mutable (and hence unhashable), byte arrays otherwise provide the same interface and functionality as immutable bytes objects.

The extension module \texttt{array} provides an additional example of a mutable sequence type.

Set types
These represent unordered, finite sets of unique, immutable objects. As such, they cannot be indexed by any subscript.
However, they can be iterated over, and the built-in function `len()` returns the number of items in a set. Common uses for sets are fast membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference.

For set elements, the same immutability rules apply as for dictionary keys. Note that numeric types obey the normal rules for numeric comparison: if two numbers compare equal (e.g., 1 and 1.0), only one of them can be contained in a set.

There are currently two intrinsic set types:

Sets
These represent a mutable set. They are created by the built-in `set()` constructor and can be modified afterwards by several methods, such as `add()`.

Frozen sets
These represent an immutable set. They are created by the built-in `frozenset()` constructor. As a frozenset is immutable and `hashable`, it can be used again as an element of another set, or as a dictionary key.

Mappings
These represent finite sets of objects indexed by arbitrary index sets. The subscript notation `a[k]` selects the item indexed by `k` from the mapping `a`; this can be used in expressions and as the target of assignments or `del` statements. The built-in function `len()` returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

Dictionaries
These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that the efficient implementation of dictionaries requires a key's hash value to remain constant. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (e.g., 1 and 1.0) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are mutable; they can be created by the `{...}` notation (see section *Dictionary displays*).

The extension modules *dbm*, *gdbm*, and *bsddb* provide additional examples of mapping types.

**Callable types**

These are the types to which the function call operation (see section *Calls*) can be applied:

**User-defined functions**

A user-defined function object is created by a function definition (see section *Function definitions*). It should be called with an argument list containing the same number of items as the function's formal parameter list.

**Special attributes:**

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>func_doc</td>
<td>The function's documentation string, or None if unavailable</td>
<td>Writable</td>
</tr>
<tr>
<td><strong>doc</strong></td>
<td>Another way of spelling func_doc</td>
<td>Writable</td>
</tr>
<tr>
<td>Attribute</td>
<td>Description</td>
<td>Writability</td>
</tr>
<tr>
<td>----------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>-------------</td>
</tr>
<tr>
<td><code>func_name</code></td>
<td>The function’s name</td>
<td>Writable</td>
</tr>
<tr>
<td><code>__name__</code></td>
<td>Another way of spelling <code>func_name</code></td>
<td>Writable</td>
</tr>
<tr>
<td><code>__module__</code></td>
<td>The name of the module the function was defined in, or <code>None</code> if unavailable.</td>
<td>Writable</td>
</tr>
<tr>
<td><code>func_defaults</code></td>
<td>A tuple containing default argument values for those arguments that have defaults, or <code>None</code> if no arguments have a default value</td>
<td>Writable</td>
</tr>
<tr>
<td><code>func_code</code></td>
<td>The code object representing the compiled function body.</td>
<td>Writable</td>
</tr>
<tr>
<td><code>func_globals</code></td>
<td>A reference to the dictionary that holds the function’s global variables — the global namespace of the module in which the function was defined.</td>
<td>Read-only</td>
</tr>
<tr>
<td><code>func_dict</code></td>
<td>The namespace supporting arbitrary function attributes.</td>
<td>Writable</td>
</tr>
<tr>
<td><code>func_closure</code></td>
<td><code>None</code> or a tuple of cells that contain bindings for the function's free variables.</td>
<td>Read-only</td>
</tr>
</tbody>
</table>

Most of the attributes labelled “Writable” check the type of the assigned value.

*Changed in version 2.4:* `func_name` is now writable.

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-
defined functions. Function attributes on built-in functions may be supported in the future.

Additional information about a function’s definition can be retrieved from its code object; see the description of internal types below.

User-defined methods
A user-defined method object combines a class, a class instance (or None) and any callable object (normally a user-defined function).

Special read-only attributes: im_self is the class instance object, im_func is the function object; im_class is the class of im_self for bound methods or the class that asked for the method for unbound methods; __doc__ is the method’s documentation (same as im_func.__doc__); __name__ is the method name (same as im_func.__name__); __module__ is the name of the module the method was defined in, or None if unavailable.

Changed in version 2.2: im_self used to refer to the class that defined the method.

Changed in version 2.6: For 3.0 forward-compatibility, im_func is also available as __func__, and im_self as __self__.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object, an unbound user-defined method object, or a class method object. When
the attribute is a user-defined method object, a new method object is only created if the class from which it is being retrieved is the same as, or a derived class of, the class stored in the original method object; otherwise, the original method object is used as it is.

When a user-defined method object is created by retrieving a user-defined function object from a class, its `im_self` attribute is `None` and the method object is said to be unbound. When one is created by retrieving a user-defined function object from a class via one of its instances, its `im_self` attribute is the instance, and the method object is said to be bound. In either case, the new method's `im_class` attribute is the class from which the retrieval takes place, and its `im_func` attribute is the original function object.

When a user-defined method object is created by retrieving another method object from a class or instance, the behaviour is the same as for a function object, except that the `im_func` attribute of the new instance is not the original method object but its `im_func` attribute.

When a user-defined method object is created by retrieving a class method object from a class or instance, its `im_self` attribute is the class itself (the same as the `im_class` attribute), and its `im_func` attribute is the function object underlying the class method.

When an unbound user-defined method object is called, the underlying function (`im_func`) is called, with the restriction that the first argument must be an instance of the proper class (`im_class`) or of a derived class thereof.

When a bound user-defined method object is called, the
underlying function (\texttt{im\_func}) is called, inserting the class instance (\texttt{im\_self}) in front of the argument list. For instance, when \texttt{c} is a class which contains a definition for a function \texttt{f()}, and \texttt{x} is an instance of \texttt{c}, calling \texttt{x.f(1)} is equivalent to calling \texttt{c.f(x, 1)}.

When a user-defined method object is derived from a class method object, the “class instance” stored in \texttt{im\_self} will actually be the class itself, so that calling either \texttt{x.f(1)} or \texttt{c.f(1)} is equivalent to calling \texttt{f(C,1)} where \texttt{f} is the underlying function.

Note that the transformation from function object to (unbound or bound) method object happens each time the attribute is retrieved from the class or instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this \textit{only} happens when the function is an attribute of the class.

Generator functions
A function or method which uses the \texttt{yield} statement (see section \textit{The \texttt{yield} statement}) is called a \textit{generator function}. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling the iterator’s \texttt{next()} method will cause the function to execute until it provides a value using the \texttt{yield} statement. When the function executes a \texttt{return} statement or falls off the end, a \texttt{StopIteration} exception is raised and the iterator will have
reached the end of the set of values to be returned.

Built-in functions
A built-in function object is a wrapper around a C function. Examples of built-in functions are `len()` and `math.sin()` (math is a standard built-in module). The number and type of the arguments are determined by the C function. Special read-only attributes: `__doc__` is the function's documentation string, or `None` if unavailable; `__name__` is the function's name; `__self__` is set to `None` (but see the next item); `__module__` is the name of the module the function was defined in or `None` if unavailable.

Built-in methods
This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit extra argument. An example of a built-in method is `alist.append()`, assuming `alist` is a list object. In this case, the special read-only attribute `__self__` is set to the object denoted by `list`.

Class Types
Class types, or “new-style classes,” are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override `__new__()`. The arguments of the call are passed to `__new__()` and, in the typical case, to `__init__()` to initialize the new instance.

Classic Classes
Class objects are described below. When a class object is called, a new class instance (also described below) is created and returned. This implies a call to the class's `__init__()` method if it has one. Any arguments are passed on to the
__init__() method. If there is no __init__() method, the class must be called without arguments.

Class instances

Class instances are described below. Class instances are callable only when the class has a __call__() method; \( x(\text{arguments}) \) is a shorthand for \( x.__call__(\text{arguments}) \).

Modules

Modules are imported by the import statement (see section The import statement). A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the func_globals attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., \( m.x \) is equivalent to \( m.__dict__["x"] \). A module object does not contain the code object used to initialize the module (since it isn’t needed once the initialization is done).

Attribute assignment updates the module’s namespace dictionary, e.g., \( m.x = 1 \) is equivalent to \( m.__dict__["x"] = 1 \).

Special read-only attribute: __dict__ is the module’s namespace as a dictionary object.

Predefined (writable) attributes: __name__ is the module’s name; __doc__ is the module’s documentation string, or None if unavailable; __file__ is the pathname of the file from which the module was loaded, if it was loaded from a file. The __file__ attribute is not present for C modules that are statically linked into the interpreter; for extension modules loaded dynamically from a shared library, it is the pathname of the shared library file.

Classes

Both class types (new-style classes) and class objects (old-
style/classic classes) are typically created by class definitions (see section *Class definitions*). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., `c.x` is translated to `c.__dict__['x']` (although for new-style classes in particular there are a number of hooks which allow for other means of locating attributes). When the attribute name is not found there, the attribute search continues in the base classes. For old-style classes, the search is depth-first, left-to-right in the order of occurrence in the base class list. New-style classes use the more complex C3 method resolution order which behaves correctly even in the presence of ‘diamond’ inheritance structures where there are multiple inheritance paths leading back to a common ancestor. Additional details on the C3 MRO used by new-style classes can be found in the documentation accompanying the 2.3 release at http://www.python.org/download/releases/2.3/mro/.

When a class attribute reference (for class `c`, say) would yield a user-defined function object or an unbound user-defined method object whose associated class is either `c` or one of its base classes, it is transformed into an unbound user-defined method object whose `im_class` attribute is `c`. When it would yield a class method object, it is transformed into a bound user-defined method object whose `im_class` and `im_self` attributes are both `c`. When it would yield a static method object, it is transformed into the object wrapped by the static method object. See section *Implementing Descriptors* for another way in which attributes retrieved from a class may differ from those actually contained in its `__dict__` (note that only new-style classes support descriptors).

Class attribute assignments update the class’s dictionary, never the dictionary of a base class.
A class object can be called (see above) to yield a class instance (see below).

Special attributes: __name__ is the class name; __module__ is the module name in which the class was defined; __dict__ is the dictionary containing the class's namespace; __bases__ is a tuple (possibly empty or a singleton) containing the base classes, in the order of their occurrence in the base class list; __doc__ is the class's documentation string, or None if undefined.

Class instances
A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the search continues with the class attributes. If a class attribute is found that is a user-defined function object or an unbound user-defined method object whose associated class is the class (call it c) of the instance for which the attribute reference was initiated or one of its bases, it is transformed into a bound user-defined method object whose im_class attribute is c and whose im_self attribute is the instance. Static method and class method objects are also transformed, as if they had been retrieved from class c; see above under “Classes”. See section Implementing Descriptors for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's __dict__. If no class attribute is found, and the object's class has a __getattr__() method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's dictionary, never a class's dictionary. If the class has a __setattr__() or __delattr__() method, this is called instead of updating the instance dictionary directly.
Class instances can pretend to be numbers, sequences, or mappings if they have methods with certain special names. See section *Special method names*.

Special attributes: `__dict__` is the attribute dictionary; `__class__` is the instance’s class.

**Files**

A file object represents an open file. File objects are created by the `open()` built-in function, and also by `os.popen()`, `os.fopen()`, and the `makefile()` method of socket objects (and perhaps by other functions or methods provided by extension modules). The objects `sys.stdin`, `sys.stdout` and `sys.stderr` are initialized to file objects corresponding to the interpreter’s standard input, output and error streams. See *File Objects* for complete documentation of file objects.

**Internal types**

A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of the interpreter, but they are mentioned here for completeness.

**Code objects**

Code objects represent *byte-compiled* executable Python code, or *bytecode*. The difference between a code object and a function object is that the function object contains an explicit reference to the function’s globals (the module in which it was defined), while a code object contains no context; also the default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: `co_name` gives the function name;
co_argcount is the number of positional arguments (including arguments with default values); co_nlocals is the number of local variables used by the function (including arguments); co_varnames is a tuple containing the names of the local variables (starting with the argument names); co_cellvars is a tuple containing the names of local variables that are referenced by nested functions; co_freevars is a tuple containing the names of free variables; co_code is a string representing the sequence of bytecode instructions; co_consts is a tuple containing the literals used by the bytecode; co_names is a tuple containing the names used by the bytecode; co_filename is the filename from which the code was compiled; co_firstlineno is the first line number of the function; co_lnotab is a string encoding the mapping from bytecode offsets to line numbers (for details see the source code of the interpreter); co_stacksize is the required stack size (including local variables); co_flags is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for co_flags: bit 0x04 is set if the function uses the *arguments syntax to accept an arbitrary number of positional arguments; bit 0x08 is set if the function uses the **keywords syntax to accept arbitrary keyword arguments; bit 0x20 is set if the function is a generator.

Future feature declarations (from __future__ import division) also use bits in co_flags to indicate whether a code object was compiled with a particular feature enabled: bit 0x2000 is set if the function was compiled with future division enabled; bits 0x10 and 0x1000 were used in earlier versions of Python.
Other bits in **co_flags** are reserved for internal use.

If a code object represents a function, the first item in **co_consts** is the documentation string of the function, or **None** if undefined.

Frame objects
Frame objects represent execution frames. They may occur in traceback objects (see below).

Special read-only attributes: **f_back** is to the previous stack frame (towards the caller), or **None** if this is the bottom stack frame; **f_code** is the code object being executed in this frame; **f_locals** is the dictionary used to look up local variables; **f_globals** is used for global variables; **f_builtins** is used for built-in (intrinsic) names; **f_restricted** is a flag indicating whether the function is executing in restricted execution mode; **f_lasti** gives the precise instruction (this is an index into the bytecode string of the code object).

Special writable attributes: **f_trace**, if not **None**, is a function called at the start of each source code line (this is used by the debugger); **f_exc_type**, **f_exc_value**, **f_exc_traceback** represent the last exception raised in the parent frame provided another exception was ever raised in the current frame (in all other cases they are None); **f_lineno** is the current line number of the frame — writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to **f_lineno**.

Traceback objects
Traceback objects represent a stack trace of an exception. A traceback object is created when an exception occurs. When
the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section The try statement.) It is accessible as `sys.exc_traceback`, and also as the third item of the tuple returned by `sys.exc_info()`. The latter is the preferred interface, since it works correctly when the program is using multiple threads. When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as `sys.last_traceback`.

Special read-only attributes: `tb_next` is the next level in the stack trace (towards the frame where the exception occurred), or `None` if there is no next level; `tb_frame` points to the execution frame of the current level; `tb_lineno` gives the line number where the exception occurred; `tb_lasti` indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a `try` statement with no matching except clause or with a finally clause.

Slice objects

Slice objects are used to represent slices when extended slice syntax is used. This is a slice using two colons, or multiple slices or ellipses separated by commas, e.g., `a[i:j:step]`, `a[i:j, k:l]`, or `a[... , i:j]`. They are also created by the built-in `slice()` function.

Special read-only attributes: `start` is the lower bound; `stop` is the upper bound; `step` is the step value; each is `None` if omitted. These attributes can have any type.
Slice objects support one method:

slice.indices(self, length)

This method takes a single integer argument length and computes information about the extended slice that the slice object would describe if applied to a sequence of length items. It returns a tuple of three integers; respectively these are the start and stop indices and the step or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices.

*New in version 2.3.*

Static method objects

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are not themselves callable, although the objects they wrap usually are. Static method objects are created by the built-in staticmethod() constructor.

Class method objects

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under “User-defined methods”. Class method objects are created by the built-in classmethod() constructor.
3.3. New-style and classic classes

Classes and instances come in two flavors: old-style (or classic) and new-style.

Up to Python 2.1, old-style classes were the only flavour available to the user. The concept of (old-style) class is unrelated to the concept of type: if $x$ is an instance of an old-style class, then $x.__class__$ designates the class of $x$, but $\text{type}(x)$ is always $\langle\text{type }'\text{instance}'\rangle$. This reflects the fact that all old-style instances, independently of their class, are implemented with a single built-in type, called $\text{instance}$.

New-style classes were introduced in Python 2.2 to unify classes and types. A new-style class is neither more nor less than a user-defined type. If $x$ is an instance of a new-style class, then $\text{type}(x)$ is typically the same as $x.__class__$ (although this is not guaranteed - a new-style class instance is permitted to override the value returned for $x.__class__$).

The major motivation for introducing new-style classes is to provide a unified object model with a full meta-model. It also has a number of practical benefits, like the ability to subclass most built-in types, or the introduction of “descriptors”, which enable computed properties.

For compatibility reasons, classes are still old-style by default. New-style classes are created by specifying another new-style class (i.e. a type) as a parent class, or the “top-level type” $\text{object}$ if no other parent is needed. The behaviour of new-style classes differs from that of old-style classes in a number of important details in addition to what $\text{type()}$ returns. Some of these changes are fundamental to the new object model, like the way special methods are invoked. Others are “fixes” that could not be implemented before for
compatibility concerns, like the method resolution order in case of multiple inheritance.

While this manual aims to provide comprehensive coverage of Python's class mechanics, it may still be lacking in some areas when it comes to its coverage of new-style classes. Please see http://www.python.org/doc/newstyle/ for sources of additional information.

Old-style classes are removed in Python 3.0, leaving only the semantics of new-style classes.
3.4. Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python’s approach to operator overloading, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named `__getitem__()`, and `x` is an instance of this class, then `x[i]` is roughly equivalent to `x.__getitem__(i)` for old-style classes and `type(x).__getitem__(x, i)` for new-style classes. Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined (typically `AttributeError` or `TypeError`).

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the `NodeList` interface in the W3C’s Document Object Model.)

3.4.1. Basic customization

```
oclass.__new__(cls, ...)  
```

Called to create a new instance of class `cls`. `__new__()` is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of `__new__()` should be the new object instance (usually an instance of `cls`).
Typical implementations create a new instance of the class by invoking the superclass's \_\_new\_() method using
\texttt{super(currentclass, cls).\_\_new\_(cls[, ...])} with appropriate arguments and then modifying the newly-created instance as necessary before returning it.

If \_\_new\_() returns an instance of \texttt{cls}, then the new instance's \_\_init\_() method will be invoked like \_\_init\_(self[, ...]), where \texttt{self} is the new instance and the remaining arguments are the same as were passed to \_\_new\_().

If \_\_new\_() does not return an instance of \texttt{cls}, then the new instance's \_\_init\_() method will not be invoked.

\_\_new\_() is intended mainly to allow subclasses of immutable types (like int, str, or tuple) to customize instance creation. It is also commonly overridden in custom metaclasses in order to customize class creation.

\texttt{object.\_\_init\_(self[, ...])}

Called when the instance is created. The arguments are those passed to the class constructor expression. If a base class has an \_\_init\_() method, the derived class's \_\_init\_() method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example: \texttt{BaseClass.\_\_init\_(self, [args...])}. As a special constraint on constructors, no value may be returned; doing so will cause a \texttt{TypeError} to be raised at runtime.

\texttt{object.\_\_del\_(self)}

Called when the instance is about to be destroyed. This is also called a destructor. If a base class has a \_\_del\_() method, the derived class's \_\_del\_() method, if any, must explicitly call it to
ensure proper deletion of the base class part of the instance. Note that it is possible (though not recommended!) for the \_del\_() method to postpone destruction of the instance by creating a new reference to it. It may then be called at a later time when this new reference is deleted. It is not guaranteed that \_del\_() methods are called for objects that still exist when the interpreter exits.

**Note:** del x doesn't directly call x.__del__() — the former decrements the reference count for x by one, and the latter is only called when x's reference count reaches zero. Some common situations that may prevent the reference count of an object from going to zero include: circular references between objects (e.g., a doubly-linked list or a tree data structure with parent and child pointers); a reference to the object on the stack frame of a function that caught an exception (the traceback stored in sys.exc_traceback keeps the stack frame alive); or a reference to the object on the stack frame that raised an unhandled exception in interactive mode (the traceback stored in sys.last_traceback keeps the stack frame alive). The first situation can only be remedied by explicitly breaking the cycles; the latter two situations can be resolved by storing None in sys.exc_traceback or sys.last_traceback. Circular references which are garbage are detected when the option cycle detector is enabled (it's on by default), but can only be cleaned up if there are no Python-level \_del\_() methods involved. Refer to the documentation for the gc module for more information about how \_del\_() methods are handled by the cycle detector, particularly the description of the garbage value.

**Warning:** Due to the precarious circumstances under which \_del\_() methods are invoked, exceptions that occur during
their execution are ignored, and a warning is printed to `sys.stderr` instead. Also, when `__del__()` is invoked in response to a module being deleted (e.g., when execution of the program is done), other globals referenced by the `__del__()` method may already have been deleted or in the process of being torn down (e.g., the import machinery shutting down). For this reason, `__del__()` methods should do the absolute minimum needed to maintain external invariants. Starting with version 1.5, Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the `__del__()` method is called.

```
object.__repr__(self)
```

Called by the `repr()` built-in function and by string conversions (reverse quotes) to compute the “official” string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form `<...some useful description...>` should be returned. The return value must be a string object. If a class defines `__repr__() but not __str__(), then `__repr__() is also used when an “informal” string representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

```
object.__str__(self)
```

Called by the `str()` built-in function and by the `print` statement to compute the “informal” string representation of an object. This
differs from \_\_repr\_\() in that it does not have to be a valid Python expression: a more convenient or concise representation may be used instead. The return value must be a string object.

\begin{verbatim}
object.__lt__(self, other)
object.__le__(self, other)
object.__eq__(self, other)
object.__ne__(self, other)
object.__gt__(self, other)
object.__ge__(self, other)
\end{verbatim}

\textit{New in version 2.1.}

These are the so-called “rich comparison” methods, and are called for comparison operators in preference to \_\_cmp\_\() below. The correspondence between operator symbols and method names is as follows: \( x<y \) calls \( x.__lt__(y) \), \( x\leq y \) calls \( x.__le__(y) \), \( x==y \) calls \( x.__eq__(y) \), \( x!=y \) and \( x<>y \) call \( x.__ne__(y) \), \( x>y \) calls \( x.__gt__(y) \), and \( x\geq y \) calls \( x.__ge__(y) \).

A rich comparison method may return the singleton \texttt{NotImplemented} if it does not implement the operation for a given pair of arguments. By convention, \texttt{False} and \texttt{True} are returned for a successful comparison. However, these methods can return any value, so if the comparison operator is used in a Boolean context (e.g., in the condition of an \texttt{if} statement), Python will call \texttt{bool()} on the value to determine if the result is true or false. There are no implied relationships among the comparison operators. The truth of \( x==y \) does not imply that \( x!=y \) is false. Accordingly, when defining \_\_eq\_\(), one should also define \_\_ne\_\() so that the operators will behave as expected. See the paragraph on \_\_hash\_\() for some important notes on creating \texttt{hashable} objects which support custom comparison operations.
and are usable as dictionary keys.

There are no swapped-argument versions of these methods (to be used when the left argument does not support the operation but the right argument does); rather, \_\_lt\_\_() and \_\_gt\_\_() are each other’s reflection, \_\_le\_\_() and \_\_ge\_\_() are each other’s reflection, and \_\_eq\_\_() and \_\_ne\_\_() are their own reflection.

Arguments to rich comparison methods are never coerced.

To automatically generate ordering operations from a single root operation, see \texttt{functools.total\_ordering()}.

\texttt{object.\_\_cmp\_\_(self, other)}

Called by comparison operations if rich comparison (see above) is not defined. Should return a negative integer if \texttt{self < other}, zero if \texttt{self == other}, a positive integer if \texttt{self > other}. If no \_\_cmp\_\_(), \_\_eq\_\_() or \_\_ne\_\_() operation is defined, class instances are compared by object identity (“address”). See also the description of \_\_hash\_\_() for some important notes on creating \textit{hashable} objects which support custom comparison operations and are usable as dictionary keys. (Note: the restriction that exceptions are not propagated by \_\_cmp\_\_() has been removed since Python 1.5.)

\texttt{object.\_\_rcmp\_\_(self, other)}

\textit{Changed in version 2.1:} No longer supported.

\texttt{object.\_\_hash\_\_(self)}

Called by built-in function \texttt{hash()} and for operations on members of hashed collections including \texttt{set}, \texttt{frozenset}, and \texttt{dict}. \_\_hash\_\_() should return an integer. The only required property is that objects which compare equal have the same hash value; it is advised to somehow mix together (e.g. using exclusive or) the
hash values for the components of the object that also play a part in comparison of objects.

If a class does not define a __cmp__() or __eq__() method it should not define a __hash__() operation either; if it defines __cmp__() or __eq__() but not __hash__(), its instances will not be usable in hashed collections. If a class defines mutable objects and implements a __cmp__() or __eq__() method, it should not implement __hash__(), since hashable collection implementations require that a object's hash value is immutable (if the object's hash value changes, it will be in the wrong hash bucket).

User-defined classes have __cmp__() and __hash__() methods by default; with them, all objects compare unequal (except with themselves) and x.__hash__() returns id(x).

Classes which inherit a __hash__() method from a parent class but change the meaning of __cmp__() or __eq__() such that the hash value returned is no longer appropriate (e.g. by switching to a value-based concept of equality instead of the default identity based equality) can explicitly flag themselves as being unhashable by setting __hash__ = None in the class definition. Doing so means that not only will instances of the class raise an appropriate TypeError when a program attempts to retrieve their hash value, but they will also be correctly identified as unhashable when checking isinstance(obj, collections.Hashable) (unlike classes which define their own __hash__() to explicitly raise TypeError).

*Changed in version 2.5:* __hash__() may now also return a long integer object; the 32-bit integer is then derived from the hash of that object.
Changed in version 2.6: __hash__ may now be set to None to explicitly flag instances of a class as unhashable.

object.__nonzero__(self)
Called to implement truth value testing and the built-in operation bool(); should return False or True, or their integer equivalents 0 or 1. When this method is not defined, __len__() is called, if it is defined, and the object is considered true if its result is nonzero. If a class defines neither __len__() nor __nonzero__(), all its instances are considered true.

object.__unicode__(self)
Called to implement unicode() built-in; should return a Unicode object. When this method is not defined, string conversion is attempted, and the result of string conversion is converted to Unicode using the system default encoding.

3.4.2. Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of x.name) for class instances.

object.__getattr__(self, name)
Called when an attribute lookup has not found the attribute in the usual places (i.e. it is not an instance attribute nor is it found in the class tree for self). name is the attribute name. This method should return the (computed) attribute value or raise an AttributeError exception.

Note that if the attribute is found through the normal mechanism, __getattr__() is not called. (This is an intentional asymmetry between __getattr__() and __setattr__().) This is done both for
efficiency reasons and because otherwise __getattr__() would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the __getattr__() method below for a way to actually get total control in new-style classes.

```
object. __setattr__(self, name, value)
```

Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). *name* is the attribute name, *value* is the value to be assigned to it.

If __setattr__() wants to assign to an instance attribute, it should not simply execute `self.name = value` — this would cause a recursive call to itself. Instead, it should insert the value in the dictionary of instance attributes, e.g., `self.__dict__[name] = value`. For new-style classes, rather than accessing the instance dictionary, it should call the base class method with the same name, for example, `object.__setattr__(self, name, value).

```
object. __delattr__(self, name)
```

Like __setattr__() but for attribute deletion instead of assignment. This should only be implemented if `del obj.name` is meaningful for the object.

### 3.4.2.1. More attribute access for new-style classes

The following methods only apply to new-style classes.

```
object. __getattr__(self, name)
```

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines __getattr__(),
the latter will not be called unless \_\_getattribute\_\_(\_) either calls it explicitly or raises an \texttt{AttributeError}. This method should return the (computed) attribute value or raise an \texttt{AttributeError} exception. In order to avoid infinite recursion in this method, its implementation should always call the base class method with the same name to access any attributes it needs, for example, \texttt{object.\_\_getattribute\_\_(self, name)}.

\textbf{Note:} This method may still be bypassed when looking up special methods as the result of implicit invocation via language syntax or built-in functions. See \textit{Special method lookup for new-style classes}.

### 3.4.2.2. Implementing Descriptors

The following methods only apply when an instance of the class containing the method (a so-called \textit{descriptor} class) appears in the class dictionary of another new-style class, known as the \textit{owner} class. In the examples below, “the attribute” refers to the attribute whose name is the key of the property in the owner class’ \texttt{\_\_dict\_}. Descriptors can only be implemented as new-style classes themselves.

\texttt{object.\_\_get\_\_(\_self, \_instance, \_owner\_)}

Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). \texttt{owner} is always the owner class, while \texttt{instance} is the instance that the attribute was accessed through, or \texttt{None} when the attribute is accessed through the \texttt{owner}. This method should return the (computed) attribute value or raise an \texttt{AttributeError} exception.

\texttt{object.\_\_set\_\_(\_self, \_instance, \_value\_)}
Called to set the attribute on an instance *instance* of the owner class to a new value, *value*.

```
object.__delete__(self, instance)
```

Called to delete the attribute on an instance *instance* of the owner class.

### 3.4.2.3. Invoking Descriptors

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol: `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined and how they were called. Note that descriptors are only invoked for new style objects or classes (ones that subclass `object()` or `type()`).

The starting point for descriptor invocation is a binding, `a.x`. How the arguments are assembled depends on `a`:

**Direct Call**

The simplest and least common call is when user code directly
invokes a descriptor method: `x.__get__(a)`.

**Instance Binding**

If binding to a new-style object instance, `a.x` is transformed into the call: `type(a).__dict__['x'].__get__(a, type(a))`.

**Class Binding**

If binding to a new-style class, `A.x` is transformed into the call: `A.__dict__['x'].__get__(None, A)`.

**Super Binding**

If `a` is an instance of `super`, then the binding `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately preceding `B` and then invokes the descriptor with the call: `A.__dict__['m'].__get__(obj, A)`.

For instance bindings, the precedence of descriptor invocation depends on the which descriptor methods are defined. A descriptor can define any combination of `__get__()`, `__set__()` and `__delete__()`. If it does not define `__get__()`, then accessing the attribute will return the descriptor object itself unless there is a value in the object's instance dictionary. If the descriptor defines `__set__()` and/or `__delete__()`, it is a data descriptor; if it defines neither, it is a non-data descriptor. Normally, data descriptors define both `__get__()` and `__set__()`, while non-data descriptors have just the `__get__()` method. Data descriptors with `__set__()` and `__get__()` defined always override a redefinition in an instance dictionary. In contrast, non-data descriptors can be overridden by instances.

Python methods (including `staticmethod()` and `classmethod()`) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to acquire behaviors that differ from other instances of the same class.

The `property()` function is implemented as a data descriptor.
Accordingly, instances cannot override the behavior of a property.

### 3.4.2.4. __slots__

By default, instances of both old and new-style classes have a dictionary for attribute storage. This wastes space for objects having very few instance variables. The space consumption can become acute when creating large numbers of instances.

The default can be overridden by defining `__slots__` in a new-style class definition. The `__slots__` declaration takes a sequence of instance variables and reserves just enough space in each instance to hold a value for each variable. Space is saved because `__dict__` is not created for each instance.

**__slots__**

This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. If defined in a new-style class, `__slots__` reserves space for the declared variables and prevents the automatic creation of `__dict__` and `__weakref__` for each instance.

*New in version 2.2.*

Notes on using `__slots__`

- When inheriting from a class without `__slots__`, the `__dict__` attribute of that class will always be accessible, so a `__slots__` definition in the subclass is meaningless.

- Without a `__dict__` variable, instances cannot be assigned new variables not listed in the `__slots__` definition. Attempts to assign to an unlisted variable name raises `AttributeError`. If dynamic assignment of new variables is desired, then add `__dict__` to the sequence of strings in the `__slots__` declaration.
Changed in version 2.3: Previously, adding '__dict__' to the __slots__ declaration would not enable the assignment of new attributes not specifically listed in the sequence of instance variable names.

- Without a __weakref__ variable for each instance, classes defining __slots__ do not support weak references to its instances. If weak reference support is needed, then add '__weakref__' to the sequence of strings in the __slots__ declaration.

Changed in version 2.3: Previously, adding '__weakref__' to the __slots__ declaration would not enable support for weak references.

- __slots__ are implemented at the class level by creating descriptors (Implementing Descriptors) for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by __slots__; otherwise, the class attribute would overwrite the descriptor assignment.

- The action of a __slots__ declaration is limited to the class where it is defined. As a result, subclasses will have a __dict__ unless they also define __slots__ (which must only contain names of any additional slots).

- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.

- Nonempty __slots__ does not work for classes derived from “variable-length” built-in types such as long, str and tuple.
• Any non-string iterable may be assigned to __slots__. Mappings may also be used; however, in the future, special meaning may be assigned to the values corresponding to each key.

• __class__ assignment works only if both classes have the same __slots__.

    Changed in version 2.6: Previously, __class__ assignment raised an error if either new or old class had __slots__.

### 3.4.3. Customizing class creation

By default, new-style classes are constructed using type(). A class definition is read into a separate namespace and the value of class name is bound to the result of type(name, bases, dict).

When the class definition is read, if __metaclass__ is defined then the callable assigned to it will be called instead of type(). This allows classes or functions to be written which monitor or alter the class creation process:

- Modifying the class dictionary prior to the class being created.
- Returning an instance of another class – essentially performing the role of a factory function.

These steps will have to be performed in the metaclass's __new__() method – type.__new__() can then be called from this method to create a class with different properties. This example adds a new element to the class dictionary before creating the class:

```python
class metacls(type):
    def __new__(mcs, name, bases, dict):
        dict['foo'] = 'metacls was here'
        return type.__new__(mcs, name, bases, dict)
```

You can of course also override other class methods (or add new
methods); for example defining a custom `__call__()` method in the metaclass allows custom behavior when the class is called, e.g. not always creating a new instance.

`__metaclass__`

This variable can be any callable accepting arguments for `name`, `bases`, and `dict`. Upon class creation, the callable is used instead of the built-in `type()`.

*New in version 2.2.*

The appropriate metaclass is determined by the following precedence rules:

- If `dict['__metaclass__']` exists, it is used.
- Otherwise, if there is at least one base class, its metaclass is used (this looks for a `__class__` attribute first and if not found, uses its type).
- Otherwise, if a global variable named `__metaclass__` exists, it is used.
- Otherwise, the old-style, classic metaclass (types.ClassType) is used.

The potential uses for metaclasses are boundless. Some ideas that have been explored including logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.

### 3.4.4. Customizing instance and subclass checks

*New in version 2.6.*

The following methods are used to override the default behavior of the `isinstance()` and `issubclass()` built-in functions.
In particular, the metaclass `abc.ABCMeta` implements these methods in order to allow the addition of Abstract Base Classes (ABCs) as “virtual base classes” to any class or type (including built-in types), including other ABCs.

```python
class.__instancecheck__(self, instance)
    Return true if `instance` should be considered a (direct or indirect) instance of class. If defined, called to implement `isinstance(instance, class)`.

class.__subclasscheck__(self, subclass)
    Return true if `subclass` should be considered a (direct or indirect) subclass of class. If defined, called to implement `issubclass(subclass, class)`.
```

Note that these methods are looked up on the type (metaclass) of a class. They cannot be defined as class methods in the actual class. This is consistent with the lookup of special methods that are called on instances, only in this case the instance is itself a class.

See also:

**PEP 3119 - Introducing Abstract Base Classes**

Includes the specification for customizing `isinstance()` and `issubclass()` behavior through `__instancecheck__()` and `__subclasscheck__()`, with motivation for this functionality in the context of adding Abstract Base Classes (see the `abc` module) to the language.

### 3.4.5. Emulating callable objects

```python
object.__call__(self[, args...])
    Called when the instance is “called” as a function; if this method
is defined, \( x(\text{arg1, arg2, ...}) \) is a shorthand for \( x.__call__(\text{arg1, arg2, ...}) \).

### 3.4.6. Emulating container types

The following methods can be defined to implement container objects. Containers usually are sequences (such as lists or tuples) or mappings (like dictionaries), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers \( k \) for which \( 0 \leq k < N \) where \( N \) is the length of the sequence, or slice objects, which define a range of items. (For backwards compatibility, the method \( \_\_\text{getslice}\_\_() \) (see below) can also be defined to handle simple, but not extended slices.) It is also recommended that mappings provide the methods \( \text{keys}(), \text{values}(), \text{items}(), \text{has\_\_key\_}(), \text{get}(), \text{clear}(), \text{setdefault}(), \text{iterkeys}(), \text{itervalues}(), \text{iteritems}(), \text{pop}(), \text{popitem}(), \text{copy}(), \text{and update}() \) behaving similar to those for Python's standard dictionary objects. The \text{UserDict} module provides a \text{DictMixin} class to help create those methods from a base set of \( \_\_\text{getitem}\_\_() \), \( \_\_\text{setitem}\_\_() \), \( \_\_\text{delitem}\_\_() \), and \( \text{keys}() \). Mutable sequences should provide methods \( \text{append}() \), \( \text{count}() \), \( \text{index}() \), \( \text{extend}() \), \( \text{insert}() \), \( \text{pop}() \), \( \text{remove}() \), \( \text{reverse}() \) and \( \text{sort}() \), like Python standard list objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication (meaning repetition) by defining the methods \( \_\_\text{add}\_\_() \), \( \_\_\text{radd}\_\_() \), \( \_\_\text{iadd}\_\_() \), \( \_\_\text{mul}\_\_() \), \( \_\_\text{rmul}\_\_() \) and \( \_\_\text{imul}\_\_() \) described below; they should not define \( \_\_\text{coerce}\_\_() \) or other numerical operators. It is recommended that both mappings and sequences implement the \( \_\_\text{contains}\_\_() \) method to allow efficient use of the \text{in} operator; for mappings, \text{in} should be equivalent of \text{has\_\_key\_}(); for sequences, it should search through the values. It is further recommended that
both mappings and sequences implement the \_\_iter\_() method to allow efficient iteration through the container; for mappings, \_\_iter\_() should be the same as iterkeys(); for sequences, it should iterate through the values.

object.\_\_len\_(self)
Called to implement the built-in function len(). Should return the length of the object, an integer \(\geq 0\). Also, an object that doesn’t define a \_\_nonzero\_() method and whose \_\_len\_() method returns zero is considered to be false in a Boolean context.

object.\_\_getitem\_(self, key)
Called to implement evaluation of self[key]. For sequence types, the accepted keys should be integers and slice objects. Note that the special interpretation of negative indexes (if the class wishes to emulate a sequence type) is up to the \_\_getitem\_() method. If key is of an inappropriate type, TypeError may be raised; if of a value outside the set of indexes for the sequence (after any special interpretation of negative values), IndexError should be raised. For mapping types, if key is missing (not in the container), KeyError should be raised.

Note: for loops expect that an IndexError will be raised for illegal indexes to allow proper detection of the end of the sequence.

object.\_\_setitem\_(self, key, value)
Called to implement assignment to self[key]. Same note as for \_\_getitem\_(). This should only be implemented for mappings if the objects support changes to the values for keys, or if new keys can be added, or for sequences if elements can be replaced. The same exceptions should be raised for improper key values as for
the \texttt{\_\_getitem\_\_()} method.

\textbf{\texttt{object.\_\_delitem\_\_}(self, key)}

Called to implement deletion of \texttt{self[key]}. Same note as for \texttt{\_\_getitem\_\_()}. This should only be implemented for mappings if the objects support removal of keys, or for sequences if elements can be removed from the sequence. The same exceptions should be raised for improper \texttt{key} values as for the \texttt{\_\_getitem\_\_()} method.

\textbf{\texttt{object.\_\_iter\_\_}(self)}

This method is called when an iterator is required for a container. This method should return a new iterator object that can iterate over all the objects in the container. For mappings, it should iterate over the keys of the container, and should also be made available as the method \texttt{iterkeys()}.

Iterator objects also need to implement this method; they are required to return themselves. For more information on iterator objects, see \textit{Iterator Types}.

\textbf{\texttt{object.\_\_reversed\_\_}(self)}

Called (if present) by the \texttt{reversed()} built-in to implement reverse iteration. It should return a new iterator object that iterates over all the objects in the container in reverse order.

If the \texttt{\_\_reversed\_\_} method is not provided, the \texttt{reversed()} built-in will fall back to using the sequence protocol (\texttt{\_\_len\_\_()} and \texttt{\_\_getitem\_\_()}). Objects that support the sequence protocol should only provide \texttt{\_\_reversed\_\_()} if they can provide an implementation that is more efficient than the one provided by \texttt{reversed()}.

\textit{New in version 2.6.}
The membership test operators (in and not in) are normally implemented as an iteration through a sequence. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be a sequence.

```
object.__contains__(self, item)
```

Called to implement membership test operators. Should return true if item is in self, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.

For objects that don’t define __contains__(), the membership test first tries iteration via __iter__(), then the old sequence iteration protocol via __getitem__(), see this section in the language reference.

3.4.7. Additional methods for emulation of sequence types

The following optional methods can be defined to further emulate sequence objects. Immutable sequences methods should at most only define __getslice__(); mutable sequences might define all three methods.

```
object.__getslice__(self, i, j)
```

*Deprecated since version 2.0:* Support slice objects as parameters to the __getitem__() method. (However, built-in types in CPython currently still implement __getslice__(). Therefore, you have to override it in derived classes when implementing slicing.)

Called to implement evaluation of self[i:j]. The returned object
should be of the same type as self. Note that missing i or j in the slice expression are replaced by zero or sys.maxint, respectively. If negative indexes are used in the slice, the length of the sequence is added to that index. If the instance does not implement the __len__() method, an AttributeError is raised. No guarantee is made that indexes adjusted this way are not still negative. Indexes which are greater than the length of the sequence are not modified. If no __getslice__() is found, a slice object is created instead, and passed to __getitem__() instead.

object.__setslice__(self, i, j, sequence)

Called to implement assignment to self[i:j]. Same notes for i and j as for __getslice__().

This method is deprecated. If no __setslice__() is found, or for extended slicing of the form self[i:j:k], a slice object is created, and passed to __setitem__(), instead of __setslice__() being called.

object.__delslice__(self, i, j)

Called to implement deletion of self[i:j]. Same notes for i and j as for __getslice__(). This method is deprecated. If no __delslice__() is found, or for extended slicing of the form self[i:j:k], a slice object is created, and passed to __delitem__(), instead of __delslice__() being called.

Notice that these methods are only invoked when a single slice with a single colon is used, and the slice method is available. For slice operations involving extended slice notation, or in absence of the slice methods, __getitem__(), __setitem__() or __delitem__() is called with a slice object as argument.

The following example demonstrate how to make your program or
module compatible with earlier versions of Python (assuming that methods __getitem__(), __setitem__() and __delitem__() support slice objects as arguments):

class MyClass:
    ...
    def __getitem__(self, index):
        ...
    def __setitem__(self, index, value):
        ...
    def __delitem__(self, index):
        ...

    if sys.version_info < (2, 0):
        # They won't be defined if version is at least 2.0 final
        def __getslice__(self, i, j):
            return self[max(0, i):max(0, j):]
        def __setslice__(self, i, j, seq):
            self[max(0, i):max(0, j):] = seq
        def __delslice__(self, i, j):
            del self[max(0, i):max(0, j):]
    ...

Note the calls to max(); these are necessary because of the handling of negative indices before the __*slice__() methods are called. When negative indexes are used, the __*item__() methods receive them as provided, but the __*slice__() methods get a “cooked” form of the index values. For each negative index value, the length of the sequence is added to the index before calling the method (which may still result in a negative index); this is the customary handling of negative indexes by the built-in sequence types, and the __*item__() methods are expected to do this as well. However, since they should already be doing that, negative indexes cannot be passed in; they must be constrained to the bounds of the sequence before being passed to the __*item__() methods. Calling max(0, i) conveniently returns the proper value.
3.4.8. Emulating numeric types

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

```python
type.__add__(self, other)
type.__sub__(self, other)
type.__mul__(self, other)
type.__floordiv__(self, other)
type.__mod__(self, other)
type.__divmod__(self, other)
type.__pow__(self, other[, modulo])
type.__lshift__(self, other)
type.__rshift__(self, other)
type.__and__(self, other)
type.__xor__(self, other)
type.__or__(self, other)
```

These methods are called to implement the binary arithmetic operations (+, -, *, //, %, divmod(), pow(), **, <<, >>, &, ^, |). For instance, to evaluate the expression `x + y`, where `x` is an instance of a class that has an `__add__` method, `x.__add__(y)` is called. The `__divmod__` method should be the equivalent to using `__floordiv__` and `__mod__`; it should not be related to `__truediv__` (described below). Note that `__pow__` should be defined to accept an optional third argument if the ternary version of the built-in `pow()` function is to be supported.

If one of those methods does not support the operation with the supplied arguments, it should return `NotImplemented`.

```python
type.__div__(self, other)
```
object.__truediv__(self, other)

The division operator (/) is implemented by these methods. The __truediv__() method is used when __future__.division is in effect, otherwise __div__() is used. If only one of these two methods is defined, the object will not support division in the alternate context; TypeError will be raised instead.

object.__radd__(self, other)
object.__rsub__(self, other)
object.__rmul__(self, other)
object.__rdiv__(self, other)
object.__rtruediv__(self, other)
object.__rfloordiv__(self, other)
object.__rmod__(self, other)
object.__rdivmod__(self, other)
object.__rpow__(self, other)
object.__rlshift__(self, other)
object.__rrshift__(self, other)
object.__rand__(self, other)
object.__rxor__(self, other)
object.__ror__(self, other)

These methods are called to implement the binary arithmetic operations (+, -, *, /, %, divmod(), pow(), **, <<, >>, &, ^, |) with reflected (swapped) operands. These functions are only called if the left operand does not support the corresponding operation and the operands are of different types. [2] For instance, to evaluate the expression x - y, where y is an instance of a class that has an __rsub__() method, y.__rsub__(x) is called if x.__sub__(y) returns NotImplemented.

Note that ternary pow() will not try calling __rpow__() (the coercion rules would become too complicated).
Note: If the right operand’s type is a subclass of the left operand’s type and that subclass provides the reflected method for the operation, this method will be called before the left operand’s non-reflected method. This behavior allows subclasses to override their ancestors’ operations.

```python
object.__iadd__(self, other)
object.__isub__(self, other)
object.__imul__(self, other)
object.__idiv__(self, other)
object.__itruediv__(self, other)
object.__ifloordiv__(self, other)
object.__imod__(self, other)
object.__ipow__(self, other[, modulo])
object.__ilshift__(self, other)
object.__irshift__(self, other)
object.__iand__(self, other)
object.__ixor__(self, other)
object.__ior__(self, other)
```

These methods are called to implement the augmented arithmetic assignments (+=, -=, *=, /=, //=, %=, **=, <<=, >>=, &=, ^=, |=). These methods should attempt to do the operation in-place (modifying self) and return the result (which could be, but does not have to be, self). If a specific method is not defined, the augmented assignment falls back to the normal methods. For instance, to execute the statement `x += y`, where `x` is an instance of a class that has an `__iadd__()` method, `x.__iadd__(y)` is called. If `x` is an instance of a class that does not define a `__iadd__()` method, `x.__add__(y)` and `y.__radd__(x)` are considered, as with the evaluation of `x + y`.

```python
object.__neg__(self)
```
object.__pos__(self)
object.__abs__(self)
object.__invert__(self)

Called to implement the unary arithmetic operations (`-`, `+`, `abs()`, and `~`).

object.__complex__(self)
oobject.__int__(self)
oobject.__long__(self)
oobject.__float__(self)

Called to implement the built-in functions `complex()`, `int()`, `long()`, and `float()`. Should return a value of the appropriate type.

object.__oct__(self)
oobject.__hex__(self)

Called to implement the built-in functions `oct()` and `hex()`. Should return a string value.

object.__index__(self)

Called to implement `operator.index()`. Also called whenever Python needs an integer object (such as in slicing). Must return an integer (int or long).

New in version 2.5.

object.__coerce__(self, other)

Called to implement “mixed-mode” numeric arithmetic. Should either return a 2-tuple containing `self` and `other` converted to a common numeric type, or `None` if conversion is impossible. When the common type would be the type of `other`, it is sufficient to return `None`, since the interpreter will also ask the other object to attempt a coercion (but sometimes, if the implementation of the
other type cannot be changed, it is useful to do the conversion to the other type here). A return value of `NotImplemented` is equivalent to returning `None`.

### 3.4.9. Coercion rules

This section used to document the rules for coercion. As the language has evolved, the coercion rules have become hard to document precisely; documenting what one version of one particular implementation does is undesirable. Instead, here are some informal guidelines regarding coercion. In Python 3.0, coercion will not be supported.

- If the left operand of a `%` operator is a string or Unicode object, no coercion takes place and the string formatting operation is invoked instead.

- It is no longer recommended to define a coercion operation. Mixed-mode operations on types that don't define coercion pass the original arguments to the operation.

- New-style classes (those derived from `object`) never invoke the `_coerce_()` method in response to a binary operator; the only time `_coerce_()` is invoked is when the built-in function `coerce()` is called.

- For most intents and purposes, an operator that returns `NotImplemented` is treated the same as one that is not implemented at all.

- Below, `__op__()` and `__rop__()` are used to signify the generic method names corresponding to an operator; `__iop__()` is used for the corresponding in-place operator. For example, for the operator `'+', `__add__()` and `__radd__()` are used for the left and
right variant of the binary operator, and \_iadd\_() for the in-place variant.

- For objects \(x\) and \(y\), first \(x.__op__(y)\) is tried. If this is not implemented or returns \texttt{NotImplemented}, \(y.__rop__(x)\) is tried. If this is also not implemented or returns \texttt{NotImplemented}, a \texttt{TypeError} exception is raised. But see the following exception:

- Exception to the previous item: if the left operand is an instance of a built-in type or a new-style class, and the right operand is an instance of a proper subclass of that type or class and overrides the base’s \_rop\_() method, the right operand’s \_rop\_() method is tried before the left operand’s \_op\_() method.

This is done so that a subclass can completely override binary operators. Otherwise, the left operand’s \_op\_() method would always accept the right operand: when an instance of a given class is expected, an instance of a subclass of that class is always acceptable.

- When either operand type defines a coercion, this coercion is called before that type’s \_op\_() or \_rop\_() method is called, but no sooner. If the coercion returns an object of a different type for the operand whose coercion is invoked, part of the process is redone using the new object.

- When an in-place operator (like ‘+=’) is used, if the left operand implements \_iop\_(), it is invoked without any coercion. When the operation falls back to \_op\_() and/or \_rop\_(), the normal coercion rules apply.

- In \(x + y\), if \(x\) is a sequence that implements sequence concatenation, sequence concatenation is invoked.
• In $x^* y$, if one operator is a sequence that implements sequence repetition, and the other is an integer (int or long), sequence repetition is invoked.

• Rich comparisons (implemented by methods __eq__() and so on) never use coercion. Three-way comparison (implemented by __cmp__()) does use coercion under the same conditions as other binary operations use it.

• In the current implementation, the built-in numeric types int, long, float, and complex do not use coercion. All these types implement a __coerce__() method, for use by the built-in coerce() function.

  Changed in version 2.7.

### 3.4.10. With Statement Context Managers

New in version 2.5.

A context manager is an object that defines the runtime context to be established when executing a with statement. The context manager handles the entry into, and the exit from, the desired runtime context for the execution of the block of code. Context managers are normally invoked using the with statement (described in section The with statement), but can also be used by directly invoking their methods.

Typical uses of context managers include saving and restoring various kinds of global state, locking and unlocking resources, closing opened files, etc.

For more information on context managers, see Context Manager Types.
object.__enter__(self)

Enter the runtime context related to this object. The with statement will bind this method's return value to the target(s) specified in the as clause of the statement, if any.

object.__exit__(self, exc_type, exc_value, traceback)

Exit the runtime context related to this object. The parameters describe the exception that caused the context to be exited. If the context was exited without an exception, all three arguments will be None.

If an exception is supplied, and the method wishes to suppress the exception (i.e., prevent it from being propagated), it should return a true value. Otherwise, the exception will be processed normally upon exit from this method.

Note that __exit__() methods should not reraise the passed-in exception; this is the caller's responsibility.

The specification, background, and examples for the Python with statement.

3.4.11. Special method lookup for old-style classes

For old-style classes, special methods are always looked up in exactly the same way as any other method or attribute. This is the case regardless of whether the method is being looked up explicitly as in x.__getitem__(i) or implicitly as in x[i].

This behaviour means that special methods may exhibit different
behaviour for different instances of a single old-style class if the appropriate special attributes are set differently:

```python
>>> class C:
...     pass
...
>>> c1 = C()
>>> c2 = C()
>>> c1.__len__ = lambda: 5
>>> c2.__len__ = lambda: 9
>>> len(c1)
5
>>> len(c2)
9
```

### 3.4.12. Special method lookup for new-style classes

For new-style classes, implicit invocations of special methods are only guaranteed to work correctly if defined on an object’s type, not in the object's instance dictionary. That behaviour is the reason why the following code raises an exception (unlike the equivalent example with old-style classes):

```python
>>> class C(object):
...     pass
...
>>> c = C()
>>> c.__len__ = lambda: 5
>>> len(c)
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: object of type 'C' has no len()
```

The rationale behind this behaviour lies with a number of special methods such as `__hash__()` and `__repr__()` that are implemented by all objects, including type objects. If the implicit lookup of these methods used the conventional lookup process, they would fail when invoked on the type object itself:
Incorrectly attempting to invoke an unbound method of a class in this way is sometimes referred to as ‘metaclass confusion’, and is avoided by bypassing the instance when looking up special methods:

```python
>>> type(1).__hash__(1) == hash(1)
True
>>> type(int).__hash__(int) == hash(int)
True
```

In addition to bypassing any instance attributes in the interest of correctness, implicit special method lookup generally also bypasses the `__getattribute__()` method even of the object’s metaclass:

```python
>>> class Meta(type):
...     def __getattribute__(*args):
...         print "Metaclass getattribute invoked"
...         return type.__getattribute__(*args)
...

>>> class C(object):
...     __metaclass__ = Meta
...     def __len__(self):
...         return 10
...     def __getattribute__(*args):
...         print "Class getattribute invoked"
...         return object.__getattribute__(*args)
...

>>> c = C()
>>> c.__len__() # Explicit lookup via instance
Class getattribute invoked
10
>>> type(c).__len__(c) # Explicit lookup via type
Metaclass getattribute invoked
10
>>> len(c) # Implicit lookup
10
```
Bypassing the \_\_getattribute\_\_() machinery in this fashion provides significant scope for speed optimisations within the interpreter, at the cost of some flexibility in the handling of special methods (the special method \textit{must} be set on the class object itself in order to be consistently invoked by the interpreter).

\textbf{Footnotes}

\footnote{It is possible in some cases to change an object's type, under certain controlled conditions. It generally isn't a good idea though, since it can lead to some very strange behaviour if it is handled incorrectly.}

\footnote{For operands of the same type, it is assumed that if the non-reflected method (such as \_\_add\_\_()) fails the operation is not supported, which is why the reflected method is not called.}
4. Execution model
4.1. Naming and binding

*Names* refer to objects. Names are introduced by name binding operations. Each occurrence of a name in the program text refers to the *binding* of that name established in the innermost function block containing the use.

A *block* is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified on the interpreter command line the first argument) is a code block. A script command (a command specified on the interpreter command line with the ‘-c’ option) is a code block. The file read by the built-in function `execfile()` is a code block. The string argument passed to the built-in function `eval()` and to the `exec` statement is a code block. The expression read and evaluated by the built-in function `input()` is a code block.

A code block is executed in an *execution frame*. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block’s execution has completed.

A *scope* defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods – this includes generator expressions since they are implemented using a function scope. This means that the following will fail:
When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block's *environment*.

If a name is bound in a block, it is a local variable of that block. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a *free variable*.

When a name is not found at all, a *NameError* exception is raised. If the name refers to a local variable that has not been bound, a *UnboundLocalError* exception is raised. *UnboundLocalError* is a subclass of *NameError*.

The following constructs bind names: formal parameters to functions, *import* statements, class and function definitions (these bind the class or function name in the defining block), and targets that are identifiers if occurring in an assignment, *for* loop header, in the second position of an *except* clause header or after *as* in a *with* statement. The *import* statement of the form `from ... import *` binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a *del* statement is also considered bound for this purpose (though the actual semantics are to unbind the name). It is illegal to unbind a name that is referenced by an enclosing scope; the compiler will report a *SyntaxError*.

Each assignment or import statement occurs within a block defined by a class or function definition or at the module level (the top-level
If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the global statement occurs within a block, all uses of the name specified in the statement refer to the binding of that name in the top-level namespace. Names are resolved in the top-level namespace by searching the global namespace, i.e. the namespace of the module containing the code block, and the builtins namespace, the namespace of the module __builtins__. The global namespace is searched first. If the name is not found there, the builtins namespace is searched. The global statement must precede all uses of the name.

The builtins namespace associated with the execution of a code block is actually found by looking up the name __builtins__ in its global namespace; this should be a dictionary or a module (in the latter case the module’s dictionary is used). By default, when in the __main__ module, __builtins__ is the built-in module __builtin__ (note: no ‘s’); when in any other module, __builtins__ is an alias for the dictionary of the __builtin__ module itself. __builtins__ can be set to a user-created dictionary to create a weak form of restricted execution.

**CPython implementation detail:** Users should not touch __builtins__; it is strictly an implementation detail. Users wanting to override values in the builtins namespace should import the
The namespace for a module is automatically created the first time a module is imported. The main module for a script is always called __main__.

The global statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

A class definition is an executable statement that may use and define names. These references follow the normal rules for name resolution. The namespace of the class definition becomes the attribute dictionary of the class. Names defined at the class scope are not visible in methods.

### 4.1.1. Interaction with dynamic features

There are several cases where Python statements are illegal when used in conjunction with nested scopes that contain free variables.

If a variable is referenced in an enclosing scope, it is illegal to delete the name. An error will be reported at compile time.

If the wild card form of import — import * — is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError.

If `exec` is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError unless the `exec` explicitly specifies the local namespace for the `exec`. (In other words, `exec obj` would be illegal, but `exec obj in ns` would be
legal.)

The `eval()`, `execfile()`, and `input()` functions and the `exec` statement do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces of the caller. Free variables are not resolved in the nearest enclosing namespace, but in the global namespace. [1] The `exec` statement and the `eval()` and `execfile()` functions have optional arguments to override the global and local namespace. If only one namespace is specified, it is used for both.
4.2. Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is raised at the point where the error is detected; it may be handled by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a runtime error (such as division by zero). A Python program can also explicitly raise an exception with the raise statement. Exception handlers are specified with the try ... except statement. The finally clause of such a statement can be used to specify cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the “termination” model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack backtrace, except when the exception is SystemExit.

Exceptions are identified by class instances. The except clause is selected depending on the class of the instance: it must reference the class of the instance or a base class thereof. The instance can be received by the handler and can carry additional information about the exceptional condition.
Exceptions can also be identified by strings, in which case the `except` clause is selected by object identity. An arbitrary value can be raised along with the identifying string which can be passed to the handler.

**Note:** Messages to exceptions are not part of the Python API. Their contents may change from one version of Python to the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the `try` statement in section *The try statement* and `raise` statement in section *The raise statement*.

**Footnotes**

[1] This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.
5. Expressions

This chapter explains the meaning of the elements of expressions in Python.

**Syntax Notes:** In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

```
name ::= othername
```

and no semantics are given, the semantics of this form of `name` are the same as for `othername`. 
5.1. Arithmetic conversions

When a description of an arithmetic operator below uses the phrase “the numeric arguments are converted to a common type,” the arguments are coerced using the coercion rules listed at Coercion rules. If both arguments are standard numeric types, the following coercions are applied:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, if either argument is a long integer, the other is converted to long integer;
- otherwise, both must be plain integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string left argument to the ‘%’ operator). Extensions can define their own coercions.
5.2. Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in reverse quotes or in parentheses, brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

\[
\begin{align*}
\text{atom} & ::= \text{identifier} \mid \text{literal} \mid \text{enclosure} \\
\text{enclosure} & ::= \text{parenth_form} \mid \text{list_display} \\
& \quad \mid \text{generator_expression} \mid \text{dict_display} \mid \text{set_display} \\
& \quad \mid \text{string_conversion} \mid \text{yield_atom}
\end{align*}
\]

5.2.1. Identifiers (Names)

An identifier occurring as an atom is a name. See section Identifiers and keywords for lexical definition and section Naming and binding for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a NameError exception.

Private name mangling: When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a private name of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name in front of the name, with leading underscores removed, and a single underscore inserted in front of the class name. For example, the identifier __spam occurring in a class named Ham will be transformed to _Ham__spam. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is extremely long (longer than 255 characters), implementation
defined truncation may happen. If the class name consists only of underscores, no transformation is done.

### 5.2.2. Literals

Python supports string literals and various numeric literals:

```
literal ::= stringliteral | integer | longinteger
        | floatnumber | imagnumber
```

Evaluation of a literal yields an object of the given type (string, integer, long integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section `Literals` for details.

All literals correspond to immutable data types, and hence the object’s identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.

### 5.2.3. Parenthesized forms

A parenthesized form is an optional expression list enclosed in parentheses:

```
parenth_form ::= "( [expression_list] )"
```

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression list.

An empty pair of parentheses yields an empty tuple object. Since
tuples are immutable, the rules for literals apply (i.e., two occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma operator. The exception is the empty tuple, for which parentheses are required — allowing unparenthesized “nothing” in expressions would cause ambiguities and allow common typos to pass uncaught.

### 5.2.4. List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
list_display ::= "[" [expression_list | list_comprehension]
list_comprehension ::= expression list_for
list_for ::= "for" target_list "in" old_expression_list
old_expression_list ::= old_expression ["," old_expression]+
old_expression ::= or_test | old_lambda_form
list_iter ::= list_for | list_if
list_if ::= "if" old_expression [list_iter]
```

A list display yields a new list object. Its contents are specified by providing either a list of expressions or a list comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a list comprehension is supplied, it consists of a single expression followed by at least one for clause and zero or more for or if clauses. In this case, the elements of the new list are those that would be produced by considering each of the for or if clauses a block, nesting from left to right, and evaluating the expression to produce a list element each time the innermost block is reached [1].

### 5.2.5. Displays for sets and dictionaries
For constructing a set or a dictionary Python provides special syntax called “displays”, each of them in two flavors:

- either the container contents are listed explicitly, or
- they are computed via a set of looping and filtering instructions, called a `comprehension`.

Common syntax elements for comprehensions are:

```
comprehension ::= expression comp_for
comp_for ::= "for" target_list "in" or_test [comp_iter]
comp_iter ::= comp_for | comp_if
comp_if ::= "if" expression_nocond [comp_iter]
```

The comprehension consists of a single expression followed by at least one `for` clause and zero or more `for` or `if` clauses. In this case, the elements of the new container are those that would be produced by considering each of the `for` or `if` clauses a block, nesting from left to right, and evaluating the expression to produce an element each time the innermost block is reached.

Note that the comprehension is executed in a separate scope, so names assigned to in the target list don’t “leak” in the enclosing scope.

### 5.2.6. Generator expressions

A generator expression is a compact generator notation in parentheses:

```
generator_expression ::= "(" expression comp_for ")"
```

A generator expression yields a new generator object. Its syntax is the same as for comprehensions, except that it is enclosed in parentheses instead of brackets or curly braces.
Variables used in the generator expression are evaluated lazily when the `__next__()` method is called for generator object (in the same fashion as normal generators). However, the leftmost `for` clause is immediately evaluated, so that an error produced by it can be seen before any other possible error in the code that handles the generator expression. Subsequent `for` clauses cannot be evaluated immediately since they may depend on the previous `for` loop. For example: `(x*y for x in range(10) for y in bar(x))`.

The parentheses can be omitted on calls with only one argument. See section `Calls` for the detail.

### 5.2.7. Dictionary displays

A dictionary display is a possibly empty series of key/datum pairs enclosed in curly braces:

A dictionary display yields a new dictionary object.

If a comma-separated sequence of key/datum pairs is given, they are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum. This means that you can specify the same key multiple times in the key/datum list, and the final dictionary’s value for that key will be the last one given.

A dict comprehension, in contrast to list and set comprehensions, needs two expressions separated with a colon followed by the usual “for” and “if” clauses. When the comprehension is run, the resulting key and value elements are inserted in the new dictionary in the
order they are produced.

Restrictions on the types of the key values are listed earlier in section *The standard type hierarchy*. (To summarize, the key type should be *hashable*, which excludes all mutable objects.) Clashes between duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.

### 5.2.8. Set displays

A set display is denoted by curly braces and distinguishable from dictionary displays by the lack of colons separating keys and values:

```
set_display ::= "{" (expression_list | comprehension) "}"
```

A set display yields a new mutable set object, the contents being specified by either a sequence of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and added to the set object. When a comprehension is supplied, the set is constructed from the elements resulting from the comprehension.

An empty set cannot be constructed with `{}`; this literal constructs an empty dictionary.

### 5.2.9. String conversions

A string conversion is an expression list enclosed in reverse (a.k.a. backward) quotes:

```
string_conversion ::= """ expression_list ""
```

A string conversion evaluates the contained expression list and converts the resulting object into a string according to rules specific to its type.
If the object is a string, a number, `None`, or a tuple, list or dictionary containing only objects whose type is one of these, the resulting string is a valid Python expression which can be passed to the built-in function `eval()` to yield an expression with the same value (or an approximation, if floating point numbers are involved).

(In particular, converting a string adds quotes around it and converts “funny” characters to escape sequences that are safe to print.)

Recursive objects (for example, lists or dictionaries that contain a reference to themselves, directly or indirectly) use `...` to indicate a recursive reference, and the result cannot be passed to `eval()` to get an equal value (`SyntaxError` will be raised instead).

The built-in function `repr()` performs exactly the same conversion in its argument as enclosing it in parentheses and reverse quotes does. The built-in function `str()` performs a similar but more user-friendly conversion.

### 5.2.10. Yield expressions

```
yield_atom ::= "(" yield_expression ")"
yield_expression ::= "yield" [expression_list]
```

*New in version 2.5.*

The `yield` expression is only used when defining a generator function, and can only be used in the body of a function definition. Using a `yield` expression in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator. That generator then controls the execution of a generator function. The execution starts when one of the generator’s methods
is called. At that time, the execution proceeds to the first `yield` expression, where it is suspended again, returning the value of `expression_list` to generator’s caller. By suspended we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack. When the execution is resumed by calling one of the generator’s methods, the function can proceed exactly as if the `yield` expression was just another external call. The value of the `yield` expression after resuming depends on the method which resumed the execution.

All of this makes generator functions quite similar to coroutines; they yield multiple times, they have more than one entry point and their execution can be suspended. The only difference is that a generator function cannot control where should the execution continue after it yields; the control is always transferred to the generator’s caller.

The following generator’s methods can be used to control the execution of a generator function:

```
generator.next()
```

Starts the execution of a generator function or resumes it at the last executed `yield` expression. When a generator function is resumed with a `next()` method, the current `yield` expression always evaluates to `None`. The execution then continues to the next `yield` expression, where the generator is suspended again, and the value of the `expression_list` is returned to `next()`’s caller. If the generator exits without yielding another value, a `StopIteration` exception is raised.

```
generator.send(value)
```

Resumes the execution and “sends” a value into the generator function. The `value` argument becomes the result of the current
yield expression. The send() method returns the next value yielded by the generator, or raises StopIteration if the generator exits without yielding another value. When send() is called to start the generator, it must be called with None as the argument, because there is no yield expression that could receive the value.

generator.throw(type[, value[, traceback]])
Raises an exception of type type at the point where generator was paused, and returns the next value yielded by the generator function. If the generator exits without yielding another value, a StopIteration exception is raised. If the generator function does not catch the passed-in exception, or raises a different exception, then that exception propagates to the caller.

generator.close()
Raises a GeneratorExit at the point where the generator function was paused. If the generator function then raises StopIteration (by exiting normally, or due to already being closed) or GeneratorExit (by not catching the exception), close returns to its caller. If the generator yields a value, a RuntimeError is raised. If the generator raises any other exception, it is propagated to the caller. close() does nothing if the generator has already exited due to an exception or normal exit.

Here is a simple example that demonstrates the behavior of generators and generator functions:

```python
>>> def echo(value=None):
...    try:
...        while True:
...            try:
...                value = (yield value)
...            except Exception, e:
...                print e
...    except GeneratorExit:
...        print 'generator exited normally'
```

```python
>>> echo()
'Execution starts when 'next()' is called for the first time.'
```

```python
>>> echo().next()  # simulator REPL
'Execution starts when 'next()' is called for the first time.'
```

```python
>>> echo().send(5)
5
```

```python
>>> echo().send(5, 6)
5
```

```python
>>> echo().send(5, 6).send(7)
7
```

```python
>>> echo().send(5, 6).send(7).send(8)
8
```

```python
>>> echo().send(5, 6).throw(17)
17
```

```python
>>> echo().send(5, 6).close()
'generator exited normally'
```

```python
>>> echo().send(5, 6).close().send(8)
RuntimeError: generator exit
```

```python
>>> echo().send(5, 6).close().send(8).send(9)
RuntimeError: generator exit
```

```python
>>> echo().send(5, 6).close().send(8).send(9).throw(10)
10
```

```python
>>> echo().send(5, 6).close().send(8).send(9).close()
'generator exited normally'
```

```python
>>> echo().send(5, 6).close().send(8).send(9).close().send(10)
RuntimeError: generator exit
```

```python
>>> echo().send(5, 6).close().send(8).send(9).close().send(10).throw(10)
10
```

```python
>>> echo().send(5, 6).close().send(8).send(9).close().send(10).throw(10).throw(11)
11
```
value = e

finally:

print "Don't forget to clean up when 'close()' is called."

>>> generator = echo(1)
>>> print generator.next()
Execution starts when 'next()' is called for the first time.
1
>>> print generator.next()
None

>>> print generator.send(2)
2

>>> generator.throw(TypeError, "spam")
TypeError('spam',)

>>> generator.close()
Don't forget to clean up when 'close()' is called.

PEP 0342 - Coroutines via Enhanced Generators

The proposal to enhance the API and syntax of generators, making them usable as simple coroutines.
5.3. Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

```
primary ::= atom | attributeref | subscription | slicing | call
```

5.3.1. Attribute references

An attribute reference is a primary followed by a period and a name:

```
attributeref ::= primary "." identifier
```

The primary must evaluate to an object of a type that supports attribute references, e.g., a module, list, or an instance. This object is then asked to produce the attribute whose name is the identifier. If this attribute is not available, the exception `AttributeError` is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

5.3.2. Subscriptions

A subscription selects an item of a sequence (string, tuple or list) or mapping (dictionary) object:

```
subscription ::= primary "[" expression_list "]"
```

The primary must evaluate to an object of a sequence or mapping type.

If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the
subscription selects the value in the mapping that corresponds to that key. (The expression list is a tuple except if it has exactly one item.)

If the primary is a sequence, the expression (list) must evaluate to a plain integer. If this value is negative, the length of the sequence is added to it (so that, e.g., \texttt{x[-1]} selects the last item of \texttt{x}.) The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero).

A string's items are characters. A character is not a separate data type but a string of exactly one character.

### 5.3.3. Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in assignment or \texttt{del} statements. The syntax for a slicing:

```
slicing ::= simple_slicing | extended_slicing
simple_slicing ::= primary "[" short_slice "]"
extended_slicing ::= primary "[" slice_list "]"
slice_list ::= slice_item ("," slice_item)* [","]
slice_item ::= expression | proper_slice | ellipsis
proper_slice ::= short_slice | long_slice
short_slice ::= [lower_bound] ":" [upper_bound]
long_slice ::= short_slice ":" [stride]
lower_bound ::= expression
upper_bound ::= expression
stride ::= expression
ellipsis ::= "..."
```

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation
as a slicing (this is the case if the slice list contains no proper slice nor ellipses). Similarly, when the slice list has exactly one short slice and no trailing comma, the interpretation as a simple slicing takes priority over that as an extended slicing.

The semantics for a simple slicing are as follows. The primary must evaluate to a sequence object. The lower and upper bound expressions, if present, must evaluate to plain integers; defaults are zero and the \texttt{sys.maxint}, respectively. If either bound is negative, the sequence’s length is added to it. The slicing now selects all items with index \( k \) such that \( i \leq k < j \) where \( i \) and \( j \) are the specified lower and upper bounds. This may be an empty sequence. It is not an error if \( i \) or \( j \) lie outside the range of valid indexes (such items don’t exist so they aren’t selected).

The semantics for an extended slicing are as follows. The primary must evaluate to a mapping object, and it is indexed with a key that is constructed from the slice list, as follows. If the slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of an ellipsis slice item is the built-in \texttt{Ellipsis} object. The conversion of a proper slice is a slice object (see section \textit{The standard type hierarchy}) whose \texttt{start}, \texttt{stop} and \texttt{step} attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting \texttt{None} for missing expressions.

\textbf{5.3.4. Calls}

A call calls a callable object (e.g., a function) with a possibly empty series of arguments:

\[
\texttt{call} \quad ::= \quad \texttt{primary } "(\) [\texttt{argument_list } [\texttt{",}]]
\]
A trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances, and certain class instances themselves are callable; extensions may define additional callable object types). All argument expressions are evaluated before the call is attempted. Please refer to section *Function definitions* for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a `TypeError` exception is raised. Otherwise, the value of the argument is placed in the slot, filling it (even if the expression is `None`, it fills the slot). When all arguments have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that
don’t specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a `TypeError` exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

**CPython implementation detail:** An implementation may provide built-in functions whose positional parameters do not have names, even if they are ‘named’ for the purpose of documentation, and which therefore cannot be supplied by keyword. In CPython, this is the case for functions implemented in C that use `PyArg_ParseTuple()` to parse their arguments.

If there are more positional arguments than there are formal parameter slots, a `TypeError` exception is raised, unless a formal parameter using the syntax `*identifier` is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a `TypeError` exception is raised, unless a formal parameter using the syntax `**identifier` is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax `*expression` appears in the function call, `expression` must evaluate to a sequence. Elements from this sequence are treated as if they were additional positional arguments; if there are positional arguments `x1,..., xN`, and `expression` evaluates to a
sequence $y_1, ..., y_M$, this is equivalent to a call with $M+N$ positional arguments $x_1, ..., x_N, y_1, ..., y_M$.

A consequence of this is that although the `*expression` syntax may appear after some keyword arguments, it is processed before the keyword arguments (and the `**expression` argument, if any – see below). So:

```python
>>> def f(a, b):
...   print a, b
...
>>> f(b=1, *(2,))
2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: f() got multiple values for keyword argument 'a'
>>> f(1, *(2,))
1 2
```

It is unusual for both keyword arguments and the `*expression` syntax to be used in the same call, so in practice this confusion does not arise.

If the syntax `**expression` appears in the function call, `expression` must evaluate to a mapping, the contents of which are treated as additional keyword arguments. In the case of a keyword appearing in both `expression` and as an explicit keyword argument, a `TypeError` exception is raised.

Formal parameters using the syntax `*identifier` or `**identifier` cannot be used as positional argument slots or as keyword argument names. Formal parameters using the syntax `(sublist)` cannot be used as keyword argument names; the outermost sublist corresponds to a single unnamed argument slot, and the argument value is assigned to the sublist using the usual tuple assignment rules after all other parameter processing is done.
A call always returns some value, possibly None, unless it raises an exception. How this value is computed depends on the type of the callable object.

If it is—

a user-defined function:
The code block for the function is executed, passing it the argument list. The first thing the code block will do is bind the formal parameters to the arguments; this is described in section Function definitions. When the code block executes a return statement, this specifies the return value of the function call.

a built-in function or method:
The result is up to the interpreter; see Built-in Functions for the descriptions of built-in functions and methods.

a class object:
A new instance of that class is returned.

a class instance method:
The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:
The class must define a __call__() method; the effect is then the same as if that method was called.
5.4. The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

```
power ::= primary ["***" u_expr]
```

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands): `-1**2` results in `-1`.

The power operator has the same semantics as the built-in `pow()` function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type. The result type is that of the arguments after coercion.

With mixed operand types, the coercion rules for binary arithmetic operators apply. For int and long int operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `10**2` returns `100`, but `10**-2` returns `0.01`. (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised).

Raising `0.0` to a negative power results in a `ZeroDivisionError`. Raising a negative number to a fractional power results in a `ValueError`.
5.5. Unary arithmetic and bitwise operations

All unary arithmetic and bitwise operations have the same priority:

\[ u_{expr} ::= \text{power} \mid "-" u_{expr} \mid "+" u_{expr} \mid "~" u_{expr} \]

The unary - (minus) operator yields the negation of its numeric argument.

The unary + (plus) operator yields its numeric argument unchanged.

The unary ~ (invert) operator yields the bitwise inversion of its plain or long integer argument. The bitwise inversion of \(x\) is defined as \(- (x+1)\). It only applies to integral numbers.

In all three cases, if the argument does not have the proper type, a \texttt{TypeError} exception is raised.
5.6. Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

\[
\begin{align*}
  m_{\text{expr}} & \ ::= \ u_{\text{expr}} \mid m_{\text{expr}} \ast u_{\text{expr}} \mid m_{\text{expr}} \div u_{\text{expr}} \mid m_{\text{expr}} \mod u_{\text{expr}} \\
  a_{\text{expr}} & \ ::= \ m_{\text{expr}} \mid a_{\text{expr}} + m_{\text{expr}} \mid a_{\text{expr}} - m_{\text{expr}}
\end{align*}
\]

The \( \ast \) (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer (plain or long) and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

The \( \div \) (division) and \( \div \) (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Plain or long integer division yields an integer of the same type; the result is that of mathematical division with the ‘floor’ function applied to the result. Division by zero raises the \textbf{ZeroDivisionError} exception.

The \( \% \) (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the \textbf{ZeroDivisionError} exception. The arguments may be floating point numbers, e.g., \( 3.14 \% 0.7 \) equals \( 0.34 \) (since \( 3.14 \) equals \( 4 * 0.7 + 0.34 \)). The modulo operator always yields a result with the same sign as its second operand (or zero); the absolute value of the result is
strictly smaller than the absolute value of the second operand [2].

The integer division and modulo operators are connected by the following identity: \( x \equiv (x/y) \times y + (x \% y) \). Integer division and modulo are also connected with the built-in function \texttt{divmod}(): \texttt{divmod}(x, y) == (x/y, x\%y). These identities don’t hold for floating point numbers; there similar identities hold approximately where \( x/y \) is replaced by \( \text{floor}(x/y) \) or \( \text{floor}(x/y) - 1 \) [3].

In addition to performing the modulo operation on numbers, the \% operator is also overloaded by string and unicode objects to perform string formatting (also known as interpolation). The syntax for string formatting is described in the Python Library Reference, section \textit{String Formatting Operations}.

\textit{Deprecated since version 2.3}: The floor division operator, the modulo operator, and the \texttt{divmod()} function are no longer defined for complex numbers. Instead, convert to a floating point number using the \texttt{abs()} function if appropriate.

The \texttt{+} (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

The \texttt{-} (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.
5.7. Shifting operations

The shifting operations have lower priority than the arithmetic operations:

\[
\text{shift_expr ::= a_expr | shift_expr ( "<<" | ">>") a_expr}
\]

These operators accept plain or long integers as arguments. The arguments are converted to a common type. They shift the first argument to the left or right by the number of bits given by the second argument.

A right shift by \( n \) bits is defined as division by \( \text{pow}(2, n) \). A left shift by \( n \) bits is defined as multiplication with \( \text{pow}(2, n) \). Negative shift counts raise a `ValueError` exception.

**Note:** In the current implementation, the right-hand operand is required to be at most `sys.maxsize`. If the right-hand operand is larger than `sys.maxsize` an `OverflowError` exception is raised.
5.8. Binary bitwise operations

Each of the three bitwise operations has a different priority level:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>and_exp</code></td>
<td>`shift_exp</td>
</tr>
<tr>
<td><code>xor_exp</code></td>
<td>`and_exp</td>
</tr>
<tr>
<td><code>or_exp</code></td>
<td>`xor_exp</td>
</tr>
</tbody>
</table>

The `&` operator yields the bitwise AND of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The `^` operator yields the bitwise XOR (exclusive OR) of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The `|` operator yields the bitwise (inclusive) OR of its arguments, which must be plain or long integers. The arguments are converted to a common type.
5.9. Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like `a < b < c` have the interpretation that is conventional in mathematics:

```plaintext
comparison ::= or_expr ( comp_operator or_expr )*  
comp_operator ::= "<" | ">" | "=" | ">=" | "<=" | "<>" | "!=" | ">is" ["not"] | ["not"] "in"
```

Comparisons yield boolean values: `True` or `False`.

Comparisons can be chained arbitrarily, e.g., `x < y <= z` is equivalent to `x < y and y <= z`, except that `y` is evaluated only once (but in both cases `z` is not evaluated at all when `x < y` is found to be false).

Formally, if `a, b, c, ..., y, z` are expressions and `op1, op2, ..., opN` are comparison operators, then `a op1 b op2 c ... y opN z` is equivalent to `a op1 b and b op2 c and ... y opN z`, except that each expression is evaluated at most once.

Note that `a op1 b op2 c` doesn’t imply any kind of comparison between `a` and `c`, so that, e.g., `x < y > z` is perfectly legal (though perhaps not pretty).

The forms `<>` and `!=` are equivalent; for consistency with C, `!=` is preferred; where `!=` is mentioned below `<>` is also accepted. The `<>` spelling is considered obsolescent.

The operators `<`, `>`, `==`, `>=`, `<=`, and `!=` compare the values of two objects. The objects need not have the same type. If both are
numbers, they are converted to a common type. Otherwise, objects of different types always compare unequal, and are ordered consistently but arbitrarily. You can control comparison behavior of objects of non-built-in types by defining a `__cmp__` method or rich comparison methods like `__gt__`, described in section *Special method names*.

(This unusual definition of comparison was used to simplify the definition of operations like sorting and the `in` and `not in` operators. In the future, the comparison rules for objects of different types are likely to change.)

Comparison of objects of the same type depends on the type:

- Numbers are compared arithmetically.

- Strings are compared lexicographically using the numeric equivalents (the result of the built-in function `ord()`) of their characters. Unicode and 8-bit strings are fully interoperable in this behavior. [4]

- Tuples and lists are compared lexicographically using comparison of corresponding elements. This means that to compare equal, each element must compare equal and the two sequences must be of the same type and have the same length.

  If not equal, the sequences are ordered the same as their first differing elements. For example, `cmp([1, 2, x], [1, 2, y])` returns the same as `cmp(x, y)`. If the corresponding element does not exist, the shorter sequence is ordered first (for example, `[1, 2] < [1, 2, 3]`).

- Mappings (dictionaries) compare equal if and only if their sorted (key, value) lists compare equal. [5] Outcomes other than equality are resolved consistently, but are not otherwise defined.
Most other objects of built-in types compare unequal unless they are the same object; the choice whether one object is considered smaller or larger than another one is made arbitrarily but consistently within one execution of a program.

The operators `in` and `not in` test for collection membership. `x in s` evaluates to true if `x` is a member of the collection `s`, and false otherwise. `x not in s` returns the negation of `x in s`. The collection membership test has traditionally been bound to sequences; an object is a member of a collection if the collection is a sequence and contains an element equal to that object. However, it makes sense for many other object types to support membership tests without being a sequence. In particular, dictionaries (for keys) and sets support membership testing.

For the list and tuple types, `x in y` is true if and only if there exists an index `i` such that `x == y[i]` is true.

For the Unicode and string types, `x in y` is true if and only if `x` is a substring of `y`. An equivalent test is `y.find(x) != -1`. Note, `x` and `y` need not be the same type; consequently, `u''ab'' in 'abc'` will return `True`. Empty strings are always considered to be a substring of any other string, so `'' in ''abc''` will return `True`.

*Changed in version 2.3:* Previously, `x` was required to be a string of length 1.

For user-defined classes which define the `__contains__() method, `x in y` is true if and only if `y.__contains__(x)` is true.

For user-defined classes which do not define `__contains__() but do define `__iter__(), `x in y` is true if some value `z` with `x == z` is
produced while iterating over \( y \). If an exception is raised during the iteration, it is as if \( \text{in} \) raised that exception.

Lastly, the old-style iteration protocol is tried: if a class defines \( \_\_\text{getitem}() \), \( \text{x in y} \) is true if and only if there is a non-negative integer index \( i \) such that \( x == y[i] \), and all lower integer indices do not raise \text{IndexError} exception. (If any other exception is raised, it is as if \( \text{in} \) raised that exception).

The operator \( \text{not in} \) is defined to have the inverse true value of \( \text{in} \).

The operators \( \text{is} \) and \( \text{is not} \) test for object identity: \( x \ \text{is} \ y \) is true if and only if \( x \) and \( y \) are the same object. \( x \ \text{is not} \ y \) yields the inverse truth value. [7]
5.10. Boolean operations

| or_test  ::= | and_test     | or_test  "or" and_test |
| and_test ::= | not_test    | and_test "and" not_test |
| not_test ::= | comparison  | "not" not_test |

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: `False`, `None`, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true. (See the `__nonzero__()` special method for a way to change this.)

The operator `not` yields `True` if its argument is false, `False` otherwise.

The expression `x and y` first evaluates `x`; if `x` is false, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

The expression `x or y` first evaluates `x`; if `x` is true, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

(Note that neither `and` nor `or` restrict the value and type they return to `False` and `True`, but rather return the last evaluated argument. This is sometimes useful, e.g., if `s` is a string that should be replaced by a default value if it is empty, the expression `s or 'foo'` yields the desired value. Because `not` has to invent a value anyway, it does not bother to return a value of the same type as its argument, so e.g., `not 'foo'` yields `False`, not `'`.)

5.11. Conditional Expressions

New in version 2.5.

Conditional expressions (sometimes called a “ternary operator”) have the lowest priority of all Python operations.

The expression \( x \text{ if } C \text{ else } y \) first evaluates the condition, \( C \ (\text{not } x) \); if \( C \) is true, \( x \) is evaluated and its value is returned; otherwise, \( y \) is evaluated and its value is returned.

See PEP 308 for more details about conditional expressions.
Lambda forms (lambda expressions) have the same syntactic position as expressions. They are a shorthand to create anonymous functions; the expression `lambda arguments: expression` yields a function object. The unnamed object behaves like a function object defined with

```python
def name(arguments):
    return expression
```

See section *Function definitions* for the syntax of parameter lists. Note that functions created with lambda forms cannot contain statements.
An expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

The trailing comma is required only to create a single tuple (a.k.a. a singleton); it is optional in all other cases. A single expression without a trailing comma doesn’t create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: ()..)
5.14. Evaluation order

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
expr1(expr2, expr3, *expr4, **expr5)
expr3, expr4 = expr1, expr2
The following table summarizes the operator precedences in Python, from lowest precedence (least binding) to highest precedence (most binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for comparisons, including tests, which all have the same precedence and chain from left to right — see section *Comparisons* — and exponentiation, which groups from right to left).

In Python 2.3 and later releases, a list comprehension “leaks” the control variables of each for it contains into the containing scope. However, this behavior is deprecated, and relying on it will not work in Python 3.0.

While $\text{abs}(x\%y) < \text{abs}(y)$ is true mathematically, for floats it may not be true numerically due to roundoff. For example, and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that $-1e-100 \% 1e100$ have the same sign as $1e100$, the computed result is $-1e-100 + 1e100$, which is numerically exactly equal to $1e100$. Function $\text{fmod}()$ in the `math` module returns a result whose sign matches the sign of the first argument instead, and so returns $-1e-100$ in this case. Which approach is more appropriate depends on the application.

If $x$ is very close to an exact integer multiple of $y$, it’s possible for $\text{floor}(x/y)$ to be one larger than $(x-x\%y)/y$ due to rounding. In such cases, Python returns the latter result, in order to preserve that $\text{divmod}(x,y)[0] \times y + x \% y$ be very close to $x$.

While comparisons between unicode strings make sense at the byte level, they may be counter-intuitive to users. For example, the strings u"\u00C7" and u"\u0043\u0327" compare differently, even though they both represent the same unicode character (LATIN CAPITAL LETTER C WITH CEDILLA). To compare strings in a human recognizable way, compare using `unicodedata.normalize()`.

The implementation computes this efficiently, without constructing lists or sorting.

Earlier versions of Python used lexicographic comparison of the sorted (key, value) lists, but this was very expensive for the common case of comparing for equality. An even earlier version of Python compared dictionaries by identity only, but this...
caused surprises because people expected to be able to test a dictionary for emptiness by comparing it to `{}`.
Due to automatic garbage-collection, free lists, and the dynamic nature of descriptors, you may notice seemingly unusual behaviour in certain uses of the `is` operator, like those involving comparisons between instance methods, or constants. Check their documentation for more info.

The power operator `**` binds less tightly than an arithmetic or bitwise unary operator on its right, that is, `2**-1` is `0.5`. 

[7]  
[8]
Simple statements are comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::=  expression_stmt
  |  assert_stmt
  |  assignment_stmt
  |  augmented_assignment_stmt
  |  pass_stmt
  |  del_stmt
  |  print_stmt
  |  return_stmt
  |  yield_stmt
  |  raise_stmt
  |  break_stmt
  |  continue_stmt
  |  import_stmt
  |  global_stmt
  |  exec_stmt
```
6.1. Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value `None`). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::= expression_list
```

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not `None`, it is converted to a string using the built-in `repr()` function and the resulting string is written to standard output (see section *The print statement*) on a line by itself. (Expression statements yielding `None` are not written, so that procedure calls do not cause any output.)
6.2. Assignment statements

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

```
assignment_stmt ::= (target_list "=")+ (expression_list | yield_expression)
target_list ::= target ("," target)* [","]
target ::= identifier
         | "(" target_list ")"
         | "[" target_list "]"|
         | attributeref
         | subscription
         | slicing
```

(See section `Primaries` for the syntax definitions for the last three symbols.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section `The standard type hierarchy`).

Assignment of an object to a target list is recursively defined as follows.

- If the target list is a single target: The object is assigned to that
target.

- If the target list is a comma-separated list of targets: The object must be an iterable with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets. (This rule is relaxed as of Python 1.5; in earlier versions, the object had to be a tuple. Since strings are sequences, an assignment like \( a, b = "xy\) is now legal as long as the string has the right length.)

Assignment of an object to a single target is recursively defined as follows.

- If the target is an identifier (name):
  - If the name does not occur in a `global` statement in the current code block: the name is bound to the object in the current local namespace.
  - Otherwise: the name is bound to the object in the current global namespace.

The name is rebound if it was already bound. This may cause the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor (if it has one) to be called.

- If the target is a target list enclosed in parentheses or in square brackets: The object must be an iterable with the same number of items as there are targets in the target list, and its items are assigned, from left to right, to the corresponding targets.

- If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, `TypeError` is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an
exception (usually but not necessarily `AttributeError`).

Note: If the object is a class instance and the attribute reference occurs on both sides of the assignment operator, the RHS expression, `a.x` can access either an instance attribute or (if no instance attribute exists) a class attribute. The LHS target `a.x` is always set as an instance attribute, creating it if necessary. Thus, the two occurrences of `a.x` do not necessarily refer to the same attribute: if the RHS expression refers to a class attribute, the LHS creates a new instance attribute as the target of the assignment:

```python
class Cls:
    x = 3  # class variable
inst = Cls()
inst.x = inst.x + 1  # writes inst.x as 4 leaving Cls.x as
                      # 3
```

This description does not necessarily apply to descriptor attributes, such as properties created with `property()`.

- If the target is a subscription: The primary expression in the reference is evaluated. It should yield either a mutable sequence object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

  If the primary is a mutable sequence object (such as a list), the subscript must yield a plain integer. If it is negative, the sequence’s length is added to it. The resulting value must be a nonnegative integer less than the sequence’s length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, `IndexError` is raised (assignment to a subscripted sequence cannot add new items to a list).

  If the primary is a mapping object (such as a dictionary), the
subscript must have a type compatible with the mapping's key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

- If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence’s length. The bounds should evaluate to (small) integers. If either bound is negative, the sequence’s length is added to it. The resulting bounds are clipped to lie between zero and the sequence’s length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned sequence, thus changing the length of the target sequence, if the object allows it.

**CPython implementation detail:** In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.

**WARNING:** Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are ‘safe’ (for example \(a, b = b, a\) swaps two variables), overlaps within the collection of assigned-to variables are not safe! For instance, the following program prints \([0, 2]\):

```python
x = [0, 1]
```
Augmented assignment statements

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```plaintext
augmented_assignment_stmt ::= augtarget augop (expression_list | augtarget)
augtarget ::= identifier |attributeref |subscription
augop ::= "+=" | "-=" | "*=" | "/=" | "//=" | "%=" | "**=" | ">>=" | "<<=" | "&=" | "^=" | "|="
```

(See section *Primaries* for the syntax definitions for the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like `x += 1` can be rewritten as `x = x + 1` to achieve a similar, but not exactly equal effect. In the augmented version, `x` is only evaluated once. Also, when possible, the actual operation is performed *in-place*, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible *in-place* behavior, the binary operation performed by augmented assignment is the same
as the normal binary operations.

For targets which are attribute references, the same caveat about class and instance attributes applies as for regular assignments.
6.3. The **assert** statement

Assert statements are a convenient way to insert debugging assertions into a program:

> assert_stmt ::= "assert" expression ["," expression]

The simple form, `assert expression`, is equivalent to

```python
if __debug__:
    if not expression: raise AssertionError
```

The extended form, `assert expression1, expression2`, is equivalent to

```python
if __debug__:
    if not expression1: raise AssertionError(expression2)
```

These equivalences assume that `__debug__` and `AssertionError` refer to the built-in variables with those names. In the current implementation, the built-in variable `__debug__` is `True` under normal circumstances, `False` when optimization is requested (command line option `-O`). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to `__debug__` are illegal. The value for the built-in variable is determined when the interpreter starts.
6.4. The `pass` statement

```
pass_stmt ::= "pass"
```

`pass` is a null operation — when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```python
def f(arg): pass  # a function that does nothing (yet)
class C: pass     # a class with no methods (yet)
```
6.5. The `del` statement

```
del_stmt ::= "del" target_list
```

Deletion is recursively defined very similar to the way assignment is defined. Rather that spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

It is illegal to delete a name from the local namespace if it occurs as a free variable in a nested block.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).
6.6. The `print` statement

```
print_stmt ::= "print" ([expression ("," expression)* ["","")] |
">>" expression [""," expression]+ ["","]]
```

`print` evaluates each expression in turn and writes the resulting object to standard output (see below). If an object is not a string, it is first converted to a string using the rules for string conversions. The (resulting or original) string is then written. A space is written before each object is (converted and) written, unless the output system believes it is positioned at the beginning of a line. This is the case (1) when no characters have yet been written to standard output, (2) when the last character written to standard output is a whitespace character except `' '`, or (3) when the last write operation on standard output was not a `print` statement. (In some cases it may be functional to write an empty string to standard output for this reason.)

**Note:** Objects which act like file objects but which are not the built-in file objects often do not properly emulate this aspect of the file object’s behavior, so it is best not to rely on this.

A `\n` character is written at the end, unless the `print` statement ends with a comma. This is the only action if the statement contains just the keyword `print`.

Standard output is defined as the file object named `stdout` in the built-in module `sys`. If no such object exists, or if it does not have a `write()` method, a `RuntimeError` exception is raised.

`print` also has an extended form, defined by the second portion of the syntax described above. This form is sometimes referred to as
“print chevron.” In this form, the first expression after the `>>` must evaluate to a “file-like” object, specifically an object that has a `write()` method as described above. With this extended form, the subsequent expressions are printed to this file object. If the first expression evaluates to `None`, then `sys.stdout` is used as the file for output.
6.7. The return statement

\[
\text{return_stmt ::= "return" [expression_list]}
\]

\text{return} may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else None is substituted.

\text{return} leaves the current function call with the expression list (or None) as return value.

When \text{return} passes control out of a \text{try} statement with a \text{finally} clause, that \text{finally} clause is executed before really leaving the function.

In a generator function, the \text{return} statement is not allowed to include an \text{expression_list}. In that context, a bare \text{return} indicates that the generator is done and will cause \text{StopIteration} to be raised.
6.8. The yield statement

yield_stmt ::= yield_expression

The yield statement is only used when defining a generator function, and is only used in the body of the generator function. Using a yield statement in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator iterator, or more commonly, a generator. The body of the generator function is executed by calling the generator’s next() method repeatedly until it raises an exception.

When a yield statement is executed, the state of the generator is frozen and the value of expression_list is returned to next()'s caller. By “frozen” we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack: enough information is saved so that the next time next() is invoked, the function can proceed exactly as if the yield statement were just another external call.

As of Python version 2.5, the yield statement is now allowed in the try clause of a try ... finally construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator’s close() method will be called, allowing any pending finally clauses to execute.

Note: In Python 2.2, the yield statement was only allowed when the generators feature has been enabled. This __future__ import statement was used to enable the feature:
from __future__ import generators

See also:

**PEP 0255 - Simple Generators**
The proposal for adding generators and the `yield` statement to Python.

**PEP 0342 - Coroutines via Enhanced Generators**
The proposal that, among other generator enhancements, proposed allowing `yield` to appear inside a `try ... finally` block.
6.9. The `raise` statement

`raise_stmt ::= "raise" [expression ["," expression ["," expression]]]

If no expressions are present, `raise` re-raises the last exception that was active in the current scope. If no exception is active in the current scope, a `TypeError` exception is raised indicating that this is an error (if running under IDLE, a `Queue.Empty` exception is raised instead).

Otherwise, `raise` evaluates the expressions to get three objects, using `None` as the value of omitted expressions. The first two objects are used to determine the `type` and `value` of the exception.

If the first object is an instance, the type of the exception is the class of the instance, the instance itself is the value, and the second object must be `None`.

If the first object is a class, it becomes the type of the exception. The second object is used to determine the exception value: If it is an instance of the class, the instance becomes the exception value. If the second object is a tuple, it is used as the argument list for the class constructor; if it is `None`, an empty argument list is used, and any other object is treated as a single argument to the constructor. The instance so created by calling the constructor is used as the exception value.

If a third object is present and not `None`, it must be a traceback object (see section *The standard type hierarchy*), and it is substituted instead of the current location as the place where the exception occurred. If the third object is present and not a traceback object or `None`, a `TypeError` exception is raised. The three-expression form of
raise is useful to re-raise an exception transparently in an except clause, but raise with no expressions should be preferred if the exception to be re-raised was the most recently active exception in the current scope.

Additional information on exceptions can be found in section Exceptions, and information about handling exceptions is in section The try statement.
6.10. The `break` statement

```
break_stmt ::= "break"
```

`break` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional `else` clause if the loop has one.

If a `for` loop is terminated by `break`, the loop control target keeps its current value.

When `break` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the loop.
6.11. The `continue` statement

```plaintext
continue_stmt ::= "continue"
```

`continue` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition or `finally` clause within that loop. It continues with the next cycle of the nearest enclosing loop.

When `continue` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really starting the next loop cycle.
6.12. The `import` statement

Import statements are executed in two steps: (1) find a module, and initialize it if necessary; (2) define a name or names in the local namespace (of the scope where the `import` statement occurs). The statement comes in two forms differing on whether it uses the `from` keyword. The first form (without `from`) repeats these steps for each identifier in the list. The form with `from` performs step (1) once, and then performs step (2) repeatedly.

To understand how step (1) occurs, one must first understand how Python handles hierarchical naming of modules. To help organize modules and provide a hierarchy in naming, Python has a concept of packages. A package can contain other packages and modules while modules cannot contain other modules or packages. From a file system perspective, packages are directories and modules are files. The original specification for packages is still available to read, although minor details have changed since the writing of that document.

Once the name of the module is known (unless otherwise specified, the term “module” will refer to both packages and modules), searching for the module or package can begin. The first place checked is `sys.modules`, the cache of all modules that have been
imported previously. If the module is found there then it is used in step (2) of import.

If the module is not found in the cache, then \texttt{sys.meta\_path} is searched (the specification for \texttt{sys.meta\_path} can be found in PEP 302). The object is a list of \texttt{finder} objects which are queried in order as to whether they know how to load the module by calling their \texttt{find\_module()} method with the name of the module. If the module happens to be contained within a package (as denoted by the existence of a dot in the name), then a second argument to \texttt{find\_module()} is given as the value of the \texttt{__path__} attribute from the parent package (everything up to the last dot in the name of the module being imported). If a finder can find the module it returns a \texttt{loader} (discussed later) or returns \texttt{None}.

If none of the finders on \texttt{sys.meta\_path} are able to find the module then some implicitly defined finders are queried. Implementations of Python vary in what implicit meta path finders are defined. The one they all do define, though, is one that handles \texttt{sys.path\_hooks}, \texttt{sys.path\_importer\_cache}, and \texttt{sys.path}.

The implicit finder searches for the requested module in the “paths” specified in one of two places (“paths” do not have to be file system paths). If the module being imported is supposed to be contained within a package then the second argument passed to \texttt{find\_module()}, \texttt{__path__} on the parent package, is used as the source of paths. If the module is not contained in a package then \texttt{sys.path} is used as the source of paths.

Once the source of paths is chosen it is iterated over to find a finder that can handle that path. The dict at \texttt{sys.path\_importer\_cache} caches finders for paths and is checked for a finder. If the path does not have a finder cached then \texttt{sys.path\_hooks} is searched by calling each object in the list with a single argument of the path, returning a
finder or raises `ImportError`. If a finder is returned then it is cached in `sys.path_importer_cache` and then used for that path entry. If no finder can be found but the path exists then a value of `None` is stored in `sys.path_importer_cache` to signify that an implicit, file-based finder that handles modules stored as individual files should be used for that path. If the path does not exist then a finder which always returns `None` is placed in the cache for the path.

If no finder can find the module then `ImportError` is raised. Otherwise some finder returned a loader whose `load_module()` method is called with the name of the module to load (see PEP 302 for the original definition of loaders). A loader has several responsibilities to perform on a module it loads. First, if the module already exists in `sys.modules` (a possibility if the loader is called outside of the import machinery) then it is to use that module for initialization and not a new module. But if the module does not exist in `sys.modules` then it is to be added to that dict before initialization begins. If an error occurs during loading of the module and it was added to `sys.modules` it is to be removed from the dict. If an error occurs but the module was already in `sys.modules` it is left in the dict.

The loader must set several attributes on the module. `_name__` is to be set to the name of the module. `_file__` is to be the “path” to the file unless the module is built-in (and thus listed in `sys.builtin_module_names`) in which case the attribute is not set. If what is being imported is a package then `_path__` is to be set to a list of paths to be searched when looking for modules and packages contained within the package being imported. `_package__` is optional but should be set to the name of package that contains the module or package (the empty string is used for module not contained in a package). `_loader__` is also optional but should be set to the loader object that is loading the module.
If an error occurs during loading then the loader raises `ImportError` if some other exception is not already being propagated. Otherwise the loader returns the module that was loaded and initialized.

When step (1) finishes without raising an exception, step (2) can begin.

The first form of `import` statement binds the module name in the local namespace to the module object, and then goes on to import the next identifier, if any. If the module name is followed by `as`, the name following `as` is used as the local name for the module.

The `from` form does not bind the module name: it goes through the list of identifiers, looks each one of them up in the module found in step (1), and binds the name in the local namespace to the object thus found. As with the first form of `import`, an alternate local name can be supplied by specifying “`as` localname”. If a name is not found, `ImportError` is raised. If the list of identifiers is replaced by a star (`'*'`), all public names defined in the module are bound in the local namespace of the `import` statement..

The public names defined by a module are determined by checking the module’s namespace for a variable named `_all_`; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in `_all_` are all considered public and are required to exist. If `_all_` is not defined, the set of public names includes all names found in the module’s namespace which do not begin with an underscore character (`'_'`). `_all_` should contain the entire public API. It is intended to avoid accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The `from` form with `*` may only occur in a module scope. If the wild
card form of import — import * — is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError.

When specifying what module to import you do not have to specify the absolute name of the module. When a module or package is contained within another package it is possible to make a relative import within the same top package without having to mention the package name. By using leading dots in the specified module or package after from you can specify how high to traverse up the current package hierarchy without specifying exact names. One leading dot means the current package where the module making the import exists. Two dots means up one package level. Three dots is up two levels, etc. So if you execute from .. import mod from a module in the pkg package then you will end up importing pkg.mod. If you execute from ..subpkg2 import mod from within pkg.subpkg1 you will import pkg.subpkg2.mod. The specification for relative imports is contained within PEP 328.

importlib.import_module() is provided to support applications that determine which modules need to be loaded dynamically.

### 6.12.1. Future statements

A future statement is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python. The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

future_statement ::= "from" "__future__" "import" feature ["as" ("," feature ["as" name])]*
A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The features recognized by Python 2.6 are `unicode_literals`, `print_function`, `absolute_import`, `division`, `generators`, `nested_scopes` and `with_statement`. `generators`, `with_statement`, `nested_scopes` are redundant in Python version 2.6 and above because they are always enabled.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module `__future__`, described later, and it will be imported in the usual way at the time the future statement is executed.
The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```python
import __future__ [as name]
```

That is not a future statement; it’s an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by an `exec` statement or calls to the built-in functions `compile()` and `execfile()` that occur in a module `m` containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can, starting with Python 2.2 be controlled by optional arguments to `compile()` — see the documentation of that function for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the `-i` option, is passed a script name to execute, and the script includes a future statement, it will be in effect in the interactive session started after the script is executed.

**See also:**

**PEP 236 - Back to the __future__**

The original proposal for the __future__ mechanism.
6.13. The `global` statement

```
global_stmt ::= "global" identifier ("," identifier)*
```

The `global` statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without `global`, although free variables may refer to globals without being declared global.

Names listed in a `global` statement must not be used in the same code block textually preceding that `global` statement.

Names listed in a `global` statement must not be defined as formal parameters or in a `for` loop control target, `class` definition, function definition, or `import` statement.

**CPython implementation detail:** The current implementation does not enforce the latter two restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.

**Programmer’s note:** the `global` is a directive to the parser. It applies only to code parsed at the same time as the `global` statement. In particular, a `global` statement contained in an `exec` statement does not affect the code block containing the `exec` statement, and code contained in an `exec` statement is unaffected by `global` statements in the code containing the `exec` statement. The same applies to the `eval()`, `execfile()` and `compile()` functions.
This statement supports dynamic execution of Python code. The first expression should evaluate to either a string, an open file object, or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed (unless a syntax error occurs). [1] If it is an open file, the file is parsed until EOF and executed. If it is a code object, it is simply executed. In all cases, the code that's executed is expected to be valid as file input (see section File input). Be aware that the return and yield statements may not be used outside of function definitions even within the context of code passed to the exec statement.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only the first expression after in is specified, it should be a dictionary, which will be used for both the global and the local variables. If two expressions are given, they are used for the global and local variables, respectively. If provided, locals can be any mapping object.

*Changed in version 2.4:* Formerly, locals was required to be a dictionary.

As a side effect, an implementation may insert additional keys into the dictionaries given besides those corresponding to variable names set by the executed code. For example, the current implementation may add a reference to the dictionary of the built-in module __builtin__ under the key __builtins__ (!).

**Programmer’s hints:** dynamic evaluation of expressions is supported by the built-in function eval(). The built-in functions
`globals()` and `locals()` return the current global and local dictionary, respectively, which may be useful to pass around for use by `exec`.

Footnotes

[1] Note that the parser only accepts the Unix-style end of line convention. If you are reading the code from a file, make sure to use universal newline mode to convert Windows or Mac-style newlines.
7. Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The if, while and for statements implement traditional control flow constructs. try specifies exception handlers and/or cleanup code for a group of statements. Function and class definitions are also syntactically compound statements.

Compound statements consist of one or more ‘clauses.’ A clause consists of a header and a ‘suite.’ The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header’s colon, or it can be one or more indented statements on subsequent lines. Only the latter form of suite can contain nested compound statements; the following is illegal, mostly because it wouldn’t be clear to which if clause a following else clause would belong:

```
if test1: if test2: print x
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the print statements are executed:

```
if x < y < z: print x; print y; print z
```

Summarizing:
| compound_stmt ::= | if_stmt   |
|                | | while_stmt   |
|                | | for_stmt     |
|                | | try_stmt     |
|                | | with_stmt    |
|                | | funcdef      |
|                | | classdef     |
|                | | decorated    |

| suite ::= | stmt_list NEWLINE | NEWLINE INDENT statement |
| statement ::= | stmt_list NEWLINE | compound_stmt |
| stmt_list ::= | simple_stmt (";" simple_stmt)* [";"] |

Note that statements always end in a `NEWLINE` possibly followed by a `DEDENT`. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the ‘dangling `else`’ problem is solved in Python by requiring nested `if` statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.
7.1. The if statement

The if statement is used for conditional execution:

```plaintext
ifStmt ::= "if" expression ":" suite
         ( "elif" expression ":" suite )* 
         ["else" ":" suite]
```

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section Boolean operations for the definition of true and false); then that suite is executed (and no other part of the if statement is executed or evaluated). If all expressions are false, the suite of the else clause, if present, is executed.
7.2. The **while** statement

The **while** statement is used for repeated execution as long as an expression is true:

```plaintext
while_stmt ::= "while" expression ":" suite
               ["else" ":" suite]
```

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the **else** clause, if present, is executed and the loop terminates.

A **break** statement executed in the first suite terminates the loop without executing the **else** clause’s suite. A **continue** statement executed in the first suite skips the rest of the suite and goes back to testing the expression.
7.3. The for statement

The for statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::= "for" target_list "in" expression_list ":" suite
            ["else" ":" suite]
```

The expression list is evaluated once; it should yield an iterable object. An iterator is created for the result of the expression_list. The suite is then executed once for each item provided by the iterator, in the order of ascending indices. Each item in turn is assigned to the target list using the standard rules for assignments, and then the suite is executed. When the items are exhausted (which is immediately when the sequence is empty), the suite in the else clause, if present, is executed, and the loop terminates.

A break statement executed in the first suite terminates the loop without executing the else clause’s suite. A continue statement executed in the first suite skips the rest of the suite and continues with the next item, or with the else clause if there was no next item.

The suite may assign to the variable(s) in the target list; this does not affect the next item assigned to it.

The target list is not deleted when the loop is finished, but if the sequence is empty, it will not have been assigned to at all by the loop. Hint: the built-in function range() returns a sequence of integers suitable to emulate the effect of Pascal's for i := a to b do; e.g., range(3) returns the list [0, 1, 2].

Note: There is a subtlety when the sequence is being modified by
the loop (this can only occur for mutable sequences, i.e. lists). An internal counter is used to keep track of which item is used next, and this is incremented on each iteration. When this counter has reached the length of the sequence the loop terminates. This means that if the suite deletes the current (or a previous) item from the sequence, the next item will be skipped (since it gets the index of the current item which has already been treated). Likewise, if the suite inserts an item in the sequence before the current item, the current item will be treated again the next time through the loop. This can lead to nasty bugs that can be avoided by making a temporary copy using a slice of the whole sequence, e.g.,

```python
for x in a[:]:
    if x < 0: a.remove(x)
```
7.4. The try statement

The try statement specifies exception handlers and/or cleanup code for a group of statements:

```plaintext
try_stmt ::= try1_stmt | try2_stmt
try1_stmt ::= "try" ":" suite
             ("except" [expression [("as" | ",") target]] ":" 
               ["else" ":" suite]  
               ["finally" ":" suite]
try2_stmt ::= "try" ":" suite  
             "finally" ":" suite
```

*Changed in version 2.5:* In previous versions of Python, `try...except...finally` did not work. `try...except` had to be nested in `try...finally`.

The except clause(s) specify one or more exception handlers. When no exception occurs in the try clause, no exception handler is executed. When an exception occurs in the try suite, a search for an exception handler is started. This search inspects the except clauses in turn until one is found that matches the exception. An expression-less except clause, if present, must be last; it matches any exception. For an except clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is “compatible” with the exception. An object is compatible with an exception if it is the class or a base class of the exception object, a tuple containing an item compatible with the exception, or, in the (deprecated) case of string exceptions, is the raised string itself (note that the object identities must match, i.e. it must be the same string object, not just a string with the same value).

If no except clause matches the exception, the search for an
exception handler continues in the surrounding code and on the invocation stack. [1]

If the evaluation of an expression in the header of an except clause raises an exception, the original search for a handler is canceled and a search starts for the new exception in the surrounding code and on the call stack (it is treated as if the entire try statement raised the exception).

When a matching except clause is found, the exception is assigned to the target specified in that except clause, if present, and the except clause's suite is executed. All except clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire try statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the try clause of the inner handler, the outer handler will not handle the exception.)

Before an except clause's suite is executed, details about the exception are assigned to three variables in the sys module: sys.exc_type receives the object identifying the exception; sys.exc_value receives the exception's parameter; sys.exc_traceback receives a traceback object (see section The standard type hierarchy) identifying the point in the program where the exception occurred. These details are also available through the sys.exc_info() function, which returns a tuple (exc_type, exc_value, exc_traceback). Use of the corresponding variables is deprecated in favor of this function, since their use is unsafe in a threaded program. As of Python 1.5, the variables are restored to their previous values (before the call) when returning from a function that handled an exception.

The optional else clause is executed if and when control flows off the end of the try clause. [2] Exceptions in the else clause are not
handled by the preceding `except` clauses.

If `finally` is present, it specifies a ‘cleanup’ handler. The `try` clause is executed, including any `except` and `else` clauses. If an exception occurs in any of the clauses and is not handled, the exception is temporarily saved. The `finally` clause is executed. If there is a saved exception, it is re-raised at the end of the `finally` clause. If the `finally` clause raises another exception or executes a `return` or `break` statement, the saved exception is lost. The exception information is not available to the program during execution of the `finally` clause.

When a `return`, `break` or `continue` statement is executed in the `try` suite of a `try...finally` statement, the `finally` clause is also executed ‘on the way out.’ A `continue` statement is illegal in the `finally` clause. (The reason is a problem with the current implementation — this restriction may be lifted in the future).

Additional information on exceptions can be found in section *Exceptions*, and information on using the `raise` statement to generate exceptions may be found in section *The raise statement*.
7.5. The `with` statement

*New in version 2.5.*

The `with` statement is used to wrap the execution of a block with methods defined by a context manager (see section *With Statement Context Managers*). This allows common `try...except...finally` usage patterns to be encapsulated for convenient reuse.

```
with_stmt ::= "with" with_item ("," with_item)* ":" suite
with_item ::= expression ["as" target]
```

The execution of the `with` statement with one “item” proceeds as follows:

1. The context expression is evaluated to obtain a context manager.
2. The context manager’s `__exit__()` is loaded for later use.
3. The context manager’s `__enter__() method is invoked.
4. If a target was included in the `with` statement, the return value from `__enter__()` is assigned to it.

**Note:** The `with` statement guarantees that if the `__enter__()` method returns without an error, then `__exit__()` will always be called. Thus, if an error occurs during the assignment to the target list, it will be treated the same as an error occurring within the suite would be. See step 6 below.

5. The suite is executed.
6. The context manager’s `__exit__() method is invoked. If an
exception caused the suite to be exited, its type, value, and traceback are passed as arguments to __exit__(). Otherwise, three None arguments are supplied.

If the suite was exited due to an exception, and the return value from the __exit__() method was false, the exception is reraised. If the return value was true, the exception is suppressed, and execution continues with the statement following the with statement.

If the suite was exited for any reason other than an exception, the return value from __exit__() is ignored, and execution proceeds at the normal location for the kind of exit that was taken.

With more than one item, the context managers are processed as if multiple with statements were nested:

```python
with A() as a, B() as b:
    suite
```

is equivalent to

```python
with A() as a:
    with B() as b:
        suite
```

**Note:** In Python 2.5, the with statement is only allowed when the with_statement feature has been enabled. It is always enabled in Python 2.6.

*Changed in version 2.7:* Support for multiple context expressions.

**See also:**
**PEP 0343 - The “with” statement**

The specification, background, and examples for the Python `with` statement.
7.6. Function definitions

A function definition defines a user-defined function object (see section The standard type hierarchy):

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.

The function definition does not execute the function body; this gets executed only when the function is called. [3]

A function definition may be wrapped by one or more decorator expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code:
@f1(arg)
@f2
def func(): pass

is equivalent to:

def func(): pass
func = f1(arg)(f2(func))

When one or more top-level parameters have the form \textit{parameter} = \textit{expression}, the function is said to have “default parameter values.” For a parameter with a default value, the corresponding argument may be omitted from a call, in which case the parameter’s default value is substituted. If a parameter has a default value, all following parameters must also have a default value — this is a syntactic restriction that is not expressed by the grammar.

**Default parameter values are evaluated when the function definition is executed.** This means that the expression is evaluated once, when the function is defined, and that that same “pre-computed” value is used for each call. This is especially important to understand when a default parameter is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default value is in effect modified. This is generally not what was intended. A way around this is to use \texttt{None} as the default, and explicitly test for it in the body of the function, e.g.:

```python
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
    penguin.append("property of the zoo")
    return penguin
```

Function call semantics are described in more detail in section \textit{Calls}. A function call always assigns values to all parameters mentioned in the parameter list, either from position arguments, from keyword
arguments, or from default values. If the form “*identifier” is present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form “**identifier” is present, it is initialized to a new dictionary receiving any excess keyword arguments, defaulting to a new empty dictionary.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda forms, described in section *Lambdas*. Note that the lambda form is merely a shorthand for a simplified function definition; a function defined in a “def” statement can be passed around or assigned to another name just like a function defined by a lambda form. The “def” form is actually more powerful since it allows the execution of multiple statements.

**Programmer’s note:** Functions are first-class objects. A “def” form executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the def. See section *Naming and binding* for details.
A class definition defines a class object (see section *The standard type hierarchy*):

- **classdef** ::= "class" *classname* [inheritance] ":" *suite*
- **inheritance** ::= "(" *expression_list* ")"
- **classname** ::= *identifier*

A class definition is an executable statement. It first evaluates the inheritance list, if present. Each item in the inheritance list should evaluate to a class object or class type which allows subclassing. The class's suite is then executed in a new execution frame (see section *Naming and binding*), using a newly created local namespace and the original global namespace. (Usually, the suite contains only function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. [4] A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.

**Programmer's note:** Variables defined in the class definition are class variables; they are shared by all instances. To create instance variables, they can be set in a method with `self.name = value`. Both class and instance variables are accessible through the notation “`self.name`“, and an instance variable hides a class variable with the same name when accessed in this way. Class variables can be used as defaults for instance variables, but using mutable values there can lead to unexpected results. For *new-style classes*, descriptors can be used to create instance variables with different implementation details.

Class definitions, like function definitions, may be wrapped by one or
more decorator expressions. The evaluation rules for the decorator expressions are the same as for functions. The result must be a class object, which is then bound to the class name.

Footnotes

[1] The exception is propagated to the invocation stack only if there is no finally clause that negates the exception. Currently, control “flows off the end” except in the case of an exception or the execution of a return, continue, or break statement.

[2] A string literal appearing as the first statement in the function body is transformed into the function's __doc__ attribute and therefore the function’s docstring.

[3] A string literal appearing as the first statement in the class body is transformed into the namespace's __doc__ item and therefore the class's docstring.
8. Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.
8.1. Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for `sys` (various system services), `__builtin__` (built-in functions, exceptions and `None`) and `__main__`. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of `__main__`.

Under Unix, a complete program can be passed to the interpreter in three forms: with the `-c string` command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.
8.2. File input

All input read from non-interactive files has the same form:

\[
\text{file_input ::= (NEWLINE | statement)}^*\]

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the `exec` statement;
8.3. Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::= [stmt_list] NEWLINE | compound_stmt NEWLINE
```

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.
8.4. Expression input

There are two forms of expression input. Both ignore leading whitespace. The string argument to `eval()` must have the following form:

```plaintext
eval_input ::= expression_list NEWLINE*
```

The input line read by `input()` must have the following form:

```plaintext
input_input ::= expression_list NEWLINE
```

Note: to read ‘raw’ input line without interpretation, you can use the built-in function `raw_input()` or the `readline()` method of file objects.
9. Full Grammar specification

This is the full Python grammar, as it is read by the parser generator and used to parse Python source files:
1. Introduction

The “Python library” contains several different kinds of components.

It contains data types that would normally be considered part of the “core” of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions — objects that can be used by all Python code without the need of an import statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, such as access to specific hardware; others provide interfaces that are specific to a particular application domain, like the World Wide Web. Some modules are available in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized “from the inside out:” it first describes the built-in data types, then the built-in functions and exceptions, and finally the modules, grouped in chapters of related modules. The
ordering of the chapters as well as the ordering of the modules within each chapter is roughly from most relevant to least important.

This means that if you start reading this manual from the start, and skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don’t have to read it like a novel — you can also browse the table of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module `random`) and read a section or two. Regardless of the order in which you read the sections of this manual, it helps to start with chapter `Built-in Functions`, as the remainder of the manual assumes familiarity with this material.

Let the show begin!
2. Built-in Functions

The Python interpreter has a number of functions built into it that are always available. They are listed here in alphabetical order.

abs(x)
Return the absolute value of a number. The argument may be a plain or long integer or a floating point number. If the argument is a complex number, its magnitude is returned.

all(iterable)
Return True if all elements of the iterable are true (or if the iterable is empty). Equivalent to:

```python
def all(iterable):
    for element in iterable:
        if not element:
            return False
    return True
```

New in version 2.5.

any(iterable)
Return True if any element of the iterable is true. If the iterable is empty, return False. Equivalent to:

```python
def any(iterable):
    for element in iterable:
        if element:
            return True
    return False
```

New in version 2.5.

basestring()
This abstract type is the superclass for str and unicode. It cannot
be called or instantiated, but it can be used to test whether an object is an instance of `str` or `unicode`. `isinstance(obj, basestring)` is equivalent to `isinstance(obj, (str, unicode)).` 

*New in version 2.3.*

**bin(x)**

Convert an integer number to a binary string. The result is a valid Python expression. If `x` is not a Python `int` object, it has to define an `__index__()` method that returns an integer.

*New in version 2.6.*

**bool([x])**

Convert a value to a Boolean, using the standard truth testing procedure. If `x` is false or omitted, this returns `False`; otherwise it returns `True`. `bool` is also a class, which is a subclass of `int`. Class `bool` cannot be subclassed further. Its only instances are `False` and `True`.

*New in version 2.2.1.*

*Changed in version 2.3:* If no argument is given, this function returns `False`.

**callable(object)**

Return `True` if the `object` argument appears callable, `False` if not. If this returns true, it is still possible that a call fails, but if it is false, calling `object` will never succeed. Note that classes are callable (calling a class returns a new instance); class instances are callable if they have a `__call__()` method.

**chr(i)**

Return a string of one character whose ASCII code is the integer
For example, `chr(97)` returns the string `'a'`. This is the inverse of `ord()`. The argument must be in the range `[0..255]`, inclusive; `ValueError` will be raised if `i` is outside that range. See also `unichr()`.

**classmethod(function)**

Return a class method for `function`.

A class method receives the class as implicit first argument, just like an instance method receives the instance. To declare a class method, use this idiom:

```python
class C:
    @classmethod
    def f(cls, arg1, arg2, ...): ...
```

The `@classmethod` form is a function *decorator* — see the description of function definitions in *Function definitions* for details.

It can be called either on the class (such as `c.f()`) or on an instance (such as `c().f()`). The instance is ignored except for its class. If a class method is called for a derived class, the derived class object is passed as the implied first argument.

Class methods are different than C++ or Java static methods. If you want those, see `staticmethod()` in this section.

For more information on class methods, consult the documentation on the standard type hierarchy in *The standard type hierarchy*.

*New in version 2.2.*

*Changed in version 2.4:* Function decorator syntax added.
\texttt{cmp(x, y)}

Compare the two objects \( x \) and \( y \) and return an integer according to the outcome. The return value is negative if \( x < y \), zero if \( x == y \) and strictly positive if \( x > y \).

\texttt{compile(source, filename, mode[, flags[, dont_inherit]])}

Compile the \texttt{source} into a code or AST object. Code objects can be executed by an \texttt{exec} statement or evaluated by a call to \texttt{eval()}. \texttt{source} can either be a string or an AST object. Refer to the \texttt{ast} module documentation for information on how to work with AST objects.

The \texttt{filename} argument should give the file from which the code was read; pass some recognizable value if it wasn’t read from a file (\texttt{'<string>'} is commonly used).

The \texttt{mode} argument specifies what kind of code must be compiled; it can be \texttt{'exec'} if \texttt{source} consists of a sequence of statements, \texttt{'eval'} if it consists of a single expression, or \texttt{'single'} if it consists of a single interactive statement (in the latter case, expression statements that evaluate to something other than \texttt{None} will be printed).

The optional arguments \texttt{flags} and \texttt{dont_inherit} control which future statements (see PEP 236) affect the compilation of \texttt{source}. If neither is present (or both are zero) the code is compiled with those future statements that are in effect in the code that is calling \texttt{compile}. If the \texttt{flags} argument is given and \texttt{dont_inherit} is not (or is zero) then the future statements specified by the \texttt{flags} argument are used in addition to those that would be used anyway. If \texttt{dont_inherit} is a non-zero integer then the \texttt{flags} argument is it – the future statements in effect around the call to \texttt{compile} are ignored.
Future statements are specified by bits which can be bitwise ORed together to specify multiple statements. The bitfield required to specify a given feature can be found as the `compiler_flag` attribute on the `_Feature` instance in the `__future__` module.

This function raises `SyntaxError` if the compiled source is invalid, and `TypeError` if the source contains null bytes.

**Note:** When compiling a string with multi-line code in 'single' or 'eval' mode, input must be terminated by at least one newline character. This is to facilitate detection of incomplete and complete statements in the `code` module.

*Changed in version 2.3:* The `flags` and `dont_inherit` arguments were added.

*Changed in version 2.6:* Support for compiling AST objects.

*Changed in version 2.7:* Allowed use of Windows and Mac newlines. Also input in 'exec' mode does not have to end in a newline anymore.

`complex([real[, imag]])`
Create a complex number with the value `real + imag*j` or convert a string or number to a complex number. If the first parameter is a string, it will be interpreted as a complex number and the function must be called without a second parameter. The second parameter can never be a string. Each argument may be any numeric type (including complex). If `imag` is omitted, it defaults to zero and the function serves as a numeric conversion function like `int()`, `long()` and `float()`. If both arguments are omitted, returns `0j`. 
The complex type is described in *Numeric Types — int, float, long, complex*.

`delattr(object, name)`

This is a relative of `setattr()`. The arguments are an object and a string. The string must be the name of one of the object's attributes. The function deletes the named attribute, provided the object allows it. For example, `delattr(x, 'foobar')` is equivalent to `del x.foobar`.

`dict([arg])`

Create a new data dictionary, optionally with items taken from `arg`. The dictionary type is described in *Mapping Types — dict*.

For other containers see the built in `list`, `set`, and `tuple` classes, and the `collections` module.

`dir([object])`

Without arguments, return the list of names in the current local scope. With an argument, attempt to return a list of valid attributes for that object.

If the object has a method named `_dir__()`, this method will be called and must return the list of attributes. This allows objects that implement a custom `_getattr__()` or `_getattribute__()` function to customize the way `dir()` reports their attributes.

If the object does not provide `_dir__()`, the function tries its best to gather information from the object’s `_dict__` attribute, if defined, and from its type object. The resulting list is not necessarily complete, and may be inaccurate when the object has a custom `_getattr__()`.
The default `dir()` mechanism behaves differently with different types of objects, as it attempts to produce the most relevant, rather than complete, information:

- If the object is a module object, the list contains the names of the module’s attributes.
- If the object is a type or class object, the list contains the names of its attributes, and recursively of the attributes of its bases.
- Otherwise, the list contains the object’s attributes’ names, the names of its class’s attributes, and recursively of the attributes of its class’s base classes.

The resulting list is sorted alphabetically. For example:

```python
>>> import struct
>>> dir()  # doctest: +SKIP
['__builtins__', '__doc__', '__name__', 'struct']
>>> dir(struct)  # doctest: +NORMALIZE_WHITESPACE
['Struct', '__builtins__', '__doc__', '__file__', '__name__', '__package__', '_clearcache', 'calcsize', 'error', 'pack', 'unpack', 'unpack_from']
```

```python
>>> class Foo(object):
...     def __dir__(self):
...         return ['kan', 'ga', 'roo']
...

>>> f = Foo()
>>> dir(f)
['ga', 'kan', 'roo']
```

**Note:** Because `dir()` is supplied primarily as a convenience for use at an interactive prompt, it tries to supply an interesting set of names more than it tries to supply a rigorously or consistently defined set of names, and its detailed behavior may change across releases. For example, metaclass attributes are not in the result list when the argument is a class.

```
divmod(a, b)
```
Take two (non complex) numbers as arguments and return a pair of numbers consisting of their quotient and remainder when using long division. With mixed operand types, the rules for binary arithmetic operators apply. For plain and long integers, the result is the same as $(a \div b, a \mod b)$. For floating point numbers the result is $(q, a \mod b)$, where $q$ is usually \texttt{math.floor}(a / b) but may be 1 less than that. In any case $q \times b + a \mod b$ is very close to $a$, if $a \mod b$ is non-zero it has the same sign as $b$, and $0 \leq \text{abs}(a \mod b) < \text{abs}(b)$.

*Changed in version 2.3:* Using \texttt{divmod()} with complex numbers is deprecated.

\texttt{enumerate(sequence[, start=0])}

Return an enumerate object. \texttt{sequence} must be a sequence, an \texttt{iterator}, or some other object which supports iteration. The \texttt{next()} method of the iterator returned by \texttt{enumerate()} returns a tuple containing a count (from \texttt{start} which defaults to 0) and the corresponding value obtained from iterating over \texttt{iterable}. \texttt{enumerate()} is useful for obtaining an indexed series: $(0, \text{seq}[0]), (1, \text{seq}[1]), (2, \text{seq}[2]), \ldots$ For example:

```python
>>> for i, season in enumerate(['Spring', 'Summer', 'Fall', ...
...     print i, season
0 Spring
1 Summer
2 Fall
3 Winter
```

*New in version 2.3.*

*New in version 2.6:* The \texttt{start} parameter.

\texttt{eval(expression[, globals[, locals]]})
The arguments are a string and optional globals and locals. If provided, *globals* must be a dictionary. If provided, *locals* can be any mapping object.

*Changed in version 2.4:* formerly *locals* was required to be a dictionary.

The *expression* argument is parsed and evaluated as a Python expression (technically speaking, a condition list) using the *globals* and *locals* dictionaries as global and local namespace. If the *globals* dictionary is present and lacks ‘__builtins__’, the current globals are copied into *globals* before *expression* is parsed. This means that *expression* normally has full access to the standard *__builtin__* module and restricted environments are propagated. If the *locals* dictionary is omitted it defaults to the *globals* dictionary. If both dictionaries are omitted, the expression is executed in the environment where *eval()* is called. The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```python
>>> x = 1
>>> print eval('x+1')
2
```

This function can also be used to execute arbitrary code objects (such as those created by *compile()*). In this case pass a code object instead of a string. If the code object has been compiled with *'exec'* as the *mode* argument, *eval()*‘s return value will be *None*.

Hints: dynamic execution of statements is supported by the *exec* statement. Execution of statements from a file is supported by the *execfile()* function. The *globals()* and *locals()* functions returns the current global and local dictionary, respectively, which may be useful to pass around for use by *eval()* or *execfile()*.
execfile(filename[, globals[, locals]])

This function is similar to the exec statement, but parses a file instead of a string. It is different from the import statement in that it does not use the module administration — it reads the file unconditionally and does not create a new module. [1]

The arguments are a file name and two optional dictionaries. The file is parsed and evaluated as a sequence of Python statements (similarly to a module) using the globals and locals dictionaries as global and local namespace. If provided, locals can be any mapping object.

Changed in version 2.4: formerly locals was required to be a dictionary.

If the locals dictionary is omitted it defaults to the globals dictionary. If both dictionaries are omitted, the expression is executed in the environment where execfile() is called. The return value is None.

Note: The default locals act as described for function locals() below: modifications to the default locals dictionary should not be attempted. Pass an explicit locals dictionary if you need to see effects of the code on locals after function execfile() returns. execfile() cannot be used reliably to modify a function’s locals.

file(filename[, mode[, bufsize]])

Constructor function for the file type, described further in section File Objects. The constructor’s arguments are the same as those of the open() built-in function described below.

When opening a file, it’s preferable to use open() instead of
invoking this constructor directly. `file` is more suited to type testing (for example, writing `isinstance(f, file)`).

*New in version 2.2.*

**filter**(function, iterable)

Construct a list from those elements of `iterable` for which `function` returns true. `iterable` may be either a sequence, a container which supports iteration, or an iterator. If `iterable` is a string or a tuple, the result also has that type; otherwise it is always a list. If `function` is `None`, the identity function is assumed, that is, all elements of `iterable` that are false are removed.

Note that `filter(function, iterable)` is equivalent to `[item for item in iterable if function(item)]` if `function` is not `None` and `[item for item in iterable if item]` if `function` is `None`.

See `itertools.ifilterfalse()` for the complementary function that returns elements of `iterable` for which `function` returns false.

**float**([x])

Convert a string or a number to floating point. If the argument is a string, it must contain a possibly signed decimal or floating point number, possibly embedded in whitespace. The argument may also be [+-]nan or [+-]inf. Otherwise, the argument may be a plain or long integer or a floating point number, and a floating point number with the same value (within Python’s floating point precision) is returned. If no argument is given, returns 0.0.

**Note:** When passing in a string, values for NaN and Infinity may be returned, depending on the underlying C library. Float accepts the strings nan, inf and -inf for NaN and positive or negative infinity. The case and a leading + are ignored as well as a leading - is ignored for NaN. Float always represents NaN.
and infinity as nan, inf or -inf.

The float type is described in *Numeric Types — int, float, long, complex*.

**format(value[, format_spec])**

Convert a *value* to a “formatted” representation, as controlled by *format_spec*. The interpretation of *format_spec* will depend on the type of the *value* argument, however there is a standard formatting syntax that is used by most built-in types: *Format Specification Mini-Language*.

**Note:** `format(value, format_spec)` merely calls `value.__format__(format_spec)`.

*New in version 2.6.*

**frozenset([iterable])**

Return a frozenset object, optionally with elements taken from *iterable*. The frozenset type is described in *Set Types — set, frozenset*.

For other containers see the built in *dict, list*, and *tuple* classes, and the *collections* module.

*New in version 2.4.*

**getattr(object, name[, default])**

Return the value of the named attributed of *object*. *name* must be a string. If the string is the name of one of the object's attributes, the result is the value of that attribute. For example, `getattr(x, 'foobar')` is equivalent to `x.foobar`. If the named attribute does not exist, *default* is returned if provided, otherwise *AttributeError* is raised.
globals()
Return a dictionary representing the current global symbol table. This is always the dictionary of the current module (inside a function or method, this is the module where it is defined, not the module from which it is called).

hasattr(object, name)
The arguments are an object and a string. The result is True if the string is the name of one of the object's attributes, False if not. (This is implemented by calling getattr(object, name) and seeing whether it raises an exception or not.)

hash(object)
Return the hash value of the object (if it has one). Hash values are integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, as is the case for 1 and 1.0).

help([object])
Invoke the built-in help system. (This function is intended for interactive use.) If no argument is given, the interactive help system starts on the interpreter console. If the argument is a string, then the string is looked up as the name of a module, function, class, method, keyword, or documentation topic, and a help page is printed on the console. If the argument is any other kind of object, a help page on the object is generated.

This function is added to the built-in namespace by the site module.

New in version 2.2.

hex(x)
Convert an integer number (of any size) to a hexadecimal string. The result is a valid Python expression.

**Note:** To obtain a hexadecimal string representation for a float, use the `float.hex()` method.

*Changed in version 2.4:* Formerly only returned an unsigned literal.

**id**(*object*)

Return the “identity” of an object. This is an integer (or long integer) which is guaranteed to be unique and constant for this object during its lifetime. Two objects with non-overlapping lifetimes may have the same `id()` value.

**CPython implementation detail:** This is the address of the object.

**input**(*prompt*)

Equivalent to `eval(raw_input(prompt))`.

**Warning:** This function is not safe from user errors! It expects a valid Python expression as input; if the input is not syntactically valid, a `SyntaxError` will be raised. Other exceptions may be raised if there is an error during evaluation. (On the other hand, sometimes this is exactly what you need when writing a quick script for expert use.)

If the `readline` module was loaded, then `input()` will use it to provide elaborate line editing and history features.

Consider using the `raw_input()` function for general input from users.
int([x, base])

Convert a string or number to a plain integer. If the argument is a string, it must contain a possibly signed decimal number representable as a Python integer, possibly embedded in whitespace. The base parameter gives the base for the conversion (which is 10 by default) and may be any integer in the range [2, 36], or zero. If base is zero, the proper radix is determined based on the contents of string; the interpretation is the same as for integer literals. (See Numeric literals.) If base is specified and x is not a string, TypeError is raised. Otherwise, the argument may be a plain or long integer or a floating point number. Conversion of floating point numbers to integers truncates (towards zero). If the argument is outside the integer range a long object will be returned instead. If no arguments are given, returns 0.

The integer type is described in Numeric Types — int, float, long, complex.

isinstance(object, classinfo)

Return true if the object argument is an instance of the classinfo argument, or of a (direct or indirect) subclass thereof. Also return true if classinfo is a type object (new-style class) and object is an object of that type or of a (direct or indirect) subclass thereof. If object is not a class instance or an object of the given type, the function always returns false. If classinfo is neither a class object nor a type object, it may be a tuple of class or type objects, or may recursively contain other such tuples (other sequence types are not accepted). If classinfo is not a class, type, or tuple of classes, types, and such tuples, a TypeError exception is raised.

Changed in version 2.2: Support for a tuple of type information was added.
issubclass(class, classinfo)

Return true if class is a subclass (direct or indirect) of classinfo. A class is considered a subclass of itself. classinfo may be a tuple of class objects, in which case every entry in classinfo will be checked. In any other case, a TypeError exception is raised.

Changed in version 2.3: Support for a tuple of type information was added.

iter(o[, sentinel])

Return an iterator object. The first argument is interpreted very differently depending on the presence of the second argument. Without a second argument, o must be a collection object which supports the iteration protocol (the __iter__() method), or it must support the sequence protocol (the __getitem__() method with integer arguments starting at 0). If it does not support either of those protocols, TypeError is raised. If the second argument, sentinel, is given, then o must be a callable object. The iterator created in this case will call o with no arguments for each call to its next() method; if the value returned is equal to sentinel, StopIteration will be raised, otherwise the value will be returned.

One useful application of the second form of iter() is to read lines of a file until a certain line is reached. The following example reads a file until "STOP" is reached:

```python
with open("mydata.txt") as fp:
    for line in iter(fp.readline, "STOP"):  
        process_line(line)
```

New in version 2.2.

len(s)

Return the length (the number of items) of an object. The
argument may be a sequence (string, tuple or list) or a mapping (dictionary).

**list([iterable])**

Return a list whose items are the same and in the same order as iterable's items. iterable may be either a sequence, a container that supports iteration, or an iterator object. If iterable is already a list, a copy is made and returned, similar to iterable[:]. For instance, list('abc') returns ['a', 'b', 'c'] and list( (1, 2, 3) ) returns [1, 2, 3]. If no argument is given, returns a new empty list, [].

list is a mutable sequence type, as documented in *Sequence Types — str, unicode, list, tuple, buffer, xrange*. For other containers see the built in dict, set, and tuple classes, and the collections module.

**locals()**

Update and return a dictionary representing the current local symbol table. Free variables are returned by locals() when it is called in function blocks, but not in class blocks.

**Note:** The contents of this dictionary should not be modified; changes may not affect the values of local and free variables used by the interpreter.

**long([x[, base]])**

Convert a string or number to a long integer. If the argument is a string, it must contain a possibly signed number of arbitrary size, possibly embedded in whitespace. The base argument is interpreted in the same way as for int(), and may only be given when x is a string. Otherwise, the argument may be a plain or long integer or a floating point number, and a long integer with
the same value is returned. Conversion of floating point numbers to integers truncates (towards zero). If no arguments are given, returns 0L.

The long type is described in *Numeric Types — int, float, long, complex*.

**map**(*function*, *iterable*, ...)

Apply *function* to every item of *iterable* and return a list of the results. If additional *iterable* arguments are passed, *function* must take that many arguments and is applied to the items from all iterables in parallel. If one iterable is shorter than another it is assumed to be extended with **None** items. If *function* is **None**, the identity function is assumed; if there are multiple arguments, *map()* returns a list consisting of tuples containing the corresponding items from all iterables (a kind of transpose operation). The *iterable* arguments may be a sequence or any iterable object; the result is always a list.

**max**(*iterable*, [*, args...]*, [*, key]*)

With a single argument *iterable*, return the largest item of a non-empty iterable (such as a string, tuple or list). With more than one argument, return the largest of the arguments.

The optional *key* argument specifies a one-argument ordering function like that used for *list.sort()*. The *key* argument, if supplied, must be in keyword form (for example, *max*(a, b, c, key=func)).

*Changed in version 2.5*: Added support for the optional *key* argument.

**memoryview**(*obj*)

Return a “memory view” object created from the given argument.
See `memoryview` type for more information.

```
min(iterable[, args...[, key]])
```

With a single argument `iterable`, return the smallest item of a non-empty iterable (such as a string, tuple or list). With more than one argument, return the smallest of the arguments.

The optional `key` argument specifies a one-argument ordering function like that used for `list.sort()`. The `key` argument, if supplied, must be in keyword form (for example, `min(a, b, c, key=func)`).

*Changed in version 2.5:* Added support for the optional `key` argument.

```
next(iterator[, default])
```

Retrieve the next item from the `iterator` by calling its `next()` method. If `default` is given, it is returned if the iterator is exhausted, otherwise `StopIteration` is raised.

*New in version 2.6.*

```
object()
```

Return a new featureless object. `object` is a base for all new style classes. It has the methods that are common to all instances of new style classes.

*New in version 2.2.*

*Changed in version 2.3:* This function does not accept any arguments. Formerly, it accepted arguments but ignored them.

```
oct(x)
```

Convert an integer number (of any size) to an octal string. The result is a valid Python expression.
Changed in version 2.4: Formerly only returned an unsigned literal.

open(filename[, mode[, bufsize]])

Open a file, returning an object of the file type described in section File Objects. If the file cannot be opened, IOError is raised. When opening a file, it’s preferable to use open() instead of invoking the file constructor directly.

The first two arguments are the same as for stdio’s fopen(): filename is the file name to be opened, and mode is a string indicating how the file is to be opened.

The most commonly-used values of mode are 'r' for reading, 'w' for writing (truncating the file if it already exists), and 'a' for appending (which on some Unix systems means that all writes append to the end of the file regardless of the current seek position). If mode is omitted, it defaults to 'r'. The default is to use text mode, which may convert '
' characters to a platform-specific representation on writing and back on reading. Thus, when opening a binary file, you should append 'b' to the mode value to open the file in binary mode, which will improve portability. (Appending 'b' is useful even on systems that don’t treat binary and text files differently, where it serves as documentation.) See below for more possible values of mode.

The optional bufsize argument specifies the file’s desired buffer size: 0 means unbuffered, 1 means line buffered, any other positive value means use a buffer of (approximately) that size. A negative bufsize means to use the system default, which is usually line buffered for tty devices and fully buffered for other files. If omitted, the system default is used. [2]

Modes 'r+', 'w+' and 'a+' open the file for updating (note that
'w+' truncates the file). Append 'b' to the mode to open the file in binary mode, on systems that differentiate between binary and text files; on systems that don't have this distinction, adding the 'b' has no effect.

In addition to the standard `fopen()` values `mode` may be 'u' or 'rU'. Python is usually built with universal newline support; supplying 'u' opens the file as a text file, but lines may be terminated by any of the following: the Unix end-of-line convention '\n', the Macintosh convention '\r', or the Windows convention '\r\n'. All of these external representations are seen as '\n' by the Python program. If Python is built without universal newline support a `mode` with 'u' is the same as normal text mode. Note that file objects so opened also have an attribute called `newlines` which has a value of `None` (if no newlines have yet been seen), '\n', '\r', '\r\n', or a tuple containing all the newline types seen.

Python enforces that the mode, after stripping 'u', begins with 'r', 'w' or 'a'.

Python provides many file handling modules including `fileinput`, `os`, `os.path`, `tempfile`, and `shutil`.

*Changed in version 2.5:* Restriction on first letter of mode string introduced.

`ord(c)`

Given a string of length one, return an integer representing the Unicode code point of the character when the argument is a unicode object, or the value of the byte when the argument is an 8-bit string. For example, `ord('a')` returns the integer 97, `ord(u'\u2020')` returns 8224. This is the inverse of `chr()` for 8-bit
strings and of \texttt{unichr()} for unicode objects. If a unicode argument is given and Python was built with UCS2 Unicode, then the character's code point must be in the range \([0..65535]\) inclusive; otherwise the string length is two, and a \texttt{TypeError} will be raised.

\texttt{pow(x, y[, z])}

Return \(x\) to the power \(y\); if \(z\) is present, return \(x\) to the power \(y\), modulo \(z\) (computed more efficiently than \texttt{pow(x, y) \% z}). The two-argument form \texttt{pow(x, y)} is equivalent to using the power operator: \(x**y\).

The arguments must have numeric types. With mixed operand types, the coercion rules for binary arithmetic operators apply. For int and long int operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, \(10**2\) returns \(100\), but \(10**-2\) returns \(0.01\). (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised.) If the second argument is negative, the third argument must be omitted. If \(z\) is present, \(x\) and \(y\) must be of integer types, and \(y\) must be non-negative. (This restriction was added in Python 2.2. In Python 2.1 and before, floating 3-argument \texttt{pow()} returned platform-dependent results depending on floating-point rounding accidents.)

\texttt{print([object, ...][, sep='\t'][, end='\n'][, file=sys.stdout])}

Print \texttt{object(s)} to the stream \texttt{file}, separated by \texttt{sep} and followed by \texttt{end}. \texttt{sep}, \texttt{end} and \texttt{file}, if present, must be given as keyword arguments.
All non-keyword arguments are converted to strings like `str()` does and written to the stream, separated by `sep` and followed by `end`. Both `sep` and `end` must be strings; they can also be `None`, which means to use the default values. If no `object` is given, `print()` will just write `end`.

The `file` argument must be an object with a `write(string)` method; if it is not present or `None`, `sys.stdout` will be used.

**Note:** This function is not normally available as a built-in since the name `print` is recognized as the `print` statement. To disable the statement and use the `print()` function, use this future statement at the top of your module:

```python
from __future__ import print_function
```

*New in version 2.6.*

`property([fget[, fset[, fdel[, doc]]]])`

Return a property attribute for *new-style classes* (classes that derive from `object`).

`fget` is a function for getting an attribute value, likewise `fset` is a function for setting, and `fdel` a function for del'ing, an attribute. Typical use is to define a managed attribute `x`:

```python
class C(object):
    def __init__(self):
        self._x = None

    def getx(self):
        return self._x
    def setx(self, value):
        self._x = value
    def delx(self):
        del self._x
```
If given, doc will be the docstring of the property attribute. Otherwise, the property will copy fget's docstring (if it exists). This makes it possible to create read-only properties easily using `property()` as a decorator:

class Parrot(object):
    def __init__(self):
        self._voltage = 100000

    @property
    def voltage(self):
        """Get the current voltage."""
        return self._voltage

turns the `voltage()` method into a “getter” for a read-only attribute with the same name.

A property object has getter, setter, and deleter methods usable as decorators that create a copy of the property with the corresponding accessor function set to the decorated function. This is best explained with an example:

class C(object):
    def __init__(self):
        self._x = None

    @property
    def x(self):
        """I'm the 'x' property."""
        return self._x

    @x.setter
    def x(self, value):
        self._x = value

    @x.deleter
    def x(self):
        del self._x
This code is exactly equivalent to the first example. Be sure to give the additional functions the same name as the original property (x in this case.)

The returned property also has the attributes \texttt{fget}, \texttt{fset}, and \texttt{fdel} corresponding to the constructor arguments.

\textit{New in version 2.2.}

\textit{Changed in version 2.5: Use fget's docstring if no doc given.}

\textit{Changed in version 2.6: The getter, setter, and deleter attributes were added.}

\textbf{range([start], stop[, step])}

This is a versatile function to create lists containing arithmetic progressions. It is most often used in \texttt{for} loops. The arguments must be plain integers. If the \texttt{step} argument is omitted, it defaults to 1. If the \texttt{start} argument is omitted, it defaults to 0. The full form returns a list of plain integers \([\texttt{start}, \texttt{start} + \texttt{step}, \texttt{start} + 2 \times \texttt{step}, \ldots]\. If \texttt{step} is positive, the last element is the largest \(\texttt{start} + i \times \texttt{step}\) less than \texttt{stop}; if \texttt{step} is negative, the last element is the smallest \(\texttt{start} + i \times \texttt{step}\) greater than \texttt{stop}. \texttt{step} must not be zero (or else \texttt{ValueError} is raised). Example:

```
>>> range(10)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> range(1, 11)
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
>>> range(0, 30, 5)
[0, 5, 10, 15, 20, 25]
>>> range(0, 10, 3)
[0, 3, 6, 9]
>>> range(0, -10, -1)
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
>>> range(0)
[]
```
raw_input([prompt])

If the prompt argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that. When EOF is read, EOFError is raised. Example:

```
>>> s = raw_input('---> ')
   --> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
```

If the readline module was loaded, then raw_input() will use it to provide elaborate line editing and history features.

reduce(function, iterable[, initializer])

Apply function of two arguments cumulatively to the items of iterable, from left to right, so as to reduce the iterable to a single value. For example, reduce(lambda x, y: x+y, [1, 2, 3, 4, 5]) calculates (((((1+2)+3)+4)+5). The left argument, x, is the accumulated value and the right argument, y, is the update value from the iterable. If the optional initializer is present, it is placed before the items of the iterable in the calculation, and serves as a default when the iterable is empty. If initializer is not given and iterable contains only one item, the first item is returned.

reload(module)

Reload a previously imported module. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the module argument).
When `reload(module)` is executed:

- Python modules' code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module’s dictionary. The `init` function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

If a module is syntactically correct but its initialization fails, the first `import` statement for it does not bind its name locally, but does store a (partially initialized) module object in `sys.modules`. To reload the module you must first `import` it again (this will bind the name to the partially initialized module object) before you can `reload()` it.

When a module is reloaded, its dictionary (containing the module’s global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module’s advantage if it maintains a global table or cache of objects — with a `try` statement it can test for the table’s presence and skip its initialization if desired:

```python
try:
    cache
```
It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for `sys`, `__main__` and `__builtin__`. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.*name*`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

`repr(object)`

Return a string containing a printable representation of an object. This is the same value yielded by conversions (reverse quotes). It is sometimes useful to be able to access this operation as an ordinary function. For many types, this function makes an attempt to return a string that would yield an object with the same value when passed to `eval()`, otherwise the representation is a string enclosed in angle brackets that contains the name of the type of the object together with additional information often including the name and address of the object. A class can control what this function returns for its instances by defining a `__repr__()` method.

`reversed(seq)`

Return a reverse `iterator`. `seq` must be an object which has a
**_reversed_**( ) method or supports the sequence protocol (the **_len_**( ) method and the **_getitem_**( ) method with integer arguments starting at 0).

*New in version 2.4.*

*Changed in version 2.6:* Added the possibility to write a custom **_reversed_**( ) method.

**round**( x[, n])

Return the floating point value x rounded to n digits after the decimal point. If n is omitted, it defaults to zero. The result is a floating point number. Values are rounded to the closest multiple of 10 to the power minus n; if two multiples are equally close, rounding is done away from 0 (so, for example, `round(0.5)` is `1.0` and `round(-0.5)` is `-1.0`).

**set**( [ iterable])

Return a new set, optionally with elements taken from iterable. The set type is described in *Set Types — set, frozenset.*

For other containers see the built in dict, list, and tuple classes, and the collections module.

*New in version 2.4.*

**setattr**( object, name, value)

This is the counterpart of **getattr**( ). The arguments are an object, a string and an arbitrary value. The string may name an existing attribute or a new attribute. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

**slice**( [ start], stop[, step])
Return a slice object representing the set of indices specified by `range(start, stop, step)`. The start and step arguments default to None. Slice objects have read-only data attributes start, stop and step which merely return the argument values (or their default). They have no other explicit functionality; however they are used by Numerical Python and other third party extensions. Slice objects are also generated when extended indexing syntax is used. For example: `a[start:stop:step]` or `a[start:stop, i]`. See `itertools.islice()` for an alternate version that returns an iterator.

```
sorted(iterable[, cmp[, key[, reverse]]])
```

Return a new sorted list from the items in iterable.

The optional arguments cmp, key, and reverse have the same meaning as those for the list.sort() method (described in section Mutable Sequence Types).

cmp specifies a custom comparison function of two arguments (iterable elements) which should return a negative, zero or positive number depending on whether the first argument is considered smaller than, equal to, or larger than the second argument: `cmp=lambda x,y: cmp(x.lower(), y.lower())`. The default value is None.

key specifies a function of one argument that is used to extract a comparison key from each list element: `key=functools.lower`. The default value is None (compare the elements directly).

reverse is a boolean value. If set to True, then the list elements are sorted as if each comparison were reversed.

In general, the key and reverse conversion processes are much faster than specifying an equivalent cmp function. This is
because `cmp` is called multiple times for each list element while `key` and `reverse` touch each element only once. Use `functools.cmp_to_key()` to convert an old-style `cmp` function to a `key` function.

For sorting examples and a brief sorting tutorial, see Sorting HowTo.

*New in version 2.4.*

**staticmethod**(function)

Return a static method for `function`.

A static method does not receive an implicit first argument. To declare a static method, use this idiom:

```
class C:
    @staticmethod
    def f(arg1, arg2, ...): ...
```

The `@staticmethod` form is a function *decorator* – see the description of function definitions in *Function definitions* for details.

It can be called either on the class (such as `c.f()`) or on an instance (such as `c().f()`). The instance is ignored except for its class.

Static methods in Python are similar to those found in Java or C++. For a more advanced concept, see `classmethod()` in this section.

For more information on static methods, consult the documentation on the standard type hierarchy in *The standard type hierarchy*. 
New in version 2.2.

Changed in version 2.4: Function decorator syntax added.

`str([object])`

Return a string containing a nicely printable representation of an object. For strings, this returns the string itself. The difference with `repr(object)` is that `str(object)` does not always attempt to return a string that is acceptable to `eval()`; its goal is to return a printable string. If no argument is given, returns the empty string, `'.'`.

For more information on strings see *Sequence Types — str, unicode, list, tuple, buffer, xrange* which describes sequence functionality (strings are sequences), and also the string-specific methods described in the *String Methods* section. To output formatted strings use template strings or the `%` operator described in the *String Formatting Operations* section. In addition see the *String Services* section. See also `unicode()`.

`sum(iterable[, start])`

Sums `start` and the items of an `iterable` from left to right and returns the total. `start` defaults to 0. The `iterable`'s items are normally numbers, and are not allowed to be strings. The fast, correct way to concatenate a sequence of strings is by calling `''.join(sequence)`. Note that `sum(range(n), m)` is equivalent to `reduce(operator.add, range(n), m)`. To add floating point values with extended precision, see `math.fsum()`.

New in version 2.3.

`super(type[, object-or-type])`

Return a proxy object that delegates method calls to a parent or
sibling class of \textit{type}. This is useful for accessing inherited methods that have been overridden in a class. The search order is same as that used by \texttt{getattr()} except that the \textit{type} itself is skipped.

The \texttt{__mro__} attribute of the \textit{type} lists the method resolution search order used by both \texttt{getattr()} and \texttt{super()}. The attribute is dynamic and can change whenever the inheritance hierarchy is updated.

If the second argument is omitted, the super object returned is unbound. If the second argument is an object, \texttt{isinstance(obj, type)} must be true. If the second argument is a type, \texttt{issubclass(type2, type)} must be true (this is useful for classmethods).

\textbf{Note:} \texttt{super()} only works for \textit{new-style classes}.

There are two typical use cases for \texttt{super}. In a class hierarchy with single inheritance, \texttt{super} can be used to refer to parent classes without naming them explicitly, thus making the code more maintainable. This use closely parallels the use of \texttt{super} in other programming languages.

The second use case is to support cooperative multiple inheritance in a dynamic execution environment. This use case is unique to Python and is not found in statically compiled languages or languages that only support single inheritance. This makes it possible to implement “diamond diagrams” where multiple base classes implement the same method. Good design dictates that this method have the same calling signature in every case (because the order of calls is determined at runtime, because that order adapts to changes in the class hierarchy, and because that order can include sibling classes that are unknown
prior to runtime).

For both use cases, a typical superclass call looks like this:

```python
class C(B):
    def method(self, arg):
        super(C, self).method(arg)
```

Note that `super()` is implemented as part of the binding process for explicit dotted attribute lookups such as `super().__getitem__(name)`. It does so by implementing its own `__getattribute__()` method for searching classes in a predictable order that supports cooperative multiple inheritance. Accordingly, `super()` is undefined for implicit lookups using statements or operators such as `super()[name]`.

Also note that `super()` is not limited to use inside methods. The two argument form specifies the arguments exactly and makes the appropriate references.

*New in version 2.2.*

tuple([iterable])

Return a tuple whose items are the same and in the same order as `iterable`'s items. `iterable` may be a sequence, a container that supports iteration, or an iterator object. If `iterable` is already a tuple, it is returned unchanged. For instance, `tuple('abc')` returns ('a', 'b', 'c') and `tuple([1, 2, 3])` returns (1, 2, 3). If no argument is given, returns a new empty tuple, ().

tuple is an immutable sequence type, as documented in *Sequence Types — str, unicode, list, tuple, buffer, xrange*. For other containers see the built in `dict`, `list`, and `set` classes, and the `collections` module.
**type**(*object*)
Return the type of an *object*. The return value is a type object. The *isinstance()* built-in function is recommended for testing the type of an object.

With three arguments, *type()* functions as a constructor as detailed below.

**type**(name, bases, dict)
Return a new type object. This is essentially a dynamic form of the *class* statement. The *name* string is the class name and becomes the *__name__* attribute; the *bases* tuple itemizes the base classes and becomes the *__bases__* attribute; and the *dict* dictionary is the namespace containing definitions for class body and becomes the *__dict__* attribute. For example, the following two statements create identical *type* objects:

```python
>>> class X(object):
...     a = 1
...     ...
>>> X = type('X', (object,), dict(a=1))
```

*New in version 2.2.*

**unichr**(i)
Return the Unicode string of one character whose Unicode code is the integer *i*. For example, *unichr*(97) returns the string u'a'. This is the inverse of *ord()* for Unicode strings. The valid range for the argument depends how Python was configured – it may be either UCS2 [0..0xFFFF] or UCS4 [0..0x10FFFF]. *ValueError* is raised otherwise. For ASCII and 8-bit strings see *chr()*.

*New in version 2.0.*

**unicode**(object[, encoding[, errors]])
Return the Unicode string version of `object` using one of the following modes:

If `encoding` and/or `errors` are given, `unicode()` will decode the object which can either be an 8-bit string or a character buffer using the codec for `encoding`. The `encoding` parameter is a string giving the name of an encoding; if the encoding is not known, `LookupError` is raised. Error handling is done according to `errors`; this specifies the treatment of characters which are invalid in the input encoding. If `errors` is `'strict'` (the default), a `ValueError` is raised on errors, while a value of `'ignore'` causes errors to be silently ignored, and a value of `'replace'` causes the official Unicode replacement character, `U+FFFD`, to be used to replace input characters which cannot be decoded. See also the `codecs` module.

If no optional parameters are given, `unicode()` will mimic the behaviour of `str()` except that it returns Unicode strings instead of 8-bit strings. More precisely, if `object` is a Unicode string or subclass it will return that Unicode string without any additional decoding applied.

For objects which provide a `__unicode__()` method, it will call this method without arguments to create a Unicode string. For all other objects, the 8-bit string version or representation is requested and then converted to a Unicode string using the codec for the default encoding in `'strict'` mode.

For more information on Unicode strings see `Sequence Types — str, unicode, list, tuple, buffer, xrange` which describes sequence functionality (Unicode strings are sequences), and also the string-specific methods described in the `String Methods` section. To output formatted strings use template strings or the `%` operator described in the `String Formatting Operations` section. In addition
see the *String Services* section. See also `str()`.

*New in version 2.0.*

*Changed in version 2.2:* Support for `__unicode__()` added.

**vars([*object*])**

Without an argument, act like `locals()`.

With a module, class or class instance object as argument (or anything else that has a `__dict__` attribute), return that attribute.

**Note:** The returned dictionary should not be modified: the effects on the corresponding symbol table are undefined. [3]

**xrange([*start*, *stop*, *step]*)**

This function is very similar to `range()`, but returns an “xrange object” instead of a list. This is an opaque sequence type which yields the same values as the corresponding list, without actually storing them all simultaneously. The advantage of `xrange()` over `range()` is minimal (since `xrange()` still has to create the values when asked for them) except when a very large range is used on a memory-starved machine or when all of the range's elements are never used (such as when the loop is usually terminated with `break`).

**CPython implementation detail:** `xrange()` is intended to be simple and fast. Implementations may impose restrictions to achieve this. The C implementation of Python restricts all arguments to native C longs (“short” Python integers), and also requires that the number of elements fit in a native C long. If a larger range is needed, an alternate version can be crafted using the `itertools` module: `islice(count(start, step),`
zip([iterable, ...])

This function returns a list of tuples, where the \( i \)-th tuple contains the \( i \)-th element from each of the argument sequences or iterables. The returned list is truncated in length to the length of the shortest argument sequence. When there are multiple arguments which are all of the same length, zip() is similar to map() with an initial argument of None. With a single sequence argument, it returns a list of 1-tuples. With no arguments, it returns an empty list.

The left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into \( n \)-length groups using `zip(*[iter(s)]*n)`.

zip() in conjunction with the `*` operator can be used to unzip a list:

```python
g>>> x = [1, 2, 3]
g>>> y = [4, 5, 6]
g>>> zipped = zip(x, y)
g>>> zipped
[(1, 4), (2, 5), (3, 6)]
g>>> x2, y2 = zip(*zipped)
g>>> x == list(x2) and y == list(y2)
True
```

New in version 2.0.

Changed in version 2.4: Formerly, `zip()` required at least one argument and `zip()` raised a TypeError instead of returning an empty list.

`__import__(name[, globals[, locals[, fromlist[, level]]]])`
Note: This is an advanced function that is not needed in everyday Python programming.

This function is invoked by the import statement. It can be replaced (by importing the __builtin__ module and assigning to __builtin__.__import__) in order to change semantics of the import statement, but nowadays it is usually simpler to use import hooks (see PEP 302). Direct use of __import__() is rare, except in cases where you want to import a module whose name is only known at runtime.

The function imports the module name, potentially using the given globals and locals to determine how to interpret the name in a package context. The fromlist gives the names of objects or submodules that should be imported from the module given by name. The standard implementation does not use its locals argument at all, and uses its globals only to determine the package context of the import statement.

level specifies whether to use absolute or relative imports. The default is -1 which indicates both absolute and relative imports will be attempted. 0 means only perform absolute imports. Positive values for level indicate the number of parent directories to search relative to the directory of the module calling __import__().

When the name variable is of the form package.module, normally, the top-level package (the name up till the first dot) is returned, not the module named by name. However, when a non-empty fromlist argument is given, the module named by name is returned.

For example, the statement import spam results in bytecode resembling the following code:
spam = __import__('spam', globals(), locals(), [], -1)

The statement `import spam.ham` results in this call:

spam = __import__('spam.ham', globals(), locals(), [], -1)

Note how `__import__()` returns the toplevel module here because this is the object that is bound to a name by the `import` statement.

On the other hand, the statement `from spam.ham import eggs, sausage as saus` results in

```python
_temp = __import__('spam.ham', globals(), locals(), ['eggs', 'sausage'], -1)
eggs = _temp.eggs
saus = _temp.sausage
```

Here, the `spam.ham` module is returned from `__import__()`. From this object, the names to import are retrieved and assigned to their respective names.

If you simply want to import a module (potentially within a package) by name, you can call `__import__()` and then look it up in `sys.modules`:

```python
>>> import sys
>>> name = 'foo.bar.baz'
>>> __import__(name)
<module 'foo' from ...>
>>> baz = sys.modules[name]
>>> baz
<module 'foo.bar.baz' from ...>
```

*Changed in version 2.5:* The level parameter was added.

*Changed in version 2.5:* Keyword support for parameters was added.
3. Non-essential Built-in Functions

There are several built-in functions that are no longer essential to learn, know or use in modern Python programming. They have been kept here to maintain backwards compatibility with programs written for older versions of Python.

Python programmers, trainers, students and book writers should feel free to bypass these functions without concerns about missing something important.

**apply**(*function, args[, keywords]*)

The `function` argument must be a callable object (a user-defined or built-in function or method, or a class object) and the `args` argument must be a sequence. The `function` is called with `args` as the argument list; the number of arguments is the length of the tuple. If the optional `keywords` argument is present, it must be a dictionary whose keys are strings. It specifies keyword arguments to be added to the end of the argument list. Calling `apply()` is different from just calling `function(args)`, since in that case there is always exactly one argument. The use of `apply()` is equivalent to `function(*args, **keywords).

* Deprecated since version 2.3: Use the extended call syntax with `*args` and `**keywords` instead.

**buffer**(*object[, offset[, size]])

The `object` argument must be an object that supports the buffer call interface (such as strings, arrays, and buffers). A new buffer object will be created which references the `object` argument. The buffer object will be a slice from the beginning of `object` (or from the specified `offset`). The slice will extend to the end of `object` (or
will have a length given by the size argument).

\textbf{coerce}(x, y)

Return a tuple consisting of the two numeric arguments converted to a common type, using the same rules as used by arithmetic operations. If coercion is not possible, raise \texttt{TypeError}.

\textbf{intern}(string)

Enter \texttt{string} in the table of “interned” strings and return the interned string – which is \texttt{string} itself or a copy. Interning strings is useful to gain a little performance on dictionary lookup – if the keys in a dictionary are interned, and the lookup key is interned, the key comparisons (after hashing) can be done by a pointer compare instead of a string compare. Normally, the names used in Python programs are automatically interned, and the dictionaries used to hold module, class or instance attributes have interned keys.

\textit{Changed in version 2.3:} Interned strings are not immortal (like they used to be in Python 2.2 and before); you must keep a reference to the return value of \texttt{intern()} around to benefit from it.

\textbf{Footnotes}

[1] It is used relatively rarely so does not warrant being made into a statement.

Specifying a buffer size currently has no effect on systems that don’t have \texttt{setvbuf()}. The interface to specify the buffer size is not done using a method that calls \texttt{setvbuf()}, because that may dump core when called after any I/O has been performed, and there’s no reliable way to determine whether this is the case.

In the current implementation, local variable bindings cannot normally be affected this way, but variables retrieved from other scopes (such as modules) can be. This may change.
4. Built-in Constants

A small number of constants live in the built-in namespace. They are:

**False**
The false value of the `bool` type.

*New in version 2.3.*

**True**
The true value of the `bool` type.

*New in version 2.3.*

**None**
The sole value of `types.NoneType`. `None` is frequently used to represent the absence of a value, as when default arguments are not passed to a function.

*Changed in version 2.4:* Assignments to `None` are illegal and raise a `SyntaxError`.

**NotImplemented**
Special value which can be returned by the “rich comparison” special methods (`__eq__()`, `__lt__()`, and friends), to indicate that the comparison is not implemented with respect to the other type.

**Ellipsis**
Special value used in conjunction with extended slicing syntax.

**__debug__**
This constant is true if Python was not started with an `-O` option. Assignments to `__debug__` are illegal and raise a `SyntaxError`. See also the `assert` statement.
4.1. Constants added by the site module

The site module (which is imported automatically during startup, except if the -S command-line option is given) adds several constants to the built-in namespace. They are useful for the interactive interpreter built-in shell and should not be used in programs.

\[
\text{quit}([\text{code}=\text{None}])
\]
\[
\text{exit}([\text{code}=\text{None}])
\]

Objects that when printed, print a message like “Use quit() or Ctrl-D (i.e. EOF) to exit”, and when called, raise SystemExit with the specified exit code.

\[
\text{copyright}
\]
\[
\text{license}
\]
\[
\text{credits}
\]

Objects that when printed, print a message like “Type license() to see the full license text”, and when called, display the corresponding text in a pager-like fashion (one screen at a time).
5. Built-in Types

The following sections describe the standard types that are built into the interpreter.

**Note:** Historically (until release 2.2), Python's built-in types have differed from user-defined types because it was not possible to use the built-in types as the basis for object-oriented inheritance. This limitation no longer exists.

The principal built-in types are numerics, sequences, mappings, files, classes, instances and exceptions.

Some operations are supported by several object types; in particular, practically all objects can be compared, tested for truth value, and converted to a string (with the `repr()` function or the slightly different `str()` function). The latter function is implicitly used when an object is written by the `print()` function.
5.1. Truth Value Testing

Any object can be tested for truth value, for use in an \textbf{if} or \textbf{while} condition or as operand of the Boolean operations below. The following values are considered false:

- \texttt{None}
- \texttt{False}
- zero of any numeric type, for example, \texttt{0}, \texttt{0L}, \texttt{0.0}, \texttt{0j}.
- any empty sequence, for example, '\texttt{''}, \texttt{()}, \texttt{[]}.
- any empty mapping, for example, \texttt{[]}.
- instances of user-defined classes, if the class defines a \underline{\texttt{__nonzero__}}() or \underline{\texttt{__len__}}() method, when that method returns the integer zero or \texttt{bool} value \texttt{False}. [1]

All other values are considered true — so objects of many types are always true.

Operations and built-in functions that have a Boolean result always return \texttt{0} or \texttt{False} for false and \texttt{1} or \texttt{True} for true, unless otherwise stated. (Important exception: the Boolean operations \texttt{or} and \texttt{and} always return one of their operands.)
5.2. Boolean Operations — and, or, not

These are the Boolean operations, ordered by ascending priority:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x or y</td>
<td>if x is false, then y, else x</td>
<td>(1)</td>
</tr>
<tr>
<td>x and y</td>
<td>if x is false, then x, else y</td>
<td>(2)</td>
</tr>
<tr>
<td>not x</td>
<td>if x is false, then True, else False</td>
<td>(3)</td>
</tr>
</tbody>
</table>

Notes:

1. This is a short-circuit operator, so it only evaluates the second argument if the first one is False.
2. This is a short-circuit operator, so it only evaluates the second argument if the first one is True.
3. not has a lower priority than non-Boolean operators, so not a == b is interpreted as not (a == b), and a == not b is a syntax error.
5.3. Comparisons

Comparison operations are supported by all objects. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily; for example, \( x < y \leq z \) is equivalent to \( x < y \) and \( y \leq z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

This table summarizes the comparison operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>strictly less than</td>
<td></td>
</tr>
<tr>
<td>&lt;=</td>
<td>less than or equal</td>
<td></td>
</tr>
<tr>
<td>&gt;</td>
<td>strictly greater than</td>
<td></td>
</tr>
<tr>
<td>&gt;=</td>
<td>greater than or equal</td>
<td></td>
</tr>
<tr>
<td>==</td>
<td>equal</td>
<td></td>
</tr>
<tr>
<td>!=</td>
<td>not equal</td>
<td>(1)</td>
</tr>
<tr>
<td>is</td>
<td>object identity</td>
<td></td>
</tr>
<tr>
<td>is not</td>
<td>negated object identity</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. \( != \) can also be written \( <> \), but this is an obsolete usage kept for backwards compatibility only. New code should always use \( != \).

Objects of different types, except different numeric types and different string types, never compare equal; such objects are ordered consistently but arbitrarily (so that sorting a heterogeneous array yields a consistent result). Furthermore, some types (for example, file objects) support only a degenerate notion of comparison where any two objects of that type are unequal. Again, such objects are ordered arbitrarily but consistently. The \( <, \leq, > \) and \( \geq \) operators will
raise a `TypeError` exception when any operand is a complex number.

Instances of a class normally compare as non-equal unless the class defines the `__cmp__()` method. Refer to `Basic customization` for information on the use of this method to effect object comparisons.

**CPython implementation detail:** Objects of different types except numbers are ordered by their type names; objects of the same types that don’t support proper comparison are ordered by their address.

Two more operations with the same syntactic priority, `in` and `not in`, are supported only by sequence types (below).
5.4. Numeric Types — int, float, long, complex

There are four distinct numeric types: *plain integers, long integers, floating point numbers*, and *complex numbers*. In addition, Booleans are a subtype of plain integers. Plain integers (also just called *integers*) are implemented using *long* in C, which gives them at least 32 bits of precision (*sys.maxint* is always set to the maximum plain integer value for the current platform, the minimum value is \(-sys.maxint-1\)). Long integers have unlimited precision. Floating point numbers are implemented using *double* in C. All bets on their precision are off unless you happen to know the machine you are working with.

Complex numbers have a real and imaginary part, which are each implemented using *double* in C. To extract these parts from a complex number \(z\), use \(z.\text{real}\) and \(z.\text{imag}\).

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including binary, hex, and octal numbers) yield plain integers unless the value they denote is too large to be represented as a plain integer, in which case they yield a long integer. Integer literals with an 'L' or 'l' suffix yield long integers ('L' is preferred because '1l' looks too much like eleven!). Numeric literals containing a decimal point or an exponent sign yield floating point numbers. Appending 'j' or 'J' to a numeric literal yields a complex number with a zero real part. A complex numeric literal is the sum of a real and an imaginary part.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the “narrower” type is widened to that of the other, where plain
integer is narrower than long integer is narrower than floating point is narrower than complex. Comparisons between numbers of mixed type use the same rule. [2] The constructors \texttt{int()}, \texttt{long()}, \texttt{float()}, and \texttt{complex()} can be used to produce numbers of a specific type.

All built-in numeric types support the following operations. See \textit{The power operator} and later sections for the operators’ priorities.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>(x + y)</td>
<td>sum of (x) and (y)</td>
<td></td>
</tr>
<tr>
<td>(x - y)</td>
<td>difference of (x) and (y)</td>
<td></td>
</tr>
<tr>
<td>(x \times y)</td>
<td>product of (x) and (y)</td>
<td></td>
</tr>
<tr>
<td>(x / y)</td>
<td>quotient of (x) and (y)</td>
<td>(1)</td>
</tr>
<tr>
<td>(x \div y)</td>
<td>(floored) quotient of (x) and (y)</td>
<td>(4)(5)</td>
</tr>
<tr>
<td>(x % y)</td>
<td>remainder of (x / y)</td>
<td>(4)</td>
</tr>
<tr>
<td>-(x)</td>
<td>(x) negated</td>
<td></td>
</tr>
<tr>
<td>+(x)</td>
<td>(x) unchanged</td>
<td></td>
</tr>
<tr>
<td>(\text{abs}(x))</td>
<td>absolute value or magnitude of (x)</td>
<td>(3)</td>
</tr>
<tr>
<td>(\text{int}(x))</td>
<td>(x) converted to integer</td>
<td>(2)</td>
</tr>
<tr>
<td>(\text{long}(x))</td>
<td>(x) converted to long integer</td>
<td>(2)</td>
</tr>
<tr>
<td>(\text{float}(x))</td>
<td>(x) converted to floating point</td>
<td>(6)</td>
</tr>
<tr>
<td>(\text{complex}(\text{re,im}))</td>
<td>a complex number with real part (\text{re}), imaginary part (\text{im}). (\text{im}) defaults to zero.</td>
<td></td>
</tr>
<tr>
<td>(c.\text{conjugate}())</td>
<td>conjugate of the complex number (c). (\text{Identity on real numbers})</td>
<td></td>
</tr>
<tr>
<td>(\text{divmod}(x, y))</td>
<td>the pair ((x \div y, x % y))</td>
<td>(3)(4)</td>
</tr>
<tr>
<td>(\text{pow}(x, y))</td>
<td>(x) to the power (y)</td>
<td>(3)(7)</td>
</tr>
<tr>
<td>(x \times y)</td>
<td>(x) to the power (y)</td>
<td>(7)</td>
</tr>
</tbody>
</table>

Notes:

1. For (plain or long) integer division, the result is an integer. The result is always rounded towards minus infinity: \(1/2\) is 0, \((-1)/2\) is
-1, 1/(-2) is -1, and (-1)/(-2) is 0. Note that the result is a long integer if either operand is a long integer, regardless of the numeric value.

2. Conversion from floats using \texttt{int()} or \texttt{long()} truncates toward zero like the related function, \texttt{math.trunc()}. Use the function \texttt{math.floor()} to round downward and \texttt{math.ceil()} to round upward.

3. See \textit{Built-in Functions} for a full description.

4. Complex floor division operator, modulo operator, and \texttt{divmod()}.

\begin{quote}
\textit{Deprecated since version 2.3:} Instead convert to float using \texttt{abs()} if appropriate.
\end{quote}

5. Also referred to as integer division. The resultant value is a whole integer, though the result's type is not necessarily \texttt{int}.

6. \texttt{float} also accepts the strings “nan” and “inf” with an optional prefix “+” or “-” for Not a Number (NaN) and positive or negative infinity.

\textit{New in version 2.6.}

7. Python defines \texttt{pow(0, 0)} and \texttt{0 ** 0} to be 1, as is common for programming languages.

All \texttt{numbers.Real} types (\texttt{int}, \texttt{long}, and \texttt{float}) also include the following operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{math.trunc(x)}</td>
<td>\texttt{x} truncated to Integral</td>
<td></td>
</tr>
<tr>
<td>\texttt{round(x[, n])}</td>
<td>\texttt{x} rounded to \texttt{n} digits, rounding half to even. If \texttt{n} is omitted, it defaults to 0.</td>
<td></td>
</tr>
</tbody>
</table>
math.floor(x)  
the greatest integral float <= x

math.ceil(x)  
the least integral float >= x

### 5.4.1. Bit-string Operations on Integer Types

Plain and long integer types support additional operations that make sense only for bit-strings. Negative numbers are treated as their 2’s complement value (for long integers, this assumes a sufficiently large number of bits that no overflow occurs during the operation).

The priorities of the binary bitwise operations are all lower than the numeric operations and higher than the comparisons; the unary operation ~ has the same priority as the other unary numeric operations (+ and -).

This table lists the bit-string operations sorted in ascending priority:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>y</td>
<td>bitwise or of x and y</td>
</tr>
<tr>
<td>x</td>
<td>(^ y )</td>
<td>bitwise exclusive or of x and y</td>
</tr>
<tr>
<td>x</td>
<td>&amp; y</td>
<td>bitwise and of x and y</td>
</tr>
<tr>
<td>x</td>
<td>&lt;&lt; n</td>
<td>x shifted left by n bits</td>
</tr>
<tr>
<td>x</td>
<td>&gt;&gt; n</td>
<td>x shifted right by n bits</td>
</tr>
<tr>
<td>~x</td>
<td></td>
<td>the bits of x inverted</td>
</tr>
</tbody>
</table>

Notes:

1. Negative shift counts are illegal and cause a ValueError to be raised.
2. A left shift by n bits is equivalent to multiplication by \(\text{pow}(2, n)\). A long integer is returned if the result exceeds the range of plain integers.
3. A right shift by n bits is equivalent to division by \(\text{pow}(2, n)\).
5.4.2. Additional Methods on Integer Types

**int.** `bit_length()`

**long.** `bit_length()`

Return the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros:

```python
>>> n = -37
>>> bin(n)
'-0b100101'
>>> n.bit_length()
6
```

More precisely, if `x` is nonzero, then `x.bit_length()` is the unique positive integer `k` such that `2**(k-1) <= abs(x) < 2**k`. Equivalently, when `abs(x)` is small enough to have a correctly rounded logarithm, then `k = 1 + int(log(abs(x), 2))`. If `x` is zero, then `x.bit_length()` returns 0.

Equivalent to:

```python
def bit_length(self):
    s = bin(self)  # binary representation: bin(-37) -> '-0b100101'
    s = s.lstrip('-0b')  # remove leading zeros and minus sign
    return len(s)  # len('100101') -> 6
```

*New in version 2.7.*

5.4.3. Additional Methods on Float

The float type has some additional methods.

**float.** `as_integer_ratio()`

Return a pair of integers whose ratio is exactly equal to the original float and with a positive denominator. Raises
**OverflowError** on infinities and a **ValueError** on NaNs.

*New in version 2.6.*

Two methods support conversion to and from hexadecimal strings. Since Python's floats are stored internally as binary numbers, converting a float to or from a *decimal* string usually involves a small rounding error. In contrast, hexadecimal strings allow exact representation and specification of floating-point numbers. This can be useful when debugging, and in numerical work.

**float.hex()**

Return a representation of a floating-point number as a hexadecimal string. For finite floating-point numbers, this representation will always include a leading `0x` and a trailing `p` and exponent.

*New in version 2.6.*

**float.fromhex(s)**

Class method to return the float represented by a hexadecimal string `s`. The string `s` may have leading and trailing whitespace.

*New in version 2.6.*

Note that `float.hex()` is an instance method, while `float.fromhex()` is a class method.

A hexadecimal string takes the form:

```
[sign] ['0x'] integer ['.' fraction] ['p' exponent]
```

where the optional `sign` may by either `+` or `-`, `integer` and `fraction` are strings of hexadecimal digits, and `exponent` is a decimal integer with an optional leading sign. Case is not significant, and there must
be at least one hexadecimal digit in either the integer or the fraction. This syntax is similar to the syntax specified in section 6.4.4.2 of the C99 standard, and also to the syntax used in Java 1.5 onwards. In particular, the output of `float.hex()` is usable as a hexadecimal floating-point literal in C or Java code, and hexadecimal strings produced by C's `%a` format character or Java's `Double.toHexString` are accepted by `float.fromhex()`.

Note that the exponent is written in decimal rather than hexadecimal, and that it gives the power of 2 by which to multiply the coefficient. For example, the hexadecimal string `0x3.a7p10` represents the floating-point number $(3 + 10./16 + 7./16**2) * 2.0**10$, or 3740.0:

```python
g>> float.fromhex('0x3.a7p10')
3740.0
```

Applying the reverse conversion to 3740.0 gives a different hexadecimal string representing the same number:

```python
g>> float.hex(3740.0)
'0x1.d380000000000p+11'
```
5.5. Iterator Types

*New in version 2.2.*

Python supports a concept of iteration over containers. This is implemented using two distinct methods; these are used to allow user-defined classes to support iteration. Sequences, described below in more detail, always support the iteration methods.

One method needs to be defined for container objects to provide iteration support:

```python
container.__iter__()
```

Return an iterator object. The object is required to support the iterator protocol described below. If a container supports different types of iteration, additional methods can be provided to specifically request iterators for those iteration types. (An example of an object supporting multiple forms of iteration would be a tree structure which supports both breadth-first and depth-first traversal.) This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

The iterator objects themselves are required to support the following two methods, which together form the *iterator protocol*:

```python
iterator.__iter__()
```

Return the iterator object itself. This is required to allow both containers and iterators to be used with the `for` and `in` statements.

```python
iterator.next()
```

Return the next item from the container. If there are no further items, raise the `StopIteration` exception.
Python defines several iterator objects to support iteration over general and specific sequence types, dictionaries, and other more specialized forms. The specific types are not important beyond their implementation of the iterator protocol.

The intention of the protocol is that once an iterator’s `next()` method raises `StopIteration`, it will continue to do so on subsequent calls. Implementations that do not obey this property are deemed broken. (This constraint was added in Python 2.3; in Python 2.2, various iterators are broken according to this rule.)

### 5.5.1. Generator Types

Python's `generator` objects provide a convenient way to implement the iterator protocol. If a container object’s `__iter__()` method is implemented as a generator, it will automatically return an iterator object (technically, a generator object) supplying the `__iter__()` and `next()` methods. More information about generators can be found in the documentation for the `yield` expression.
There are six sequence types: strings, Unicode strings, lists, tuples, buffers, and xrange objects.

For other containers see the built in `dict` and `set` classes, and the `collections` module.

String literals are written in single or double quotes: 'xyzzy', "frobozz". See String literals for more about string literals. Unicode strings are much like strings, but are specified in the syntax using a preceding \u character: u'abc', u'def'. In addition to the functionality described here, there are also string-specific methods described in the String Methods section. Lists are constructed with square brackets, separating items with commas: [a, b, c]. Tuples are constructed by the comma operator (not within square brackets), with or without enclosing parentheses, but an empty tuple must have the enclosing parentheses, such as a, b, c or (). A single item tuple must have a trailing comma, such as (d,).

Buffer objects are not directly supported by Python syntax, but can be created by calling the built-in function `buffer()`. They don’t support concatenation or repetition.

Objects of type xrange are similar to buffers in that there is no specific syntax to create them, but they are created using the `xrange()` function. They don’t support slicing, concatenation or repetition, and using in, not in, min() or max() on them is inefficient.

Most sequence types support the following operations. The in and
not in operations have the same priorities as the comparison operations. The + and * operations have the same priority as the corresponding numeric operations. Additional methods are provided for *Mutable Sequence Types*.

This table lists the sequence operations sorted in ascending priority (operations in the same box have the same priority). In the table, s and t are sequences of the same type; n, i and j are integers:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x in s</td>
<td><strong>True</strong> if an item of s is equal to x, else <strong>False</strong></td>
<td>(1)</td>
</tr>
<tr>
<td>x not in s</td>
<td><strong>False</strong> if an item of s is equal to x, else <strong>True</strong></td>
<td>(1)</td>
</tr>
<tr>
<td>s + t</td>
<td>the concatenation of s and t</td>
<td>(6)</td>
</tr>
<tr>
<td>s * n, n * s</td>
<td>n shallow copies of s concatenated</td>
<td>(2)</td>
</tr>
<tr>
<td>s[i]</td>
<td>i’th item of s, origin 0</td>
<td>(3)</td>
</tr>
<tr>
<td>s[i:j]</td>
<td>slice of s from i to j</td>
<td>(3)(4)</td>
</tr>
<tr>
<td>s[i:j:k]</td>
<td>slice of s from i to j with step k</td>
<td>(3)(5)</td>
</tr>
<tr>
<td>len(s)</td>
<td>length of s</td>
<td></td>
</tr>
<tr>
<td>min(s)</td>
<td>smallest item of s</td>
<td></td>
</tr>
<tr>
<td>max(s)</td>
<td>largest item of s</td>
<td></td>
</tr>
</tbody>
</table>

Sequence types also support comparisons. In particular, tuples and lists are compared lexicographically by comparing corresponding elements. This means that to compare equal, every element must compare equal and the two sequences must be of the same type and have the same length. (For full details see *Comparisons* in the language reference.)

Notes:

1. When s is a string or Unicode string object the in and not in operations act like a substring test. In Python versions before
2.3, \( x \) had to be a string of length 1. In Python 2.3 and beyond, \( x \) may be a string of any length.

2. Values of \( n \) less than 0 are treated as 0 (which yields an empty sequence of the same type as \( s \)). Note also that the copies are shallow; nested structures are not copied. This often haunts new Python programmers; consider:

```python
>>> lists = [[]] * 3
>>> lists
[[], [], []]
>>> lists[0].append(3)
>>> lists
[[3], [3], [3]]
```

What has happened is that [[]] is a one-element list containing an empty list, so all three elements of [[]] * 3 are (pointers to) this single empty list. Modifying any of the elements of \( \text{lists} \) modifies this single list. You can create a list of different lists this way:

```python
>>> lists = [[] for i in range(3)]
>>> lists[0].append(3)
>>> lists[1].append(5)
>>> lists[2].append(7)
>>> lists
[[3], [5], [7]]
```

3. If \( i \) or \( j \) is negative, the index is relative to the end of the string: \( \text{len}(s) + i \) or \( \text{len}(s) + j \) is substituted. But note that \(-0\) is still 0.

4. The slice of \( s \) from \( i \) to \( j \) is defined as the sequence of items with index \( k \) such that \( i \leq k < j \). If \( i \) or \( j \) is greater than \( \text{len}(s) \), use \( \text{len}(s) \). If \( i \) is omitted or \textbf{None}, use 0. If \( j \) is omitted or \textbf{None}, use \( \text{len}(s) \). If \( i \) is greater than or equal to \( j \), the slice is empty.
5. The slice of \( s \) from \( i \) to \( j \) with step \( k \) is defined as the sequence of items with index \( x = i + n \times k \) such that \( 0 \leq n < (j - i)/k \). In other words, the indices are \( i, i + k, i + 2k, i + 3k \) and so on, stopping when \( j \) is reached (but never including \( j \)). If \( i \) or \( j \) is greater than \( \text{len}(s) \), use \( \text{len}(s) \). If \( i \) or \( j \) are omitted or \( \text{None} \), they become “end” values (which end depends on the sign of \( k \)). Note, \( k \) cannot be zero. If \( k \) is \( \text{None} \), it is treated like \( 1 \).

6. **CPython implementation detail:** If \( s \) and \( t \) are both strings, some Python implementations such as CPython can usually perform an in-place optimization for assignments of the form \( s = s + t \) or \( s += t \). When applicable, this optimization makes quadratic run-time much less likely. This optimization is both version and implementation dependent. For performance sensitive code, it is preferable to use the \( \text{str.join()} \) method which assures consistent linear concatenation performance across versions and implementations.

   *Changed in version 2.4:* Formerly, string concatenation never occurred in-place.

### 5.6.1. String Methods

Below are listed the string methods which both 8-bit strings and Unicode objects support.

In addition, Python’s strings support the sequence type methods described in the *Sequence Types — str, unicode, list, tuple, buffer, xrange* section. To output formatted strings use template strings or the \% operator described in the *String Formatting Operations* section. Also, see the \re\ module for string functions based on regular expressions.
str. **capitalize()**

Return a copy of the string with only its first character capitalized.

For 8-bit strings, this method is locale-dependent.

str. **center(width[, fillchar])**

Return centered in a string of length *width*. Padding is done using the specified *fillchar* (default is a space).

*Changed in version 2.4:* Support for the *fillchar* argument.

str. **count(sub[, start[, end]])**

Return the number of non-overlapping occurrences of substring *sub* in the range *[start, end]*. Optional arguments *start* and *end* are interpreted as in slice notation.

str. **decode([encoding[, errors]])**

Decodes the string using the codec registered for *encoding*. *encoding* defaults to the default string encoding. *errors* may be given to set a different error handling scheme. The default is '*strict*', meaning that encoding errors raise *UnicodeError*. Other possible values are 'ignore', 'replace' and any other name registered via *codecs.register_error()*, see section *Codec Base Classes*.

*New in version 2.2.*

*Changed in version 2.3:* Support for other error handling schemes added.

*Changed in version 2.7:* Support for keyword arguments added.

str. **encode([encoding[, errors]])**

Return an encoded version of the string. Default encoding is the
current default string encoding. \texttt{errors} may be given to set a different error handling scheme. The default for \texttt{errors} is \texttt{'strict'}, meaning that encoding errors raise a \texttt{UnicodeError}. Other possible values are \texttt{'ignore'}, \texttt{'replace'}, \texttt{'xmlcharrefreplace'}, \texttt{'backslashreplace'} and any other name registered via \texttt{codecs.register_error()}, see section \texttt{Codec Base Classes}. For a list of possible encodings, see section \texttt{Standard Encodings}.

\textit{New in version 2.0.}

\textit{Changed in version 2.3:} Support for \texttt{'xmlcharrefreplace'} and \texttt{'backslashreplace'} and other error handling schemes added.

\textit{Changed in version 2.7:} Support for keyword arguments added.

\begin{verbatim}
str.\texttt{endswith}(suffix[, start[, end]])
\end{verbatim}
Return \texttt{True} if the string ends with the specified \texttt{suffix}, otherwise return \texttt{False}. \texttt{suffix} can also be a tuple of suffixes to look for. With optional \texttt{start}, test beginning at that position. With optional \texttt{end}, stop comparing at that position.

\textit{Changed in version 2.5:} Accept tuples as \texttt{suffix}.

\begin{verbatim}
str.\texttt{expandtabs}(\textit{tabsize})
\end{verbatim}
Return a copy of the string where all tab characters are replaced by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. If \texttt{tabsize} is not given, a tab size of 8 characters is assumed. This doesn't understand other non-printing characters or escape sequences.

\begin{verbatim}
str.\texttt{find}(sub[, start[, end]])
\end{verbatim}
Return the lowest index in the string where substring \texttt{sub} is
found, such that *sub* is contained in the slice *s[start:end]*. Optional arguments *start* and *end* are interpreted as in slice notation. Return -1 if *sub* is not found.

**str.format(*args, **kwargs)**

Perform a string formatting operation. The string on which this method is called can contain literal text or replacement fields delimited by braces `{}`. Each replacement field contains either the numeric index of a positional argument, or the name of a keyword argument. Returns a copy of the string where each replacement field is replaced with the string value of the corresponding argument.

```python
>>> "The sum of 1 + 2 is {0}".format(1+2)
'The sum of 1 + 2 is 3'
```

See *Format String Syntax* for a description of the various formatting options that can be specified in format strings.

This method of string formatting is the new standard in Python 3.0, and should be preferred to the `%` formatting described in *String Formatting Operations* in new code.

*New in version 2.6.*

**str.index(*sub[, start[, end]]*)**

Like *find()* but raise *ValueError* when the substring is not found.

**str.isalnum()**

Return true if all characters in the string are alphanumeric and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.
str. **isalpha**()
Return true if all characters in the string are alphabetic and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

str. **isdigit**()
Return true if all characters in the string are digits and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

str. **islower**()
Return true if all cased characters in the string are lowercase and there is at least one cased character, false otherwise.

For 8-bit strings, this method is locale-dependent.

str. **isspace**()
Return true if there are only whitespace characters in the string and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

str. **istitle**()
Return true if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. Return false otherwise.

For 8-bit strings, this method is locale-dependent.

str. **isupper**()
Return true if all cased characters in the string are uppercase and there is at least one cased character, false otherwise.
For 8-bit strings, this method is locale-dependent.

**str. `join(iterable)`**

Return a string which is the concatenation of the strings in the `iterable iterable`. The separator between elements is the string providing this method.

**str. `ljust(width[, fillchar])`**

Return the string left justified in a string of length `width`. Padding is done using the specified `fillchar` (default is a space). The original string is returned if `width` is less than `len(s)`.

*Changed in version 2.4:* Support for the `fillchar` argument.

**str. `lower()`**

Return a copy of the string converted to lowercase.

For 8-bit strings, this method is locale-dependent.

**str. `lstrip([chars])`**

Return a copy of the string with leading characters removed. The `chars` argument is a string specifying the set of characters to be removed. If omitted or `None`, the `chars` argument defaults to removing whitespace. The `chars` argument is not a prefix; rather, all combinations of its values are stripped:

```python
>>> '   spacious   '.lstrip()
'spacious'
>>> 'www.example.com'.lstrip('cmowz.')</p>
'example.com'
```

*Changed in version 2.2.2:* Support for the `chars` argument.

**str. `partition(sep)`**

Split the string at the first occurrence of `sep`, and return a 3-tuple containing the part before the separator, the separator itself, and
the part after the separator. If the separator is not found, return a 3-tuple containing the string itself, followed by two empty strings.

New in version 2.5.

\textbf{str. \texttt{replace}(old, new[, count])}

Return a copy of the string with all occurrences of substring \texttt{old} replaced by \texttt{new}. If the optional argument \texttt{count} is given, only the first \texttt{count} occurrences are replaced.

\textbf{str. \texttt{rfind}(sub[, start[, end]])}

Return the highest index in the string where substring \texttt{sub} is found, such that \texttt{sub} is contained within \texttt{s[start:end]}. Optional arguments \texttt{start} and \texttt{end} are interpreted as in slice notation. Return -1 on failure.

\textbf{str. \texttt{rindex}(sub[, start[, end]])}

Like \texttt{rfind()} but raises \texttt{ValueError} when the substring \texttt{sub} is not found.

\textbf{str. \texttt{rjust}(width[, fillchar])}

Return the string right justified in a string of length \texttt{width}. Padding is done using the specified \texttt{fillchar} (default is a space). The original string is returned if \texttt{width} is less than \texttt{len(s)}.

\emph{Changed in version 2.4:} Support for the \texttt{fillchar} argument.

\textbf{str. \texttt{rpartition}(sep)}

Split the string at the last occurrence of \texttt{sep}, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing two empty strings, followed by the string itself.

New in version 2.5.
str. **rsplit**([sep[, maxsplit]])

Return a list of the words in the string, using sep as the delimiter string. If maxsplit is given, at most maxsplit splits are done, the rightmost ones. If sep is not specified or None, any whitespace string is a separator. Except for splitting from the right, rsplit() behaves like split() which is described in detail below.

*New in version 2.4.*

str. **rstrip**(chars)

Return a copy of the string with trailing characters removed. The chars argument is a string specifying the set of characters to be removed. If omitted or None, the chars argument defaults to removing whitespace. The chars argument is not a suffix; rather, all combinations of its values are stripped:

```python
>>> 'spacious'.rstrip()
'spacious'
>>> 'mississippi'.rstrip('ipz')
'mississ'
```

*Changed in version 2.2.2: Support for the chars argument.*

str. **split**([sep[, maxsplit]])

Return a list of the words in the string, using sep as the delimiter string. If maxsplit is given, at most maxsplit splits are done (thus, the list will have at most maxsplit+1 elements). If maxsplit is not specified, then there is no limit on the number of splits (all possible splits are made).

If sep is given, consecutive delimiters are not grouped together and are deemed to delimit empty strings (for example, '1,,2'.split(',')) returns ['1', '', '2']). The sep argument may consist of multiple characters (for example,
"1<>2<>3".split("<>") returns ['1', '2', '3']). Splitting an empty string with a specified separator returns [''].

If sep is not specified or is None, a different splitting algorithm is applied: runs of consecutive whitespace are regarded as a single separator, and the result will contain no empty strings at the start or end if the string has leading or trailing whitespace. Consequently, splitting an empty string or a string consisting of just whitespace with a None separator returns [].

For example, ' 1 2 3 '.split() returns ['1', '2', '3'], and ' 1 2 3 '.split(None, 1) returns ['1', '2 3 '].

str.splitlines([keepends])
Return a list of the lines in the string, breaking at line boundaries. Line breaks are not included in the resulting list unless keepends is given and true.

str.startswith(prefix[, start[, end]])
Return True if string starts with the prefix, otherwise return False. prefix can also be a tuple of prefixes to look for. With optional start, test string beginning at that position. With optional end, stop comparing string at that position.

Changed in version 2.5: Accept tuples as prefix.

str.strip([chars])
Return a copy of the string with the leading and trailing characters removed. The chars argument is a string specifying the set of characters to be removed. If omitted or None, the chars argument defaults to removing whitespace. The chars argument is not a prefix or suffix; rather, all combinations of its values are stripped:
spacious

'example'

*Changed in version 2.2.2:* Support for the `chars` argument.

**str.swapcase()**

Return a copy of the string with uppercase characters converted to lowercase and vice versa.

For 8-bit strings, this method is locale-dependent.

**str.title()**

Return a titlecased version of the string where words start with an uppercase character and the remaining characters are lowercase.

The algorithm uses a simple language-independent definition of a word as groups of consecutive letters. The definition works in many contexts but it means that apostrophes in contractions and possessives form word boundaries, which may not be the desired result:

```python
>>> "they're bill's friends from the UK".title()
"They'Re Bill'S Friends From The Uk"
```

A workaround for apostrophes can be constructed using regular expressions:

```python
>>> import re
def titlecase(s):
    return re.sub(r"[A-Za-z]+('[A-Za-z]+)?", 
                  lambda mo: mo.group(0)[0].upper() + 
                              mo.group(0)[1:].lower()

>>> titlecase("they're bill's friends.")
"They're Bill's Friends."
```
For 8-bit strings, this method is locale-dependent.

\texttt{str.translate(table[, deletechars])}

Return a copy of the string where all characters occurring in the optional argument \texttt{deletechars} are removed, and the remaining characters have been mapped through the given translation table, which must be a string of length 256.

You can use the \texttt{maketrans()} helper function in the \texttt{string} module to create a translation table. For string objects, set the \texttt{table} argument to \texttt{None} for translations that only delete characters:

\begin{verbatim}
>>> 'read this short text'.translate(None, 'aeiou')
'rd ths shrt txt'
\end{verbatim}

\textit{New in version 2.6:} Support for a \texttt{None} table argument.

For Unicode objects, the \texttt{translate()} method does not accept the optional \texttt{deletechars} argument. Instead, it returns a copy of the \texttt{s} where all characters have been mapped through the given translation table which must be a mapping of Unicode ordinals to Unicode ordinals, Unicode strings or \texttt{None}. Unmapped characters are left untouched. Characters mapped to \texttt{None} are deleted. Note, a more flexible approach is to create a custom character mapping codec using the \texttt{codecs} module (see \texttt{encodings.cp1251} for an example).

\texttt{str.upper()}

Return a copy of the string converted to uppercase.

For 8-bit strings, this method is locale-dependent.

\texttt{str.zfill(width)}

Return the numeric string left filled with zeros in a string of length
width. A sign prefix is handled correctly. The original string is returned if width is less than \texttt{len(s)}.

\textit{New in version 2.2.2.}

The following methods are present only on unicode objects:

\texttt{unicode.isnumeric()}

Return \texttt{True} if there are only numeric characters in \texttt{S}, \texttt{False} otherwise. Numeric characters include digit characters, and all characters that have the Unicode numeric value property, e.g. U+2155, VULGAR FRACTION ONE FIFTH.

\texttt{unicode.isdecimal()}

Return \texttt{True} if there are only decimal characters in \texttt{S}, \texttt{False} otherwise. Decimal characters include digit characters, and all characters that can be used to form decimal-radix numbers, e.g. U+0660, ARABIC-INDIC DIGIT ZERO.

### 5.6.2. String Formatting Operations

String and Unicode objects have one unique built-in operation: the \% operator (modulo). This is also known as the string \textit{formatting} or \textit{interpolation} operator. Given \texttt{format \% values} (where \texttt{format} is a string or Unicode object), \% conversion specifications in \texttt{format} are replaced with zero or more elements of \texttt{values}. The effect is similar to the using \texttt{sprintf()} in the C language. If \texttt{format} is a Unicode object, or if any of the objects being converted using the \texttt{\%s} conversion are Unicode objects, the result will also be a Unicode object.

If \texttt{format} requires a single argument, \texttt{values} may be a single non-tuple object. [4] Otherwise, \texttt{values} must be a tuple with exactly the number of items specified by the format string, or a single mapping
object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The '%\' character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, (somename)).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an '*\' (asterisk), the actual width is read from the next element of the tuple in values, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a '.' (dot) followed by the precision. If specified as '*\' (an asterisk), the actual width is read from the next element of the tuple in values, and the value to convert comes after the precision.
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the string must include a parenthesised mapping key into that dictionary inserted immediately after the '%\' character. The mapping key selects the value to be formatted from the mapping. For example:

```python
>>> print '%(language)s has %(#)03d quote types.' % {
    ...    'language': "Python", "#": 2}
Python has 002 quote types.
```

In this case no * specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:
<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'#'</td>
<td>The value conversion will use the “alternate form” (where defined below).</td>
</tr>
<tr>
<td>'0'</td>
<td>The conversion will be zero padded for numeric values.</td>
</tr>
<tr>
<td>'-'</td>
<td>The converted value is left adjusted (overrides the '0' conversion if both are given).</td>
</tr>
<tr>
<td>' '</td>
<td>(a space) A blank should be left before a positive number (or empty string) produced by a signed conversion.</td>
</tr>
<tr>
<td>'+'</td>
<td>A sign character ('+' or '-' ) will precede the conversion (overrides a “space” flag).</td>
</tr>
</tbody>
</table>

A length modifier (h, l, or L) may be present, but is ignored as it is not necessary for Python – so e.g. %ld is identical to %d.

The conversion types are:

<table>
<thead>
<tr>
<th>Conversion</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'d'</td>
<td>Signed integer decimal.</td>
<td></td>
</tr>
<tr>
<td>'i'</td>
<td>Signed integer decimal.</td>
<td></td>
</tr>
<tr>
<td>'o'</td>
<td>Signed octal value.</td>
<td>(1)</td>
</tr>
<tr>
<td>'u'</td>
<td>Obsolete type – it is identical to 'd'.</td>
<td>(7)</td>
</tr>
<tr>
<td>'x'</td>
<td>Signed hexadecimal (lowercase).</td>
<td>(2)</td>
</tr>
<tr>
<td>'X'</td>
<td>Signed hexadecimal (uppercase).</td>
<td>(2)</td>
</tr>
<tr>
<td>'e'</td>
<td>Floating point exponential format (lowercase).</td>
<td>(3)</td>
</tr>
<tr>
<td>'E'</td>
<td>Floating point exponential format (uppercase).</td>
<td>(3)</td>
</tr>
<tr>
<td>'f'</td>
<td>Floating point decimal format.</td>
<td>(3)</td>
</tr>
<tr>
<td>'F'</td>
<td>Floating point decimal format.</td>
<td>(3)</td>
</tr>
<tr>
<td>'g'</td>
<td>Floating point format. Uses lowercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise.</td>
<td>(4)</td>
</tr>
<tr>
<td>'G'</td>
<td>Floating point format. Uses uppercase exponential format if exponent is less than -4 or not less than precision, decimal format</td>
<td>(4)</td>
</tr>
</tbody>
</table>
otherwise.

<table>
<thead>
<tr>
<th>Conversion</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>'c'</code></td>
<td>Single character (accepts integer or single character string).</td>
</tr>
<tr>
<td><code>'r'</code></td>
<td>String (converts any Python object using <code>repr()</code>). (5)</td>
</tr>
<tr>
<td><code>'s'</code></td>
<td>String (converts any Python object using <code>str()</code>). (6)</td>
</tr>
<tr>
<td><code>'%'</code></td>
<td>No argument is converted, results in a <code>'%'</code> character in the result.</td>
</tr>
</tbody>
</table>

Notes:

1. The alternate form causes a leading zero (`'0'`) to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

2. The alternate form causes a leading `'0x'` or `'0X'` (depending on whether the `'x'` or `'X'` format was used) to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

3. The alternate form causes the result to always contain a decimal point, even if no digits follow it.

   The precision determines the number of digits after the decimal point and defaults to 6.

4. The alternate form causes the result to always contain a decimal point, and trailing zeroes are not removed as they would otherwise be.

   The precision determines the number of significant digits before and after the decimal point and defaults to 6.

5. The `%r` conversion was added in Python 2.0.
The precision determines the maximal number of characters used.

6. If the object or format provided is a `unicode` string, the resulting string will also be `unicode`.

The precision determines the maximal number of characters used.

7. See PEP 237.

Since Python strings have an explicit length, `%s` conversions do not assume that \"\0\" is the end of the string.

Changed in version 2.7: `%f` conversions for numbers whose absolute value is over 1e50 are no longer replaced by `%g` conversions.

Additional string operations are defined in standard modules `string` and `re`.

### 5.6.3. XRange Type

The `xrange` type is an immutable sequence which is commonly used for looping. The advantage of the `xrange` type is that an `xrange` object will always take the same amount of memory, no matter the size of the range it represents. There are no consistent performance advantages.

XRange objects have very little behavior: they only support indexing, iteration, and the `len()` function.

### 5.6.4. Mutable Sequence Types

List objects support additional operations that allow in-place
modification of the object. Other mutable sequence types (when added to the language) should also support these operations. Strings and tuples are immutable sequence types: such objects cannot be modified once created. The following operations are defined on mutable sequence types (where $x$ is an arbitrary object):

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>$s[i] = x$</td>
<td>item $i$ of $s$ is replaced by $x$</td>
<td></td>
</tr>
<tr>
<td>$s[i:j] = t$</td>
<td>slice of $s$ from $i$ to $j$ is replaced by the contents of the iterable $t$</td>
<td></td>
</tr>
<tr>
<td>del $s[i:j]$</td>
<td>same as $s[i:j] = []$</td>
<td></td>
</tr>
<tr>
<td>$s[i:j:k] = t$</td>
<td>the elements of $s[i:j:k]$ are replaced by those of $t$</td>
<td>(1)</td>
</tr>
<tr>
<td>del $s[i:j:k]$</td>
<td>removes the elements of $s[i:j:k]$ from the list</td>
<td></td>
</tr>
<tr>
<td>s.append(x)</td>
<td>same as $s[len(s):len(s)] = [x]$</td>
<td>(2)</td>
</tr>
<tr>
<td>s.extend(x)</td>
<td>same as $s[len(s):len(s)] = x$</td>
<td>(3)</td>
</tr>
<tr>
<td>s.count(x)</td>
<td>return number of $i$'s for which $s[i] == x$</td>
<td></td>
</tr>
<tr>
<td>s.index(x[, i[, j]])</td>
<td>return smallest $k$ such that $s[k] == x$ and $i \leq k &lt; j$</td>
<td>(4)</td>
</tr>
<tr>
<td>s.insert(i, x)</td>
<td>same as $s[i:i] = [x]$</td>
<td>(5)</td>
</tr>
<tr>
<td>s.pop([i])</td>
<td>same as $x = s[i]$; del $s[i]$; return $x$</td>
<td>(6)</td>
</tr>
<tr>
<td>s.remove(x)</td>
<td>same as del $s[s.index(x)]$</td>
<td>(4)</td>
</tr>
<tr>
<td>s.reverse()</td>
<td>reverses the items of $s$ in place</td>
<td>(7)</td>
</tr>
<tr>
<td>s.sort([cmp[, key[, reverse]]])</td>
<td>sort the items of $s$ in place</td>
<td>(7)(8)(9)(10)</td>
</tr>
</tbody>
</table>
Notes:

1. \( t \) must have the same length as the slice it is replacing.

2. The C implementation of Python has historically accepted multiple parameters and implicitly joined them into a tuple; this no longer works in Python 2.0. Use of this misfeature has been deprecated since Python 1.4.

3. \( x \) can be any iterable object.

4. Raises \texttt{ValueError} when \( x \) is not found in \( s \). When a negative index is passed as the second or third parameter to the \texttt{index()} method, the list length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices.

   \textit{Changed in version 2.3}: Previously, \texttt{index()} didn't have arguments for specifying start and stop positions.

5. When a negative index is passed as the first parameter to the \texttt{insert()} method, the list length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices.

   \textit{Changed in version 2.3}: Previously, all negative indices were truncated to zero.

6. The \texttt{pop()} method is only supported by the list and array types. The optional argument \( i \) defaults to \texttt{-1}, so that by default the last item is removed and returned.

7. The \texttt{sort()} and \texttt{reverse()} methods modify the list in place for economy of space when sorting or reversing a large list. To remind you that they operate by side effect, they don't return the sorted or reversed list.

8. The \texttt{sort()} method takes optional arguments for controlling the
comparisons.

cmp specifies a custom comparison function of two arguments (list items) which should return a negative, zero or positive number depending on whether the first argument is considered smaller than, equal to, or larger than the second argument: \( \text{cmp} = \lambda x, y: \text{cmp}(x.\text{lower()}, y.\text{lower()}) \). The default value is None.

key specifies a function of one argument that is used to extract a comparison key from each list element: key=str.lower. The default value is None.

reverse is a boolean value. If set to True, then the list elements are sorted as if each comparison were reversed.

In general, the key and reverse conversion processes are much faster than specifying an equivalent cmp function. This is because cmp is called multiple times for each list element while key and reverse touch each element only once. Use functools.cmp_to_key() to convert an old-style cmp function to a key function.

Changed in version 2.3: Support for None as an equivalent to omitting cmp was added.

Changed in version 2.4: Support for key and reverse was added.

9. Starting with Python 2.3, the sort() method is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal — this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).
10. **CPython implementation detail:** While a list is being sorted, the effect of attempting to mutate, or even inspect, the list is undefined. The C implementation of Python 2.3 and newer makes the list appear empty for the duration, and raises `ValueError` if it can detect that the list has been mutated during a sort.
5.7. Set Types — set, frozenset

A set object is an unordered collection of distinct hashable objects. Common uses include membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference. (For other containers see the built in dict, list, and tuple classes, and the collections module.)

New in version 2.4.

Like other collections, sets support x in set, len(set), and for x in set. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

There are currently two built-in set types, set and frozenset. The set type is mutable — the contents can be changed using methods like add() and remove(). Since it is mutable, it has no hash value and cannot be used as either a dictionary key or as an element of another set. The frozenset type is immutable and hashable — its contents cannot be altered after it is created; it can therefore be used as a dictionary key or as an element of another set.

Non-empty sets (not frozensets) can be created by placing a comma-separated list of elements within braces, for example: {'jack', 'sjoerd'}, in addition to the set constructor.

The constructors for both classes work the same:

```
class set([iterable])
class frozenset([iterable])
```

Return a new set or frozenset object whose elements are taken
from *iterable*. The elements of a set must be hashable. To represent sets of sets, the inner sets must be *frozenset* objects. If *iterable* is not specified, a new empty set is returned.

Instances of *set* and *frozenset* provide the following operations:

**len(s)**
Return the cardinality of set *s*.

**x in s**
Test *x* for membership in *s*.

**x not in s**
Test *x* for non-membership in *s*.

**isdisjoint(other)**
Return True if the set has no elements in common with *other*. Sets are disjoint if and only if their intersection is the empty set.

*New in version 2.6.*

**issubset(other)**

*set <= other*  
Test whether every element in the set is in *other*.

**set < other**  
Test whether the set is a true subset of *other*, that is, *set <= other and set != other*.

**issuperset(other)**

*set >= other*  
Test whether every element in *other* is in the set.

**set > other**  
Test whether the set is a true superset of *other*, that is, *set >= other and set != other*. 
union(other, ...)  
set | other | ...  
Return a new set with elements from the set and all others.

*Changed in version 2.6:* Accepts multiple input iterables.

intersection(other, ...)  
set & other & ...  
Return a new set with elements common to the set and all others.

*Changed in version 2.6:* Accepts multiple input iterables.

difference(other, ...)  
set - other - ...  
Return a new set with elements in the set that are not in the others.

*Changed in version 2.6:* Accepts multiple input iterables.

symmetric_difference(other)  
set ^ other  
Return a new set with elements in either the set or other but not both.

copy()  
Return a new set with a shallow copy of s.

Note, the non-operator versions of `union()`, `intersection()`, `difference()`, and `symmetric_difference()` methods will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `set('abc') & 'cbs'` in favor of the more readable `set('abc').intersection('cbs')`. 
Both `set` and `frozenset` support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

Instances of `set` are compared to instances of `frozenset` based on their members. For example, `set('abc') == frozenset('abc')` returns `True` and so does `set('abc') in set([frozenset('abc')])`. 

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so all of the following return `False`: `a<b`, `a==b`, or `a>b`. Accordingly, sets do not implement the `__cmp__()` method.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

Set elements, like dictionary keys, must be `hashable`.

Binary operations that mix `set` instances with `frozenset` return the type of the first operand. For example: `frozenset('ab') | set('bc')` returns an instance of `frozenset`.

The following table lists operations available for `set` that do not apply to immutable instances of `frozenset`:

```
update(other, ...)  
set | other | ...  
    Update the set, adding elements from all others.
```
Changed in version 2.6: Accepts multiple input iterables.

`intersection_update(other, ...)`

```
set &= other & ...
```

Update the set, keeping only elements found in it and all others.

Changed in version 2.6: Accepts multiple input iterables.

`difference_update(other, ...)`

```
set -= other | ...
```

Update the set, removing elements found in others.

Changed in version 2.6: Accepts multiple input iterables.

`symmetric_difference_update(other)`

```
set ^= other
```

Update the set, keeping only elements found in either set, but not in both.

`add(elem)`

Add element `elem` to the set.

`remove(elem)`

Remove element `elem` from the set. Raises `KeyError` if `elem` is not contained in the set.

`discard(elem)`

Remove element `elem` from the set if it is present.

`pop()`

Remove and return an arbitrary element from the set. Raises `KeyError` if the set is empty.

`clear()`

Remove all elements from the set.
Note, the non-operator versions of the `update()`, `intersection_update()`, `difference_update()`, and `symmetric_difference_update()` methods will accept any iterable as an argument.

Note, the `elem` argument to the `__contains__()`, `remove()`, and `discard()` methods may be a set. To support searching for an equivalent frozenset, the `elem` set is temporarily mutated during the search and then restored. During the search, the `elem` set should not be read or mutated since it does not have a meaningful value.

See also:

*Comparison to the built-in set types*

Differences between the `sets` module and the built-in set types.
5.8. Mapping Types — dict

A mapping object maps hashable values to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the dictionary. (For other containers see the built in list, set, and tuple classes, and the collections module.)

A dictionary's keys are almost arbitrary values. Values that are not hashable, that is, values containing lists, dictionaries or other mutable types (that are compared by value rather than by object identity) may not be used as keys. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (such as 1 and 1.0) then they can be used interchangeably to index the same dictionary entry. (Note however, that since computers store floating-point numbers as approximations it is usually unwise to use them as dictionary keys.)

Dictionaries can be created by placing a comma-separated list of key: value pairs within braces, for example: {'jack': 4098, 'sjoerd': 4127} or {4098: 'jack', 4127: 'sjoerd'}, or by the dict constructor.

```
class dict([arg])
```

Return a new dictionary initialized from an optional positional argument or from a set of keyword arguments. If no arguments are given, return a new empty dictionary. If the positional argument arg is a mapping object, return a dictionary mapping the same keys to the same values as does the mapping object. Otherwise the positional argument must be a sequence, a container that supports iteration, or an iterator object. The elements of the argument must each also be of one of those kinds, and each must in turn contain exactly two objects. The first is used as a key in the new dictionary, and the second as the
key’s value. If a given key is seen more than once, the last value associated with it is retained in the new dictionary.

If keyword arguments are given, the keywords themselves with their associated values are added as items to the dictionary. If a key is specified both in the positional argument and as a keyword argument, the value associated with the keyword is retained in the dictionary. For example, these all return a dictionary equal to \{"one": 2, "two": 3\}:

- `dict(one=2, two=3)`
- `dict({'one': 2, 'two': 3})`
- `dict(zip(('one', 'two'), (2, 3)))`
- `dict([['two', 3], ['one', 2]])`

The first example only works for keys that are valid Python identifiers; the others work with any valid keys.

*New in version 2.2.*

*Changed in version 2.3:* Support for building a dictionary from keyword arguments added.

These are the operations that dictionaries support (and therefore, custom mapping types should support too):

**`len(d)`**

Return the number of items in the dictionary `d`.

**`d[key]`**

Return the item of `d` with key `key`. Raises a `KeyError` if `key` is not in the map.

*New in version 2.5:* If a subclass of `dict` defines a method `__missing__(())`, if the key `key` is not present, the `d[key]` operation calls that method with the key `key` as argument. The
d[key] operation then returns or raises whatever is returned or raised by the `__missing__(key)` call if the key is not present. No other operations or methods invoke `__missing__()`. If `__missing__()` is not defined, `KeyError` is raised. `__missing__()` must be a method; it cannot be an instance variable. For an example, see `collections.defaultdict`.

```
d[key] = value
```
Set `d[key]` to `value`.

```
del d[key]
```
Remove `d[key]` from `d`. Raises a `KeyError` if `key` is not in the map.

```
key in d
```
Return `True` if `d` has a key `key`, else `False`.

*New in version 2.2.*

```
key not in d
```
Equivalent to `not key in d`.

*New in version 2.2.*

```
iter(d)
```
Return an iterator over the keys of the dictionary. This is a shortcut for `iterkeys()`.

```
clear()
```
Remove all items from the dictionary.

```
copy()
```
Return a shallow copy of the dictionary.

```
fromkeys(seq[, value])
```

Create a new dictionary with keys from seq and values set to value.

`fromkeys()` is a class method that returns a new dictionary. value defaults to None.

*New in version 2.3.*

**get(key[, default])**
Return the value for key if key is in the dictionary, else default. If default is not given, it defaults to None, so that this method never raises a KeyError.

**has_key(key)**
Test for the presence of key in the dictionary. `has_key()` is deprecated in favor of `key in d`.

**items()**
Return a copy of the dictionary's list of (key, value) pairs.

**CPython implementation detail:** Keys and values are listed in an arbitrary order which is non-random, varies across Python implementations, and depends on the dictionary's history of insertions and deletions.

If `items()`, `keys()`, `values()`, `iteritems()`, `iterkeys()`, and `itervalues()` are called with no intervening modifications to the dictionary, the lists will directly correspond. This allows the creation of (value, key) pairs using `zip()`: `pairs = zip(d.values(), d.keys())`. The same relationship holds for the `iterkeys()` and `itervalues()` methods: `pairs = zip(d.itervalues(), d.iterkeys())` provides the same value for `pairs`. Another way to create the same list is `pairs = [(v,
for (k, v) in d.iteritems()]

iteritems()  
Return an iterator over the dictionary's (key, value) pairs.  
See the note for dict.items().

Using iteritems() while adding or deleting entries in the dictionary may raise a RuntimeError or fail to iterate over all entries.

New in version 2.2.

iterkeys()  
Return an iterator over the dictionary's keys. See the note for dict.items().

Using iterkeys() while adding or deleting entries in the dictionary may raise a RuntimeError or fail to iterate over all entries.

New in version 2.2.

itervalues()  
Return an iterator over the dictionary's values. See the note for dict.items().

Using itervalues() while adding or deleting entries in the dictionary may raise a RuntimeError or fail to iterate over all entries.

New in version 2.2.

keys()  
Return a copy of the dictionary's list of keys. See the note for
dict.items().

**pop(key[, default])**
If `key` is in the dictionary, remove it and return its value, else return `default`. If `default` is not given and `key` is not in the dictionary, a `KeyError` is raised.

*New in version 2.3.*

**popitem()**
Remove and return an arbitrary `(key, value)` pair from the dictionary.

`popitem()` is useful to destructively iterate over a dictionary, as often used in set algorithms. If the dictionary is empty, calling `popitem()` raises a `KeyError`.

**setdefault(key[, default])**
If `key` is in the dictionary, return its value. If not, insert `key` with a value of `default` and return `default`. `default` defaults to `None`.

**update([other])**
Update the dictionary with the key/value pairs from `other`, overwriting existing keys. Return `None`.

`update()` accepts either another dictionary object or an iterable of key/value pairs (as a tuple or other iterable of length two). If keyword arguments are specified, the dictionary is then updated with those key/value pairs: `d.update(red=1, blue=2)`.

*Changed in version 2.4:* Allowed the argument to be an iterable of key/value pairs and allowed keyword arguments.
values()
  Return a copy of the dictionary’s list of values. See the note for dict.items().

viewitems()
  Return a new view of the dictionary’s items ((key, value) pairs). See below for documentation of view objects.

  New in version 2.7.

viewkeys()
  Return a new view of the dictionary’s keys. See below for documentation of view objects.

  New in version 2.7.

viewvalues()
  Return a new view of the dictionary’s values. See below for documentation of view objects.

  New in version 2.7.

5.8.1. Dictionary view objects

The objects returned by dict.viewkeys(), dict.viewvalues() and dict.viewitems() are view objects. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes.

Dictionary views can be iterated over to yield their respective data, and support membership tests:

len(dictview)
  Return the number of entries in the dictionary.

iter(dictview)
Return an iterator over the keys, values or items (represented as tuples of (key, value)) in the dictionary.

Keys and values are iterated over in an arbitrary order which is non-random, varies across Python implementations, and depends on the dictionary’s history of insertions and deletions. If keys, values and items views are iterated over with no intervening modifications to the dictionary, the order of items will directly correspond. This allows the creation of (value, key) pairs using zip(): pairs = zip(d.values(), d.keys()). Another way to create the same list is pairs = [(v, k) for (k, v) in d.items()].

Iterating views while adding or deleting entries in the dictionary may raise a `RuntimeError` or fail to iterate over all entries.

```
x in dictview
```

Return `True` if `x` is in the underlying dictionary's keys, values or items (in the latter case, `x` should be a (key, value) tuple).

Keys views are set-like since their entries are unique and hashable. If all values are hashable, so that (key, value) pairs are unique and hashable, then the items view is also set-like. (Values views are not treated as set-like since the entries are generally not unique.) Then these set operations are available (“other” refers either to another view or a set):

```
dictview & other
```

Return the intersection of the dictview and the other object as a new set.

```
dictview | other
```

Return the union of the dictview and the other object as a new set.
**dictview - other**

Return the difference between the dictview and the other object (all elements in *dictview* that aren't in *other*) as a new set.

**dictview ^ other**

Return the symmetric difference (all elements either in *dictview* or *other*, but not in both) of the dictview and the other object as a new set.

An example of dictionary view usage:

```python
>>> dishes = {'eggs': 2, 'sausage': 1, 'bacon': 1, 'spam': 500}
>>> keys = dishes.viewkeys()
>>> values = dishes.viewvalues()

>>> # iteration
>>> n = 0
>>> for val in values:
...    n += val
>>> print(n)
504

>>> # keys and values are iterated over in the same order
>>> list(keys)
['eggs', 'bacon', 'sausage', 'spam']
>>> list(values)
[2, 1, 1, 500]

>>> # view objects are dynamic and reflect dict changes
>>> del dishes['eggs']
>>> del dishes['sausage']
>>> list(keys)
['spam', 'bacon']

>>> # set operations
>>> keys & {'eggs', 'bacon', 'salad'}
{'bacon'}
```
5.9. File Objects

File objects are implemented using C’s `stdio` package and can be created with the built-in `open()` function. File objects are also returned by some other built-in functions and methods, such as `os.popen()` and `os.fdopen()` and the `makefile()` method of socket objects. Temporary files can be created using the `tempfile` module, and high-level file operations such as copying, moving, and deleting files and directories can be achieved with the `shutil` module.

When a file operation fails for an I/O-related reason, the exception `IOError` is raised. This includes situations where the operation is not defined for some reason, like `seek()` on a tty device or writing a file opened for reading.

Files have the following methods:

```python
file.close()
```

Close the file. A closed file cannot be read or written any more. Any operation which requires that the file be open will raise a `ValueError` after the file has been closed. Calling `close()` more than once is allowed.

As of Python 2.5, you can avoid having to call this method explicitly if you use the `with` statement. For example, the following code will automatically close `f` when the `with` block is exited:

```python
from __future__ import with_statement # This isn't required

with open("hello.txt") as f:
    for line in f:
        print line
```
In older versions of Python, you would have needed to do this to get the same effect:

```python
def open("hello.txt")
try:
    for line in f:
        print line
finally:
    f.close()
```

**Note:** Not all “file-like” types in Python support use as a context manager for the `with` statement. If your code is intended to work with any file-like object, you can use the function `contextlib.closing()` instead of using the object directly.

**file.**`flush()`
Flush the internal buffer, like `stdio's` `fflush()`. This may be a noop on some file-like objects.

**Note:** `flush()` does not necessarily write the file’s data to disk. Use `flush()` followed by `os.fsync()` to ensure this behavior.

**file.**`fileno()`
Return the integer “file descriptor” that is used by the underlying implementation to request I/O operations from the operating system. This can be useful for other, lower level interfaces that use file descriptors, such as the `fcntl` module or `os.read()` and friends.

**Note:** File-like objects which do not have a real file descriptor should not provide this method!
Return `True` if the file is connected to a tty(-like) device, else `False`.

**Note:** If a file-like object is not associated with a real file, this method should *not* be implemented.

```python
file.next()
```

A file object is its own iterator, for example `iter(f)` returns `f` (unless `f` is closed). When a file is used as an iterator, typically in a `for` loop (for example, `for line in f: print line`), the `next()` method is called repeatedly. This method returns the next input line, or raises `StopIteration` when EOF is hit when the file is open for reading (behavior is undefined when the file is open for writing). In order to make a `for` loop the most efficient way of looping over the lines of a file (a very common operation), the `next()` method uses a hidden read-ahead buffer. As a consequence of using a read-ahead buffer, combining `next()` with other file methods (like `readline()`) does not work right. However, using `seek()` to reposition the file to an absolute position will flush the read-ahead buffer.

*New in version 2.3.*

```python
file.read([size])
```

Read at most `size` bytes from the file (less if the read hits EOF before obtaining `size` bytes). If the `size` argument is negative or omitted, read all data until EOF is reached. The bytes are returned as a string object. An empty string is returned when EOF is encountered immediately. (For certain files, like ttys, it makes sense to continue reading after an EOF is hit.) Note that this method may call the underlying C function `fread()` more than once in an effort to acquire as close to `size` bytes as possible. Also note that when in non-blocking mode, less data than was
requested may be returned, even if no size parameter was given.

**Note:** This function is simply a wrapper for the underlying fread() C function, and will behave the same in corner cases, such as whether the EOF value is cached.

**file.readline([size])**
Read one entire line from the file. A trailing newline character is kept in the string (but may be absent when a file ends with an incomplete line). [5] If the size argument is present and non-negative, it is a maximum byte count (including the trailing newline) and an incomplete line may be returned. An empty string is returned only when EOF is encountered immediately.

**Note:** Unlike stdio's fgets(), the returned string contains null characters ('\0') if they occurred in the input.

**file.readlines([sizehint])**
Read until EOF using readline() and return a list containing the lines thus read. If the optional sizehint argument is present, instead of reading up to EOF, whole lines totalling approximately sizehint bytes (possibly after rounding up to an internal buffer size) are read. Objects implementing a file-like interface may choose to ignore sizehint if it cannot be implemented, or cannot be implemented efficiently.

**file.xreadlines()**
This method returns the same thing as iter(f).

*New in version 2.1.*

*Deprecated since version 2.3: Use for line in file instead.*
file.seek(offset[, whence])

Set the file's current position, like stdio's fseek(). The whence argument is optional and defaults to os.SEEK_SET or 0 (absolute file positioning); other values are os.SEEK_CUR or 1 (seek relative to the current position) and os.SEEK_END or 2 (seek relative to the file's end). There is no return value.

For example, f.seek(2, os.SEEK_CUR) advances the position by two and f.seek(-3, os.SEEK_END) sets the position to the third to last.

Note that if the file is opened for appending (mode 'a' or 'a+'), any seek() operations will be undone at the next write. If the file is only opened for writing in append mode (mode 'a'), this method is essentially a no-op, but it remains useful for files opened in append mode with reading enabled (mode 'a+'). If the file is opened in text mode (without 'b'), only offsets returned by tell() are legal. Use of other offsets causes undefined behavior.

Note that not all file objects are seekable.

*Changed in version 2.6:* Passing float values as offset has been deprecated.

file.tell()

Return the file's current position, like stdio's ftell().

**Note:** On Windows, tell() can return illegal values (after an fgets()) when reading files with Unix-style line-endings. Use binary mode ('rb') to circumvent this problem.

file.truncate([size])
Truncate the file's size. If the optional size argument is present, the file is truncated to (at most) that size. The size defaults to the current position. The current file position is not changed. Note that if a specified size exceeds the file's current size, the result is platform-dependent: possibilities include that the file may remain unchanged, increase to the specified size as if zero-filled, or increase to the specified size with undefined new content. Availability: Windows, many Unix variants.

file.write(str)
Write a string to the file. There is no return value. Due to buffering, the string may not actually show up in the file until the flush() or close() method is called.

file.writelines(sequence)
Write a sequence of strings to the file. The sequence can be any iterable object producing strings, typically a list of strings. There is no return value. (The name is intended to match readlines(); writelines() does not add line separators.)

Files support the iterator protocol. Each iteration returns the same result as file.readline(), and iteration ends when the readline() method returns an empty string.

File objects also offer a number of other interesting attributes. These are not required for file-like objects, but should be implemented if they make sense for the particular object.

file.closed
bool indicating the current state of the file object. This is a read-only attribute; the close() method changes the value. It may not be available on all file-like objects.

file.encoding
The encoding that this file uses. When Unicode strings are
written to a file, they will be converted to byte strings using this encoding. In addition, when the file is connected to a terminal, the attribute gives the encoding that the terminal is likely to use (that information might be incorrect if the user has misconfigured the terminal). The attribute is read-only and may not be present on all file-like objects. It may also be **None**, in which case the file uses the system default encoding for converting Unicode strings.

*New in version 2.3.*

**file.errors**

The Unicode error handler used along with the encoding.

*New in version 2.6.*

**file.mode**

The I/O mode for the file. If the file was created using the `open()` built-in function, this will be the value of the `mode` parameter. This is a read-only attribute and may not be present on all file-like objects.

**file.name**

If the file object was created using `open()`, the name of the file. Otherwise, some string that indicates the source of the file object, of the form `<...>`. This is a read-only attribute and may not be present on all file-like objects.

**file.newlines**

If Python was built with the `--with-universal-newlines` option to `configure` (the default) this read-only attribute exists, and for files opened in universal newline read mode it keeps track of the types of newlines encountered while reading the file. The values it can take are `'\r'`, `'\n'`, `'\r\n'`, **None** (unknown, no newlines read yet) or a tuple containing all the newline types seen, to indicate that multiple newline conventions were encountered. For files not
opened in universal newline read mode the value of this attribute will be `None`.

`file.softspace`

Boolean that indicates whether a space character needs to be printed before another value when using the `print` statement. Classes that are trying to simulate a file object should also have a writable `softspace` attribute, which should be initialized to zero. This will be automatic for most classes implemented in Python (care may be needed for objects that override attribute access); types implemented in C will have to provide a writable `softspace` attribute.

**Note:** This attribute is not used to control the `print` statement, but to allow the implementation of `print` to keep track of its internal state.
5.10. memoryview type

memoryview objects allow Python code to access the internal data of an object that supports the buffer protocol without copying. Memory is generally interpreted as simple bytes.

```python
class memoryview(obj)
Create a memoryview that references obj. obj must support the buffer protocol. Built-in objects that support the buffer protocol include str and bytearray (but not unicode).

len(view) returns the total number of bytes in the memoryview, view.

A memoryview supports slicing to expose its data. Taking a single index will return a single byte. Full slicing will result in a subview:

```python
>>> v = memoryview('abcefg')
>>> v[1]
'b'
>>> v[-1]
'g'
>>> v[1:4]
<memory at 0x77ab28>
>>> str(v[1:4])
'bce'
>>> v[3:-1]
<memory at 0x744f18>
>>> str(v[4:-1])
'f'
```

If the object the memoryview is over supports changing its data, the memoryview supports slice assignment:

```python
>>> data = bytearray('abcefg')
>>> v = memoryview(data)
>>> v.readonly
False
```
Notice how the size of the memoryview object cannot be changed.

memoryview has two methods:

tobytes()
Return the data in the buffer as a bytestring (an object of class str).

tolist()
Return the data in the buffer as a list of integers.

>>> memoryview(b'abc').tolist()
[97, 98, 99]

There are also several readonly attributes available:

format
A string containing the format (in struct module style) for each element in the view. This defaults to 'B', a simple bytestring.

itemsize
The size in bytes of each element of the memoryview.

shape
A tuple of integers the length of ndim giving the shape of the memory as a N-dimensional array.
**ndim**

An integer indicating how many dimensions of a multi-dimensional array the memory represents.

**strides**

A tuple of integers the length of `ndim` giving the size in bytes to access each element for each dimension of the array.
5.11. Context Manager Types

New in version 2.5.

Python's `with` statement supports the concept of a runtime context defined by a context manager. This is implemented using two separate methods that allow user-defined classes to define a runtime context that is entered before the statement body is executed and exited when the statement ends.

The context management protocol consists of a pair of methods that need to be provided for a context manager object to define a runtime context:

```python
contextmanager.__enter__()
```

Enter the runtime context and return either this object or another object related to the runtime context. The value returned by this method is bound to the identifier in the `as` clause of `with` statements using this context manager.

An example of a context manager that returns itself is a file object. File objects return themselves from `__enter__()` to allow `open()` to be used as the context expression in a `with` statement.

An example of a context manager that returns a related object is the one returned by `decimal.localcontext()`. These managers set the active decimal context to a copy of the original decimal context and then return the copy. This allows changes to be made to the current decimal context in the body of the `with` statement without affecting code outside the `with` statement.

```python
contextmanager.__exit__(exc_type, exc_val, exc_tb)
```

Exit the runtime context and return a Boolean flag indicating if
any exception that occurred should be suppressed. If an exception occurred while executing the body of the `with` statement, the arguments contain the exception type, value and traceback information. Otherwise, all three arguments are `None`.

Returning a true value from this method will cause the `with` statement to suppress the exception and continue execution with the statement immediately following the `with` statement. Otherwise the exception continues propagating after this method has finished executing. Exceptions that occur during execution of this method will replace any exception that occurred in the body of the `with` statement.

The exception passed in should never be reraised explicitly - instead, this method should return a false value to indicate that the method completed successfully and does not want to suppress the raised exception. This allows context management code (such as `contextlib.nested`) to easily detect whether or not an `__exit__()` method has actually failed.

Python defines several context managers to support easy thread synchronisation, prompt closure of files or other objects, and simpler manipulation of the active decimal arithmetic context. The specific types are not treated specially beyond their implementation of the context management protocol. See the `contextlib` module for some examples.

Python's `generators` and the `contextlib.contextmanager` `decorator` provide a convenient way to implement these protocols. If a generator function is decorated with the `contextlib.contextmanager` decorator, it will return a context manager implementing the necessary `__enter__()` and `__exit__()` methods, rather than the iterator produced by an undecorated generator function.
Extension types wanting to define these methods must provide them as a normal Python accessible method. Compared to the overhead of setting up the runtime context, the overhead of a single class dictionary lookup is negligible.
5.12. Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

5.12.1. Modules

The only special operation on a module is attribute access: `m.name`, where `m` is a module and `name` accesses a name defined in `m`'s symbol table. Module attributes can be assigned to. (Note that the `import` statement is not, strictly speaking, an operation on a module object; `import foo` does not require a module object named `foo` to exist, rather it requires an (external) definition for a module named `foo` somewhere.)

A special member of every module is `__dict__`. This is the dictionary containing the module’s symbol table. Modifying this dictionary will actually change the module’s symbol table, but direct assignment to the `__dict__` attribute is not possible (you can write `m.__dict__['a'] = 1`, which defines `m.a` to be 1, but you can’t write `m.__dict__ = {}`). Modifying `__dict__` directly is not recommended.

Modules built into the interpreter are written like this: `<module 'sys' (built-in)>`. If loaded from a file, they are written as `<module 'os' from '/usr/local/lib/pythonX.Y/os.pyc'>`.

5.12.2. Classes and Class Instances

See *Objects, values and types* and *Class definitions* for these.

5.12.3. Functions
Function objects are created by function definitions. The only operation on a function object is to call it: `func(argument-list)`.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

See *Function definitions* for more information.

## 5.12.4. Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as `append()` on lists) and class instance methods. Built-in methods are described with the types that support them.

The implementation adds two special read-only attributes to class instance methods: `m.im_self` is the object on which the method operates, and `m.im_func` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.im_func(m.im_self, arg-1, arg-2, ..., arg-n)`.

Class instance methods are either *bound* or *unbound*, referring to whether the method was accessed through an instance or a class, respectively. When a method is unbound, its `im_self` attribute will be `None` and if called, an explicit `self` object must be passed as the first argument. In this case, `self` must be an instance of the unbound method’s class (or a subclass of that class), otherwise a `TypeError` is raised.

Like function objects, methods objects support getting arbitrary attributes. However, since method attributes are actually stored on the underlying function object (`meth.im_func`), setting method
attributes on either bound or unbound methods is disallowed. Attempting to set a method attribute results in a TypeError being raised. In order to set a method attribute, you need to explicitly set it on the underlying function object:

```python
class C:
    def method(self):
        pass

c = C()
c.method.im_func.whoami = 'my name is c'
```

See The standard type hierarchy for more information.

### 5.12.5. Code Objects

Code objects are used by the implementation to represent “pseudo-compiled” executable Python code such as a function body. They differ from function objects because they don’t contain a reference to their global execution environment. Code objects are returned by the built-in `compile()` function and can be extracted from function objects through their `func_code` attribute. See also the `code` module.

A code object can be executed or evaluated by passing it (instead of a source string) to the `exec` statement or the built-in `eval()` function.

See The standard type hierarchy for more information.

### 5.12.6. Type Objects

Type objects represent the various object types. An object’s type is accessed by the built-in function `type()`. There are no special operations on types. The standard module `types` defines names for all standard built-in types.
Types are written like this: `<type 'int'>`.

5.12.7. The Null Object

This object is returned by functions that don't explicitly return a value. It supports no special operations. There is exactly one null object, named `None` (a built-in name).

It is written as `None`.

5.12.8. The Ellipsis Object

This object is used by extended slice notation (see `Slicings`). It supports no special operations. There is exactly one ellipsis object, named `Ellipsis` (a built-in name).

It is written as `Ellipsis`.

5.12.9. Boolean Values

Boolean values are the two constant objects `False` and `True`. They are used to represent truth values (although other values can also be considered false or true). In numeric contexts (for example when used as the argument to an arithmetic operator), they behave like the integers 0 and 1, respectively. The built-in function `bool()` can be used to cast any value to a Boolean, if the value can be interpreted as a truth value (see section Truth Value Testing above).

They are written as `False` and `True`, respectively.

5.12.10. Internal Objects

See `The standard type hierarchy` for this information. It describes stack frame objects, traceback objects, and slice objects.
5.13. Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant. Some of these are not reported by the \texttt{dir()} built-in function.

\texttt{object.\_\_dict\_}

A dictionary or other mapping object used to store an object's (writable) attributes.

\texttt{object.\_\_methods\_}

\textit{ Deprecated since version 2.2: Use the built-in function \texttt{dir()} to get a list of an object's attributes. This attribute is no longer available. }

\texttt{object.\_\_members\_}

\textit{ Deprecated since version 2.2: Use the built-in function \texttt{dir()} to get a list of an object's attributes. This attribute is no longer available. }

\texttt{instance.\_\_class\_}

The class to which a class instance belongs.

\texttt{class.\_\_bases\_}

The tuple of base classes of a class object.

\texttt{class.\_\_name\_}

The name of the class or type.

The following attributes are only supported by \textit{new-style classes}.

\texttt{class.\_\_mro\_}

This attribute is a tuple of classes that are considered when looking for base classes during method resolution.
class.\texttt{mro()}\n
This method can be overridden by a metaclass to customize the method resolution order for its instances. It is called at class instantiation, and its result is stored in \texttt{__mro__}.

class.\texttt{__subclasses__}()

Each new-style class keeps a list of weak references to its immediate subclasses. This method returns a list of all those references still alive. Example:

\begin{verbatim}
>>> int.__subclasses__()
[<type 'bool'>]
\end{verbatim}

Footnotes

[1] Additional information on these special methods may be found in the Python Reference Manual (\textit{Basic customization}).

[2] As a consequence, the list [1, 2] is considered equal to [1.0, 2.0], and similarly for tuples.

[3] They must have since the parser can't tell the type of the operands.

[4] To format only a tuple you should therefore provide a singleton tuple whose only element is the tuple to be formatted.

[5] The advantage of leaving the newline on is that returning an empty string is then an unambiguous EOF indication. It is also possible (in cases where it might matter, for example, if you want to make an exact copy of a file while scanning its lines) to tell whether the last line of a file ended in a newline or not (yes this happens!).
6. Built-in Exceptions

Exceptions should be class objects. The exceptions are defined in the module `exceptions`. This module never needs to be imported explicitly: the exceptions are provided in the built-in namespace as well as the `exceptions` module.

For class exceptions, in a `try` statement with an `except` clause that mentions a particular class, that clause also handles any exception classes derived from that class (but not exception classes from which it is derived). Two exception classes that are not related via subclassing are never equivalent, even if they have the same name.

The built-in exceptions listed below can be generated by the interpreter or built-in functions. Except where mentioned, they have an “associated value” indicating the detailed cause of the error. This may be a string or a tuple containing several items of information (e.g., an error code and a string explaining the code). The associated value is the second argument to the `raise` statement. If the exception class is derived from the standard root class `BaseException`, the associated value is present as the exception instance's `args` attribute.

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition “just like” the situation in which the interpreter raises the same exception; but beware that there is nothing to prevent user code from raising an inappropriate error.

The built-in exception classes can be sub-classed to define new exceptions; programmers are encouraged to at least derive new exceptions from the `Exception` class and not `BaseException`. More information on defining exceptions is available in the Python Tutorial.
under *User-defined Exceptions*.

The following exceptions are only used as base classes for other exceptions.

**exception** BaseException
The base class for all built-in exceptions. It is not meant to be directly inherited by user-defined classes (for that use Exception). If `str()` or `unicode()` is called on an instance of this class, the representation of the argument(s) to the instance are returned or the empty string when there were no arguments. All arguments are stored in `args` as a tuple.

*New in version 2.5.*

**exception** Exception
All built-in, non-system-exiting exceptions are derived from this class. All user-defined exceptions should also be derived from this class.

*Changed in version 2.5:* Changed to inherit from BaseException.

**exception** StandardError
The base class for all built-in exceptions except StopIteration, GeneratorExit, KeyboardInterrupt and SystemExit. StandardError itself is derived from Exception.

**exception** ArithmeticError
The base class for those built-in exceptions that are raised for various arithmetic errors: OverflowError, ZeroDivisionError, FloatingPointError.

**exception** LookupError
The base class for the exceptions that are raised when a key or index used on a mapping or sequence is invalid: IndexError,
**KeyError**. This can be raised directly by `codecs.lookup()`.

**exception EnvironmentError**

The base class for exceptions that can occur outside the Python system: **IOError**, **OSError**. When exceptions of this type are created with a 2-tuple, the first item is available on the instance's `errno` attribute (it is assumed to be an error number), and the second item is available on the `strerror` attribute (it is usually the associated error message). The tuple itself is also available on the `args` attribute.

*New in version 1.5.2.*

When an `EnvironmentError` exception is instantiated with a 3-tuple, the first two items are available as above, while the third item is available on the `filename` attribute. However, for backwards compatibility, the `args` attribute contains only a 2-tuple of the first two constructor arguments.

The `filename` attribute is `None` when this exception is created with other than 3 arguments. The `errno` and `strerror` attributes are also `None` when the instance was created with other than 2 or 3 arguments. In this last case, `args` contains the verbatim constructor arguments as a tuple.

The following exceptions are the exceptions that are actually raised.

**exception AssertionError**

Raised when an `assert` statement fails.

**exception AttributeError**

Raised when an attribute reference (see `Attribute references`) or assignment fails. (When an object does not support attribute references or attribute assignments at all, `TypeError` is raised.)
exception **EOFError**

Raised when one of the built-in functions (`input()` or `raw_input()`) hits an end-of-file condition (EOF) without reading any data. (N.B.: the `file.read()` and `file.readline()` methods return an empty string when they hit EOF.)

exception **FloatingPointError**

Raised when a floating point operation fails. This exception is always defined, but can only be raised when Python is configured with the `--with-fpectl` option, or the `WANT_SIGFPE_HANDLER` symbol is defined in the `pyconfig.h` file.

exception **GeneratorExit**

Raise when a generator's `close()` method is called. It directly inherits from `BaseException` instead of `StandardError` since it is technically not an error.

    New in version 2.5.

    *Changed in version 2.6:* Changed to inherit from `BaseException`.

exception **IOError**

Raised when an I/O operation (such as a `print` statement, the built-in `open()` function or a method of a file object) fails for an I/O-related reason, e.g., “file not found” or “disk full”.

This class is derived from `EnvironmentError`. See the discussion above for more information on exception instance attributes.

    *Changed in version 2.6:* Changed `socket.error` to use this as a base class.

exception **ImportError**

Raised when an `import` statement fails to find the module
definition or when a `from ... import` fails to find a name that is to be imported.

*exception* **IndexError**
Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not a plain integer, **TypeError** is raised.)

*exception* **KeyError**
Raised when a mapping (dictionary) key is not found in the set of existing keys.

*exception* **KeyboardInterrupt**
Raised when the user hits the interrupt key (normally `Control-C` or `Delete`). During execution, a check for interrupts is made regularly. Interrupts typed when a built-in function `input()` or `raw_input()` is waiting for input also raise this exception. The exception inherits from **BaseException** so as to not be accidentally caught by code that catches **Exception** and thus prevent the interpreter from exiting.

*Changed in version 2.5:* Changed to inherit from **BaseException**.

*exception* **MemoryError**
Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C’s `malloc()` function), the interpreter may not always be able to completely recover from this situation; it nevertheless raises an exception so that a stack traceback can be printed, in case a run-away program was the cause.

*exception* **NameError**
Raised when a local or global name is not found. This applies only to unqualified names. The associated value is an error message that includes the name that could not be found.

**exception** `NotImplementedError`

This exception is derived from `RuntimeError`. In user defined base classes, abstract methods should raise this exception when they require derived classes to override the method.

*New in version 1.5.2.*

**exception** `OSError`

This exception is derived from `EnvironmentError`. It is raised when a function returns a system-related error (not for illegal argument types or other incidental errors). The `errno` attribute is a numeric error code from `errno`, and the `strerror` attribute is the corresponding string, as would be printed by the C function `perror()`. See the module `errno`, which contains names for the error codes defined by the underlying operating system.

For exceptions that involve a file system path (such as `chdir()` or `unlink()`), the exception instance will contain a third attribute, `filename`, which is the file name passed to the function.

*New in version 1.5.2.*

**exception** `OverflowError`

Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for long integers (which would rather raise `MemoryError` than give up) and for most operations with plain integers, which return a long integer instead. Because of the lack of standardization of floating point exception handling in C, most floating point operations also aren’t checked.

**exception** `ReferenceError`
This exception is raised when a weak reference proxy, created by
the `weakref.proxy()` function, is used to access an attribute of
the referent after it has been garbage collected. For more
information on weak references, see the `weakref` module.

*New in version 2.2:* Previously known as the
`weakref.ReferenceError` exception.

**exception RuntimeError**

Raised when an error is detected that doesn’t fall in any of the
other categories. The associated value is a string indicating what
precisely went wrong. (This exception is mostly a relic from a
previous version of the interpreter; it is not used very much any
more.)

**exception StopIteration**

Raised by an iterator’s `next()` method to signal that there are no
further values. This is derived from `Exception` rather than
`StandardError`, since this is not considered an error in its normal
application.

*New in version 2.2.*

**exception SyntaxError**

Raised when the parser encounters a syntax error. This may
occur in an `import` statement, in an `exec` statement, in a call to
the built-in function `eval()` or `input()`, or when reading the initial
script or standard input (also interactively).

Instances of this class have attributes `filename`, `lineno`, `offset`
and `text` for easier access to the details. `str()` of the exception
instance returns only the message.

**exception SystemError**
Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-level terms).

You should report this to the author or maintainer of your Python interpreter. Be sure to report the version of the Python interpreter (\texttt{sys.version}; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

\textit{exception} \texttt{SystemExit}  
This exception is raised by the \texttt{sys.exit()} function. When it is not handled, the Python interpreter exits; no stack traceback is printed. If the associated value is a plain integer, it specifies the system exit status (passed to C's \texttt{exit()} function); if it is \texttt{None}, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

Instances have an attribute \texttt{code} which is set to the proposed exit status or error message (defaulting to \texttt{None}). Also, this exception derives directly from \texttt{BaseException} and not \texttt{StandardError}, since it is not technically an error.

A call to \texttt{sys.exit()} is translated into an exception so that clean-up handlers (\texttt{finally} clauses of \texttt{try} statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The \texttt{os._exit()} function can be used if it is absolutely positively necessary to exit immediately (for example, in the child process after a call to \texttt{fork()}).

The exception inherits from \texttt{BaseException} instead of \texttt{StandardError} or \texttt{Exception} so that it is not accidentally caught
by code that catches `Exception`. This allows the exception to properly propagate up and cause the interpreter to exit.

*Changed in version 2.5:* Changed to inherit from `BaseException`.

**exception** `TypeError`

Raised when an operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

**exception** `UnboundLocalError`

Raised when a reference is made to a local variable in a function or method, but no value has been bound to that variable. This is a subclass of `NameError`.

*New in version 2.0.*

**exception** `UnicodeError`

Raised when a Unicode-related encoding or decoding error occurs. It is a subclass of `ValueError`.

*New in version 2.0.*

**exception** `UnicodeEncodeError`

Raised when a Unicode-related error occurs during encoding. It is a subclass of `UnicodeError`.

*New in version 2.3.*

**exception** `UnicodeDecodeError`

Raised when a Unicode-related error occurs during decoding. It is a subclass of `UnicodeError`.

*New in version 2.3.*

**exception** `UnicodeTranslateError`
Raised when a Unicode-related error occurs during translating. It is a subclass of UnicodeError.

*New in version 2.3.*

**exception** **ValueError**

Raised when a built-in operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as IndexError.

**exception** **VMSError**

Only available on VMS. Raised when a VMS-specific error occurs.

**exception** **WindowsError**

Raised when a Windows-specific error occurs or when the error number does not correspond to an errno value. The winerror and strerror values are created from the return values of the GetLastError() and FormatMessage() functions from the Windows Platform API. The errno value maps the winerror value to corresponding errno.h values. This is a subclass of OSError.

*New in version 2.0.*

*Changed in version 2.5:* Previous versions put the GetLastError() codes into errno.

**exception** **ZeroDivisionError**

Raised when the second argument of a division or modulo operation is zero. The associated value is a string indicating the type of the operands and the operation.

The following exceptions are used as warning categories; see the warnings module for more information.
exception Warning
   Base class for warning categories.

exception UserWarning
   Base class for warnings generated by user code.

exception DeprecationWarning
   Base class for warnings about deprecated features.

exception PendingDeprecationWarning
   Base class for warnings about features which will be deprecated in the future.

exception SyntaxWarning
   Base class for warnings about dubious syntax

exception RuntimeWarning
   Base class for warnings about dubious runtime behavior.

exception FutureWarning
   Base class for warnings about constructs that will change semantically in the future.

exception ImportWarning
   Base class for warnings about probable mistakes in module imports.

   New in version 2.5.

exception UnicodeWarning
   Base class for warnings related to Unicode.

   New in version 2.5.
6.1. Exception hierarchy

The class hierarchy for built-in exceptions is:
7. String Services

The modules described in this chapter provide a wide range of string manipulation operations.

In addition, Python’s built-in string classes support the sequence type methods described in the *Sequence Types — str, unicode, list, tuple, buffer, xrange* section, and also the string-specific methods described in the *String Methods* section. To output formatted strings use template strings or the `%` operator described in the *String Formatting Operations* section. Also, see the *re* module for string functions based on regular expressions.

- 7.11. `fpformat` — Floating point conversions
7.1. `string` — Common string operations

The `string` module contains a number of useful constants and classes, as well as some deprecated legacy functions that are also available as methods on strings. In addition, Python's built-in string classes support the sequence type methods described in the `Sequence Types — str, unicode, list, tuple, buffer, xrange` section, and also the string-specific methods described in the `String Methods` section. To output formatted strings use template strings or the `%` operator described in the `String Formatting Operations` section. Also, see the `re` module for string functions based on regular expressions.
7.1.1. String constants

The constants defined in this module are:

- **string.ascii_letters**
  The concatenation of the `ascii_lowercase` and `ascii_uppercase` constants described below. This value is not locale-dependent.

- **string.ascii_lowercase**
  The lowercase letters 'abcdefghijklmnopqrstuvwxyz'. This value is not locale-dependent and will not change.

- **string.ascii_uppercase**
  The uppercase letters 'ABCDEFGHIJKLMNOPQRSTUVWXYZ'. This value is not locale-dependent and will not change.

- **string.digits**
  The string '0123456789'.

- **string.hexdigits**
  The string '0123456789abcdefABCDEF'.

- **string.letters**
  The concatenation of the strings `lowercase` and `uppercase` described below. The specific value is locale-dependent, and will be updated when `locale.setlocale()` is called.

- **string.lowercase**
  A string containing all the characters that are considered lowercase letters. On most systems this is the string 'abcdefghijklmnopqrstuvwxyz'. The specific value is locale-dependent, and will be updated when `locale.setlocale()` is called.
string. **octdigits**

The string '01234567'.

string. **punctuation**

String of ASCII characters which are considered punctuation characters in the c locale.

string. **printable**

String of characters which are considered printable. This is a combination of `digits, letters, punctuation, and whitespace`.

string. **uppercase**

A string containing all the characters that are considered uppercase letters. On most systems this is the string 'ABCDEFGHIJKLMNOPQRSTUVWXYZ'. The specific value is locale-dependent, and will be updated when `locale.setlocale()` is called.

string. **whitespace**

A string containing all characters that are considered whitespace. On most systems this includes the characters space, tab, linefeed, return, formfeed, and vertical tab.
7.1.2. String Formatting

*New in version 2.6.*

The built-in str and unicode classes provide the ability to do complex variable substitutions and value formatting via the `str.format()` method described in PEP 3101. The `Formatter` class in the `string` module allows you to create and customize your own string formatting behaviors using the same implementation as the built-in `format()` method.

```python
class string.Formatter

The `Formatter` class has the following public methods:

```format``(format_string, *args, **kwargs)

`format()` is the primary API method. It takes a format template string, and an arbitrary set of positional and keyword argument. `format()` is just a wrapper that calls `vformat()`.

```vformat``(format_string, args, kwargs)

This function does the actual work of formatting. It is exposed as a separate function for cases where you want to pass in a predefined dictionary of arguments, rather than unpacking and repacking the dictionary as individual arguments using the `*args` and `**kwargs` syntax. `vformat()` does the work of breaking up the format template string into character data and replacement fields. It calls the various methods described below.

In addition, the `Formatter` defines a number of methods that are intended to be replaced by subclasses:

```parse``(format_string)

```
Loop over the format_string and return an iterable of tuples (literal_text, field_name, format_spec, conversion). This is used by `vformat()` to break the string in to either literal text, or replacement fields.

The values in the tuple conceptually represent a span of literal text followed by a single replacement field. If there is no literal text (which can happen if two replacement fields occur consecutively), then literal_text will be a zero-length string. If there is no replacement field, then the values of field_name, format_spec and conversion will be `None`.

`get_field(field_name, args, kwargs)`

Given field_name as returned by `parse()` (see above), convert it to an object to be formatted. Returns a tuple (obj, used_key). The default version takes strings of the form defined in PEP 3101, such as “0[name]” or “label.title”. args and kwargs are as passed in to `vformat()`. The return value used_key has the same meaning as the key parameter to `get_value()`.

`get_value(key, args, kwargs)`

Retrieve a given field value. The key argument will be either an integer or a string. If it is an integer, it represents the index of the positional argument in args; if it is a string, then it represents a named argument in kwargs.

The args parameter is set to the list of positional arguments to `vformat()`, and the kwargs parameter is set to the dictionary of keyword arguments.

For compound field names, these functions are only called for the first component of the field name; Subsequent components are handled through normal attribute and
indexing operations.

So for example, the field expression ‘0.name’ would cause get_value() to be called with a key argument of 0. The name attribute will be looked up after get_value() returns by calling the built-in getattr() function.

If the index or keyword refers to an item that does not exist, then an IndexError or KeyError should be raised.

cHECK_UNUSED_ARGS(used_args, args, kwargs)
Implement checking for unused arguments if desired. The arguments to this function is the set of all argument keys that were actually referred to in the format string (integers for positional arguments, and strings for named arguments), and a reference to the args and kwargs that was passed to vformat. The set of unused args can be calculated from these parameters. check_unused_args() is assumed to throw an exception if the check fails.

FORMAT_FIELD(value, format_spec)
format_field() simply calls the global format() built-in. The method is provided so that subclasses can override it.

CONVERT_FIELD(value, conversion)
Converts the value (returned by get_field()) given a conversion type (as in the tuple returned by the parse() method). The default version understands ‘r’ (repr) and ‘s’ (str) conversion types.
7.1.3. Format String Syntax

The `str.format()` method and the `Formatter` class share the same syntax for format strings (although in the case of `Formatter`, subclasses can define their own format string syntax).

Format strings contain “replacement fields” surrounded by curly braces `{}`. Anything that is not contained in braces is considered literal text, which is copied unchanged to the output. If you need to include a brace character in the literal text, it can be escaped by doubling: `{{` and `}}`.

The grammar for a replacement field is as follows:

```
replacement_field ::= "{" [field_name] ["!" conversion] "}"
field_name ::= arg_name ("." attribute_name | "[" element_index "]")
arg_name ::= [identifier | integer]
attribute_name ::= identifier
element_index ::= integer | index_string
index_string ::= <any source character except "]"> +
conversion ::= "r" | "s"
format_spec ::= <described in the next section>
```

In less formal terms, the replacement field can start with a `field_name` that specifies the object whose value is to be formatted and inserted into the output instead of the replacement field. The `field_name` is optionally followed by a `conversion` field, which is preceded by an exclamation point `!`, and a `format_spec`, which is preceded by a colon `:`. These specify a non-default format for the replacement value.

See also the `Format Specification Mini-Language` section.

The `field_name` itself begins with an `arg_name` that is either either a number or a keyword. If it’s a number, it refers to a positional
argument, and if it’s a keyword, it refers to a named keyword argument. If the numerical arg_names in a format string are 0, 1, 2, ... in sequence, they can all be omitted (not just some) and the numbers 0, 1, 2, ... will be automatically inserted in that order. The arg_name can be followed by any number of index or attribute expressions. An expression of the form '.name' selects the named attribute using getattr(), while an expression of the form '[index]' does an index lookup using __getitem__().

*Changed in version 2.7:* The positional argument specifiers can be omitted, so '{ }' is equivalent to '{0} {1}'.

Some simple format string examples:

```
"First, thou shalt count to {0}" # References first positional
"Bring me a {}" # Implicitly references the first positional argument
"From {} to {}" # Same as "From {0} to {1}"
"My quest is {name}" # References keyword argument
"Weight in tons {0.weight}" # 'weight' attribute of first positional argument
"Units destroyed: {players[0]}" # First element of keyword argument
```

The conversion field causes a type coercion before formatting. Normally, the job of formatting a value is done by the __format__() method of the value itself. However, in some cases it is desirable to force a type to be formatted as a string, overriding its own definition of formatting. By converting the value to a string before calling __format__(), the normal formatting logic is bypassed.

Two conversion flags are currently supported: '!s' which calls str() on the value, and '!r' which calls repr().

Some examples:

```
"Harold's a clever {0!s}" # Calls str() on the argument
"Bring out the holy {name!r}" # Calls repr() on the argument
```
The `format_spec` field contains a specification of how the value should be presented, including such details as field width, alignment, padding, decimal precision and so on. Each value type can define its own “formatting mini-language” or interpretation of the `format_spec`.

Most built-in types support a common formatting mini-language, which is described in the next section.

A `format_spec` field can also include nested replacement fields within it. These nested replacement fields can contain only a field name; conversion flags and format specifications are not allowed. The replacement fields within the `format_spec` are substituted before the `format_spec` string is interpreted. This allows the formatting of a value to be dynamically specified.

See the *Format examples* section for some examples.

### 7.1.3.1. Format Specification Mini-Language

“Format specifications” are used within replacement fields contained within a format string to define how individual values are presented (see *Format String Syntax*). They can also be passed directly to the built-in `format()` function. Each formattable type may define how the format specification is to be interpreted.

Most built-in types implement the following options for format specifications, although some of the formatting options are only supported by the numeric types.

A general convention is that an empty format string ("") produces the same result as if you had called `str()` on the value. A non-empty format string typically modifies the result.

The general form of a *standard format specifier* is:
The *fill* character can be any character other than ‘}’ (which signifies the end of the field). The presence of a fill character is signaled by the next character, which must be one of the alignment options. If the second character of *format_spec* is not a valid alignment option, then it is assumed that both the fill character and the alignment option are absent.

The meaning of the various alignment options is as follows:

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'&lt;'</td>
<td>Forces the field to be left-aligned within the available space (this is the default).</td>
</tr>
<tr>
<td>'&gt;'</td>
<td>Forces the field to be right-aligned within the available space.</td>
</tr>
<tr>
<td>'='</td>
<td>Forces the padding to be placed after the sign (if any) but before the digits. This is used for printing fields in the form ‘+000000120’. This alignment option is only valid for numeric types.</td>
</tr>
<tr>
<td>'^'</td>
<td>Forces the field to be centered within the available space.</td>
</tr>
</tbody>
</table>

Note that unless a minimum field width is defined, the field width will always be the same size as the data to fill it, so that the alignment option has no meaning in this case.

The *sign* option is only valid for number types, and can be one of the following:

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>Symbol</td>
<td>Description</td>
</tr>
<tr>
<td>--------</td>
<td>-------------</td>
</tr>
<tr>
<td>'+'</td>
<td>indicates that a sign should be used for both positive as well as negative numbers.</td>
</tr>
<tr>
<td>'-'</td>
<td>indicates that a sign should be used only for negative numbers (this is the default behavior).</td>
</tr>
<tr>
<td>space</td>
<td>indicates that a leading space should be used on positive numbers, and a minus sign on negative numbers.</td>
</tr>
</tbody>
</table>

The '#' option is only valid for integers, and only for binary, octal, or hexadecimal output. If present, it specifies that the output will be prefixed by '0b', '0o', or '0x', respectively.

The ',' option signals the use of a comma for a thousands separator. For a locale aware separator, use the 'n' integer presentation type instead.

*Changed in version 2.7:* Added the ',' option (see also PEP 378).

*Width* is a decimal integer defining the minimum field width. If not specified, then the field width will be determined by the content.

If the width field is preceded by a zero ('0') character, this enables zero-padding. This is equivalent to an *alignment* type of '=' and a *fill* character of '0'.

The *precision* is a decimal number indicating how many digits should be displayed after the decimal point for a floating point value formatted with 'f' and 'F', or before and after the decimal point for a floating point value formatted with 'g' or 'G'. For non-number types the field indicates the maximum field size - in other words, how many characters will be used from the field content. The *precision* is not allowed for integer values.

Finally, the *type* determines how the data should be presented.
The available string presentation types are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'s'</td>
<td>String format. This is the default type for strings and may be omitted.</td>
</tr>
<tr>
<td>None</td>
<td>The same as 's'.</td>
</tr>
</tbody>
</table>

The available integer presentation types are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'b'</td>
<td>Binary format. Outputs the number in base 2.</td>
</tr>
<tr>
<td>'c'</td>
<td>Character. Converts the integer to the corresponding unicode character before printing.</td>
</tr>
<tr>
<td>'d'</td>
<td>Decimal Integer. Outputs the number in base 10.</td>
</tr>
<tr>
<td>'o'</td>
<td>Octal format. Outputs the number in base 8.</td>
</tr>
<tr>
<td>'x'</td>
<td>Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9.</td>
</tr>
<tr>
<td>'X'</td>
<td>Hex format. Outputs the number in base 16, using upper-case letters for the digits above 9.</td>
</tr>
<tr>
<td>'n'</td>
<td>Number. This is the same as 'd', except that it uses the current locale setting to insert the appropriate number separator characters.</td>
</tr>
<tr>
<td>None</td>
<td>The same as 'd'.</td>
</tr>
</tbody>
</table>

In addition to the above presentation types, integers can be formatted with the floating point presentation types listed below (except 'n' and None). When doing so, `float()` is used to convert the integer to a floating point number before formatting.

The available presentation types for floating point and decimal values are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'e'</td>
<td>Exponent notation. Prints the number in scientific notation using the letter ‘e’ to indicate the exponent.</td>
</tr>
<tr>
<td>'E'</td>
<td>Exponent notation. Same as 'e' except it uses an upper case 'E' as the separator character.</td>
</tr>
<tr>
<td>'f'</td>
<td>Fixed point. Displays the number as a fixed-point number.</td>
</tr>
<tr>
<td>'F'</td>
<td>Fixed point. Same as 'f'.</td>
</tr>
<tr>
<td>'g'</td>
<td>General format. For a given precision ( p \geq 1 ), this rounds the number to ( p ) significant digits and then formats the result in either fixed-point format or in scientific notation, depending on its magnitude. The precise rules are as follows: suppose that the result formatted with presentation type 'e' and precision ( p-1 ) would have exponent ( \exp ). Then if (-4 \leq \exp &lt; p), the number is formatted with presentation type 'f' and precision ( p-1-\exp ). Otherwise, the number is formatted with presentation type 'e' and precision ( p-1 ). In both cases insignificant trailing zeros are removed from the significand, and the decimal point is also removed if there are no remaining digits following it. Positive and negative infinity, positive and negative zero, and nans, are formatted as inf, -inf, 0, -0 and nan respectively, regardless of the precision. A precision of 0 is treated as equivalent to a precision of 1.</td>
</tr>
<tr>
<td>'G'</td>
<td>General format. Same as 'g' except switches to 'E' if the number gets too large. The representations of infinity and NaN are uppercased, too.</td>
</tr>
<tr>
<td>'n'</td>
<td>Number. This is the same as 'g', except that it uses the current locale setting to insert the appropriate number separator characters.</td>
</tr>
<tr>
<td>'%'</td>
<td>Percentage. Multiplies the number by 100 and displays in fixed ('f') format, followed by a percent sign.</td>
</tr>
<tr>
<td>None</td>
<td>The same as 'g'.</td>
</tr>
</tbody>
</table>

## 7.1.3.2. Format examples

This section contains examples of the new format syntax and comparison with the old %-formatting.

In most of the cases the syntax is similar to the old %-formatting, with the addition of the {} and with : used instead of %. For example, `%03.2f` can be translated to `{:03.2f}`.

The new format syntax also supports new and different options, shown in the follow examples.

### Accessing arguments by position:

```python
>>> '{0}, {1}, {2}'.format('a', 'b', 'c')
'a, b, c'
>>> '{}{0}{1}'.format('abra', 'cad')  # arguments' indices can be repeated
'abracadabra'
```

### Accessing arguments by name:

```python
>>> 'Coordinates: {latitude}, {longitude}'.format(latitude='37.24N', longitude='-115.81W')
'Coordinates: 37.24N, -115.81W'
>>> 'Coordinates: {latitude}, {longitude}'.format(**coord)  # unpacking argument sequence
'Coordinates: 37.24N, -115.81W'
```
Accessing arguments' attributes:

```python
>>> c = 3-5j
>>> ('The complex number {0} is formed from the real part {0.real} and the imaginary part {0.imag}.').format(c)
'The complex number (3-5j) is formed from the real part 3.0 and the imaginary part -5.0.'
```

```python
class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y
    def __str__(self):
        return 'Point({self.x}, {self.y})'.format(self=self)

>>> str(Point(4, 2))
'Point(4, 2)'
```

Accessing arguments' items:

```python
>>> coord = (3, 5)
>>> 'X: {0[0]}; Y: {0[1]}'.format(coord)
'X: 3; Y: 5'
```

Replacing `%s` and `%r`:

```python
>>> "repr() shows quotes: {!r}; str() doesn't: {!s}".format('test1', 'test2')
'repr() shows quotes: 'test1'; str() doesn't: test2'
```

Aligning the text and specifying a width:

```python
>>> '{:<30}'.format('left aligned')
'left aligned'
>>> '{:>30}'.format('right aligned')
'right aligned'
>>> '{:^30}'.format('centered')
'centered'
>>> '{:*^30}'.format('centered')  # use '*' as a fill char
'**********centered**********'
```

Replacing `%+f`, `%f`, and `%f` and specifying a sign:
Replacing `%x` and `%o` and converting the value to different bases:

```python
>>> # format also supports binary numbers
>>> "int: {0:d}; hex: {0:x}; oct: {0:o}; bin: {0:b}".format(42)
' int: 42; hex: 2a; oct: 52; bin: 101010'
>>> # with 0x, 0o, or 0b as prefix:
>>> "int: {0:d}; hex: {0:#x}; oct: {0:#o}; bin: {0:#b}".format(42)
' int: 42; hex: 0x2a; oct: 0o52; bin: 0b101010'
```

Using the comma as a thousands separator:

```python
>>> '{:,}'.format(1234567890)
'1,234,567,890'
```

Expressing a percentage:

```python
>>> points = 19.5
>>> total = 22
>>> 'Correct answers: {:.2%}'.format(points/total)
'Correct answers: 88.64%'
```

Using type-specific formatting:

```python
>>> import datetime
>>> d = datetime.datetime(2010, 7, 4, 12, 15, 58)
>>> '{:%Y-%m-%d %H:%M:%S}'.format(d)
'2010-07-04 12:15:58'
```

Nesting arguments and more complex examples:

```python
>>> for align, text in zip('<^>', ['left', 'center', 'right']):
...     '{0:{align}{fill}16}'.format(text, fill=align, align=align)
```
>>> octets = [192, 168, 0, 1]
>>> '{:02X}{:02X}{:02X}{:02X}'.format(*octets)
'C0A80001'
>>> int(_, 16)
3232235521
>>> width = 5
>>> for num in range(5, 12):
...     for base in 'dXob':
...         print '{0:{width}{base}}'.format(num, base=base, width=width),
...     print
...     5 5 5 101
6 6 6 110
7 7 7 111
8 8 10 1000
9 9 11 1001
10 A 12 1010
11 B 13 1011
7.1.4. Template strings

New in version 2.4.

Templates provide simpler string substitutions as described in PEP 292. Instead of the normal %-based substitutions, Templates support $-based substitutions, using the following rules:

- $ is an escape; it is replaced with a single $.
- $identifier names a substitution placeholder matching a mapping key of "identifier". By default, "identifier" must spell a Python identifier. The first non-identifier character after the $ character terminates this placeholder specification.
- ${identifier} is equivalent to $identifier. It is required when valid identifier characters follow the placeholder but are not part of the placeholder, such as "${noun}ification".

Any other appearance of $ in the string will result in a ValueError being raised.

The string module provides a Template class that implements these rules. The methods of Template are:

class string.Template(template)
    The constructor takes a single argument which is the template string.

    substitute(mapping[, **kws])
    Performs the template substitution, returning a new string. mapping is any dictionary-like object with keys that match the placeholders in the template. Alternatively, you can provide keyword arguments, where the keywords are the
placeholders. When both *mapping* and *kws* are given and there are duplicates, the placeholders from *kws* take precedence.

```python
safe_substitute(mapping[,**kws])
```
Like `substitute()`, except that if placeholders are missing from *mapping* and *kws*, instead of raising a `KeyError` exception, the original placeholder will appear in the resulting string intact. Also, unlike with `substitute()`, any other appearances of the $ will simply return $ instead of raising `ValueError`.

While other exceptions may still occur, this method is called “safe” because substitutions always tries to return a usable string instead of raising an exception. In another sense, `safe_substitute()` may be anything other than safe, since it will silently ignore malformed templates containing dangling delimiters, unmatched braces, or placeholders that are not valid Python identifiers.

*Template* instances also provide one public data attribute:

```python
template
This is the object passed to the constructor's *template* argument. In general, you shouldn’t change it, but read-only access is not enforced.
```

Here is an example of how to use a Template:

```python
>>> from string import Template
>>> s = Template('who likes what')
>>> s.substitute(who='tim', what='kung pao')
'tim likes kung pao'
>>> d = dict(who='tim')
>>> Template('Give $who $100').substitute(d)
Traceback (most recent call last):
[...]
```
ValueError: Invalid placeholder in string: line 1, col 10
>>> Template('$who likes $what').substitute(d)
Traceback (most recent call last):
[...]
KeyError: 'what'
>>> Template('$who likes $what').safe_substitute(d)
'tim likes $what'
```

Advanced usage: you can derive subclasses of `Template` to customize the placeholder syntax, delimiter character, or the entire regular expression used to parse template strings. To do this, you can override these class attributes:

- **delimiter** – This is the literal string describing a placeholder introducing delimiter. The default value is `.`. Note that this should *not* be a regular expression, as the implementation will call `re.escape()` on this string as needed.

- **idpattern** – This is the regular expression describing the pattern for non-braced placeholders (the braces will be added automatically as appropriate). The default value is the regular expression `[_a-z][_a-z0-9]*`.

Alternatively, you can provide the entire regular expression pattern by overriding the class attribute `pattern`. If you do this, the value must be a regular expression object with four named capturing groups. The capturing groups correspond to the rules given above, along with the invalid placeholder rule:

- **escaped** – This group matches the escape sequence, e.g. `$$`, in the default pattern.
- **named** – This group matches the unbraced placeholder name; it should not include the delimiter in capturing group.
- **braced** – This group matches the brace enclosed placeholder name; it should not include either the delimiter or braces in the capturing group.
- **invalid** – This group matches any other delimiter pattern (usually
a single delimiter), and it should appear last in the regular expression.
7.1.5. String functions

The following functions are available to operate on string and Unicode objects. They are not available as string methods.

**string.** `capwords(s[, sep])`
Split the argument into words using `str.split()`, capitalize each word using `str.capitalize()`, and join the capitalized words using `str.join()`. If the optional second argument `sep` is absent or `None`, runs of whitespace characters are replaced by a single space and leading and trailing whitespace are removed, otherwise `sep` is used to split and join the words.

**string.** `maketrans(from, to)`
Return a translation table suitable for passing to `translate()`, that will map each character in `from` into the character at the same position in `to`; `from` and `to` must have the same length.

**Note:** Don't use strings derived from `lowercase` and `uppercase` as arguments; in some locales, these don't have the same length. For case conversions, always use `str.lower()` and `str.upper()`.
### 7.1.6. Deprecated string functions

The following list of functions are also defined as methods of string and Unicode objects; see section *String Methods* for more information on those. You should consider these functions as deprecated, although they will not be removed until Python 3.0. The functions defined in this module are:

**string.atoi(s)**

*Deprecated since version 2.0: Use the int() built-in function.*

Convert string s to an integer in the given base. The string must consist of one or more digits, optionally preceded by a sign (+ or -). The base defaults to 10. If it is 0, a default base is chosen depending on the leading characters of the string (after stripping the sign): 0x or 0X means 16, 0 means 8, anything else means 10. If base is 16, a leading 0x or 0X is always accepted, though not required. This behaves identically to the built-in function

**string.atof(s)**

*Deprecated since version 2.0: Use the float() built-in function.*

Convert a string to a floating point number. The string must have the standard syntax for a floating point literal in Python, optionally preceded by a sign (+ or -). Note that this behaves identical to the built-in function float() when passed a string.

**Note:** When passing in a string, values for NaN and Infinity may be returned, depending on the underlying C library. The specific set of strings accepted which cause these values to be returned depends entirely on the C library and is known to vary.
int() when passed a string. (Also note: for a more flexible interpretation of numeric literals, use the built-in function `eval()`.)

```python
string atol(s[, base])
```

*Deprecated since version 2.0: Use the `long()` built-in function.*

Convert string s to a long integer in the given base. The string must consist of one or more digits, optionally preceded by a sign (+ or -). The base argument has the same meaning as for `atoi()`. A trailing 1 or L is not allowed, except if the base is 0. Note that when invoked without base or with base set to 10, this behaves identical to the built-in function `long()` when passed a string.

```python
string capitalize(word)
```

Return a copy of word with only its first character capitalized.

```python
string expandtabs(s[, tabsize])
```

Expand tabs in a string replacing them by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. This doesn’t understand other non-printing characters or escape sequences. The tab size defaults to 8.

```python
string find(s, sub[, start[, end]])
```

Return the lowest index in s where the substring sub is found such that sub is wholly contained in s[start:end]. Return -1 on failure. Defaults for start and end and interpretation of negative values is the same as for slices.

```python
string rfind(s, sub[, start[, end]])
```

Like `find()` but find the highest index.
string.\texttt{index}(s, sub[, start[, end]])
Like \texttt{find()} but raise \texttt{ValueError} when the substring is not found.

string.\texttt{rindex}(s, sub[, start[, end]])
Like \texttt{rfind()} but raise \texttt{ValueError} when the substring is not found.

string.\texttt{count}(s, sub[, start[, end]])
Return the number of (non-overlapping) occurrences of substring \texttt{sub} in string \texttt{s[start:end]}. Defaults for \texttt{start} and \texttt{end} and interpretation of negative values are the same as for slices.

string.\texttt{lower}(s)
Return a copy of \texttt{s}, but with upper case letters converted to lower case.

string.\texttt{split}(s[, sep[, maxsplit]])
Return a list of the words of the string \texttt{s}. If the optional second argument \texttt{sep} is absent or \texttt{None}, the words are separated by arbitrary strings of whitespace characters (space, tab, newline, return, formfeed). If the second argument \texttt{sep} is present and not \texttt{None}, it specifies a string to be used as the word separator. The returned list will then have one more item than the number of non-overlapping occurrences of the separator in the string. The optional third argument \texttt{maxsplit} defaults to 0. If it is nonzero, at most \texttt{maxsplit} number of splits occur, and the remainder of the string is returned as the final element of the list (thus, the list will have at most \texttt{maxsplit+1} elements).

The behavior of \texttt{split} on an empty string depends on the value of \texttt{sep}. If \texttt{sep} is not specified, or specified as \texttt{None}, the result will be an empty list. If \texttt{sep} is specified as any string, the result will be a list containing one element which is an empty string.
string.\n\n\n\n**rsplit(s[, sep[, maxsplit]])**

Return a list of the words of the string s, scanning s from the end. To all intents and purposes, the resulting list of words is the same as returned by split(), except when the optional third argument maxsplit is explicitly specified and nonzero. When maxsplit is nonzero, at most maxsplit number of splits – the rightmost ones – occur, and the remainder of the string is returned as the first element of the list (thus, the list will have at most maxsplit+1 elements).

*New in version 2.4.*

string.\n\n**splitfields(s[, sep[, maxsplit]])**

This function behaves identically to split(). (In the past, split() was only used with one argument, while splitfields() was only used with two arguments.)

string.\n\n**join(words[, sep])**

Concatenate a list or tuple of words with intervening occurrences of sep. The default value for sep is a single space character. It is always true that string.join(string.split(s, sep), sep) equals s.

string.\n\n**joinfields(words[, sep])**

This function behaves identically to join(). (In the past, join() was only used with one argument, while joinfields() was only used with two arguments.) Note that there is no joinfields() method on string objects; use the join() method instead.

string.\n\n**lstrip(s[, chars])**

Return a copy of the string with leading characters removed. If chars is omitted or None, whitespace characters are removed. If
given and not None, chars must be a string; the characters in the string will be stripped from the beginning of the string this method is called on.

*Changed in version 2.2.3:* The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

```python
string.rstrip(s[, chars])
```

Return a copy of the string with trailing characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the end of the string this method is called on.

*Changed in version 2.2.3:* The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

```python
string.strip(s[, chars])
```

Return a copy of the string with leading and trailing characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the both ends of the string this method is called on.

*Changed in version 2.2.3:* The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

```python
string.swapcase(s)
```

Return a copy of s, but with lower case letters converted to upper case and vice versa.

```python
string.translate(s, table[, deletechars])
```

Delete all characters from s that are in deletechars (if present), and then translate the characters using table, which must be a
256-character string giving the translation for each character value, indexed by its ordinal. If `table` is `None`, then only the character deletion step is performed.

```python
string.upper(s)
```

Return a copy of `s`, but with lower case letters converted to upper case.

```python
string.ljust(s, width[, fillchar])
string.rjust(s, width[, fillchar])
string.center(s, width[, fillchar])
```

These functions respectively left-justify, right-justify and center a string in a field of given width. They return a string that is at least `width` characters wide, created by padding the string `s` with the character `fillchar` (default is a space) until the given width on the right, left or both sides. The string is never truncated.

```python
string.zfill(s, width)
```

Pad a numeric string on the left with zero digits until the given width is reached. Strings starting with a sign are handled correctly.

```python
string.replace(str, old, new[, maxreplace])
```

Return a copy of string `str` with all occurrences of substring `old` replaced by `new`. If the optional argument `maxreplace` is given, the first `maxreplace` occurrences are replaced.
This module provides regular expression matching operations similar to those found in Perl. Both patterns and strings to be searched can be Unicode strings as well as 8-bit strings.

Regular expressions use the backslash character ('\') to indicate special forms or to allow special characters to be used without invoking their special meaning. This collides with Python's usage of the same character for the same purpose in string literals; for example, to match a literal backslash, one might have to write '\\' as the pattern string, because the regular expression must be \, and each backslash must be expressed as \ inside a regular Python string literal.

The solution is to use Python's raw string notation for regular expression patterns; backslashes are not handled in any special way in a string literal prefixed with 'r'. So r"\n" is a two-character string containing \ and n, while "\n" is a one-character string containing a newline. Usually patterns will be expressed in Python code using this raw string notation.

It is important to note that most regular expression operations are available as module-level functions and RegexObject methods. The functions are shortcuts that don't require you to compile a regex object first, but miss some fine-tuning parameters.

See also:

Mastering Regular Expressions
   Book on regular expressions by Jeffrey Friedl, published by O'Reilly. The second edition of the book no longer covers
Python at all, but the first edition covered writing good regular expression patterns in great detail.
7.2.1. Regular Expression Syntax

A regular expression (or RE) specifies a set of strings that matches it; the functions in this module let you check if a particular string matches a given regular expression (or if a given regular expression matches a particular string, which comes down to the same thing).

Regular expressions can be concatenated to form new regular expressions; if $A$ and $B$ are both regular expressions, then $AB$ is also a regular expression. In general, if a string $p$ matches $A$ and another string $q$ matches $B$, the string $pq$ will match $AB$. This holds unless $A$ or $B$ contain low precedence operations; boundary conditions between $A$ and $B$; or have numbered group references. Thus, complex expressions can easily be constructed from simpler primitive expressions like the ones described here. For details of the theory and implementation of regular expressions, consult the Friedl book referenced above, or almost any textbook about compiler construction.

A brief explanation of the format of regular expressions follows. For further information and a gentler presentation, consult the Regular Expression HOWTO.

Regular expressions can contain both special and ordinary characters. Most ordinary characters, like 'A', 'a', or '0', are the simplest regular expressions; they simply match themselves. You can concatenate ordinary characters, so last matches the string 'last'. (In the rest of this section, we'll write RE's in this special style, usually without quotes, and strings to be matched 'in single quotes'.)

Some characters, like '|' or '(', are special. Special characters either stand for classes of ordinary characters, or affect how the
regular expressions around them are interpreted. Regular expression pattern strings may not contain null bytes, but can specify the null byte using the `\n` notation, e.g., `\x00`.

The special characters are:

`.`

(Dot.) In the default mode, this matches any character except a newline. If the `DOTALL` flag has been specified, this matches any character including a newline.

`^`

(Caret.) Matches the start of the string, and in `MULTILINE` mode also matches immediately after each newline.

`$`

Matches the end of the string or just before the newline at the end of the string, and in `MULTILINE` mode also matches before a newline. `foo` matches both ‘foo’ and ‘foobar’, while the regular expression `foo$` matches only ‘foo’. More interestingly, searching for `foo.$` in `'foo\nfoo2\n'` matches ‘foo2’ normally, but ‘foo1’ in `MULTILINE` mode; searching for a single `$` in `'foo\n'` will find two (empty) matches: one just before the newline, and one at the end of the string.

`*`

Causes the resulting RE to match 0 or more repetitions of the preceding RE, as many repetitions as are possible. `ab*` will match ‘a’, ‘ab’, or ‘a’ followed by any number of ‘b’s.

`+`

Causes the resulting RE to match 1 or more repetitions of the preceding RE. `ab+` will match ‘a’ followed by any non-zero number of ‘b’s; it will not match just ‘a’.

`?`

Causes the resulting RE to match 0 or 1 repetitions of the preceding RE. `ab?` will match either ‘a’ or ‘ab’.
*?, +?, ??

The ‘*’, ‘+’, and ‘?’ qualifiers are all greedy; they match as much text as possible. Sometimes this behaviour isn’t desired; if the RE `<.*>` is matched against `<H1>title</H1>'`, it will match the entire string, and not just `<H1>'`. Adding ‘?’ after the qualifier makes it perform the match in non-greedy or minimal fashion; as few characters as possible will be matched. Using `.\*?` in the previous expression will match only `<H1>'`.

{m}

Specifies that exactly m copies of the previous RE should be matched; fewer matches cause the entire RE not to match. For example, a{6} will match exactly six 'a' characters, but not five.

{m, n}

Causes the resulting RE to match from m to n repetitions of the preceding RE, attempting to match as many repetitions as possible. For example, a{3,5} will match from 3 to 5 'a' characters. Omitting m specifies a lower bound of zero, and omitting n specifies an infinite upper bound. As an example, a{4,}b will match aaaaab or a thousand 'a' characters followed by a b, but not aaab. The comma may not be omitted or the modifier would be confused with the previously described form.

{m, n}?

Causes the resulting RE to match from m to n repetitions of the preceding RE, attempting to match as few repetitions as possible. This is the non-greedy version of the previous qualifier. For example, on the 6-character string 'aaaaaa', a{3,5} will match 5 'a' characters, while a{3,5}? will only match 3 characters.

\`
Either escapes special characters (permitting you to match characters like ‘*’, ‘?’), and so forth), or signals a special sequence; special sequences are discussed below.
If you’re not using a raw string to express the pattern, remember that Python also uses the backslash as an escape sequence in string literals; if the escape sequence isn’t recognized by Python’s parser, the backslash and subsequent character are included in the resulting string. However, if Python would recognize the resulting sequence, the backslash should be repeated twice. This is complicated and hard to understand, so it’s highly recommended that you use raw strings for all but the simplest expressions.

[]

Used to indicate a set of characters. Characters can be listed individually, or a range of characters can be indicated by giving two characters and separating them by a '-'. Special characters are not active inside sets. For example, [akm$] will match any of the characters 'a', 'k', 'm', or '$'; [a-z] will match any lowercase letter, and [a-zA-Z0-9] matches any letter or digit. Character classes such as \w or \s (defined below) are also acceptable inside a range, although the characters they match depends on whether **locale** or **unicode** mode is in force. If you want to include a ']' or a '-' inside a set, precede it with a backslash, or place it as the first character. The pattern [ ]] will match ' ]', for example.

You can match the characters not within a range by *complementing* the set. This is indicated by including a '^' as the first character of the set; '^' elsewhere will simply match the '^' character. For example, [^5] will match any character except '5', and [^a] will match any character except '^'.

Note that inside [ ] the special forms and special characters lose their meanings and only the syntaxes described here are valid. For example, +, *, (, ), and so on are treated as literals inside
[]], and backreferences cannot be used inside [].

A|B, where A and B can be arbitrary REs, creates a regular expression that will match either A or B. An arbitrary number of REs can be separated by the '|' in this way. This can be used inside groups (see below) as well. As the target string is scanned, REs separated by '|' are tried from left to right. When one pattern completely matches, that branch is accepted. This means that once A matches, B will not be tested further, even if it would produce a longer overall match. In other words, the '|' operator is never greedy. To match a literal '|', use \|, or enclose it inside a character class, as in \[].

(...)
Matches whatever regular expression is inside the parentheses, and indicates the start and end of a group; the contents of a group can be retrieved after a match has been performed, and can be matched later in the string with the \number special sequence, described below. To match the literals '(', or ')', use \ or \), or enclose them inside a character class: \[()]\].

(?...) This is an extension notation (a '?' following a '(' is not meaningful otherwise). The first character after the '?' determines what the meaning and further syntax of the construct is. Extensions usually do not create a new group; (?P<name>...) is the only exception to this rule. Following are the currently supported extensions.

(?iLmsux) (One or more letters from the set 'i', 'L', 'm', 's', 'u', 'x'.) The group matches the empty string; the letters set the corresponding flags: re.I (ignore case), re.L (locale dependent), re.M (multi-line), re.S (dot matches all), re.U (Unicode
dependent), and \texttt{re.x} (verbose), for the entire regular expression. (The flags are described in \textit{Module Contents}.) This is useful if you wish to include the flags as part of the regular expression, instead of passing a \textit{flag} argument to the \texttt{\texttt{re.compile}} function.

Note that the \texttt{(？x)} flag changes how the expression is parsed. It should be used first in the expression string, or after one or more whitespace characters. If there are non-whitespace characters before the flag, the results are undefined.

\texttt{(？:...)}

A non-grouping version of regular parentheses. Matches whatever regular expression is inside the parentheses, but the substring matched by the group \textit{cannot} be retrieved after performing a match or referenced later in the pattern.

\texttt{(？P<name>...)}

Similar to regular parentheses, but the substring matched by the group is accessible within the rest of the regular expression via the symbolic group name \textit{name}. Group names must be valid Python identifiers, and each group name must be defined only once within a regular expression. A symbolic group is also a numbered group, just as if the group were not named. So the group named \texttt{id} in the example below can also be referenced as the numbered group \texttt{1}.

For example, if the pattern is \texttt{(？P?id>[a-zA-Z_]\w*)}, the group can be referenced by its name in arguments to methods of match objects, such as \texttt{m.group('id')} or \texttt{m.end('id')}, and also by name in the regular expression itself (using \texttt{(？P=id)}) and replacement text given to \texttt{.sub()} (using \texttt{\g<id>}).

\texttt{(？P=name)}

Matches whatever text was matched by the earlier group named
name.

(?#...)
A comment; the contents of the parentheses are simply ignored.

(?!...)
Matches if ... doesn't match next. This is a negative lookahead assertion. For example, Isaac (?!Asimov) will match 'Isaac ' only if it's not followed by 'Asimov'.

(>=...)
Matches if ... matches next, but doesn't consume any of the string. This is called a lookahead assertion. For example, Isaac (?=Asimov) will match 'Isaac ' only if it's followed by 'Asimov'.

(<=...)
Matches if the current position in the string is preceded by a match for ... that ends at the current position. This is called a positive lookbehind assertion. (?<=abc)def will find a match in abcdef, since the lookbehind will back up 3 characters and check if the contained pattern matches. The contained pattern must only match strings of some fixed length, meaning that abc or a|b are allowed, but a* and a{3,4} are not. Note that patterns which start with positive lookbehind assertions will never match at the beginning of the string being searched; you will most likely want to use the search() function rather than the match() function:

```python
>>> import re
>>> m = re.search('(?<=abc)def', 'abcdef')
>>> m.group(0)
'def'
```

This example looks for a word following a hyphen:

```python
>>> m = re.search('(?<=-)\w+', 'spam-egg')
>>> m.group(0)
'egg'
```
(?!...)
Matches if the current position in the string is not preceded by a match for .... This is called a negative lookbehind assertion. Similar to positive lookbehind assertions, the contained pattern must only match strings of some fixed length. Patterns which start with negative lookbehind assertions may match at the beginning of the string being searched.

(?id/name)yes-pattern|no-pattern
Will try to match with yes-pattern if the group with given id or name exists, and with no-pattern if it doesn't. no-pattern is optional and can be omitted. For example, (<)?(\w+@\w+(?:\w+)+)(?1>) is a poor email matching pattern, which will match with '<user@host.com>' as well as 'user@host.com', but not with '<user@host.com'.

*New in version 2.4.*

The special sequences consist of \ and a character from the list below. If the ordinary character is not on the list, then the resulting RE will match the second character. For example, \$ matches the character $.

\number
Matches the contents of the group of the same number. Groups are numbered starting from 1. For example, (.+)|1 matches 'the the' or '55 55', but not 'the end' (note the space after the group). This special sequence can only be used to match one of the first 99 groups. If the first digit of number is 0, or number is 3 octal digits long, it will not be interpreted as a group match, but as the character with octal value number. Inside the ']' and ']' of a character class, all numeric escapes are treated as characters.

\A
Matches only at the start of the string.
\b

Matches the empty string, but only at the beginning or end of a word. A word is defined as a sequence of alphanumerical or underscore characters, so the end of a word is indicated by whitespace or a non-alphanumerical, non-underscore character. Note that \b is defined as the boundary between \w and \W, so the precise set of characters deemed to be alphanumerical depends on the values of the UNICODE and LOCALE flags. Inside a character range, \b represents the backspace character, for compatibility with Python’s string literals.

\B

Matches the empty string, but only when it is not at the beginning or end of a word. This is just the opposite of \b, so is also subject to the settings of LOCALE and UNICODE.

\d

When the UNICODE flag is not specified, matches any decimal digit; this is equivalent to the set [0-9]. With UNICODE, it will match whatever is classified as a decimal digit in the Unicode character properties database.

\D

When the UNICODE flag is not specified, matches any non-digit character; this is equivalent to the set [^0-9]. With UNICODE, it will match anything other than character marked as digits in the Unicode character properties database.

\s

When the LOCALE and UNICODE flags are not specified, matches any whitespace character; this is equivalent to the set [ \t\n\r\f\v]. With LOCALE, it will match this set plus whatever characters are defined as space for the current locale. If UNICODE is set, this will match the characters [ \t\n\r\f\v] plus whatever is classified as space in the Unicode character properties database.
When the `LOCALE` and `UNICODE` flags are not specified, matches any non-whitespace character; this is equivalent to the set `[^\t\n\r\f\v]`. With `LOCALE`, it will match any character not in this set, and not defined as space in the current locale. If `UNICODE` is set, this will match anything other than `[^\t\n\r\f\v]` and characters marked as space in the Unicode character properties database.

When the `LOCALE` and `UNICODE` flags are not specified, matches any alphanumeric character and the underscore; this is equivalent to the set `[a-zA-Z0-9_]`. With `LOCALE`, it will match the set `[0-9_]` plus whatever characters are defined as alphanumeric for the current locale. If `UNICODE` is set, this will match the characters `[0-9_]` plus whatever is classified as alphanumeric in the Unicode character properties database.

When the `LOCALE` and `UNICODE` flags are not specified, matches any non-alphanumeric character; this is equivalent to the set `[^a-zA-Z0-9_]`. With `LOCALE`, it will match any character not in the set `[0-9_]`, and not defined as alphanumeric for the current locale. If `UNICODE` is set, this will match anything other than `[0-9_]` and characters marked as alphanumeric in the Unicode character properties database.

Matches only at the end of the string.

Most of the standard escapes supported by Python string literals are also accepted by the regular expression parser:

```
\a \b \f \n \r \t \v \x \\ 
```
Octal escapes are included in a limited form: If the first digit is a 0, or if there are three octal digits, it is considered an octal escape. Otherwise, it is a group reference. As for string literals, octal escapes are always at most three digits in length.
7.2.2. Matching vs Searching

Python offers two different primitive operations based on regular expressions: **match** checks for a match only at the beginning of the string, while **search** checks for a match anywhere in the string (this is what Perl does by default).

Note that match may differ from search even when using a regular expression beginning with `'^'`: `'^'` matches only at the start of the string, or in **MULTILINE** mode also immediately following a newline. The “match” operation succeeds only if the pattern matches at the start of the string regardless of mode, or at the starting position given by the optional `pos` argument regardless of whether a newline precedes it.

```python
>>> re.match("c", "abcdef")  # No match
>>> re.search("c", "abcdef")  # Match
<_sre.SRE_Match object at ...>
```
The module defines several functions, constants, and an exception. Some of the functions are simplified versions of the full featured methods for compiled regular expressions. Most non-trivial applications always use the compiled form.

\[ \text{re.compile}(\text{pattern}[, \text{flags}]) \]

Compile a regular expression pattern into a regular expression object, which can be used for matching using its \text{match()} and \text{search()} methods, described below.

The expression's behaviour can be modified by specifying a \text{flags} value. Values can be any of the following variables, combined using bitwise OR (the | operator).

The sequence

\begin{verbatim}
prog = re.compile(pattern)
result = prog.match(string)
\end{verbatim}

is equivalent to

\begin{verbatim}
result = re.match(pattern, string)
\end{verbatim}

but using \text{re.compile()} and saving the resulting regular expression object for reuse is more efficient when the expression will be used several times in a single program.

\textbf{Note:} The compiled versions of the most recent patterns passed to \text{re.match()}, \text{re.search()} or \text{re.compile()} are cached, so programs that use only a few regular expressions at a time needn't worry about compiling regular expressions.
re. **I**
re. **IGNORECASE**
Perform case-insensitive matching; expressions like \[A-Z\] will match lowercase letters, too. This is not affected by the current locale.

re. **L**
re. **LOCALE**
Make \w, \W, \b, \B, \s and \S dependent on the current locale.

re. **M**
re. **MULTILINE**
When specified, the pattern character ^ matches at the beginning of the string and at the beginning of each line (immediately following each newline); and the pattern character $ matches at the end of the string and at the end of each line (immediately preceding each newline). By default, ^ matches only at the beginning of the string, and $ only at the end of the string and immediately before the newline (if any) at the end of the string.

re. **S**
re. **DOTALL**
Make the . special character match any character at all, including a newline; without this flag, . will match anything except a newline.

re. **U**
re. **UNICODE**
Make \w, \W, \b, \B, \d, \D, \s and \S dependent on the Unicode character properties database.

*New in version 2.0.*

re. **X**
re. **VERBOSE**
This flag allows you to write regular expressions that look nicer. Whitespace within the pattern is ignored, except when in a character class or preceded by an unescaped backslash, and, when a line contains a '#', neither in a character class or preceded by an unescaped backslash, all characters from the leftmost such '#' through the end of the line are ignored.

That means that the two following regular expression objects that match a decimal number are functionally equal:

```python
a = re.compile(r"\d + # the integral part \. # the decimal point \d * # some fractional digits"", re.X)
b = re.compile(r"\d+.\d*")
```

**re.search(pattern, string[, flags])**

Scan through `string` looking for a location where the regular expression `pattern` produces a match, and return a corresponding `MatchObject` instance. Return `None` if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

**re.match(pattern, string[, flags])**

If zero or more characters at the beginning of `string` match the regular expression `pattern`, return a corresponding `MatchObject` instance. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

**Note:** If you want to locate a match anywhere in `string`, use `search()` instead.

**re.split(pattern, string[, maxsplit=0, flags=0])**

Split `string` by the occurrences of `pattern`. If capturing parentheses are used in `pattern`, then the text of all groups in the
pattern are also returned as part of the resulting list. If \texttt{maxsplit} is nonzero, at most \texttt{maxsplit} splits occur, and the remainder of the string is returned as the final element of the list. (Incompatibility note: in the original Python 1.5 release, \texttt{maxsplit} was ignored. This has been fixed in later releases.)

\begin{Verbatim}
>>> re.split('\\W+', 'Words, words, words."
['Words', 'words', 'words', '"
>>> re.split('(\\W+)\', 'Words, words, words."
['Words', 'words', 'words', '"
>>> re.split('\\W+', 'Words, words, words.', 1)
[Words', 'words, words."
>>> re.split('[a-f]+', '0a3B9', flags=re.IGNORECASE)
['0', '3', '9']
\end{Verbatim}

If there are capturing groups in the separator and it matches at the start of the string, the result will start with an empty string. The same holds for the end of the string:

\begin{Verbatim}
>>> re.split('(\\W+)\', '...words, words..."
['...', 'words', 'words', '...'
\end{Verbatim}

That way, separator components are always found at the same relative indices within the result list (e.g., if there’s one capturing group in the separator, the 0th, the 2nd and so forth).

Note that \texttt{split} will never split a string on an empty pattern match. For example:

\begin{Verbatim}
>>> re.split('x\*', 'foo')
['foo']
>>> re.split("(?m)^$", "foo
\n"nbar\n")
['foo
\nbar\n']
\end{Verbatim}

\textit{Changed in version 2.7,3.1:} Added the optional flags argument.

\texttt{re.findall(pattern, string\texttt[, flags])}

Return all non-overlapping matches of \texttt{pattern} in \texttt{string}, as a list
of strings. The string is scanned left-to-right, and matches are returned in
the order found. If one or more groups are present in the pattern, return a list
of groups; this will be a list of tuples if the pattern has more than one group.
Empty matches are included in the result unless they touch the beginning of
another match.

*New in version 1.5.2.*

*Changed in version 2.4:* Added the optional flags argument.

`re.finditer(pattern, string[, flags])`

Return an iterator yielding `MatchObject` instances over all non-overlapping
matches for the RE pattern in string. The string is scanned left-to-right,
and matches are returned in the order found. Empty matches are included in
the result unless they touch the beginning of another match.

*New in version 2.2.*

*Changed in version 2.4:* Added the optional flags argument.

`re.sub(pattern, repl, string[, count, flags])`

Return the string obtained by replacing the leftmost non-overlapping
currences of pattern in string by the replacement repl. If the pattern isn’t
found, string is returned unchanged. repl can be a string or a function;
if it is a string, any backslash escapes in it are processed. That is, \n is converted to a single newline character, \r is converted to a linefeed,
and so forth. Unknown escapes such as \j are left alone. Backreferences,
such as \6, are replaced with the substring matched by group 6
in the pattern. For example:

```python
>>> re.sub(r'def\s+([a-zA-Z_]\[a-zA-Z_0-9\]*)\s*\((\s*\)\:\',
       'r\'static PyObject*\npy_\1(\void)\n\',
       'def myfunc():')
```
'static PyObject* npy_myfunc(void) \n{'

If `repl` is a function, it is called for every non-overlapping occurrence of `pattern`. The function takes a single match object argument, and returns the replacement string. For example:

```python
>>> def dashrepl(matchobj):
...     if matchobj.group(0) == '-': return ''
...     else: return '-'

>>> re.sub('-', '{1,2}', 'pro----gram-files')
'pro--gram files'
>>> re.sub(r'\sAND\s', ' & ', 'Baked Beans And Spam', flags=re.IGNORECASE)
'Baked Beans & Spam'
```

The pattern may be a string or an RE object.

The optional argument `count` is the maximum number of pattern occurrences to be replaced; `count` must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous match, so `sub('x*\n', '-', 'abc')` returns `'-a-b-c-'`.

In addition to character escapes and backreferences as described above, `\g<name>` will use the substring matched by the group named `name`, as defined by the `(?P<name>...)` syntax. `\g<number>` uses the corresponding group number; `\g<2>` is therefore equivalent to `\2`, but isn’t ambiguous in a replacement such as `\g<2>\0`. `\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character ‘\0’. The backreference `\g<0>` substitutes in the entire substring matched by the RE.

`Changed in version 2.7, 3.1:` Added the optional flags argument.

```python
re.subn(pattern, repl, string[, count, flags])
```

Perform the same operation as `sub()`, but return a tuple
Changed in version 2.7,3.1: Added the optional flags argument.

`re.escape(string)`
Return `string` with all non-alphanumerics backslashed; this is useful if you want to match an arbitrary literal string that may have regular expression metacharacters in it.

`exception re.error`
Exception raised when a string passed to one of the functions here is not a valid regular expression (for example, it might contain unmatched parentheses) or when some other error occurs during compilation or matching. It is never an error if a string contains no match for a pattern.
7.2.4. Regular Expression Objects

class re.RegexObject

The RegexObject class supports the following methods and attributes:

search(string[, pos[, endpos]])

Scan through string looking for a location where this regular expression produces a match, and return a corresponding MatchObject instance. Return None if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional second parameter pos gives an index in the string where the search is to start; it defaults to 0. This is not completely equivalent to slicing the string; the \'^' pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter endpos limits how far the string will be searched; it will be as if the string is endpos characters long, so only the characters from pos to endpos - 1 will be searched for a match. If endpos is less than pos, no match will be found, otherwise, if rx is a compiled regular expression object, rx.search(string, 0, 50) is equivalent to rx.search(string[:50], 0).

```python
>>> pattern = re.compile("d")
>>> pattern.search("dog")  # Match at index 0
<_sre.SRE_Match object at ...>
>>> pattern.search("dog", 1)  # No match; search doesn't
```
match(string[, pos[, endpos]])
If zero or more characters at the beginning of string match this regular expression, return a corresponding MatchObject instance. Return None if the string does not match the pattern; note that this is different from a zero-length match.

The optional pos and endpos parameters have the same meaning as for the search() method.

Note: If you want to locate a match anywhere in string, use search() instead.

>>> pattern = re.compile("o")
>>> pattern.match("dog")  # No match as "o" is not at the start of "dog".
>>> pattern.match("dog", 1)  # Match as "o" is the 2nd character
<_sre.SRE_Match object at ...>

split(string[, maxsplit=0])
Identical to the split() function, using the compiled pattern.

findall(string[, pos[, endpos]])
Similar to the findall() function, using the compiled pattern, but also accepts optional pos and endpos parameters that limit the search region like for match().

finditer(string[, pos[, endpos]])
Similar to the finditer() function, using the compiled pattern, but also accepts optional pos and endpos parameters that limit the search region like for match().

sub(repl, string[, count=0])
Identical to the sub() function, using the compiled pattern.
subn(repl, string[, count=0])

Identical to the subn() function, using the compiled pattern.

flags
The flags argument used when the RE object was compiled, or 0 if no flags were provided.

groups
The number of capturing groups in the pattern.

groupindex
A dictionary mapping any symbolic group names defined by (?P<id>) to group numbers. The dictionary is empty if no symbolic groups were used in the pattern.

pattern
The pattern string from which the RE object was compiled.
7.2.5. Match Objects

class re.MatchObject

Match Objects always have a boolean value of True, so that you can test whether e.g. `match()` resulted in a match with a simple if statement. They support the following methods and attributes:

`expand(template)`

Return the string obtained by doing backslash substitution on the template string `template`, as done by the `sub()` method. Escapes such as \n are converted to the appropriate characters, and numeric backreferences (\1, \2) and named backreferences (\g<1>, \g<name>) are replaced by the contents of the corresponding group.

`group([group1,...])`

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, `group1` defaults to zero (the whole match is returned). If a `groupN` argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range [1..99], it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an `IndexError` exception is raised. If a group is contained in a part of the pattern that did not match, the corresponding result is None. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

>>> m = re.match(r"(\w+) (\w+)", "Isaac Newton, physicist"
>>> m.group(0) # The entire match
'Isaac Newton'
>>> m.group(1)  # The first parenthesized subgroup.
'Isaac'
>>> m.group(2)  # The second parenthesized subgroup.
'Newton'
>>> m.group(1, 2)  # Multiple arguments give us a tuple
('Isaac', 'Newton')

If the regular expression uses the (?P<name>...) syntax, the group\text{N} arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an ValueError exception is raised.

A moderately complicated example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Malcolm Reynolds")
>>> m.group('first_name')
'Malcolm'
>>> m.group('last_name')
'Reynolds'
```

Named groups can also be referred to by their index:

```python
>>> m.group(1)
'Malcolm'
>>> m.group(2)
'Reynolds'
```

If a group matches multiple times, only the last match is accessible:

```python
>>> m = re.match(r"(.+)", "a1b2c3")  # Matches 3 times.
>>> m.group(1)  # Returns only the
'c3'
```

\text{groups}([\text{default}])

Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The default
argument is used for groups that did not participate in the match; it defaults to None. (Incompatibility note: in the original Python 1.5 release, if the tuple was one element long, a string would be returned instead. In later versions (from 1.5.1 on), a singleton tuple is returned in such cases.)

For example:

```python
>>> m = re.match(r"(\d+)\.(\d+)", "24.1632")
>>> m.groups()
('24', '1632')
```

If we make the decimal place and everything after it optional, not all groups might participate in the match. These groups will default to None unless the default argument is given:

```python
>>> m = re.match(r"(\d+)\.?\d+"ırım, "24")
>>> m.groups()  # Second group defaults to None.
('24', None)
>>> m.groups('0')  # Now, the second group defaults to '0'.
('24', '0')
```

`groupdict([default])`

Return a dictionary containing all the named subgroups of the match, keyed by the subgroup name. The default argument is used for groups that did not participate in the match; it defaults to None. For example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Malcolm Reynolds")
>>> m.groupdict()
{'first_name': 'Malcolm', 'last_name': 'Reynolds'}
```

`start([group])`

`end([group])`

Return the indices of the start and end of the substring
matched by *group*. *group* defaults to zero (meaning the whole matched substring). Return -1 if *group* exists but did not contribute to the match. For a match object *m*, and a group *g* that did contribute to the match, the substring matched by group *g* (equivalent to *m.group(g)*) is

```python
m.string[m.start(g):m.end(g)]
```

Note that *m.start(group)* will equal *m.end(group)* if *group* matched a null string. For example, after `m = re.search('b(c?)', 'cba')`, *m.start(0)* is 1, *m.end(0)* is 2, *m.start(1)* and *m.end(1)* are both 2, and *m.start(2)* raises an IndexError exception.

An example that will remove *remove_this* from email addresses:

```python
>>> email = "tony@tiremove_thisger.net"
>>> m = re.search("remove_this", email)
>>> email[:m.start()] + email[m.end():]
'tony@tiger.net'
```

**span([group])**

For *MatchObject* *m*, return the 2-tuple (*m.start(group)*, *m.end(group)*). Note that if *group* did not contribute to the match, this is (-1, -1). *group* defaults to zero, the entire match.

**pos**

The value of *pos* which was passed to the *search()* or *match()* method of the *RegexObject*. This is the index into the string at which the RE engine started looking for a match.

**endpos**

The value of *endpos* which was passed to the *search()* or
**match()** method of the *RegexObject*. This is the index into the string beyond which the RE engine will not go.

**lastindex**

The integer index of the last matched capturing group, or **None** if no group was matched at all. For example, the expressions `(a)b`, `((a)(b))`, and `((ab))` will have **lastindex == 1** if applied to the string `'ab'`, while the expression `(a)(b)` will have **lastindex == 2**, if applied to the same string.

**lastgroup**

The name of the last matched capturing group, or **None** if the group didn’t have a name, or if no group was matched at all.

**re**

The regular expression object whose **match()** or **search()** method produced this **MatchObject** instance.

**string**

The string passed to **match()** or **search()**.
7.2.6. Examples

7.2.6.1. Checking For a Pair

In this example, we'll use the following helper function to display match objects a little more gracefully:

```python
def displaymatch(match):
    if match is None:
        return None
    return '<Match: %r, groups=%r>' % (match.group(), match.groups())
```

Suppose you are writing a poker program where a player's hand is represented as a 5-character string with each character representing a card, “a” for ace, “k” for king, “q” for queen, j for jack, “0” for 10, and “1” through “9” representing the card with that value.

To see if a given string is a valid hand, one could do the following:

```python
>>> valid = re.compile(r'[0-9akqj]{5}$')
>>> displaymatch(valid.match("ak05q"))  # Valid.
"<Match: 'ak05q', groups=()>
>>> displaymatch(valid.match("ak05e"))  # Invalid.
>>> displaymatch(valid.match("ak0"))  # Invalid.
>>> displaymatch(valid.match("727ak"))  # Valid.
"<Match: '727ak', groups=()>
```

That last hand, "727ak", contained a pair, or two of the same valued cards. To match this with a regular expression, one could use backreferences as such:

```python
>>> pair = re.compile(r".*(.).*\1")
>>> displaymatch(pair.match("717ak"))  # Pair of 7s.
"<Match: '717', groups=('7',)>
>>> displaymatch(pair.match("718ak"))  # No pairs.
>>> displaymatch(pair.match("354aa"))  # Pair of aces.
"<Match: '354aa', groups=('a',)>"
```
To find out what card the pair consists of, one could use the `group()` method of `MatchObject` in the following manner:

```python
>>> pair.match("717ak").group(1)
'7'
```

# Error because `re.match()` returns None, which doesn't have a `group()` method:

```python
>>> pair.match("718ak").group(1)
Traceback (most recent call last):
  File "<pyshell#23>", line 1, in <module>
    re.match(r".*(.).*\1", "718ak").group(1)
AttributeError: 'NoneType' object has no attribute 'group'
```

```python
>>> pair.match("354aa").group(1)
'a'
```

## 7.2.6.2. Simulating scanf()

Python does not currently have an equivalent to `scanf()`. Regular expressions are generally more powerful, though also more verbose, than `scanf()` format strings. The table below offers some more-or-less equivalent mappings between `scanf()` format tokens and regular expressions.

<table>
<thead>
<tr>
<th><code>scanf()</code> Token</th>
<th>Regular Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>%c</code></td>
<td>.</td>
</tr>
<tr>
<td><code>%5c</code></td>
<td>{5}</td>
</tr>
<tr>
<td><code>%d</code></td>
<td>[+-]?d+</td>
</tr>
<tr>
<td><code>%e</code>, <code>%E</code>, <code>%f</code>, <code>%g</code></td>
<td>[+-]?(\d+(\d*)?.</td>
</tr>
<tr>
<td><code>%i</code></td>
<td>[+-]?(0[xX][\dA-Fa-f]+</td>
</tr>
<tr>
<td><code>%o</code></td>
<td>0[0-7]*</td>
</tr>
<tr>
<td><code>%s</code></td>
<td>\S+</td>
</tr>
<tr>
<td><code>%u</code></td>
<td>\d+</td>
</tr>
<tr>
<td><code>%x</code>, <code>%X</code></td>
<td>0[xX][\dA-Fa-f]+</td>
</tr>
</tbody>
</table>
To extract the filename and numbers from a string like

```
/usr/sbin/sendmail - 0 errors, 4 warnings
```

you would use a `scanf()` format like

```
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```
(\S+) - (\d+) errors, (\d+) warnings
```

### 7.2.6.3. Avoiding recursion

If you create regular expressions that require the engine to perform a lot of recursion, you may encounter a `RuntimeError` exception with the message `maximum recursion limit exceeded`. For example,

```
>>> s = 'Begin ' + 1000*'a very long string ' + 'end'
>>> re.match('Begin (\w| )*? end', s).end()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/usr/local/lib/python2.5/re.py", line 132, in match
    return _compile(pattern, flags).match(string)
RuntimeError: maximum recursion limit exceeded
```

You can often restructure your regular expression to avoid recursion.

Starting with Python 2.3, simple uses of the `*?` pattern are special-cased to avoid recursion. Thus, the above regular expression can avoid recursion by being recast as `Begin [a-zA-Z0-9_]*?end`. As a further benefit, such regular expressions will run faster than their recursive equivalents.

### 7.2.6.4. search() vs. match()
In a nutshell, `match()` only attempts to match a pattern at the beginning of a string where `search()` will match a pattern anywhere in a string. For example:

```python
>>> re.match("o", "dog")  # No match as "o" is not the first letter
>>> re.search("o", "dog")  # Match as search() looks everywhere
<_sre.SRE_Match object at ...>
```

**Note:** The following applies only to regular expression objects like those created with `re.compile("pattern")`, not the primitives `re.match(pattern, string)` or `re.search(pattern, string)`.

`match()` has an optional second parameter that gives an index in the string where the search is to start:

```python
>>> pattern = re.compile("o")
>>> pattern.match("dog")  # No match as "o" is not at the start
# Equivalent to the above expression as 0 is the default starting index
>>> pattern.match("dog", 0)
# Match as "o" is the 2nd character of "dog" (index 0 is the first)
>>> pattern.match("dog", 1)
<_sre.SRE_Match object at ...>
>>> pattern.match("dog", 2)  # No match as "o" is not the third character
```

### 7.2.6.5. Making a Phonebook

`split()` splits a string into a list delimited by the passed pattern. The method is invaluable for converting textual data into data structures that can be easily read and modified by Python as demonstrated in the following example that creates a phonebook.

First, here is the input. Normally it may come from a file, here we are using triple-quoted string syntax:
The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```python
>>> input = """Ross McFluff: 834.345.1254 155 Elm Street
... Ronald Heathmore: 892.345.3428 436 Finley Avenue
... Frank Burger: 925.541.7625 662 South Dogwood Way
... Heather Albrecht: 548.326.4584 919 Park Place"

The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```
>>> entries = re.split("\n+", input)
>>> entries
['Ross McFluff: 834.345.1254 155 Elm Street',
 'Ronald Heathmore: 892.345.3428 436 Finley Avenue',
 'Frank Burger: 925.541.7625 662 South Dogwood Way',
 'Heather Albrecht: 548.326.4584 919 Park Place']
```

Finally, split each entry into a list with first name, last name, telephone number, and address. We use the `maxsplit` parameter of `split()` because the address has spaces, our splitting pattern, in it:

```
>>> [re.split(':?\s', entry, 3) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155 Elm Street'],
 ['Ronald', 'Heathmore', '892.345.3428', '436 Finley Avenue'],
 ['Frank', 'Burger', '925.541.7625', '662 South Dogwood Way'],
 ['Heather', 'Albrecht', '548.326.4584', '919 Park Place']]
```

The `:?:` pattern matches the colon after the last name, so that it does not occur in the result list. With a `maxsplit` of 4, we could separate the house number from the street name:

```
>>> [re.split(':?\s', entry, 4) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155', 'Elm Street'],
 ['Ronald', 'Heathmore', '892.345.3428', '436', 'Finley Avenue'],
 ['Frank', 'Burger', '925.541.7625', '662', 'South Dogwood Way'],
 ['Heather', 'Albrecht', '548.326.4584', '919', 'Park Place']]
```

7.2.6.6. Text Munging
sub() replaces every occurrence of a pattern with a string or the result of a function. This example demonstrates using sub() with a function to “munge” text, or randomize the order of all the characters in each word of a sentence except for the first and last characters:

```python
>>> def repl(m):
...     inner_word = list(m.group(2))
...     random.shuffle(inner_word)
...     return m.group(1) + ''.join(inner_word) + m.group(3)

>>> text = "Professor Abdolmalek, please report your absences promptly."
>>> re.sub("\w(\w+)(\w)", repl, text)
'Poefsrosr Aealmlobdk, pslaee reorpt your abnseces plmrptoy.'
```

7.2.6.7. Finding all Adverbs

findall() matches all occurrences of a pattern, not just the first one as search() does. For example, if one was a writer and wanted to find all of the adverbs in some text, he or she might use findall() in the following manner:

```python
>>> text = "He was carefully disguised but captured quickly by police."
>>> re.findall(r"\w+ly", text)
['carefully', 'quickly']
```

7.2.6.8. Finding all Adverbs and their Positions

If one wants more information about all matches of a pattern than the matched text, finditer() is useful as it provides instances of MatchObject instead of strings. Continuing with the previous example, if one was a writer who wanted to find all of the adverbs and their positions in some text, he or she would use finditer() in the following manner:
Raw string notation (r"text") keeps regular expressions sane. Without it, every backslash ('\') in a regular expression would have to be prefixed with another one to escape it. For example, the two following lines of code are functionally identical:

```python
>>> re.match(r"\W(.)\1\W", " ff ")
<_sre.SRE_Match object at ...>
>>> re.match("\W(.)\1\W", " ff ")
<_sre.SRE_Match object at ...>
```

When one wants to match a literal backslash, it must be escaped in the regular expression. With raw string notation, this means r"\\". Without raw string notation, one must use "\\\", making the following lines of code functionally identical:

```python
>>> re.match(r"\\", r"\\")
<_sre.SRE_Match object at ...>
>>> re.match("\\\", r"\\")
<_sre.SRE_Match object at ...>
```
This module performs conversions between Python values and C structs represented as Python strings. This can be used in handling binary data stored in files or from network connections, among other sources. It uses *Format Strings* as compact descriptions of the layout of the C structs and the intended conversion to/from Python values.

**Note:** By default, the result of packing a given C struct includes pad bytes in order to maintain proper alignment for the C types involved; similarly, alignment is taken into account when unpacking. This behavior is chosen so that the bytes of a packed struct correspond exactly to the layout in memory of the corresponding C struct. To handle platform-independent data formats or omit implicit pad bytes, use *standard* size and alignment instead of *native* size and alignment: see *Byte Order, Size, and Alignment* for details.
7.3.1. Functions and Exceptions

The module defines the following exception and functions:

*exception* `struct.error`

Exception raised on various occasions; argument is a string describing what is wrong.

*struct.* `pack(fmt, v1, v2, ...)`

Return a string containing the values `v1, v2, ...` packed according to the given format. The arguments must match the values required by the format exactly.

*struct.* `pack_into(fmt, buffer, offset, v1, v2, ...)`

Pack the values `v1, v2, ...` according to the given format, write the packed bytes into the writable `buffer` starting at `offset`. Note that the offset is a required argument.

*New in version 2.5.*

*struct.* `unpack(fmt, string)`

Unpack the string (presumably packed by `pack(fmt, ...)` according to the given format. The result is a tuple even if it contains exactly one item. The string must contain exactly the amount of data required by the format (\(\text{len(string)}\) must equal `calcsize(fmt)`).

*struct.* `unpack_from(fmt, buffer[, offset=0])`

Unpack the `buffer` according to the given format. The result is a tuple even if it contains exactly one item. The `buffer` must contain at least the amount of data required by the format (\(\text{len(buffer[offset:])}\) must be at least `calcsize(fmt)`).
New in version 2.5.

struct. `calcsize(fmt)`

Return the size of the struct (and hence of the string) corresponding to the given format.
7.3.2. Format Strings

Format strings are the mechanism used to specify the expected layout when packing and unpacking data. They are built up from **Format Characters**, which specify the type of data being packed/unpacked. In addition, there are special characters for controlling the **Byte Order, Size, and Alignment**.

7.3.2.1. Byte Order, Size, and Alignment

By default, C types are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:

<table>
<thead>
<tr>
<th>Character</th>
<th>Byte order</th>
<th>Size</th>
<th>Alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>@</td>
<td>native</td>
<td>native</td>
<td>native</td>
</tr>
<tr>
<td>=</td>
<td>native</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>&lt;</td>
<td>little-endian</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>&gt;</td>
<td>big-endian</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>!</td>
<td>network (= big-endian)</td>
<td>standard</td>
<td>none</td>
</tr>
</tbody>
</table>

If the first character is not one of these, '@' is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Intel x86 and AMD64 (x86-64) are little-endian; Motorola 68000 and PowerPC G5 are big-endian; ARM and Intel Itanium feature switchable endianness (bi-endian). Use `sys.byteorder` to check the endianness of your system.
Native size and alignment are determined using the C compiler's `sizeof` expression. This is always combined with native byte order.

Standard size depends only on the format character; see the table in the *Format Characters* section.

Note the difference between `@` and `=`: both use native byte order, but the size and alignment of the latter is standardized.

The form `!` is available for those poor souls who claim they can’t remember whether network byte order is big-endian or little-endian.

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of `<` or `>`.

Notes:

1. Padding is only automatically added between successive structure members. No padding is added at the beginning or the end of the encoded struct.
2. No padding is added when using non-native size and alignment, e.g. with `<`, `>`, `=`, and `!`.
3. To align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count of zero. See *Examples*.

### 7.3.2.2. Format Characters

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types. The ‘Standard size’ column refers to the size of the packed value in bytes when using standard size; that is, when the format string starts with one of `<`, `>`, `!` or `=`. When using native size, the size of the packed value is platform-dependent.
<table>
<thead>
<tr>
<th>Format</th>
<th>C Type</th>
<th>Python type</th>
<th>Standard size</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>pad byte</td>
<td>no value</td>
<td></td>
<td></td>
</tr>
<tr>
<td>c</td>
<td>char</td>
<td>string of length 1</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td>b</td>
<td>signed char</td>
<td>integer</td>
<td>1</td>
<td>(3)</td>
</tr>
<tr>
<td>B</td>
<td>unsigned char</td>
<td>integer</td>
<td>1</td>
<td>(3)</td>
</tr>
<tr>
<td>?</td>
<td>_Bool</td>
<td>bool</td>
<td>1</td>
<td>(1)</td>
</tr>
<tr>
<td>h</td>
<td>short</td>
<td>integer</td>
<td>2</td>
<td>(3)</td>
</tr>
<tr>
<td>H</td>
<td>unsigned short</td>
<td>integer</td>
<td>2</td>
<td>(3)</td>
</tr>
<tr>
<td>i</td>
<td>int</td>
<td>integer</td>
<td>4</td>
<td>(3)</td>
</tr>
<tr>
<td>I</td>
<td>unsigned int</td>
<td>integer</td>
<td>4</td>
<td>(3)</td>
</tr>
<tr>
<td>l</td>
<td>long</td>
<td>integer</td>
<td>4</td>
<td>(3)</td>
</tr>
<tr>
<td>L</td>
<td>unsigned long</td>
<td>integer</td>
<td>4</td>
<td>(3)</td>
</tr>
<tr>
<td>q</td>
<td>long long</td>
<td>integer</td>
<td>8</td>
<td>(2), (3)</td>
</tr>
<tr>
<td>Q</td>
<td>unsigned long long</td>
<td>integer</td>
<td>8</td>
<td>(2), (3)</td>
</tr>
<tr>
<td>f</td>
<td>float</td>
<td>float</td>
<td>4</td>
<td>(4)</td>
</tr>
<tr>
<td>d</td>
<td>double</td>
<td>float</td>
<td>8</td>
<td>(4)</td>
</tr>
<tr>
<td>s</td>
<td>char[]</td>
<td>string</td>
<td></td>
<td></td>
</tr>
<tr>
<td>p</td>
<td>char[]</td>
<td>string</td>
<td></td>
<td></td>
</tr>
<tr>
<td>P</td>
<td>void *</td>
<td>integer</td>
<td>(5), (3)</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. The '??' conversion code corresponds to the _Bool type defined by C99. If this type is not available, it is simulated using a char. In standard mode, it is always represented by one byte.

   *New in version 2.6.*

2. The 'q' and 'Q' conversion codes are available in native mode only if the platform C compiler supports C long long, or, on Windows, __int64. They are always available in standard
modes.

New in version 2.2.

3. When attempting to pack a non-integer using any of the integer conversion codes, if the non-integer has a \_\_index\_() method then that method is called to convert the argument to an integer before packing. If no \_\_index\_() method exists, or the call to \_\_index\_() raises TypeError, then the \_\_int\_() method is tried. However, the use of \_\_int\_() is deprecated, and will raise DeprecationWarning.

Changed in version 2.7: Use of the \_\_index\_() method for non-integers is new in 2.7.

Changed in version 2.7: Prior to version 2.7, not all integer conversion codes would use the \_\_int\_() method to convert, and DeprecationWarning was raised only for float arguments.

4. For the 'f' and 'd' conversion codes, the packed representation uses the IEEE 754 binary32 (for 'f') or binary64 (for 'd') format, regardless of the floating-point format used by the platform.

5. The 'P' format character is only available for the native byte ordering (selected as the default or with the '@' byte order character). The byte order character '=' chooses to use little- or big-endian ordering based on the host system. The struct module does not interpret this as native ordering, so the 'P' format is not available.

A format character may be preceded by an integral repeat count. For example, the format string '4h' means exactly the same as 'hhhh'.
Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

For the 's' format character, the count is interpreted as the size of the string, not a repeat count like for the other format characters; for example, '10s' means a single 10-byte string, while '10c' means 10 characters. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting string always has exactly the specified number of bytes. As a special case, '0s' means a single, empty string (while '0c' means 0 characters).

The 'p' format character encodes a “Pascal string”, meaning a short variable-length string stored in a fixed number of bytes. The count is the total number of bytes stored. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to pack() is too long (longer than the count minus 1), only the leading count-1 bytes of the string are stored. If the string is shorter than count-1, it is padded with null bytes so that exactly count bytes in all are used. Note that for unpack(), the 'p' format character consumes count bytes, but that the string returned can never contain more than 255 characters.

For the 'P' format character, the return value is a Python integer or long integer, depending on the size needed to hold a pointer when it has been cast to an integer type. A NULL pointer will always be returned as the Python integer 0. When packing pointer-sized values, Python integer or long integer objects may be used. For example, the Alpha and Merced processors use 64-bit pointer values, meaning a Python long integer will be used to hold the pointer; other platforms use 32-bit pointers and will use a Python integer.

For the '?' format character, the return value is either True or False. When packing, the truth value of the argument object is used. Either
0 or 1 in the native or standard bool representation will be packed, and any non-zero value will be True when unpacking.

### 7.3.2.3. Examples

**Note:** All examples assume a native byte order, size, and alignment with a big-endian machine.

A basic example of packing/unpacking three integers:

```python
>>> from struct import *
>>> pack('hhl', 1, 2, 3)
'\x00\x01\x00\x00\x02\x00\x00\x00\x03'
>>> unpack('hhl', '\x00\x01\x00\x00\x02\x00\x00\x00\x03')
(1, 2, 3)
>>> calcsize('hhl')
8
```

Unpacked fields can be named by assigning them to variables or by wrapping the result in a named tuple:

```python
>>> record = 'raymond \x32\x12\x08\x01\x08'
>>> name, serialnum, school, gradelevel = unpack('<10sHHb', record)
>>> from collections import namedtuple
>>> Student = namedtuple('Student', 'name serialnum school gradelevel')
>>> Student._make(unpack('<10sHHb', s))
Student(name='raymond ', serialnum=4658, school=264, gradelevel=8)
```

The ordering of format characters may have an impact on size since the padding needed to satisfy alignment requirements is different:

```python
>>> pack('ci', '*', 0x12131415)
'*\x00\x00\x00\x12\x13\x14\x15'
>>> pack('ic', 0x12131415, '*')
'\x12\x13\x14\x15*'
>>> calcsize('ci')
8
>>> calcsize('ic')
```

The following format 'llh0l' specifies two pad bytes at the end, assuming longs are aligned on 4-byte boundaries:

```python
>>> pack('llh0l', 1, 2, 3)
'\x00\x00\x00\x01\x00\x00\x00\x02\x00\x03\x00\x00'
```

This only works when native size and alignment are in effect; standard size and alignment does not enforce any alignment.

**See also:**

**Module array**

Packed binary storage of homogeneous data.

**Module xdrlib**

Packing and unpacking of XDR data.
7.3.3. Classes

The `struct` module also defines the following type:

```python
class struct.Struct(format)
```

Return a new Struct object which writes and reads binary data according to the format string `format`. Creating a Struct object once and calling its methods is more efficient than calling the `struct` functions with the same format since the format string only needs to be compiled once.

*New in version 2.5.*

Compiled Struct objects support the following methods and attributes:

- `pack(v1, v2, ...)`
  Identical to the `pack()` function, using the compiled format. 
  `(len(result) will equal self.size.)`

- `pack_into(buffer, offset, v1, v2, ...)`
  Identical to the `pack_into()` function, using the compiled format.

- `unpack(string)`
  Identical to the `unpack()` function, using the compiled format. 
  `(len(string) must equal self.size).`

- `unpack_from(buffer[, offset=0])`
  Identical to the `unpack_from()` function, using the compiled format. 
  `(len(buffer[offset:]) must be at least self.size).`
The format string used to construct this Struct object.

**size**

The calculated size of the struct (and hence of the string) corresponding to `format`.
7.4. difflib — Helpers for computing deltas

New in version 2.1.

This module provides classes and functions for comparing sequences. It can be used for example, for comparing files, and can produce difference information in various formats, including HTML and context and unified diffs. For comparing directories and files, see also, the filecmp module.

class difflib.SequenceMatcher
This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are hashable. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980’s by Ratcliff and Obershelp under the hyperbolic name “gestalt pattern matching.” The idea is to find the longest contiguous matching subsequence that contains no “junk” elements (the Ratcliff and Obershelp algorithm doesn’t address junk). The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that “look right” to people.

Timing: The basic Ratcliff-Obershelp algorithm is cubic time in the worst case and quadratic time in the expected case. SequenceMatcher is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

class difflib.Differ
This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses `SequenceMatcher` both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a Differ delta begins with a two-letter code:

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'-'</td>
<td>line unique to sequence 1</td>
</tr>
<tr>
<td>'+'</td>
<td>line unique to sequence 2</td>
</tr>
<tr>
<td>'-'</td>
<td>line common to both sequences</td>
</tr>
<tr>
<td>'?'</td>
<td>line not present in either input sequence</td>
</tr>
</tbody>
</table>

Lines beginning with `?' attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

`class difflib.Htm1Diff`

This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual difference mode.

The constructor for this class is:

```
__init__([tabsize[, wrapcolumn][, linejunk][, charjunk]])
```

Initializes instance of `Htm1Diff`.

`tabsize` is an optional keyword argument to specify tab stop spacing and defaults to 8.
wrapcolumn is an optional keyword to specify column number where lines are broken and wrapped, defaults to None where lines are not wrapped.

linejunk and charjunk are optional keyword arguments passed into ndiff() (used by HtmlDiff to generate the side by side HTML differences). See ndiff() documentation for argument default values and descriptions.

The following methods are public:

make_file(fromlines, tolines[, fromdesc][, todesc][, context][, numlines])

Compares fromlines and tolines (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.

fromdesc and todesc are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

context and numlines are both optional keyword arguments. Set context to True when contextual differences are to be shown, else the default is False to show the full files. numlines defaults to 5. When context is True numlines controls the number of context lines which surround the difference highlights. When context is False numlines controls the number of lines which are shown before a difference highlight when using the “next” hyperlinks (setting to zero would cause the “next” hyperlinks to place the next difference highlight at the top of the browser without any leading context).
make_table(fromlines, tolines[, fromdesc][, todesc][, context][, numlines])

Compares fromlines and tolines (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the make_file() method.

Tools/scripts/diff.py is a command-line front-end to this class and contains a good example of its use.

New in version 2.4.

difflib.context_diff(a, b[, fromfile][, tofile][, fromfiledate][, tofiledate][, n][, lineterm])

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by n which defaults to three.

By default, the diff control lines (those with *** or ---) are created with a trailing newline. This is helpful so that inputs created from file.readlines() result in diffs that are suitable for use with file.writelines() since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the lineterm argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and
modification times. Any or all of these may be specified using strings for `fromfile`, `tofile`, `fromfiledate`, and `tofiledate`. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon
', 'eggs
', 'ham
', 'guido
']
>>> s2 = ['python
', 'eggy
', 'hamster
', 'guido
']
>>> for line in context_diff(s1, s2, fromfile='before.py', t...
    ...   sys.stdout.write(line)  # doctest: +NORMALIZE_WHITESPACE
*** before.py
--- after.py
***************
*** 1,4 ****
! bacon
! eggs
! ham
! guidedo
--- 1,4 ----
! python
! eggy
! hamster
! guidedo
```

See *A command-line interface to difflib* for a more detailed example.

*New in version 2.3.*

`difflib.get_close_matches(word, possibilities[, n][, cutoff])`

Return a list of the best “good enough” matches. `word` is a sequence for which close matches are desired (typically a string), and `possibilities` is a list of sequences against which to match `word` (typically a list of strings).

Optional argument `n` (default 3) is the maximum number of close matches to return; `n` must be greater than 0.

Optional argument `cutoff` (default 0.6) is a float in the range [0,
Possibilities that don't score at least that similar to word are ignored.

The best (no more than $n$) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

```python
grep_close_matches('appel', ['ape', 'apple', 'peach', 'puppy']) ['apple', 'ape']
grep_close_matches('wheel', keyword.kwlist) ['while']
grep_close_matches('apple', keyword.kwlist) []
grep_close_matches('accept', keyword.kwlist) ['except']
```

difflib.ndiff(a, b[, linejunk][, charjunk])

Compare $a$ and $b$ (lists of strings); return a Differ-style delta (a generator generating the delta lines).

Optional keyword parameters linejunk and charjunk are for filter functions (or None):

- **linejunk**: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is (None), starting with Python 2.3. Before then, the default was the module-level function `IS_LINE_JUNK()`, which filters out lines without visible characters, except for at most one pound character (`#`). As of Python 2.3, the underlying `SequenceMatcher` class does a dynamic analysis of which lines are so frequent as to constitute noise, and this usually works better than the pre-2.3 default.

- **charjunk**: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function `IS_CHARACTER_JUNK()`, which filters out
whitespace characters (a blank or tab; note: bad idea to include newline in this!).

_Tools/scripts/ndiff.py_ is a command-line front-end to this function.

```
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1),
...                   'ore\ntree\nemu\n'.splitlines(1))
>>> print ''.join(diff),
- one
? ^
+ ore
? ^
- two
- three
? -
+ tree
+ emu
```

difflib. **restore**(sequence, which)

Return one of the two sequences that generated a delta.

Given a _sequence_ produced by _Differ.compare()_ or _ndiff(),_ extract lines originating from file 1 or 2 (parameter which), stripping off line prefixes.

Example:

```
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1),
...                   'ore\ntree\nemu\n'.splitlines(1))
>>> diff = list(diff) # materialize the generated delta into
```

```
>>> print ''.join(restore(diff, 1)),
one
two
three
>>> print ''.join(restore(diff, 2)),
ore
tree
emu
```
difflib.unified_diff(a, b[, fromfile][, tofile][, fromfiledate][, tofiledate][, n][, lineterm])

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a inline style (instead of separate before/after blocks). The number of context lines is set by n which defaults to three.

By default, the diff control lines (those with ---, +++ or @@) are created with a trailing newline. This is helpful so that inputs created from file.readlines() result in diffs that are suitable for use with file.writelines() since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the lineterm argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for fromfile, tofile, fromfiledate, and tofiledate. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon
', 'eggs
', 'ham
', 'guido
']
>>> s2 = ['python
', 'eggy
', 'hamster
', 'guido
']
>>> for line in unified_diff(s1, s2, fromfile='before.py', tofile='after.py'):
...     sys.stdout.write(line)  # doctest: +NORMALIZE_WHITESPACE
--- before.py
+++ after.py
@@ -1,4 +1,4 @@
-bacon
-eggs
-ham
+python
+eggy
```
See A command-line interface to difflib for a more detailed example.

New in version 2.3.

difflib.IS_LINE_JUNK(line)
Return true for ignorable lines. The line line is ignorable if line is blank or contains a single '#' , otherwise it is not ignorable. Used as a default for parameter linejunk in ndiff() before Python 2.3.

difflib.IS_CHARACTER_JUNK(ch)
Return true for ignorable characters. The character ch is ignorable if ch is a space or tab, otherwise it is not ignorable. Used as a default for parameter charjunk in ndiff().

Pattern Matching: The Gestalt Approach
Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in Dr. Dobb’s Journal in July, 1988.
The `SequenceMatcher` class has this constructor:

```python
class difflib.SequenceMatcher([isjunk[, a[, b]]])
```

Optional argument `isjunk` must be `None` (the default) or a one-argument function that takes a sequence element and returns true if and only if the element is “junk” and should be ignored. Passing `None` for `isjunk` is equivalent to passing `lambda x: 0`; in other words, no elements are ignored. For example, pass:

```python
lambda x: x in " \t"
```

if you're comparing lines as sequences of characters, and don't want to synch up on blanks or hard tabs.

The optional arguments `a` and `b` are sequences to be compared; both default to empty strings. The elements of both sequences must be `hashable`.

`SequenceMatcher` objects have the following methods:

```python
set_seqs(a, b)
```

Set the two sequences to be compared.

`SequenceMatcher` computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use `set_seq2()` to set the commonly used sequence once and call `set_seq1()` repeatedly, once for each of the other sequences.

```python
set_seq1(a)
```

Set the first sequence to be compared. The second sequence
to be compared is not changed.

\textbf{set\_seq2}(b)

Set the second sequence to be compared. The first sequence to be compared is not changed.

\textbf{find\_longest\_match}(alo, ahi, blo, bhi)

Find longest matching block in $a[alo:ahi]$ and $b[blo:bhi]$.

If \texttt{isjunk} was omitted or \texttt{None}, \texttt{find\_longest\_match()} returns \((i, j, k)\) such that $a[i:i+k]$ is equal to $b[j:j+k]$, where $alo \leq i \leq i+k \leq ahi$ and $blo \leq j \leq j+k \leq bhi$. For all \((i', j', k')\) meeting those conditions, the additional conditions $k \geq k'$, $i \leq i'$, and if $i = i'$, $j \leq j'$ are also met. In other words, of all maximal matching blocks, return one that starts earliest in $a$, and of all those maximal matching blocks that start earliest in $a$, return the one that starts earliest in $b$.

\begin{verbatim}
>>> s = SequenceMatcher(None, "abcd", "abcd abcd")
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=0, b=4, size=5)
\end{verbatim}

If \texttt{isjunk} was provided, first the longest matching block is determined as above, but with the additional restriction that no junk element appears in the block. Then that block is extended as far as possible by matching (only) junk elements on both sides. So the resulting block never matches on junk except as identical junk happens to be adjacent to an interesting match.

Here's the same example as before, but considering blanks to be junk. That prevents 'abcd' from matching the 'abcd' at the tail end of the second sequence directly. Instead only the 'abcd' can match, and matches the leftmost 'abcd' in the second sequence:
If no blocks match, this returns \((a0, b0, 0)\).

*Changed in version 2.6:* This method returns a named tuple
\[\text{Match}(a, b, \text{size})\].

**get_matching_blocks()**
Return list of triples describing matching subsequences. Each triple is of the form \((i, j, n)\), and means that \(a[i:i+n] == b[j:j+n]\). The triples are monotonically increasing in \(i\) and \(j\).

The last triple is a dummy, and has the value \((\text{len}(a), \text{len}(b), 0)\). It is the only triple with \(n == 0\). If \((i, j, n)\) and \((i', j', n')\) are adjacent triples in the list, and the second is not the last triple in the list, then \(i+n != i'\) or \(j+n != j'\); in other words, adjacent triples always describe non-adjacent equal blocks.

*Changed in version 2.5:* The guarantee that adjacent triples always describe non-adjacent blocks was implemented.

**get_opcodes()**
Return list of 5-tuples describing how to turn \(a\) into \(b\). Each tuple is of the form \((\text{tag}, i1, i2, j1, j2)\). The first tuple has \(i1 == j1 == 0\), and remaining tuples have \(i1\) equal to the \(i2\) from the preceding tuple, and, likewise, \(j1\) equal to the previous \(j2\).
The *tag* values are strings, with these meanings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'replace'</td>
<td><code>a[i1:i2]</code> should be replaced by <code>b[j1:j2]</code>.</td>
</tr>
<tr>
<td>'delete'</td>
<td><code>a[i1:i2]</code> should be deleted. Note that <code>j1 == j2</code> in this case.</td>
</tr>
<tr>
<td>'insert'</td>
<td><code>b[j1:j2]</code> should be inserted at <code>a[i1:i1]</code>. Note that <code>i1 == i2</code> in this case.</td>
</tr>
<tr>
<td>'equal'</td>
<td><code>a[i1:i2] == b[j1:j2]</code> (the sub-sequences are equal).</td>
</tr>
</tbody>
</table>

For example:

```python
>>> a = "qabxcd"
>>> b = "abycdf"
```

```python
>>> s = SequenceMatcher(None, a, b)
```

```python
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
...     print ("%7s a[%d:%d] (%s) b[%d:%d] (%s)" %
...     (tag, i1, i2, a[i1:i2], j1, j2, b[j1:j2]))
...
```

```
delete a[0:1] (q) b[0:0] ()
equal a[1:3] (ab) b[0:2] (ab)
replace a[3:4] (x) b[2:3] (y)
```

### get_grouped_opcodes([n])

Return a *generator* of groups with up to `n` lines of context.

Starting with the groups returned by *get_opcodes()* , this method splits out smaller change clusters and eliminates intervening ranges which have no changes.

The groups are returned in the same format as *get_opcodes()*.

*New in version 2.3.*

### ratio()

...
Return a measure of the sequences' similarity as a float in the range [0, 1].

Where T is the total number of elements in both sequences, and M is the number of matches, this is 2.0*M / T. Note that this is 1.0 if the sequences are identical, and 0.0 if they have nothing in common.

This is expensive to compute if get_matching_blocks() or get_opcodes() hasn't already been called, in which case you may want to try quick_ratio() or real_quick_ratio() first to get an upper bound.

**quick_ratio()**
Return an upper bound on ratio() relatively quickly.

This isn’t defined beyond that it is an upper bound on ratio(), and is faster to compute.

**real_quick_ratio()**
Return an upper bound on ratio() very quickly.

This isn’t defined beyond that it is an upper bound on ratio(), and is faster to compute than either ratio() or quick_ratio().

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although quick_ratio() and real_quick_ratio() are always at least as large as ratio():

```python
>>> s = SequenceMatcher(None, "abcd", "bcde")
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
```
1.0
7.4.2. SequenceMatcher Examples

This example compares two strings, considering blanks to be “junk:"

```python
>>> s = SequenceMatcher(lambda x: x == " ",
... "private Thread currentThread;",
... "private volatile Thread currentThread;"
```

`ratio()` returns a float in [0, 1], measuring the similarity of the sequences. As a rule of thumb, a `ratio()` value over 0.6 means the sequences are close matches:

```python
>>> print round(s.ratio(), 3)
0.866
```

If you're only interested in where the sequences match, `get_matching_blocks()` is handy:

```python
>>> for block in s.get_matching_blocks():
...     print "a[%d] and b[%d] match for %d elements" % block
a[0] and b[0] match for 8 elements
a[8] and b[17] match for 21 elements
a[29] and b[38] match for 0 elements
```

Note that the last tuple returned by `get_matching_blocks()` is always a dummy, `(len(a), len(b), 0)`, and this is the only case in which the last tuple element (number of elements matched) is 0.

If you want to know how to change the first sequence into the second, use `get_opcodes()`:

```python
>>> for opcode in s.get_opcodes():
...     print "%s a[%d:%d] b[%d:%d]" % opcode
equal a[0:8] b[0:8]
same a[8:8] b[8:17]
```
See also:

- The `get_close_matches()` function in this module which shows how simple code building on `SequenceMatcher` can be used to do useful work.
- Simple version control recipe for a small application built with `SequenceMatcher`. 
Note that **Differ**-generated deltas make no claim to be minimal diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The **Differ** class has this constructor:

```python
class difflib.Differ([linejunk[, charjunk]])
```

Optional keyword parameters *linejunk* and *charjunk* are for filter functions (or *None*):

- **linejunk**: A function that accepts a single string argument, and returns true if the string is junk. The default is *None*, meaning that no line is considered junk.

- **charjunk**: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is *None*, meaning that no character is considered junk.

**Differ** objects are used (deltas generated) via a single method:

```python
compare(a, b)
```

Compare two sequences of lines, and generate the delta (a sequence of lines).

Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the `readlines()` method of file-like objects. The delta generated also consists of newline-terminated strings, ready
to be printed as-is via the `writelines()` method of a file-like object.
7.4.4. Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the `readlines()` method of file-like objects):

```python
>>> text1 = ''' 1. Beautiful is better than ugly.
... 2. Explicit is better than implicit.
... 3. Simple is better than complex.
... 4. Complex is better than complicated.
... '''.splitlines(1)
>>> len(text1)
4
>>> text1[0][-1]
'
' >>> text2 = ''' 1. Beautiful is better than ugly.
... 3. Simple is better than complex.
... 4. Complicated is better than complex.
... 5. Flat is better than nested.
... '''.splitlines(1)
```

Next we instantiate a Differ object:

```python
>>> d = Differ()
```

Note that when instantiating a `Differ` object we may pass functions to filter out line and character “junk.” See the `Differ()` constructor for details.

Finally, we compare the two:

```python
>>> result = list(d.compare(text1, text2))
```

`result` is a list of strings, so let’s pretty-print it:

```python
>>> from pprint import pprint
```
As a single multi-line string it looks like this:
7.4.5. A command-line interface to difflib

This example shows how to use difflib to create a **diff-like utility.** It is also contained in the Python source distribution, as `Tools/scripts/diff.py`.

""" Command line interface to difflib.py providing diffs in four formats:

* ndiff: lists every line and highlights interline changes.
* context: highlights clusters of changes in a before/after format.
* unified: highlights clusters of changes in an inline format.
* html: generates side by side comparison with change highlights.

"""

```python
import sys, os, time, difflib, optparse
def main():
    # Configure the option parser
    usage = "usage: %prog [options] fromfile tofile"
    parser = optparse.OptionParser(usage)
    parser.add_option("-c", action="store_true", default=False,
                      help='Produce a context format diff (default)

                      """
                      parser.add_option("-u", action="store_true", default=False,
                          help='Produce a unified format diff")
    hlp = 'Produce HTML side by side diff (can use -c and -l in
    parser.add_option("-m", action="store_true", default=False,
    parser.add_option("-n", action="store_true", default=False,
                      help='Produce a ndiff format diff")
    parser.add_option("-l", "--lines", type="int", default=3,
                      help='Set number of context lines (default
    (options, args) = parser.parse_args()

    if len(args) == 0:
        parser.print_help()
        sys.exit(1)
    if len(args) != 2:
        parser.error("need to specify both a fromfile and tofile")

    n = options.lines
    fromfile, tofile = args # as specified in the usage string

    # we're passing these as arguments to the diff function
```
fromdate = time.ctime(os.stat(fromfile).st_mtime)
todate = time.ctime(os.stat(tofile).st_mtime)
fromlines = open(fromfile, 'U').readlines()
tolines = open(tofile, 'U').readlines()

if options.u:
    diff = difflib.unified_diff(fromlines, tolines, fromfile, tofile, fromdate, todate, n=n)
elif options.n:
    diff = difflib.ndiff(fromlines, tolines)
elif options.m:
    diff = difflib.HtmlDiff().make_file(fromlines, tolines, tofile, context=options.c, numlines=n)
else:
    diff = difflib.context_diff(fromlines, tolines, fromfile, tofile, fromdate, todate, n=n)

# we're using writelines because diff is a generator
sys.stdout.writelines(diff)

if __name__ == '__main__':
    main()
7.5. **StringIO** — Read and write strings as files

This module implements a file-like class, **StringIO**, that reads and writes a string buffer (also known as *memory files*). See the description of file objects for operations (section *File Objects*). (For standard strings, see *str* and *unicode*.)

```python
class StringIO.
```

When a **StringIO** object is created, it can be initialized to an existing string by passing the string to the constructor. If no string is given, the **StringIO** will start empty. In both cases, the initial file position starts at zero.

The **StringIO** object can accept either Unicode or 8-bit strings, but mixing the two may take some care. If both are used, 8-bit strings that cannot be interpreted as 7-bit ASCII (that use the 8th bit) will cause a **UnicodeError** to be raised when `getvalue()` is called.

The following methods of **StringIO** objects require special mention:

**StringIO.getvalue()**

Retrieve the entire contents of the “file” at any time before the **StringIO** object’s `close()` method is called. See the note above for information about mixing Unicode and 8-bit strings; such mixing can cause this method to raise **UnicodeError**.

**StringIO.close()**

Free the memory buffer. Attempting to do further operations with a closed **StringIO** object will raise a **ValueError**.
Example usage:

```python
import StringIO

output = StringIO.StringIO()
output.write('First line.
')
print >>output, 'Second line.'

# Retrieve file contents -- this will be
# 'First line.
Second line.
'
contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
```
7.6. cStringIO — Faster version of StringIO

The module cStringIO provides an interface similar to that of the StringIO module. Heavy use of \texttt{StringIO.StringIO} objects can be made more efficient by using the function \texttt{StringIO()} from this module instead.

\texttt{cStringIO.StringIO([s])}

Return a StringIO-like stream for reading or writing.

Since this is a factory function which returns objects of built-in types, there's no way to build your own version using subclassing. It's not possible to set attributes on it. Use the original \texttt{StringIO} module in those cases.

Unlike the \texttt{StringIO} module, this module is not able to accept Unicode strings that cannot be encoded as plain ASCII strings. Calling \texttt{StringIO()} with a Unicode string parameter populates the object with the buffer representation of the Unicode string instead of encoding the string.

Another difference from the \texttt{StringIO} module is that calling \texttt{StringIO()} with a string parameter creates a read-only object. Unlike an object created without a string parameter, it does not have write methods. These objects are not generally visible. They turn up in tracebacks as \texttt{StringI} and \texttt{StringO}.

The following data objects are provided as well:

\texttt{cStringIO.InputType}

The type object of the objects created by calling \texttt{StringIO()} with a string parameter.
cStringIO. **OutputType**

The type object of the objects returned by calling `StringIO()` with no parameters.

There is a C API to the module as well; refer to the module source for more information.

Example usage:

```python
import cStringIO

output = cStringIO.StringIO()
output.write('First line.
')
print >>output, 'Second line.'

# Retrieve file contents -- this will be
# 'First line.
Second line.
'
contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
```
7.7. textwrap — Text wrapping and filling

New in version 2.3.

The textwrap module provides two convenience functions, wrap() and fill(), as well as TextWrapper, the class that does all the work, and a utility function dedent(). If you’re just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of TextWrapper for efficiency.

textwrap.wrap(text[, width[, ...]])
Wraps the single paragraph in text (a string) so every line is at most width characters long. Returns a list of output lines, without final newlines.

Optional keyword arguments correspond to the instance attributes of TextWrapper, documented below. width defaults to 70.

textwrap.fill(text[, width[, ...]])
Wraps the single paragraph in text, and returns a single string containing the wrapped paragraph. fill() is shorthand for

"\n".join(wrap(text, ...))

In particular, fill() accepts exactly the same keyword arguments as wrap().

Both wrap() and fill() work by creating a TextWrapper instance and calling a single method on it. That instance is not reused, so for applications that wrap/fill many text strings, it will be more efficient
for you to create your own TextWrapper object.

Text is preferably wrapped on whitespaces and right after the hyphens in hyphenated words; only then will long words be broken if necessary, unless TextWrapper.break_long_words is set to false.

An additional utility function, dedent(), is provided to remove indentation from strings that have unwanted whitespace to the left of the text.

textwrap.dedent(text)

Remove any common leading whitespace from every line in text.

This can be used to make triple-quoted strings line up with the left edge of the display, while still presenting them in the source code in indented form.

Note that tabs and spaces are both treated as whitespace, but they are not equal: the lines "hello" and "\thello" are considered to have no common leading whitespace. (This behaviour is new in Python 2.5; older versions of this module incorrectly expanded tabs before searching for common leading whitespace.)

For example:

def test():
    # end first line with \ to avoid the empty line!
    s = '''
    hello
    world
    '''
    print repr(s)  # prints '    hello
    world
    '  
    print repr(dedent(s))  # prints 'hello
    world'

class textwrap.TextWrapper(...)

The `TextWrapper` constructor accepts a number of optional keyword arguments. Each argument corresponds to one instance attribute, so for example

```python
wrapper = TextWrapper(initial_indent="* ")
```

is the same as

```python
wrapper = TextWrapper()
wrapper.initial_indent = "* "
```

You can re-use the same `TextWrapper` object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The `TextWrapper` instance attributes (and keyword arguments to the constructor) are as follows:

**width**

(default: 70) The maximum length of wrapped lines. As long as there are no individual words in the input text longer than `width`, `TextWrapper` guarantees that no output line will be longer than `width` characters.

**expand_tabs**

(default: True) If true, then all tab characters in text will be expanded to spaces using the `expandtabs()` method of text.

**replace_whitespace**

(default: True) If true, each whitespace character (as defined by `string.whitespace`) remaining after tab expansion will be replaced by a single space.

---

**Note:** If `expand_tabs` is false and `replace_whitespace` is true, each tab character will be replaced by a single space,
which is not the same as tab expansion.

**drop_whitespace**
(default: `True`) If true, whitespace that, after wrapping, happens to end up at the beginning or end of a line is dropped (leading whitespace in the first line is always preserved, though).

_New in version 2.6:_ Whitespace was always dropped in earlier versions.

**initial_indent**
(default: `'`) String that will be prepended to the first line of wrapped output. Counts towards the length of the first line.

**subsequent_indent**
(default: `'`) String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

**fix_sentence_endings**
(default: `False`) If true, _TextWrapper_ attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of `.`, `!`, or `?`, possibly followed by one of `'` or `''`, followed by a space. One problem with this is algorithm is that it is unable to detect the difference between “Dr.” in

```
[...] Dr. Frankenstein's monster [...]  
```

and “Spot.” in

```
[...] See Spot. See Spot run [...]  
```
**fix_sentence_endings** is false by default.

Since the sentence detection algorithm relies on `string.lowercase` for the definition of “lowercase letter,” and a convention of using two spaces after a period to separate sentences on the same line, it is specific to English-language texts.

**break_long_words**
(default: **True**) If true, then words longer than *width* will be broken in order to ensure that no lines are longer than *width*. If it is false, long words will not be broken, and some lines may be longer than *width*. (Long words will be put on a line by themselves, in order to minimize the amount by which *width* is exceeded.)

**break_on_hyphens**
(default: **True**) If true, wrapping will occur preferably on whitespaces and right after hyphens in compound words, as it is customary in English. If false, only whitespaces will be considered as potentially good places for line breaks, but you need to set **break_long_words** to false if you want truly inseparable words. Default behaviour in previous versions was to always allow breaking hyphenated words.

*New in version 2.6.*

**TextWrapper** also provides two public methods, analogous to the module-level convenience functions:

**wrap**(text)
Wraps the single paragraph in *text* (a string) so every line is at most *width* characters long. All wrapping options are taken from instance attributes of the **TextWrapper** instance. Returns
a list of output lines, without final newlines.

**fill**(text)

Wraps the single paragraph in *text*, and returns a single string containing the wrapped paragraph.
This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry which manages the codec and error handling lookup process.

It defines the following functions:

**codecs.register(search_function)**

Register a codec search function. Search functions are expected to take one argument, the encoding name in all lower case letters, and return a CodecInfo object having the following attributes:

- **name** The name of the encoding;
- **encode** The stateless encoding function;
- **decode** The stateless decoding function;
- **incrementalencoder** An incremental encoder class or factory function;
- **incrementaldecoder** An incremental decoder class or factory function;
- **streamwriter** A stream writer class or factory function;
- **streamreader** A stream reader class or factory function.

The various functions or classes take the following arguments:

- **encode** and **decode**: These must be functions or methods which have the same interface as the `encode()/decode()` methods of Codec instances (see Codec Interface). The functions/methods are expected to work in a stateless mode.
**incrementalencoder** and **incrementaldecoder**: These have to be factory functions providing the following interface:

```python
def factory(errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes **IncrementalEncoder** and **IncrementalDecoder**, respectively. Incremental codecs can maintain state.

**streamreader** and **streamwriter**: These have to be factory functions providing the following interface:

```python
def factory(stream, errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes **StreamWriter** and **StreamReader**, respectively. Stream codecs can maintain state.

Possible values for errors are

- `'strict'`: raise an exception in case of an encoding error
- `'replace'`: replace malformed data with a suitable replacement marker, such as `'?` or `\ufffd`
- `'ignore'`: ignore malformed data and continue without further notice
- `'xmlcharrefreplace'`: replace with the appropriate XML character reference (for encoding only)
- `'backslashreplace'`: replace with backslashed escape sequences (for encoding only)

as well as any other error handling name defined via `register_error()`.

In case a search function cannot find a given encoding, it should
return None.

codecs. **lookup**(encoding)

Looks up the codec info in the Python codec registry and returns a CodecInfo object as defined above.

Encodings are first looked up in the registry's cache. If not found, the list of registered search functions is scanned. If no CodecInfo object is found, a LookupError is raised. Otherwise, the CodecInfo object is stored in the cache and returned to the caller.

To simplify access to the various codecs, the module provides these additional functions which use **lookup()** for the codec lookup:

codecs. **getencoder**(encoding)

Look up the codec for the given encoding and return its encoder function.

Raises a LookupError in case the encoding cannot be found.

codecs. **getdecoder**(encoding)

Look up the codec for the given encoding and return its decoder function.

Raises a LookupError in case the encoding cannot be found.

codecs. **getincrementalencoder**(encoding)

Look up the codec for the given encoding and return its incremental encoder class or factory function.

Raises a LookupError in case the encoding cannot be found or the codec doesn’t support an incremental encoder.

*New in version 2.5.*
codecs.getincrementaldecoder(encoding)
Look up the codec for the given encoding and return its incremental decoder class or factory function.

Raises a LookupError in case the encoding cannot be found or the codec doesn’t support an incremental decoder.

New in version 2.5.

codecs.getreader(encoding)
Look up the codec for the given encoding and return its StreamReader class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.getwriter(encoding)
Look up the codec for the given encoding and return its StreamWriter class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.register_error(name, error_handler)
Register the error handling function error_handler under the name name. error_handler will be called during encoding and decoding in case of an error, when name is specified as the errors parameter.

For encoding error_handler will be called with a UnicodeEncodeError instance, which contains information about the location of the error. The error handler must either raise this or a different exception or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The encoder will encode the replacement and continue encoding the original input at the specified position. Negative position values will be treated as being relative to the
end of the input string. If the resulting position is out of bound an
IndexError will be raised.

Decoding and translating works similar, except UnicodeDecodeError or UnicodeTranslateError will be passed to
the handler and that the replacement from the error handler will
be put into the output directly.

codecs. **lookup_error**(*name*)

Return the error handler previously registered under the name
*name*.

Raises a LookupError in case the handler cannot be found.

codecs. **strict_errors**(*exception*)

Implements the strict error handling: each encoding or
decoding error raises a UnicodeError.

codecs. **replace_errors**(*exception*)

Implements the replace error handling: malformed data is
replaced with a suitable replacement character such as '?' in
bytestrings and '\ufffd' in Unicode strings.

codecs. **ignore_errors**(*exception*)

Implements the ignore error handling: malformed data is ignored
and encoding or decoding is continued without further notice.

codecs. **xmlcharrefreplace_errors**(*exception*)

Implements the xmlcharrefreplace error handling (for encoding
only): the unencodable character is replaced by an appropriate
XML character reference.

codecs. **backslashreplace_errors**(*exception*)

Implements the backslashreplace error handling (for encoding
only): the unencodable character is replaced by a backslashed escape sequence.

To simplify working with encoded files or stream, the module also defines these utility functions:

`codecs.open(filename, mode[, encoding[, errors[, buffering]]])`

Open an encoded file using the given `mode` and return a wrapped version providing transparent encoding/decoding. The default file mode is `'r'` meaning to open the file in read mode.

- **Note:** The wrapped version will only accept the object format defined by the codecs, i.e. Unicode objects for most built-in codecs. Output is also codec-dependent and will usually be Unicode as well.

- **Note:** Files are always opened in binary mode, even if no binary mode was specified. This is done to avoid data loss due to encodings using 8-bit values. This means that no automatic conversion of `\n` is done on reading and writing.

`encoding` specifies the encoding which is to be used for the file.

`errors` may be given to define the error handling. It defaults to `'strict'` which causes a `ValueError` to be raised in case an encoding error occurs.

`buffering` has the same meaning as for the built-in `open()` function. It defaults to line buffered.

`codecs.EncodedFile(file, input[, output[, errors]])`

Return a wrapped version of file which provides transparent encoding translation.

Strings written to the wrapped file are interpreted according to the
given input encoding and then written to the original file as strings using the output encoding. The intermediate encoding will usually be Unicode but depends on the specified codecs.

If output is not given, it defaults to input.

errors may be given to define the error handling. It defaults to 'strict', which causes ValueError to be raised in case an encoding error occurs.

codecs.iterencode(iterable, encoding[, errors])

Uses an incremental encoder to iteratively encode the input provided by iterable. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental encoder.

   New in version 2.5.

codecs.iterdecode(iterable, encoding[, errors])

Uses an incremental decoder to iteratively decode the input provided by iterable. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental decoder.

   New in version 2.5.

The module also provides the following constants which are useful for reading and writing to platform dependent files:

codecs.BOM
codecs.BOM_BE
codecs.BOM_LE
codecs.BOM_UTF8
codecs.BOM_UTF16
codecs.BOM_UTF16_BE
codecs.BOM_UTF16_LE
codecs.BOM_UTF32
These constants define various encodings of the Unicode byte order mark (BOM) used in UTF-16 and UTF-32 data streams to indicate the byte order used in the stream or file and in UTF-8 as a Unicode signature. `BOM_UTF16` is either `BOM_UTF16_BE` or `BOM_UTF16_LE` depending on the platform’s native byte order, `BOM` is an alias for `BOM_UTF16`, `BOM_LE` for `BOM_UTF16_LE` and `BOM_BE` for `BOM_UTF16_BE`. The others represent the BOM in UTF-8 and UTF-32 encodings.
7.8.1. Codec Base Classes

The `codecs` module defines a set of base classes which define the interface and can also be used to easily write your own codecs for use in Python.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols.

The `Codec` class defines the interface for stateless encoders/decoders.

To simplify and standardize error handling, the `encode()` and `decode()` methods may implement different error handling schemes by providing the `errors` string argument. The following string values are defined and implemented by all standard Python codecs:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'strict'</td>
<td>Raise <code>UnicodeError</code> (or a subclass); this is the default.</td>
</tr>
<tr>
<td>'ignore'</td>
<td>Ignore the character and continue with the next.</td>
</tr>
<tr>
<td>'replace'</td>
<td>Replace with a suitable replacement character; Python will use the official U+FFFD REPLACEMENT CHARACTER for the built-in Unicode codecs on decoding and ‘?’ on encoding.</td>
</tr>
<tr>
<td>'xmlcharrefreplace'</td>
<td>Replace with the appropriate XML character reference (only for encoding).</td>
</tr>
<tr>
<td>'backslashreplace'</td>
<td>Replace with backslashed escape sequences (only for encoding).</td>
</tr>
</tbody>
</table>
The set of allowed values can be extended via `register_error()`.

### 7.8.1.1. Codec Objects

The **Codec** class defines these methods which also define the function interfaces of the stateless encoder and decoder:

**Codec. encode**(
    `input[, errors]`
)

Encodes the object `input` and returns a tuple (output object, length consumed). While codecs are not restricted to use with Unicode, in a Unicode context, encoding converts a Unicode object to a plain string using a particular character set encoding (e.g., `cp1252` or `iso-8859-1`).

`errors` defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the **Codec** instance. Use **StreamCodec** for codecs which have to keep state in order to make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

**Codec. decode**(
    `input[, errors]`
)

Decodes the object `input` and returns a tuple (output object, length consumed). In a Unicode context, decoding converts a plain string encoded using a particular character set encoding to a Unicode object.

`input` must be an object which provides the `bf_getreadbuf` buffer slot. Python strings, buffer objects and memory mapped files are examples of objects providing this slot.
**errors** defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the **Codec** instance. Use **StreamCodec** for codecs which have to keep state in order to make encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The **IncrementalEncoder** and **IncrementalDecoder** classes provide the basic interface for incremental encoding and decoding. Encoding/decoding the input isn't done with one call to the stateless encoder/decoder function, but with multiple calls to the **encode()**/**decode()** method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the **encode()**/**decode()** method is the same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.

### 7.8.1.2. IncrementalEncoder Objects

*New in version 2.5.*

The **IncrementalEncoder** class is used for encoding an input in multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

```python
class codecs.IncrementalEncoder([errors])
    Constructor for an IncrementalEncoder instance.
```
All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalEncoder may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- 'strict'  Raise ValueError (or a subclass); this is the default.
- 'ignore'  Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace'  Replace with the appropriate XML character reference
- 'backslashreplace'  Replace with backslashed escape sequences.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalEncoder object.

The set of allowed values for the errors argument can be extended with register_error().

encode(object[, final])

Encodes object (taking the current state of the encoder into account) and returns the resulting encoded object. If this is the last call to encode() final must be true (the default is false).

reset()

Reset the encoder to the initial state.
7.8.1.3. IncrementalDecoder Objects

The IncrementalDecoder class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.

class codecs.IncrementalDecoder([errors])

Constructor for an IncrementalDecoder instance.

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalDecoder may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- 'strict' Raise ValueError (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalDecoder object.

The set of allowed values for the errors argument can be extended with register_error().

decode(object[, final])

Decodes object (taking the current state of the decoder into account) and returns the resulting decoded object. If this is
the last call to `decode()` final must be true (the default is false). If final is true the decoder must decode the input completely and must flush all buffers. If this isn’t possible (e.g. because of incomplete byte sequences at the end of the input) it must initiate error handling just like in the stateless case (which might raise an exception).

```python
reset()
```

Reset the decoder to the initial state.

The `StreamWriter` and `StreamReader` classes provide generic working interfaces which can be used to implement new encoding submodules very easily. See `encodings.utf_8` for an example of how this is done.

### 7.8.1.4. StreamWriter Objects

The `StreamWriter` class is a subclass of `codec` and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

```python
class codecs.StreamWriter(stream[, errors])
```

Constructor for a `StreamWriter` instance.

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

- `stream` must be a file-like object open for writing binary data.

The `StreamWriter` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the
default.

- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamWriter` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

**write**(object)

Writes the object’s contents encoded to the stream.

**writelines**(list)

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).

**reset()**

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the `StreamWriter` must also inherit all other methods and attributes from the underlying stream.

---

### 7.8.1.5. StreamReader Objects
The `StreamReader` class is a subclass of `codec` and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

```python
class codecs.StreamReader(stream[, errors])
```
Constructor for a `StreamReader` instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

`stream` must be a file-like object open for reading (binary) data.

The `StreamReader` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are defined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamReader` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
read([size[, chars[, firstline]]])
```
Decodes data from the stream and returns the resulting object.

`chars` indicates the number of characters to read from the
stream. \texttt{read()} will never return more than \textit{chars} characters, but it might return less, if there are not enough characters available.

\textit{size} indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. \textit{size} is intended to prevent having to decode huge files in one step.

\textit{firstline} indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

\textit{Changed in version 2.4: chars} argument added.

\textit{Changed in version 2.4.2: firstline} argument added.

\texttt{readline}([\textit{size[, keepends]}])

Read one line from the input stream and return the decoded data.

\textit{size}, if given, is passed as size argument to the stream's \texttt{readline()} method.

If \textit{keepends} is false line-endings will be stripped from the lines returned.

\textit{Changed in version 2.4: keepends} argument added.

\texttt{readlines}([\textit{sizehint[, keepends]}])
Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if keepends is true.

sizehint, if given, is passed as the size argument to the stream’s read() method.

reset()
Resets the codec buffers used for keeping state.

Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the StreamReader must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.

7.8.1.6. StreamReaderWriter Objects

The StreamReaderWriter allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the lookup() function to construct the instance.

class codecs.StreamReaderWriter(stream, Reader, Writer, errors)
Creates a StreamReaderWriter instance. stream must be a file-like object. Reader and Writer must be factory functions or classes providing the StreamReader and StreamWriter interface resp. Error handling is done in the same way as defined for the stream
StreamReaderWriter instances define the combined interfaces of StreamReader and StreamWriter classes. They inherit all other methods and attributes from the underlying stream.

### 7.8.1.7. StreamRecoder Objects

The StreamRecoder provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

```python
class codecs.StreamRecoder(stream, encode, decode, Reader, Writer, errors)
```

Creates a StreamRecoder instance which implements a two-way conversion: `encode` and `decode` work on the frontend (the input to `read()` and output of `write()`) while `Reader` and `Writer` work on the backend (reading and writing to the stream).

You can use these objects to do transparent direct recodings from e.g. Latin-1 to UTF-8 and back.

*stream* must be a file-like object.

*encode*, *decode* must adhere to the *Codec* interface. *Reader*, *Writer* must be factory functions or classes providing objects of the StreamReader and StreamWriter interface respectively.

*encode* and *decode* are needed for the frontend translation, *Reader* and *Writer* for the backend translation. The intermediate format used is determined by the two sets of codecs, e.g. the Unicode codecs will use Unicode as the intermediate encoding.
Error handling is done in the same way as defined for the stream readers and writers.

StreamRecoder instances define the combined interfaces of StreamReader and StreamWriter classes. They inherit all other methods and attributes from the underlying stream.
7.8.2. Encodings and Unicode

Unicode strings are stored internally as sequences of codepoints (to be precise as `Py_UNICODE` arrays). Depending on the way Python is compiled (either via `--enable-unicode=ucs2` or `--enable-unicode=ucs4`, with the former being the default) `Py_UNICODE` is either a 16-bit or 32-bit data type. Once a Unicode object is used outside of CPU and memory, CPU endianness and how these arrays are stored as bytes become an issue. Transforming a unicode object into a sequence of bytes is called encoding and recreating the unicode object from the sequence of bytes is known as decoding. There are many different methods for how this transformation can be done (these methods are also called encodings). The simplest method is to map the codepoints 0-255 to the bytes 0x0-0xff. This means that a unicode object that contains codepoints above U+00FF can’t be encoded with this method (which is called 'latin-1' or 'iso-8859-1'). `unicode.encode()` will raise a `UnicodeEncodeError` that looks like this: `UnicodeEncodeError: 'latin-1' codec can't encode character u'\u1234' in position 3: ordinal not in range(256).

There’s another group of encodings (the so called charmap encodings) that choose a different subset of all unicode code points and how these codepoints are mapped to the bytes 0x0-0xff. To see how this is done simply open e.g. `encodings/cp1252.py` (which is an encoding that is used primarily on Windows). There's a string constant with 256 characters that shows you which character is mapped to which byte value.

All of these encodings can only encode 256 of the 65536 (or 1114111) codepoints defined in unicode. A simple and straightforward way that can store each Unicode code point, is to store each codepoint as two consecutive bytes. There are two
possibilities: Store the bytes in big endian or in little endian order. These two encodings are called UTF-16-BE and UTF-16-LE respectively. Their disadvantage is that if e.g. you use UTF-16-BE on a little endian machine you will always have to swap bytes on encoding and decoding. UTF-16 avoids this problem: Bytes will always be in natural endianness. When these bytes are read by a CPU with a different endianness, then bytes have to be swapped though. To be able to detect the endianness of a UTF-16 byte sequence, there's the so called BOM (the “Byte Order Mark”). This is the Unicode character \texttt{U+FEFF}. This character will be prepended to every UTF-16 byte sequence. The byte swapped version of this character (\texttt{0xFFFE}) is an illegal character that may not appear in a Unicode text. So when the first character in an UTF-16 byte sequence appears to be a \texttt{U+FFEFE} the bytes have to be swapped on decoding. Unfortunately upto Unicode 4.0 the character \texttt{U+FEFF} had a second purpose as a \texttt{ZERO WIDTH NO-BREAK SPACE}: A character that has no width and doesn't allow a word to be split. It can e.g. be used to give hints to a ligature algorithm. With Unicode 4.0 using \texttt{U+FEFF} as a \texttt{ZERO WIDTH NO-BREAK SPACE} has been deprecated (with \texttt{U+2060} (\texttt{WORD JOINER}) assuming this role). Nevertheless Unicode software still must be able to handle \texttt{U+FEFF} in both roles: As a BOM it's a device to determine the storage layout of the encoded bytes, and vanishes once the byte sequence has been decoded into a Unicode string; as a \texttt{ZERO WIDTH NO-BREAK SPACE} it's a normal character that will be decoded like any other.

There's another encoding that is able to encoding the full range of Unicode characters: UTF-8. UTF-8 is an 8-bit encoding, which means there are no issues with byte order in UTF-8. Each byte in a UTF-8 byte sequence consists of two parts: Marker bits (the most significant bits) and payload bits. The marker bits are a sequence of zero to six 1 bits followed by a 0 bit. Unicode characters are encoded like this (with \texttt{x} being payload bits, which when concatenated give
the Unicode character):

<table>
<thead>
<tr>
<th>Range</th>
<th>Encoding</th>
</tr>
</thead>
<tbody>
<tr>
<td>U-00000000 ... U-0000007F</td>
<td>0xxxxxxx</td>
</tr>
<tr>
<td>U-00000080 ... U-000007FF</td>
<td>110xxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-00000800 ... U-0000FFFF</td>
<td>1110xxx 10xxxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-00010000 ... U-001FFFFF</td>
<td>11110xxx 10xxxxxx 10xxxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-00200000 ... U-03FFFFFF</td>
<td>111110xx 10xxxxxx 10xxxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-04000000 ... U-7FFFFFFF</td>
<td>1111110x 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx</td>
</tr>
</tbody>
</table>

The least significant bit of the Unicode character is the rightmost x bit.

As UTF-8 is an 8-bit encoding no BOM is required and any U+FEFF character in the decoded Unicode string (even if it’s the first character) is treated as a **ZERO WIDTH NO-BREAK SPACE**.

Without external information it’s impossible to reliably determine which encoding was used for encoding a Unicode string. Each charmap encoding can decode any random byte sequence. However that’s not possible with UTF-8, as UTF-8 byte sequences have a structure that doesn’t allow arbitrary byte sequences. To increase the reliability with which a UTF-8 encoding can be detected, Microsoft invented a variant of UTF-8 (that Python 2.5 calls "utf-8-sig") for its Notepad program: Before any of the Unicode characters is written to the file, a UTF-8 encoded BOM (which looks like this as a byte sequence: `\xef`, `\xbb`, `\xbf`) is written. As it’s rather improbable that any charmap encoded file starts with these byte values (which would e.g. map to

**LATIN SMALL LETTER I WITH DIAERESIS**
**RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK**
INVERTED QUESTION MARK

in iso-8859-1), this increases the probability that a utf-8-sig encoding can be correctly guessed from the byte sequence. So here the BOM is not used to be able to determine the byte order used for generating the byte sequence, but as a signature that helps in guessing the encoding. On encoding the utf-8-sig codec will write 0xef, 0xbb, 0xbf as the first three bytes to the file. On decoding utf-8-sig will skip those three bytes if they appear as the first three bytes in the file.
7.8.3. Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases; therefore, e.g. `utf-8` is a valid alias for the `utf_8` codec.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

- an ISO 8859 codeset
- a Microsoft Windows code page, which is typically derived from a 8859 codeset, but replaces control characters with additional graphic characters
- an IBM EBCDIC code page
- an IBM PC code page, which is ASCII compatible

<table>

A number of codecs are specific to Python, so their codec names have no meaning outside Python. Some of them don't convert from Unicode strings to byte strings, but instead use the property of the Python codecs machinery that any bijective function with one argument can be considered as an encoding.
For the codecs listed below, the result in the “encoding” direction is always a byte string. The result of the “decoding” direction is listed as operand type in the table.

*New in version 2.3:* The `idna` and `punycode` encodings.
New in version 2.3.

This module implements RFC 3490 (Internationalized Domain Names in Applications) and RFC 3492 (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the punycode encoding and stringprep.

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as www.Alliancefrançaise.nu) is converted into an ASCII-compatible encoding (ACE, such as www.xn--alliancefranaise-npb.nu). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP Host fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: The idna codec allows to convert between Unicode and the ACE. Furthermore, the socket module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket module. On top of that, modules that have host names as function parameters, such as httplib and ftplib, accept Unicode host names (httplib then also transparently sends an IDNA hostname in the Host field if it sends that field at all).
When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed: Applications wishing to present such host names to the user should decode them to Unicode.

The module `encodings.idna` also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The nameprep functions can be used directly if desired.

`encodings.idna.nameprep(label)`

Return the nameprepped version of `label`. The implementation currently assumes query strings, so `AllowUnassigned` is true.

`encodings.idna.ToASCII(label)`

Convert a label to ASCII, as specified in RFC 3490. `UseSTD3ASCIIrules` is assumed to be false.

`encodings.idna.ToUnicode(label)`

Convert a label to Unicode, as specified in RFC 3490.
7.8.5. encodings=utf_8_sig — UTF-8 codec with BOM signature

New in version 2.5.

This module implements a variant of the UTF-8 codec: On encoding a UTF-8 encoded BOM will be prepended to the UTF-8 encoded bytes. For the stateful encoder this is only done once (on the first write to the byte stream). For decoding an optional UTF-8 encoded BOM at the start of the data will be skipped.
This module provides access to the Unicode Character Database which defines character properties for all Unicode characters. The data in this database is based on the UnicodeData.txt file version 5.2.0 which is publicly available from ftp://ftp.unicode.org/.

The module uses the same names and symbols as defined by the UnicodeData File Format 5.2.0 (see http://www.unicode.org/reports/tr44/tr44-4.html). It defines the following functions:

```
unicodedata.lookup(name)
```
Look up character by name. If a character with the given name is found, return the corresponding Unicode character. If not found, `KeyError` is raised.

```
unicodedata.name(unichr[, default])
```
Returns the name assigned to the Unicode character `unichr` as a string. If no name is defined, `default` is returned, or, if not given, `ValueError` is raised.

```
unicodedata.decimal(unichr[, default])
```
Returns the decimal value assigned to the Unicode character `unichr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.

```
unicodedata.digit(unichr[, default])
```
Returns the digit value assigned to the Unicode character `unichr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.
unichr

- `unichr` as float. If no such value is defined, default is returned, or, if not given, ValueError is raised.

- `unichr` as string.

- Returns the bidirectional category assigned to the Unicode character `unichr` as string. If no such value is defined, an empty string is returned.

- `unichr` as integer. Returns 0 if no combining class is defined.

- Returns the east asian width assigned to the Unicode character `unichr` as string.

  *New in version 2.4.*

- `unichr` as integer. Returns 1 if the character has been identified as a “mirrored” character in bidirectional text, 0 otherwise.

- Returns the character decomposition mapping assigned to the Unicode character `unichr` as string. An empty string is returned in case no such mapping is defined.
Return the normal form `form` for the Unicode string `unistr`. Valid values for `form` are ‘NFC’, ‘NFKC’, ‘NFD’, and ‘NFKD’.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various way. For example, the character U+00C7 (LATIN CAPITAL LETTER C WITH CEDILLA) can also be expressed as the sequence U+0327 (COMBINING CEDILLA) U+0043 (LATIN CAPITAL LETTER C).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there are two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the compatibility decomposition, followed by the canonical composition.

Even if two unicode strings are normalized and look the same to a human reader, if one has combining characters and the other doesn’t, they may not compare equal.
New in version 2.3.

In addition, the module exposes the following constant:

unicodedata.unidata_version

The version of the Unicode database used in this module.

New in version 2.3.

unicodedata.ucd_3_2_0

This is an object that has the same methods as the entire module, but uses the Unicode database version 3.2 instead, for applications that require this specific version of the Unicode database (such as IDNA).

New in version 2.5.

Examples:

```python
>>> import unicodedata
>>> unicodedata.lookup('LEFT CURLY BRACKET')
u'{
>>> unicodedata.name(u'/')
'SOLIDUS'
>>> unicodedata.decimal(u'9')
9
>>> unicodedata.decimal(u'a')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: not a decimal
>>> unicodedata.category(u'A') # 'L'etter, 'u'ppercase
'Lu'
>>> unicodedata.bidirectional(u'\u0660') # 'A'rabic, 'N'umber
'AN'
```
7.10. stringprep — Internet String Preparation

*New in version 2.3.*

When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for “equality”. Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of “printable” characters.

**RFC 3454** defines a procedure for “preparing” Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the stringprep procedure are part of the profile. One example of a stringprep profile is nameprep, which is used for internationalized domain names.

The module stringprep only exposes the tables from RFC 3454. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the mkstringprep.py utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, stringprep provides the “characteristic function”, i.e. a function that returns true if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it returns the associated value. Below is a list of all functions...
available in the module.

**stringprep.in_table_a1(code)**
Determine whether `code` is in tableA.1 (Unassigned code points in Unicode 3.2).

**stringprep.in_table_b1(code)**
Determine whether `code` is in tableB.1 (Commonly mapped to nothing).

**stringprep.map_table_b2(code)**
Return the mapped value for `code` according to tableB.2 (Mapping for case-folding used with NFKC).

**stringprep.map_table_b3(code)**
Return the mapped value for `code` according to tableB.3 (Mapping for case-folding used with no normalization).

**stringprep.in_table_c11(code)**
Determine whether `code` is in tableC.1.1 (ASCII space characters).

**stringprep.in_table_c12(code)**
Determine whether `code` is in tableC.1.2 (Non-ASCII space characters).

**stringprep.in_table_c11_c12(code)**
Determine whether `code` is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

**stringprep.in_table_c21(code)**
Determine whether `code` is in tableC.2.1 (ASCII control characters).

**stringprep.in_table_c22(code)**
Determine whether \textit{code} is in table C.2.2 (Non-ASCII control characters).

\texttt{stringprep.in_table_c21_c22(code)}

Determine whether \textit{code} is in table C.2 (Control characters, union of C.2.1 and C.2.2).

\texttt{stringprep.in_table_c3(code)}

Determine whether \textit{code} is in table C.3 (Private use).

\texttt{stringprep.in_table_c4(code)}

Determine whether \textit{code} is in table C.4 (Non-character code points).

\texttt{stringprep.in_table_c5(code)}

Determine whether \textit{code} is in table C.5 (Surrogate codes).

\texttt{stringprep.in_table_c6(code)}

Determine whether \textit{code} is in table C.6 (Inappropriate for plain text).

\texttt{stringprep.in_table_c7(code)}

Determine whether \textit{code} is in table C.7 (Inappropriate for canonical representation).

\texttt{stringprep.in_table_c8(code)}

Determine whether \textit{code} is in table C.8 (Change display properties or are deprecated).

\texttt{stringprep.in_table_c9(code)}

Determine whether \textit{code} is in table C.9 (Tagging characters).

\texttt{stringprep.in_table_d1(code)}

Determine whether \textit{code} is in table D.1 (Characters with bidirectional property “R” or “AL”).
stringprep.in_table_d2(code)

Determine whether code is in tableD.2 (Characters with bidirectional property “L”).
The `fpformat` module defines functions for dealing with floating point numbers representations in 100% pure Python.

**Note:** This module is unnecessary: everything here can be done using the `%` string interpolation operator described in the *String Formatting Operations* section.

The `fpformat` module defines the following functions and an exception:

`fpformat.fix(x, digs)`

Format `x` as `[-]ddd.ddd` with `digs` digits after the point and at least one digit before. If `digs <= 0`, the decimal point is suppressed.

`x` can be either a number or a string that looks like one. `digs` is an integer.

Return value is a string.

`fpformat.sci(x, digs)`

Format `x` as `[-]d.dddE[+-]ddd` with `digs` digits after the point and exactly one digit before. If `digs <= 0`, one digit is kept and the point is suppressed.

`x` can be either a real number, or a string that looks like one. `digs`
is an integer.

Return value is a string.

**exception fpformat. NotANumber**

Exception raised when a string passed to `fix()` or `sci()` as the x parameter does not look like a number. This is a subclass of `ValueError` when the standard exceptions are strings. The exception value is the improperly formatted string that caused the exception to be raised.

Example:

```python
>>> import fpformat
>>> fpformat.fix(1.23, 1)
'1.2'
```
8. Data Types

The modules described in this chapter provide a variety of specialized data types such as dates and times, fixed-type arrays, heap queues, synchronized queues, and sets.

Python also provides some built-in data types, in particular, `dict`, `list`, `set` (which along with `frozenset`, replaces the deprecated `sets` module), and `tuple`. The `str` class can be used to handle binary data and 8-bit text, and the `unicode` class to handle Unicode text.

The following modules are documented in this chapter:

- **8.1. datetime** — Basic date and time types
  - 8.1.1. Available Types
  - 8.1.2. timedelta Objects
  - 8.1.3. date Objects
  - 8.1.4. datetime Objects
  - 8.1.5. time Objects
  - 8.1.6. tzinfo Objects
  - 8.1.7. strftime() and strptime() Behavior
- **8.2. calendar** — General calendar-related functions
- **8.3. collections** — High-performance container datatypes
  - 8.3.1. ABCs - abstract base classes
  - 8.3.2. Counter objects
  - 8.3.3. deque objects
    - 8.3.3.1. deque Recipes
  - 8.3.4. defaultdict objects
    - 8.3.4.1. defaultdict Examples
  - 8.3.5. namedtuple() Factory Function for Tuples with Named Fields
  - 8.3.6. OrderedDict objects
• 8.4. **heapq** — Heap queue algorithm
  ○ 8.4.1. Theory
• 8.5. **bisect** — Array bisection algorithm
  ○ 8.5.1. Examples
• 8.6. **array** — Efficient arrays of numeric values
• 8.7. **sets** — Unordered collections of unique elements
  ○ 8.7.1. Set Objects
  ○ 8.7.2. Example
  ○ 8.7.3. Protocol for automatic conversion to immutable
  ○ 8.7.4. Comparison to the built-in `set` types
• 8.8. **sched** — Event scheduler
  ○ 8.8.1. Scheduler Objects
• 8.9. **mutex** — Mutual exclusion support
  ○ 8.9.1. Mutex Objects
• 8.10. **queue** — A synchronized queue class
  ○ 8.10.1. Queue Objects
• 8.11. **weakref** — Weak references
  ○ 8.11.1. Weak Reference Objects
  ○ 8.11.2. Example
• 8.12. **UserDict** — Class wrapper for dictionary objects
• 8.13. **UserList** — Class wrapper for list objects
• 8.14. **UserString** — Class wrapper for string objects
• 8.15. **types** — Names for built-in types
• 8.16. **new** — Creation of runtime internal objects
• 8.17. **copy** — Shallow and deep copy operations
• 8.18. **pprint** — Data pretty printer
  ○ 8.18.1. PrettyPrinter Objects
  ○ 8.18.2. pprint Example
• 8.19. **repr** — Alternate `repr()` implementation
  ○ 8.19.1. Repr Objects
  ○ 8.19.2. Subclassing Repr Objects
8.1. datetime — Basic date and time types

New in version 2.3.

The datetime module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. For related functionality, see also the time and calendar modules.

There are two kinds of date and time objects: “naive” and “aware”. This distinction refers to whether the object has any notion of time zone, daylight saving time, or other kind of algorithmic or political time adjustment. Whether a naive datetime object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it's up to the program whether a particular number represents metres, miles, or mass. Naive datetime objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring more, datetime and time objects have an optional time zone information member, tzinfo, that can contain an instance of a subclass of the abstract tzinfo class. These tzinfo objects capture information about the offset from UTC time, the timezone name, and whether Daylight Saving Time is in effect. Note that no concrete tzinfo classes are supplied by the datetime module. Supporting timezones at whatever level of detail is required is up to the application. The rules for time adjustment across the world are more political than rational, and there is no standard suitable for every application.
The `datetime` module exports the following constants:

`datetime.MINYEAR`

The smallest year number allowed in a `date` or `datetime` object. `MINYEAR` is 1.

`datetime.MAXYEAR`

The largest year number allowed in a `date` or `datetime` object. `MAXYEAR` is 9999.

See also:

**Module calendar**

General calendar related functions.

**Module time**

Time access and conversions.
8.1.1. Available Types

class datetime.date
An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: year, month, and day.

class datetime.time
An idealized time, independent of any particular day, assuming that every day has exactly 24*60*60 seconds (there is no notion of “leap seconds” here). Attributes: hour, minute, second, microsecond, and tzinfo.

class datetime.datetime
A combination of a date and a time. Attributes: year, month, day, hour, minute, second, microsecond, and tzinfo.

class datetime.timedelta
A duration expressing the difference between two date, time, or datetime instances to microsecond resolution.

class datetime.tzinfo
An abstract base class for time zone information objects. These are used by the datetime and time classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

Objects of these types are immutable.

Objects of the date type are always naive.

An object d of type time or datetime may be naive or aware. d is aware if d.tzinfo is not None and d.tzinfo.utcoffset(d) does not
return None. If \( \text{d.tzinfo} \) is None, or if \( \text{d.tzinfo} \) is not None but \( \text{d.tzinfo.utcoffset(d)} \) returns None, \( d \) is naive.

The distinction between naive and aware doesn’t apply to timedelta objects.

Subclass relationships:

```
object
timedelta
tzinfo
time
date
    datetime
```
8.1.2. timedelta Objects

A `timedelta` object represents a duration, the difference between two dates or times.

```python
class datetime.timedelta([days, seconds, microseconds, milliseconds, minutes, hours, weeks])
```

All arguments are optional and default to 0. Arguments may be ints, longs, or floats, and may be positive or negative.

Only `days`, `seconds` and `microseconds` are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and days, seconds and microseconds are then normalized so that the representation is unique, with

- 0 <= microseconds < 1000000
- 0 <= seconds < 3600*24 (the number of seconds in one day)
- -999999999 <= days <= 999999999

If any argument is a float and there are fractional microseconds, the fractional microseconds left over from all arguments are combined and their sum is rounded to the nearest microsecond. If no argument is a float, the conversion and normalization processes are exact (no information is lost).

If the normalized value of days lies outside the indicated range, `OverflowError` is raised.
Note that normalization of negative values may be surprising at first. For example,

```python
>>> from datetime import timedelta
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
(-1, 86399, 999999)
```

Class attributes are:

**timedelta.min**

The most negative `timedelta` object, `timedelta(-999999999)`.

**timedelta.max**

The most positive `timedelta` object, `timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.

**timedelta.resolution**

The smallest possible difference between non-equal `timedelta` objects, `timedelta(microseconds=1)`.

Note that, because of normalization, `timedelta.max > -timedelta.min`. `-timedelta.max` is not representable as a `timedelta` object.

Instance attributes (read-only):

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>days</td>
<td>Between -999999999 and 9999999999 inclusive</td>
</tr>
<tr>
<td>seconds</td>
<td>Between 0 and 86399 inclusive</td>
</tr>
<tr>
<td>microseconds</td>
<td>Between 0 and 999999999 inclusive</td>
</tr>
</tbody>
</table>

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
</table>
\[
t_1 = t_2 + t_3 \quad \text{Sum of } t_2 \text{ and } t_3. \text{ Afterwards } t_1-t_2 == t_3 \text{ and } t_1-t_3 == t_2 \text{ are true. (1)}
\]

\[
t_1 = t_2 - t_3 \quad \text{Difference of } t_2 \text{ and } t_3. \text{ Afterwards } t_1 == t_2 - t_3 \text{ and } t_2 == t_1 + t_3 \text{ are true. (1)}
\]

\[
t_1 = t_2 \times i \text{ or } t_1 = i \times t_2 \quad \text{Delta multiplied by an integer or long. Afterwards } t_1 // i == t_2 \text{ is true, provided } i \neq 0.
\]

\[
t_1 = t_2 // i \quad \text{The floor is computed and the remainder (if any) is thrown away. (3)}
\]

\[
+t_1 \quad \text{Returns a timedelta object with the same value. (2)}
\]

\[
-t_1 \quad \text{equivalent to timedelta(-t_1.days, -t_1.seconds, -t_1.microseconds), and to } t1\times -1. (1)(4)
\]

\[
abs(t) \quad \text{equivalent to } +t \text{ when } t.\text{days} \geq 0, \text{ and to } -t \text{ when } t.\text{days} < 0. (2)
\]

Notes:

1. This is exact, but may overflow.
2. This is exact, and cannot overflow.
3. Division by 0 raises ZeroDivisionError.
4. -timedelta.max is not representable as a timedelta object.

In addition to the operations listed above timedelta objects support certain additions and subtractions with date and datetime objects (see below).

Comparisons of timedelta objects are supported with the timedelta object representing the smaller duration considered to be the smaller timedelta. In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a timedelta object is compared to an object of a different type, TypeError is
raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

timedelta objects are hashable (usable as dictionary keys), support efficient pickling, and in Boolean contexts, a timedelta object is considered to be true if and only if it isn’t equal to timedelta(0).

Instance methods:

timedelta.total_seconds()  
Return the total number of seconds contained in the duration. Equivalent to `(td.microseconds + (td.seconds + td.days * 24 * 3600) * 10**6) / 10**6` computed with true division enabled.

Note that for very large time intervals (greater than 270 years on most platforms) this method will lose microsecond accuracy.

*New in version 2.7.*

Example usage:

```python
>>> from datetime import timedelta
>>> year = timedelta(days=365)
>>> another_year = timedelta(weeks=40, days=84, hours=23, ...
minutes=50, seconds=600)  # adds up to 365 days
>>> year.total_seconds()
31536000.0
>>> year == another_year
True
>>> ten_years = 10 * year
>>> ten_years, ten_years.days // 365
(datetime.timedelta(3650), 10)
>>> nine_years = ten_years - year
>>> nine_years, nine_years.days // 365
(datetime.timedelta(3285), 9)
>>> three_years = nine_years // 3;
>>> three_years, three_years.days // 365
(datetime.timedelta(1095), 3)
>>> abs(three_years - ten_years) == 2 * three_years + year
True
```
8.1.3. date Objects

A **date** object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book *Calendrical Calculations*, where it’s the base calendar for all computations. See the book for algorithms for converting between proleptic Gregorian ordinals and many other calendar systems.

```python
class datetime.date(year, month, day)
```

All arguments are required. Arguments may be ints or longs, in the following ranges:

- MINYEAR <= year <= MAXYEAR
- 1 <= month <= 12
- 1 <= day <= number of days in the given month and year

If an argument outside those ranges is given, `ValueError` is raised.

Other constructors, all class methods:

```python
classmethod date.today()
```

Return the current local date. This is equivalent to `date.fromtimestamp(time.time())`.

```python
classmethod date.fromtimestamp(timestamp)
```

Return the local date corresponding to the POSIX timestamp, such as is returned by `time.time()`. This may raise `ValueError`, if the timestamp is out of the range of values supported by the
platform C `localtime()` function. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by `fromtimestamp()`.

**classmethod date.fromordinal(ordinal)**

Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. `ValueError` is raised unless $1 \leq \text{ordinal} \leq \text{date.max.toordinal()}$. For any date $d$, `date.fromordinal(d.toordinal()) == d`.

Class attributes:

**date.min**

The earliest representable date, `date(MINYEAR, 1, 1)`.

**date.max**

The latest representable date, `date(MAXYEAR, 12, 31)`.

**date.resolution**

The smallest possible difference between non-equal date objects, `timedelta(days=1)`.

Instance attributes (read-only):

**date.year**

Between `MINYEAR` and `MAXYEAR` inclusive.

**date.month**

Between 1 and 12 inclusive.

**date.day**

Between 1 and the number of days in the given month of the given year.

Supported operations:
<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>(date2 = date1 + ) timedelta</td>
<td>(date2) is timedelta.days days removed from (date1). (1)</td>
</tr>
<tr>
<td>(date2 = date1 - ) timedelta</td>
<td>Computes (date2) such that (date2 + ) timedelta == (date1). (2)</td>
</tr>
<tr>
<td>timedelta = date1 - date2</td>
<td>(3)</td>
</tr>
<tr>
<td>date1 &lt; date2</td>
<td>(date1) is considered less than (date2) when (date1) precedes (date2) in time. (4)</td>
</tr>
</tbody>
</table>

Notes:

1. \(date2\) is moved forward in time if \(\text{timedelta}.\text{days} > 0\), or backward if \(\text{timedelta}.\text{days} < 0\). Afterward \(\text{date2} - \text{date1} == \text{timedelta}.\text{days}.\text{timedelta}.\text{seconds} \) and \(\text{timedelta}.\text{microseconds}\) are ignored. \textbf{OverflowError} is raised if \(\text{date2}.\text{year}\) would be smaller than \textbf{MINYEAR} or larger than \textbf{MAXYEAR}.

2. This isn’t quite equivalent to \(\text{date1} + (-\text{timedelta})\), because \(-\text{timedelta}\) in isolation can overflow in cases where \(\text{date1} - \text{timedelta} \) does not. \(\text{timedelta}.\text{seconds} \) and \(\text{timedelta}.\text{microseconds}\) are ignored.

3. This is exact, and cannot overflow. \(\text{timedelta}.\text{seconds}\) and \(\text{timedelta}.\text{microseconds}\) are 0, and \(\text{date2} + \text{timedelta} == \text{date1}\) after.

4. In other words, \(\text{date1} < \text{date2}\) if and only if \(\text{date1}.\text{toordinal()} < \text{date2}.\text{toordinal()}\). In order to stop comparison from falling back to the default scheme of comparing object addresses, date comparison normally raises \textbf{TypeError} if the other comparand isn’t also a \textbf{date} object. However, \textbf{NotImplemented} is returned instead if the other comparand has a \text{timetuple()} attribute. This hook gives other kinds of \text{date} objects a chance at implementing mixed-type comparison. If not, when a \textbf{date} object is compared to an object of a different type, \textbf{TypeError} is raised unless the
comparison is \texttt{==} or \texttt{!=}. The latter cases return \texttt{False} or \texttt{True}, respectively.

Dates can be used as dictionary keys. In Boolean contexts, all date objects are considered to be true.

Instance methods:

\begin{itemize}
\item \texttt{date.replace(year, month, day)}
\begin{itemize}
\item Return a date with the same value, except for those members given new values by whichever keyword arguments are specified. For example, if \(d = \text{date(2002, 12, 31)}\), then \(d.\text{replace(day=26)}\) \(== \text{date(2002, 12, 26)}\).
\end{itemize}
\item \texttt{date.timetuple()}\begin{itemize}
\item Return a \texttt{time.struct_time} such as returned by \texttt{time.localtime()}. The hours, minutes and seconds are 0, and the DST flag is -1. \(d.\text{timetuple()}\) is equivalent to \texttt{time.struct_time((d.year, d.month, d.day, 0, 0, 0, d.weekday(), yday, -1))}, where \(yday = d.\text{toordinal() - date(d.year, 1, 1).toordinal()} + 1\) is the day number within the current year starting with 1 for January 1st.
\end{itemize}
\item \texttt{date.toordinal()}\begin{itemize}
\item Return the proleptic Gregorian ordinal of the date, where January 1 of year 1 has ordinal 1. For any date object \(d\), \(\text{date.fromordinal(d.toordinal()) == d}\).
\end{itemize}
\item \texttt{date.weekday()}\begin{itemize}
\item Return the day of the week as an integer, where Monday is 0 and Sunday is 6. For example, \(\text{date(2002, 12, 4).weekday()} == 2\), a Wednesday. See also \texttt{isoweekday()}.\end{itemize}
\end{itemize}
date. **isoweekday()**

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. For example, `date(2002, 12, 4).isoweekday() == 3`, a Wednesday. See also `weekday()`, `isocalendar()`.

date. **isocalendar()**

Return a 3-tuple, (ISO year, ISO week number, ISO weekday).

The ISO calendar is a widely used variant of the Gregorian calendar. See [http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm](http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm) for a good explanation.

The ISO year consists of 52 or 53 full weeks, and where a week starts on a Monday and ends on a Sunday. The first week of an ISO year is the first (Gregorian) calendar week of a year containing a Thursday. This is called week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004, so that `date(2003, 12, 29).isocalendar() == (2004, 1, 1)` and `date(2004, 1, 4).isocalendar() == (2004, 1, 7)`.

date. **isoformat()**

Return a string representing the date in ISO 8601 format, ‘YYYY-MM-DD’. For example, `date(2002, 12, 4).isoformat() == '2002-12-04'`.

date. **__str__()**

For a date `d`, `str(d)` is equivalent to `d.isoformat()`.

date. **ctime()**
Return a string representing the date, for example `date(2002, 12, 4).ctime() == 'Wed Dec 4 00:00:00 2002'`. `date().ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `date.ctime()` does not invoke) conforms to the C standard.

**date.**`strftime(format)`

Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. See section `strftime() and strptime()` Behavior.

Example of counting days to an event:

```python
>>> import time
>>> from datetime import date
>>> today = date.today()
>>> today
datetime.date(2007, 12, 5)
>>> today == date.fromtimestamp(time.time())
True
>>> my_birthday = date(today.year, 6, 24)
>>> if my_birthday < today:
...    my_birthday = my_birthday.replace(year=today.year + 1)
>>> my_birthday
datetime.date(2008, 6, 24)
>>> time_to_birthday = abs(my_birthday - today)
>>> time_to_birthday.days
202
```

Example of working with `date`:

```python
>>> from datetime import date
>>> d = date.fromordinal(730920)  # 730920th day after 1. 1. 000
>>> d
datetime.date(2002, 3, 11)
>>> t = d.timetuple()
>>> for i in t:
...    print i
```
2002  # year
3   # month
11  # day
0
0
0
0  # weekday (0 = Monday)
70  # 70th day in the year
-1

>>> ic = d.isocalendar()

>>> for i in ic:
...     print i

2002  # ISO year
11  # ISO week number
1  # ISO day number (1 = Monday)

>>> d.isoformat()
'2002-03-11'

>>> d.strftime("%d/%m/%y")
'11/03/02'

>>> d.strftime("%A %d. %B %Y")
'Monday 11. March 2002'
8.1.4. datetime Objects

A `datetime` object is a single object containing all the information from a `date` object and a `time` object. Like a `date` object, `datetime` assumes the current Gregorian calendar extended in both directions; like a time object, `datetime` assumes there are exactly 3600*24 seconds in every day.

Constructor:

```python
class datetime.datetime(year, month, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]])
```

The year, month and day arguments are required. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be ints or longs, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <= number of days in the given month and year`
- `0 <= hour < 24`
- `0 <= minute < 60`
- `0 <= second < 60`
- `0 <= microsecond < 1000000`

If an argument outside those ranges is given, `ValueError` is raised.

Other constructors, all class methods:

```python
classmethod datetime.today()
```

Return the current local datetime, with `tzinfo None`. This is equivalent to `datetime.fromtimestamp(time.time())`. See also
`now()`, `fromtimestamp()`.

**classmethod** `datetime.now([tz])`

Return the current local date and time. If optional argument `tz` is `None` or not specified, this is like `today()`, but, if possible, supplies more precision than can be gotten from going through a `time.time()` timestamp (for example, this may be possible on platforms supplying the C `gettimeofday()` function).

Else `tz` must be an instance of a class `tzinfo` subclass, and the current date and time are converted to `tz`'s time zone. In this case the result is equivalent to `tz.fromutc(datetime.utcnow().replace(tzinfo=tz))`. See also `today()`, `utcnow()`.

**classmethod** `datetime.utcnow()`

Return the current UTC date and time, with `tzinfo None`. This is like `now()`, but returns the current UTC date and time, as a naive `datetime` object. See also `now()`.

**classmethod** `datetime.fromtimestamp(timestamp[, tz])`

Return the local date and time corresponding to the POSIX timestamp, such as is returned by `time.time()`. If optional argument `tz` is `None` or not specified, the timestamp is converted to the platform's local date and time, and the returned `datetime` object is naive.

Else `tz` must be an instance of a class `tzinfo` subclass, and the timestamp is converted to `tz`'s time zone. In this case the result is equivalent to `tz.fromutc(datetime.utcfromtimestamp(timestamp).replace(tzinfo=tz))`

`fromtimestamp()` may raise `ValueError`, if the timestamp is out of
the range of values supported by the platform C \texttt{localtime()} or \texttt{gmtime()} functions. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by \texttt{fromtimestamp()}, and then it's possible to have two timestamps differing by a second that yield identical \texttt{datetime} objects. See also \texttt{utcfromtimestamp()}.

\textbf{classmethod} \texttt{datetime.utcfromtimestamp}(timestamp)

Return the UTC \texttt{datetime} corresponding to the POSIX timestamp, with \texttt{tzinfo None}. This may raise \texttt{ValueError}, if the timestamp is out of the range of values supported by the platform C \texttt{gmtime()} function. It's common for this to be restricted to years in 1970 through 2038. See also \texttt{fromtimestamp()}.

\textbf{classmethod} \texttt{datetime.fromordinal}(ordinal)

Return the \texttt{datetime} corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. \texttt{ValueError} is raised unless \(1 \leq \text{ordinal} \leq \text{datetime.max.toordinal}()\). The hour, minute, second and microsecond of the result are all 0, and \texttt{tzinfo} is \texttt{None}.

\textbf{classmethod} \texttt{datetime.combine}(date, time)

Return a new \texttt{datetime} object whose date members are equal to the given \texttt{date} object's, and whose time and \texttt{tzinfo} members are equal to the given \texttt{time} object's. For any \texttt{datetime} object \texttt{d}, \texttt{d == datetime.combine(d.date(), d.timetz())}. If \texttt{date} is a \texttt{datetime} object, its time and \texttt{tzinfo} members are ignored.

\textbf{classmethod} \texttt{datetime.strptime}(date_string, format)

Return a \texttt{datetime} corresponding to \texttt{date_string}, parsed according to \texttt{format}. This is equivalent to \texttt{datetime(*}
(time.strptime(date_string, format)[0:6])). **ValueError** is raised if the date_string and format can't be parsed by `time.strptime()` or if it returns a value which isn't a time tuple. See section `strftime()` and `strptime()` Behavior.

*New in version 2.5.*

Class attributes:

datetime.*min*

The earliest representable `datetime`, `datetime(MINYEAR, 1, 1, tzinfo=None)`.

datetime.*max*

The latest representable `datetime`, `datetime(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None)`.

datetime.*resolution*

The smallest possible difference between non-equal `datetime` objects, `timedelta(microseconds=1)`.

Instance attributes (read-only):

datetime.*year*

Between `MINYEAR` and `MAXYEAR` inclusive.

datetime.*month*

Between 1 and 12 inclusive.

datetime.*day*

Between 1 and the number of days in the given month of the given year.

datetime.*hour*

In range(24).
datetime.minute
In range(60).

datetime.second
In range(60).

datetime.microsecond
In range(1000000).

datetime.tzinfo
The object passed as the tzinfo argument to the datetime constructor, or None if none was passed.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>datetime2 = datetime1 + timedelta</td>
<td>(1)</td>
</tr>
<tr>
<td>datetime2 = datetime1 - timedelta</td>
<td>(2)</td>
</tr>
<tr>
<td>timedelta = datetime1 - datetime2</td>
<td>(3)</td>
</tr>
<tr>
<td>datetime1 &lt; datetime2</td>
<td>Compares datetime to datetime. (4)</td>
</tr>
</tbody>
</table>

1. datetime2 is a duration of timedelta removed from datetime1, moving forward in time if timedelta.days > 0, or backward if timedelta.days < 0. The result has the same tzinfo member as the input datetime, and datetime2 - datetime1 == timedelta after. OverflowError is raised if datetime2.year would be smaller than MINYEAR or larger than MAXYEAR. Note that no time zone adjustments are done even if the input is an aware object.

2. Computes the datetime2 such that datetime2 + timedelta == datetime1. As for addition, the result has the same tzinfo member as the input datetime, and no time zone adjustments are done even if the input is aware. This isn’t quite equivalent to datetime1 + (-timedelta), because -timedelta in isolation can
overflow in cases where datetime1 - timedelta does not.

3. Subtraction of a `datetime` from a `datetime` is defined only if both operands are naive, or if both are aware. If one is aware and the other is naive, `TypeError` is raised.

If both are naive, or both are aware and have the same `tzinfo` member, the `tzinfo` members are ignored, and the result is a `timedelta` object \( t \) such that \( \text{datetime2} + t == \text{datetime1} \). No time zone adjustments are done in this case.

If both are aware and have different `tzinfo` members, \( a-b \) acts as if \( a \) and \( b \) were first converted to naive UTC datetimes first. The result is \( (a\text{.replace(tzinfo=None)} - a\text{.utcoffset()}) - (b\text{.replace(tzinfo=None)} - b\text{.utcoffset()}) \) except that the implementation never overflows.

4. `datetime1` is considered less than `datetime2` when `datetime1` precedes `datetime2` in time.

If one comparand is naive and the other is aware, `TypeError` is raised. If both comparands are aware, and have the same `tzinfo` member, the common `tzinfo` member is ignored and the base datetimes are compared. If both comparands are aware and have different `tzinfo` members, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`).

**Note:** In order to stop comparison from falling back to the default scheme of comparing object addresses, `datetime` comparison normally raises `TypeError` if the other comparand isn’t also a `datetime` object. However, `NotImplemented` is returned instead if the other comparand has a `timetuple()`
This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a \texttt{datetime} object is compared to an object of a different type, \texttt{TypeError} is raised unless the comparison is \texttt{==} or \texttt{!=}. The latter cases return \texttt{False} or \texttt{True}, respectively.

\texttt{datetime} objects can be used as dictionary keys. In Boolean contexts, all \texttt{datetime} objects are considered to be true.

Instance methods:

\texttt{datetime.date()}

Return \texttt{date} object with same year, month and day.

\texttt{datetime.time()}

Return \texttt{time} object with same hour, minute, second and microsecond. \texttt{tzinfo} is \texttt{None}. See also method \texttt{timetz()}.  

\texttt{datetime.timetz()}

Return \texttt{time} object with same hour, minute, second, microsecond, and \texttt{tzinfo} members. See also method \texttt{time()}.  

\texttt{datetime.replace([year[, month[, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]]]]])}

Return a datetime with the same members, except for those members given new values by whichever keyword arguments are specified. Note that \texttt{tzinfo=None} can be specified to create a naive datetime from an aware datetime with no conversion of date and time members.

\texttt{datetime.astimezone(tz)}

Return a \texttt{datetime} object with new \texttt{tzinfo} member \texttt{tz}, adjusting the date and time members so the result is the same UTC time
as *self*, but in *tz*'s local time.

tz must be an instance of a *tzinfo* subclass, and its *utcoffset()* and *dst()* methods must not return *None*. *self* must be aware (*self.tzinfo* must not be *None*, and *self.utcoffset()* must not return *None*).

If *self.tzinfo* is *tz*, *self.astimezone(tz)* is equal to *self*: no adjustment of date or time members is performed. Else the result is local time in time zone *tz*, representing the same UTC time as *self*: after *astz = dt.astimezone(tz)*, *astz - astz.utcoffset()* will usually have the same date and time members as *dt - dt.utcoffset()*.

If you merely want to attach a time zone object *tz* to a datetime *dt* without adjustment of date and time members, use *dt.replace(tzinfo=tz)*. If you merely want to remove the time zone object from an aware datetime *dt* without conversion of date and time members, use *dt.replace(tzinfo=None)*.

Note that the default *tzinfo.fromutc()* method can be overridden in a *tzinfo* subclass to affect the result returned by *astimezone()*.

Ignoring error cases, *astimezone()* acts like:

```python
def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    # Convert self to UTC, and attach the new time zone object
    utc = (self - self.utcoffset()).replace(tzinfo=tz)
    # Convert from UTC to tz's local time.
    return tz.fromutc(utc)
```
datetime.\texttt{utcoffset()}

If \texttt{tzinfo} is \texttt{None}, returns \texttt{None}, else returns 
\texttt{self.tzinfo.utcoffset(self)}, and raises an exception if the latter
doesn't return \texttt{None}, or a \texttt{timedelta} object representing a 
whole number of minutes with magnitude less than one day.

datetime.\texttt{dst()}

If \texttt{tzinfo} is \texttt{None}, returns \texttt{None}, else returns 
\texttt{self.tzinfo.dst(self)}, and raises an exception if the latter
doesn't return \texttt{None}, or a \texttt{timedelta} object representing a whole
number of minutes with magnitude less than one day.

datetime.\texttt{tzname()}

If \texttt{tzinfo} is \texttt{None}, returns \texttt{None}, else returns 
\texttt{self.tzinfo.tzname(self)}, raises an exception if the latter
doesn't return \texttt{None} or a string object,

datetime.\texttt{timetuple()}

Return a \texttt{time.struct_time} such as returned by 
\texttt{time.localtime()}. \texttt{d.timetuple()} is equivalent to 
\texttt{time.struct_time((d.year, d.month, d.day, d.hour, d.minute, 
d.second, d.weekday(), yday, dst)), where yday = d.toordinal() - date(d.year, 1, 1).toordinal() + 1} is the day
number within the current year starting with \texttt{1} for January 1st.
The \texttt{tm_isdst} flag of the result is set according to the \texttt{dst()} method: \texttt{tzinfo} is \texttt{None} or \texttt{d.dst()} returns \texttt{None}, \texttt{tm_isdst} is set to 
\texttt{-1}; else if \texttt{d.dst()} returns a non-zero value, \texttt{tm_isdst} is set to \texttt{1};
else \texttt{tm_isdst} is set to \texttt{0}.

datetime.\texttt{utctimetuple()}

If \texttt{datetime} instance \texttt{d} is naive, this is the same as \texttt{d.timetuple()} 
except that \texttt{tm_isdst} is forced to \texttt{0} regardless of what \texttt{d.dst()}
returns. DST is never in effect for a UTC time.

If \( d \) is aware, \( d \) is normalized to UTC time, by subtracting \( d.utcoffset() \), and a `time.struct_time` for the normalized time is returned. `tm_isdst` is forced to 0. Note that the result's `tm_year` member may be `MINYEAR-1` or `MAXYEAR+1`, if \( d.year \) was `MINYEAR` or `MAXYEAR` and UTC adjustment spills over a year boundary.

`datetime.toordinal()`
Return the proleptic Gregorian ordinal of the date. The same as `self.date().toordinal()`.

`datetime.weekday()`
Return the day of the week as an integer, where Monday is 0 and Sunday is 6. The same as `self.date().weekday()`. See also `isoweekday()`.

`datetime.isoweekday()`
Return the day of the week as an integer, where Monday is 1 and Sunday is 7. The same as `self.date().isoweekday()`. See also `weekday()`, `isocalendar()`.

`datetime.isocalendar()`
Return a 3-tuple, (ISO year, ISO week number, ISO weekday). The same as `self.date().isocalendar()`.

`datetime.isoformat([sep])`
Return a string representing the date and time in ISO 8601 format, `YYYY-MM-DDTHH:MM:SS.mmmmmm` or, if `microsecond` is 0, `YYYY-MM-DDTHH:MM:SS`

If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes:
YYYY-MM-DDTHH:MM:SS.mmmmmm+HH:MM or, if microsecond is 0 YYYY-MM-DDTHH:MM:SS+HH:MM

The optional argument sep (default 'T') is a one-character separator, placed between the date and time portions of the result. For example,

```python
>>> from datetime import tzinfo, timedelta, datetime
class TZ(tzinfo):
    ...     def utcoffset(self, dt): return timedelta(minutes=-3)
    ...
>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat(' ')  '2002-12-25 00:00:00-06:39'
```

**datetime.__str__()**

For a `datetime` instance `d`, `str(d)` is equivalent to `d.isoformat(' ')`.

**datetime.ctime()**

Return a string representing the date and time, for example `datetime(2002, 12, 4, 20, 30, 40).ctime() == 'Wed Dec 4 20:30:40 2002'. d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `datetime.ctime()` does not invoke) conforms to the C standard.

**datetime.strptime(format)**

Return a string representing the date and time, controlled by an explicit format string. See section `strptime()` and `strptime()` Behavior.

Examples of working with datetime objects:

```python
>>> from datetime import datetime, date, time
>>> # Using datetime.combine()
```
>>> d = date(2005, 7, 14)
>>> t = time(12, 30)
>>> datetime.combine(d, t)
datetime.datetime(2005, 7, 14, 12, 30)
>>> # Using datetime.now() or datetime.utcnow()
>>> datetime.now()
datetime.datetime(2007, 12, 6, 16, 29, 43, 79043)  # GMT +1
>>> datetime.utcnow()
datetime.datetime(2007, 12, 6, 15, 29, 43, 79060)
>>> dt = datetime.strptime("21/11/06 16:30", "%d/%m/%y %H:%M")
>>> dt
datetime.datetime(2006, 11, 21, 16, 30)
>>> # Using datetime.timetuple() to get tuple of all attributes
>>> tt = dt.timetuple()
>>> for it in tt:
...    print it
...
2006  # year
11  # month
21  # day
16  # hour
30  # minute
0  # second
1  # weekday (0 = Monday)
325  # number of days since 1st January
-1  # dst - method tzinfo.dst() returned None
>>> # Date in ISO format
>>> ic = dt.isocalendar()
>>> for it in ic:
...    print it
...
2006  # ISO year
47  # ISO week
2  # ISO weekday
>>> # Formatting datetime
>>> dt.strftime("%A, %d. %B %Y %I:%M%p")
'Tuesday, 21. November 2006 04:30PM'

Using datetime with tzinfo:

>>> from datetime import timedelta, datetime, tzinfo
>>> class GMT1(tzinfo):
...    def __init__(self):
...        # DST starts last Sunday in
...        d = datetime(dt.year, 4, 1)  # ends last Sunday in
...
... self.dston = d - timedelta(days=d.weekday() + 1)
... d = datetime(dt.year, 11, 1)
... self.dstoff = d - timedelta(days=d.weekday() + 1)
... def dst(self, dt):
...   if self.dston <= dt.replace(tzinfo=None) < self.dstoff:
...     return timedelta(hours=1)
...   else:
...     return timedelta(0)
... def tzname(self, dt):
...   return "GMT +1"
...

>>> class GMT2(tzinfo):
...   def __init__(self):
...     d = datetime(dt.year, 4, 1)
...     self.dston = d - timedelta(days=d.weekday() + 1)
...     d = datetime(dt.year, 11, 1)
...     self.dstoff = d - timedelta(days=d.weekday() + 1)
...   def utcoffset(self, dt):
...     return timedelta(hours=1) + self.dst(dt)
...   def dst(self, dt):
...     if self.dston <= dt.replace(tzinfo=None) < self.dstoff:
...       return timedelta(hours=2)
...     else:
...       return timedelta(0)
...   def tzname(self, dt):
...     return "GMT +2"
...

>>> gmt1 = GMT1()
>>> # Daylight Saving Time
>>> dt1 = datetime(2006, 11, 21, 16, 30, tzinfo=gmt1)
>>> dt1.dst()  # doctest: +ELLIPSIS
datetime.timedelta(0)
>>> dt1.utcoffset()  # doctest: +ELLIPSIS
datetime.timedelta(0, 3600)
>>> dt2 = datetime(2006, 6, 14, 13, 0, tzinfo=gmt1)
>>> dt2.dst()  # doctest: +ELLIPSIS
datetime.timedelta(0, 3600)
>>> dt2.utcoffset()  # doctest: +ELLIPSIS
datetime.timedelta(0, 7200)
>>> # Convert datetime to another time zone
>>> dt3 = dt2.astimezone(GMT2())
>>> dt3  # doctest: +ELLIPSIS
datetime.datetime(2006, 6, 14, 14, 0, tzinfo=<GMT2 object at 0x...>)
>>> dt2  # doctest: +ELLIPSIS
datetime.datetime(2006, 6, 14, 13, 0, tzinfo=<GMT1 object at 0x...>)
>>> dt2.utctimetuple() == dt3.utctimetuple()
True
8.1.5. time Objects

A time object represents a (local) time of day, independent of any particular day, and subject to adjustment via a tzinfo object.

```python
class datetime.time(hour[, minute[, second[, microsecond[, tzinfo]]]])
```

All arguments are optional. tzinfo may be None, or an instance of a tzinfo subclass. The remaining arguments may be ints or longs, in the following ranges:

- $0 \leq \text{hour} < 24$
- $0 \leq \text{minute} < 60$
- $0 \leq \text{second} < 60$
- $0 \leq \text{microsecond} < 1000000$.

If an argument outside those ranges is given, ValueError is raised. All default to 0 except tzinfo, which defaults to None.

Class attributes:

- **time.min**
  The earliest representable time, `time(0, 0, 0, 0)`.

- **time.max**
  The latest representable time, `time(23, 59, 59, 999999)`.

- **time.resolution**
  The smallest possible difference between non-equal time objects, `timedelta(microseconds=1)`, although note that arithmetic on time objects is not supported.

Instance attributes (read-only):
time. **hour**
   In `range(24)`.

time. **minute**
   In `range(60)`.

time. **second**
   In `range(60)`.

time. **microsecond**
   In `range(1000000)`.

time. **tzinfo**
   The object passed as the tzinfo argument to the `time` constructor, or **None** if none was passed.

**Supported operations:**

- comparison of `time` to `time`, where `a` is considered less than `b` when `a` precedes `b` in time. If one comparand is naive and the other is aware, `TypeError` is raised. If both comparands are aware, and have the same `tzinfo` member, the common `tzinfo` member is ignored and the base times are compared. If both comparands are aware and have different `tzinfo` members, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`). In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a `time` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.
- hash, use as dict key
- efficient pickling
- in Boolean contexts, a `time` object is considered to be true if and only if, after converting it to minutes and subtracting `utcoffset()`
(or 0 if that's None), the result is non-zero.

Instance methods:

time.replace([hour[, minute[, second[, microsecond[, tzinfo]]]]])

Return a time with the same value, except for those members given new values by whichever keyword arguments are specified. Note that tzinfo=None can be specified to create a naive time from an aware time, without conversion of the time members.

time.isoformat()

Return a string representing the time in ISO 8601 format, HH:MM:SS.mmmmmm or, if self.microsecond is 0, HH:MM:SS If utcoffset() does not return None, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: HH:MM:SS.mmmmmm+HH:MM or, if self.microsecond is 0, HH:MM:SS+HH:MM

time.__str__()

For a time t, str(t) is equivalent to t.isoformat().

time.strftime(format)

Return a string representing the time, controlled by an explicit format string. See section strftime() and strptime() Behavior.

time.utcoffset()

If tzinfo is None, returns None, else returns self.tzinfo.utcoffset(None), and raises an exception if the latter doesn't return None or a timedelta object representing a whole number of minutes with magnitude less than one day.

time.dst()

If tzinfo is None, returns None, else returns
self.tzinfo.dst(None), and raises an exception if the latter doesn’t return None, or a timedelta object representing a whole number of minutes with magnitude less than one day.

time.tzname()

If tzinfo is None, returns None, else returns self.tzinfo.tzname(None), or raises an exception if the latter doesn’t return None or a string object.

Example:

```python
>>> from datetime import time, tzinfo
>>> class GMT1(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=1)
...     def dst(self, dt):
...         return timedelta(0)
...     def tzname(self, dt):
...         return "Europe/Prague"
...     
... >>> t = time(12, 10, 30, tzinfo=GMT1())
... >>> t  # doctest: +ELLIPSIS
datetime.time(12, 10, 30, tzinfo=<GMT1 object at 0x...>)
>>> gmt = GMT1()
>>> t.isoformat()
'12:10:30+01:00'
>>> t.dst()
datetime.timedelta(0)
>>> t.tzname()
'Europe/Prague'
>>> t.strftime("%H:%M:%S %Z")
'12:10:30 Europe/Prague'
```
8.1.6. tzinfo Objects

tzinfo is an abstract base class, meaning that this class should not be instantiated directly. You need to derive a concrete subclass, and (at least) supply implementations of the standard tzinfo methods needed by the datetime methods you use. The datetime module does not supply any concrete subclasses of tzinfo.

An instance of (a concrete subclass of) tzinfo can be passed to the constructors for datetime and time objects. The latter objects view their members as being in local time, and the tzinfo object supports methods revealing offset of local time from UTC, the name of the time zone, and DST offset, all relative to a date or time object passed to them.

Special requirement for pickling: A tzinfo subclass must have an __init__() method that can be called with no arguments, else it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of tzinfo may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware datetime objects. If in doubt, simply implement all of them.

tzinfo.utcoffset(self, dt)

Return offset of local time from UTC, in minutes east of UTC. If local time is west of UTC, this should be negative. Note that this is intended to be the total offset from UTC; for example, if a tzinfo object represents both time zone and DST adjustments, utcoffset() should return their sum. If the UTC offset isn’t known, return None. Else the value returned must be a timedelta
object specifying a whole number of minutes in the range -1439 to 1439 inclusive (1440 = 24*60; the magnitude of the offset must be less than one day). Most implementations of `utcoffset()` will probably look like one of these two:

```
return CONSTANT                  # fixed-offset class
return CONSTANT + self.dst(dt)  # daylight-aware class
```

If `utcoffset()` does not return `None`, `dst()` should not return `None` either.

The default implementation of `utcoffset()` raises `NotImplementedError`.

tzinfo.\texttt{dst}(\texttt{self}, \texttt{dt})

Return the daylight saving time (DST) adjustment, in minutes east of UTC, or `None` if DST information isn't known. Return `timedelta(0)` if DST is not in effect. If DST is in effect, return the offset as a `timedelta` object (see `utcoffset()` for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by `utcoffset()`, so there's no need to consult `dst()` unless you're interested in obtaining DST info separately. For example, `datetime.timetuple()` calls its `tzinfo` member's `dst()` method to determine how the \texttt{tm_isdst} flag should be set, and `tzinfo.fromutc()` calls `dst()` to account for DST changes when crossing time zones.

An instance \texttt{tz} of a `tzinfo` subclass that models both standard and daylight times must be consistent in this sense:

\[
\text{tz.utcoffset(dt)} - \text{tz.dst(dt)}
\]

must return the same result for every `datetime dt` with `dt.tzinfo == tz`. For sane `tzinfo` subclasses, this expression yields the
time zone’s “standard offset”, which should not depend on the date or the time, but only on geographic location. The implementation of `datetime.astimezone()` relies on this, but cannot detect violations; it’s the programmer’s responsibility to ensure it. If a `tzinfo` subclass cannot guarantee this, it may be able to override the default implementation of `tzinfo.fromutc()` to work correctly with `astimezone()` regardless.

Most implementations of `dst()` will probably look like one of these two:

```python
def dst(self):
    # a fixed-offset class: doesn't account for DST
    return timedelta(0)
```

or

```python
def dst(self):
    # Code to set dston and dstoff to the time zone's DST
    # transition times based on the input dt.year, and express
    # in standard local time. Then
    if dston <= dt.replace(tzinfo=None) < dstoff:
        return timedelta(hours=1)
    else:
        return timedelta(0)
```

The default implementation of `dst()` raises `NotImplementedError`.

`tzinfo.tzname(self, dt)`

Return the time zone name corresponding to the `datetime` object `dt`, as a string. Nothing about string names is defined by the `datetime` module, and there’s no requirement that it mean anything in particular. For example, “GMT”, “UTC”, “-500”, “-5:00”, “EDT”, “US/Eastern”, “America/New York” are all valid replies. Return `None` if a string name isn’t known. Note that this is a
method rather than a fixed string primarily because some `tzinfo`
subclasses will wish to return different names depending on the
specific value of `dt` passed, especially if the `tzinfo` class is
accounting for daylight time.

The default implementation of `tzname()` raises
`NotImplementedError`.

These methods are called by a `datetime` or `time` object, in response
to their methods of the same names. A `datetime` object passes itself
as the argument, and a `time` object passes `None` as the argument. A
`tzinfo` subclass's methods should therefore be prepared to accept a
`dt` argument of `None`, or of class `datetime`.

When `None` is passed, it’s up to the class designer to decide the best
response. For example, returning `None` is appropriate if the class
wishes to say that time objects don’t participate in the `tzinfo`
protocols. It may be more useful for `utcoffset(None)` to return the
standard UTC offset, as there is no other convention for discovering
the standard offset.

When a `datetime` object is passed in response to a `datetime`
method, `dt.tzinfo` is the same object as `self`. `tzinfo` methods can
rely on this, unless user code calls `tzinfo` methods directly. The
intent is that the `tzinfo` methods interpret `dt` as being in local time,
and not need worry about objects in other timezones.

There is one more `tzinfo` method that a subclass may wish to
override:

```
tzinfo.fromutc(self, dt)
```

This is called from the default `datetime.astimezone()`
implementation. When called from that, `dt.tzinfo` is `self`, and `dt`’s
date and time members are to be viewed as expressing a UTC time. The purpose of `fromutc()` is to adjust the date and time members, returning an equivalent datetime in `self`'s local time.

Most `tzinfo` subclasses should be able to inherit the default `fromutc()` implementation without problems. It’s strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default `fromutc()` implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of `astimezone()` and `fromutc()` may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default `fromutc()` implementation acts like:

```python
def fromutc(self, dt):
    # raise ValueError error if dt.tzinfo is not self
dtoff = dt.utcoffset()
dtdst = dt.dst()
    # raise ValueError if dtoff is None or dtdst is None
delta = dtoff - dtdst # this is self's standard offset
    if delta:
        dt += delta # convert to standard local time
dtdst = dt.dst()
        # raise ValueError if dtdst is None
        if dtdst:
            return dt + dtdst
    else:
        return dt
```

Example `tzinfo` classes:

```python
from datetime import tzinfo, timedelta, datetime
```
ZERO = timedelta(0)
HOUR = timedelta(hours=1)

# A UTC class.

class UTC(tzinfo):
    """UTC""

        def utcoffset(self, dt):
            return ZERO

        def tzname(self, dt):
            return "UTC"

        def dst(self, dt):
            return ZERO

utc = UTC()

# A class building tzinfo objects for fixed-offset time zones.
# Note that FixedOffset(0, "UTC") is a different way to build a
# UTC tzinfo object.

class FixedOffset(tzinfo):
    """Fixed offset in minutes east from UTC.""

            def __init__(self, offset, name):
                self.__offset = timedelta(minutes = offset)
                self.__name = name

            def utcoffset(self, dt):
                return self.__offset

            def tzname(self, dt):
                return self.__name

            def dst(self, dt):
                return ZERO

# A class capturing the platform's idea of local time.

import time as _time

# dt first.
if start <= dt.replace(tzinfo=None) < end:
    return HOUR
else:
    return ZERO

Eastern = USTimeZone(-5, "Eastern", "EST", "EDT")
Central = USTimeZone(-6, "Central", "CST", "CDT")
Mountain = USTimeZone(-7, "Mountain", "MST", "MDT")
Pacific = USTimeZone(-8, "Pacific", "PST", "PDT")

Note that there are unavoidable subtleties twice per year in a tzinfo subclass accounting for both standard and daylight time, at the DST transition points. For concreteness, consider US Eastern (UTC -0500), where EDT begins the minute after 1:59 (EST) on the second Sunday in March, and ends the minute after 1:59 (EDT) on the first Sunday in November:

<table>
<thead>
<tr>
<th></th>
<th>UTC</th>
<th>EST</th>
<th>EDT</th>
<th>Pacific</th>
</tr>
</thead>
<tbody>
<tr>
<td>start</td>
<td>22:MM</td>
<td>23:MM</td>
<td>0:MM</td>
<td>0:MM</td>
</tr>
<tr>
<td>end</td>
<td>23:MM</td>
<td>0:MM</td>
<td>1:MM</td>
<td>1:MM</td>
</tr>
</tbody>
</table>
When DST starts (the “start” line), the local wall clock leaps from 1:59 to 3:00. A wall time of the form 2:MM doesn’t really make sense on that day, so `astimezone(Eastern)` won’t deliver a result with `hour == 2` on the day DST begins. In order for `astimezone()` to make this guarantee, the `rzinfo.dst()` method must consider times in the “missing hour” (2:MM for Eastern) to be in daylight time.

When DST ends (the “end” line), there’s a potentially worse problem: there’s an hour that can’t be spelled unambiguously in local wall time: the last hour of daylight time. In Eastern, that’s times of the form 5:MM UTC on the day daylight time ends. The local wall clock leaps from 1:59 (daylight time) back to 1:00 (standard time) again. Local times of the form 1:MM are ambiguous. `astimezone()` mimics the local clock’s behavior by mapping two adjacent UTC hours into the same local hour then. In the Eastern example, UTC times of the form 5:MM and 6:MM both map to 1:MM when converted to Eastern. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “repeated hour” to be in standard time. This is easily arranged, as in the example, by expressing DST switch times in the time zone’s standard local time.

Applications that can’t bear such ambiguities should avoid using hybrid `tzinfo` subclasses; there are no ambiguities when using UTC, or any other fixed-offset `tzinfo` subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).
8.1.7. strftime() and strptime() Behavior

date, datetime, and time objects all support a strftime(format) method, to create a string representing the time under the control of an explicit format string. Broadly speaking, d.strftime(fmt) acts like the time module’s time.strftime(fmt, d.timetuple()) although not all objects support a timetuple() method.

Conversely, the datetime.strptime() class method creates a datetime object from a string representing a date and time and a corresponding format string. datetime.strptime(date_string, format) is equivalent to datetime(*(time.strptime(date_string, format)[0:6])).

For time objects, the format codes for year, month, and day should not be used, as time objects have no such values. If they’re used anyway, 1900 is substituted for the year, and 1 for the month and day.

For date objects, the format codes for hours, minutes, seconds, and microseconds should not be used, as date objects have no such values. If they’re used anyway, 0 is substituted for them.

New in version 2.6: time and datetime objects support a %f format code which expands to the number of microseconds in the object, zero-padded on the left to six places.

For a naive object, the %z and %Z format codes are replaced by empty strings.

For an aware object:

%z
utcoffset() is transformed into a 5-character string of the form +HHMM or -HHMM, where HH is a 2-digit string giving the number of UTC offset hours, and MM is a 2-digit string giving the number of UTC offset minutes. For example, if utcoffset() returns timedelta(hours=-3, minutes=-30), %z is replaced with the string '-0330'.

If tzname() returns None, %Z is replaced by an empty string. Otherwise %Z is replaced by the returned value, which must be a string.

The full set of format codes supported varies across platforms, because Python calls the platform C library's strftime() function, and platform variations are common.

The following is a list of all the format codes that the C standard (1989 version) requires, and these work on all platforms with a standard C implementation. Note that the 1999 version of the C standard added additional format codes.

The exact range of years for which strftime() works also varies across platforms. Regardless of platform, years before 1900 cannot be used.

</tbody>
</table>

Notes:
1. When used with the `strptime()` method, the `%f` directive accepts from one to six digits and zero pads on the right. `%f` is an extension to the set of format characters in the C standard (but implemented separately in datetime objects, and therefore always available).

2. When used with the `strptime()` method, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.

3. The range really is 0 to 61; according to the Posix standard this accounts for leap seconds and the (very rare) double leap seconds. The `time` module may produce and does accept leap seconds since it is based on the Posix standard, but the `datetime` module does not accept leap seconds in `strptime()` input nor will it produce them in `strftime()` output.

4. When used with the `strptime()` method, `%u` and `%w` are only used in calculations when the day of the week and the year are specified.

5. For example, if `utcoffset()` returns `timedelta(hours=-3, minutes=-30)`, `%z` is replaced with the string '-0330'.
This module allows you to output calendars like the Unix `cal` program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use `setfirstweekday()` to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers. For related functionality, see also the `datetime` and `time` modules.

Most of these functions and classes rely on the `datetime` module which uses an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book “Calendrical Calculations”, where it’s the base calendar for all computations.

```python
class calendar.Calendar([firstweekday])

Creates a Calendar object. firstweekday is an integer specifying the first day of the week. 0 is Monday (the default), 6 is Sunday.

A Calendar object provides several methods that can be used for preparing the calendar data for formatting. This class doesn’t do any formatting itself. This is the job of subclasses.

New in version 2.5.

Calendar instances have the following methods:

iterweekdays()```
Return an iterator for the week day numbers that will be used for one week. The first value from the iterator will be the same as the value of the \texttt{firstweekday} property.

\textbf{itermonthdates}(year, month)

Return an iterator for the month \textit{month} (1-12) in the year \textit{year}. This iterator will return all days (as \texttt{datetime.date} objects) for the month and all days before the start of the month or after the end of the month that are required to get a complete week.

\textbf{itermonthdays2}(year, month)

Return an iterator for the month \textit{month} in the year \textit{year} similar to \texttt{itermonthdates()}. Days returned will be tuples consisting of a day number and a week day number.

\textbf{itermonthdays}(year, month)

Return an iterator for the month \textit{month} in the year \textit{year} similar to \texttt{itermonthdates()}. Days returned will simply be day numbers.

\textbf{monthdatescalendar}(year, month)

Return a list of the weeks in the month \textit{month} of the \textit{year} as full weeks. Weeks are lists of seven \texttt{datetime.date} objects.

\textbf{monthdays2calendar}(year, month)

Return a list of the weeks in the month \textit{month} of the \textit{year} as full weeks. Weeks are lists of seven tuples of day numbers and weekday numbers.

\textbf{monthdayscalendar}(year, month)

Return a list of the weeks in the month \textit{month} of the \textit{year} as full weeks. Weeks are lists of seven day numbers.

\textbf{yeardatescalendar}(year[, width])
Return the data for the specified year ready for formatting. The return value is a list of month rows. Each month row contains up to \textit{width} months (defaulting to 3). Each month contains between 4 and 6 weeks and each week contains 1–7 days. Days are \texttt{datetime.date} objects.

\texttt{yeardays2calendar(year[\[, width\]])}

Return the data for the specified year ready for formatting (similar to \texttt{yeardatescalendar()}). Entries in the week lists are tuples of day numbers and weekday numbers. Day numbers outside this month are zero.

\texttt{yeardayscalendar(year[\[, width\]])}

Return the data for the specified year ready for formatting (similar to \texttt{yeardatescalendar()}). Entries in the week lists are day numbers. Day numbers outside this month are zero.

\begin{verbatim}
\texttt{class \texttt{calendar}.\texttt{TextCalendar}(firstweekday)}
\end{verbatim}

This class can be used to generate plain text calendars.

\textit{New in version} \texttt{2.5}.

\texttt{TextCalendar} instances have the following methods:

\texttt{formatmonth(theyear, themonth[\[, w[\[, l\]]\])}

Return a month’s calendar in a multi-line string. If \textit{w} is provided, it specifies the width of the date columns, which are centered. If \textit{l} is given, it specifies the number of lines that each week will use. Depends on the first weekday as specified in the constructor or set by the \texttt{setfirstweekday()} method.

\texttt{prmonth(theyear, themonth[\[, w[\[, l\]]\])}

Print a month’s calendar as returned by \texttt{formatmonth()}. 
formatyear(theyear[, w[, l[, c[, m]]]]))
Return a $m$-column calendar for an entire year as a multi-line string. Optional parameters $w$, $l$, and $c$ are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on the first weekday as specified in the constructor or set by the setfirstweekday() method. The earliest year for which a calendar can be generated is platform-dependent.

pryear(theyear[, w[, l[, c[, m]]]]))
Print the calendar for an entire year as returned by formatyear().

class calendar.HTMLCalendar([firstweekday])
This class can be used to generate HTML calendars.

New in version 2.5.

HTMLCalendar instances have the following methods:

formatmonth(theyear, themonth[, withyear])
Return a month’s calendar as an HTML table. If withyear is true the year will be included in the header, otherwise just the month name will be used.

formatyear(theyear[, width])
Return a year’s calendar as an HTML table. width (defaulting to 3) specifies the number of months per row.

formatyearpage(theyear[, width[, css[, encoding]]])
Return a year’s calendar as a complete HTML page. width (defaulting to 3) specifies the number of months per row. css is the name for the cascading style sheet to be used. None can be passed if no style sheet should be used. encoding
specifies the encoding to be used for the output (defaulting to the system default encoding).

\textit{class} \texttt{calendar.LocaleTextCalendar}([\textit{firstweekday}, \textit{locale}])

This subclass of \texttt{TextCalendar} can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

\textit{New in version 2.5.}

\textit{class} \texttt{calendar.LocaleHTMLCalendar}([\textit{firstweekday}, \textit{locale}])

This subclass of \texttt{HTMLCalendar} can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

\textit{New in version 2.5.}

For simple text calendars this module provides the following functions.

\texttt{calendar.setfirstweekday(weekday)}

Sets the weekday (0 is Monday, 6 is Sunday) to start each week. The values \texttt{MONDAY}, \texttt{TUESDAY}, \texttt{WEDNESDAY}, \texttt{THURSDAY}, \texttt{FRIDAY}, \texttt{SATURDAY}, and \texttt{SUNDAY} are provided for convenience. For example, to set the first weekday to Sunday:

\begin{verbatim}
import calendar
calendar.setfirstweekday(calendar.SUNDAY)
\end{verbatim}

\textit{New in version 2.0.}
calendar. **firstweekday()**
Returns the current setting for the weekday to start each week.

*New in version 2.0.*

calendar. **isleap(year)**
Returns **True** if *year* is a leap year, otherwise **False**.

calendar. **leapdays(y1, y2)**
Returns the number of leap years in the range from *y1* to *y2* (exclusive), where *y1* and *y2* are years.

*Changed in version 2.0:* This function didn’t work for ranges spanning a century change in Python 1.5.2.

calendar. **weekday(year, month, day)**
Returns the day of the week (0 is Monday) for *year* (1970–...), *month* (1–12), *day* (1–31).

calendar. **weekheader(n)**
Return a header containing abbreviated weekday names. *n* specifies the width in characters for one weekday.

calendar. **monthrange(year, month)**
Returns weekday of first day of the month and number of days in month, for the specified *year* and *month*.

calendar. **monthcalendar(year, month)**
Returns a matrix representing a month’s calendar. Each row represents a week; days outside of the month a represented by zeros. Each week begins with Monday unless set by **setfirstweekday()**.

calendar. **prmonth(theyear, themonth[, w[, l]])**
Prints a month’s calendar as returned by `month()`.

```python
calendar.month(yeartuple, monthtuple)
```

Returns a month’s calendar in a multi-line string using the `formatmonth()` of the `TextCalendar` class.

*New in version 2.0.*

```python
calendar.prcal(yeartuple, weektuple)
```

Prints the calendar for an entire year as returned by `calendar()`.

```python
calendar.calendar(yeartuple, weektuple)
```

Returns a 3-column calendar for an entire year as a multi-line string using the `formatyear()` of the `TextCalendar` class.

*New in version 2.0.*

```python
calendar.timegm(tupletuple)
```

An unrelated but handy function that takes a time tuple such as returned by the `gmtime()` function in the `time` module, and returns the corresponding Unix timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, `time.gmtime()` and `timegm()` are each others’ inverse.

*New in version 2.0.*

The `calendar` module exports the following data attributes:

```python
calendar.day_name
```

An array that represents the days of the week in the current locale.

```python
calendar.day_abbr
```

An array that represents the abbreviated days of the week in the locale.
current locale.

**calendar.month_name**

An array that represents the months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_name[0]` is the empty string.

**calendar.month_abbr**

An array that represents the abbreviated months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_abbr[0]` is the empty string.

**See also:**

**Module datetime**

Object-oriented interface to dates and times with similar functionality to the `time` module.

**Module time**

Low-level time related functions.
New in version 2.4.

This module implements high-performance container datatypes. Currently, there are four datatypes, `Counter`, `deque`, `OrderedDict` and `defaultdict`, and one datatype factory function, `namedtuple()`.

The specialized containers provided in this module provide alternatives to Python's general purpose built-in containers, `dict`, `list`, `set`, and `tuple`.

*Changed in version 2.4*: Added `deque`.

*Changed in version 2.5*: Added `defaultdict`.

*Changed in version 2.6*: Added `namedtuple()` and added abstract base classes.

*Changed in version 2.7*: Added `Counter` and `OrderedDict`.

In addition to containers, the collections module provides some ABCs (abstract base classes) that can be used to test whether a class provides a particular interface, for example, whether it is hashable or a mapping.
The collections module offers the following ABCs:

<table>
<thead>

<td>MappingView</td>
<td><strong>contains</strong>, <strong>iter</strong></td>
</tr>
</tbody>
</table>

These ABCs allow us to ask classes or instances if they provide particular functionality, for example:

```python
def __init__(self, iterable):
    self.elements = lst = []
    for value in iterable:
        if value not in lst:
            lst.append(value)

def __contains__(self, value):
    return value in self.elements
```

Several of the ABCs are also useful as mixins that make it easier to develop classes supporting container APIs. For example, to write a class supporting the full set API, it only necessary to supply the three underlying abstract methods: `__contains__()`, `__iter__()`, and `__len__()`. The ABC supplies the remaining methods such as `__and__()` and `isdisjoint()`
def __len__(self):
    return len(self.elements)

s1 = ListBasedSet('abcdef')
s2 = ListBasedSet('defghi')
overlap = s1 & s2  # The __and__() method is supported

Notes on using Set and MutableSet as a mixin:

1. Since some set operations create new sets, the default mixin methods need a way to create new instances from an iterable. The class constructor is assumed to have a signature in the form `ClassName(iterable)`. That assumption is factored-out to an internal classmethod called `_from_iterable()` which calls `cls(iterable)` to produce a new set. If the set mixin is being used in a class with a different constructor signature, you will need to override `from_iterable()` with a classmethod that can construct new instances from an iterable argument.

2. To override the comparisons (presumably for speed, as the semantics are fixed), redefine `__le__()` and then the other operations will automatically follow suit.

3. The set mixin provides a `_hash()` method to compute a hash value for the set; however, `__hash__()` is not defined because not all sets are hashable or immutable. To add set hashability using mixins, inherit from both `Set()` and `Hashable()`, then define `__hash__ = Set._hash`.

See also:

- **OrderedSet recipe** for an example built on `MutableSet`.
- For more about ABCs, see the `abc` module and [PEP 3119](https://www.python.org/dev/peps/pep-0319/).
8.3.2. Counter objects

A counter tool is provided to support convenient and rapid tallies. For example:

```python
>>> # Tally occurrences of words in a list
>>> cnt = Counter()
>>> for word in ['red', 'blue', 'red', 'green', 'blue', 'blue']
...     cnt[word] += 1
>>> cnt
Counter({'blue': 3, 'red': 2, 'green': 1})
```

```python
>>> # Find the ten most common words in Hamlet
>>> import re
>>> words = re.findall('\w+', open('hamlet.txt').read().lower())
>>> Counter(words).most_common(10)
[('the', 1143), ('and', 966), ('to', 762), ('of', 669), ('i', 669), ('you', 554), ('a', 546), ('my', 514), ('hamlet', 471), ('in'
```

class collections.Counter([iterable-or-mapping])

A `Counter` is a `dict` subclass for counting hashable objects. It is an unordered collection where elements are stored as dictionary keys and their counts are stored as dictionary values. Counts are allowed to be any integer value including zero or negative counts. The `Counter` class is similar to bags or multisets in other languages.

Elements are counted from an `iterable` or initialized from another `mapping` (or counter):

```python
>>> c = Counter()  # a new, empty counter
>>> c = Counter('gallahad')  # a new counter
>>> c = Counter({'red': 4, 'blue': 2})  # a new counter
>>> c = Counter(cats=4, dogs=8)  # a new counter
```

Counter objects have a dictionary interface except that they
return a zero count for missing items instead of raising a

```
KeyError:
```

```
>>> c = Counter(['eggs', 'ham'])

>>> c['bacon']
# count of a missing element is zero
0
```

Setting a count to zero does not remove an element from a counter. Use `del` to remove it entirely:

```
>>> c['sausage'] = 0
# counter entry with a zero count

>>> del c['sausage']
# del actually removes the entry
```

*New in version 2.7.*

Counter objects support three methods beyond those available for all dictionaries:

**`elements()`**

Return an iterator over elements repeating each as many times as its count. Elements are returned in arbitrary order. If an element's count is less than one, `elements()` will ignore it.

```
>>> c = Counter(a=4, b=2, c=0, d=-2)

>>> list(c.elements())
['a', 'a', 'a', 'a', 'b', 'b']
```

**`most_common([n])`**

Return a list of the `n` most common elements and their counts from the most common to the least. If `n` is not specified, `most_common()` returns *all* elements in the counter. Elements with equal counts are ordered arbitrarily:

```
>>> Counter('abracadabra').most_common(3)
[('a', 5), ('r', 2), ('b', 2)]
```
subtract([iterable-or-mapping])

Elements are subtracted from an iterable or from another mapping (or counter). Like dict.update() but subtracts counts instead of replacing them. Both inputs and outputs may be zero or negative.

```>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> d = Counter(a=1, b=2, c=3, d=4)
>>> c.subtract(d)
Counter({'a': 3, 'b': 0, 'c': -3, 'd': -6})```

The usual dictionary methods are available for Counter objects except for two which work differently for counters.

fromkeys(iterable)

This class method is not implemented for Counter objects.

update([iterable-or-mapping])

Elements are counted from an iterable or added-in from another mapping (or counter). Like dict.update() but adds counts instead of replacing them. Also, the iterable is expected to be a sequence of elements, not a sequence of (key, value) pairs.

Common patterns for working with Counter objects:

- sum(c.values()) # total of all counts
- c.clear() # reset all counts
- list(c) # list unique elements
- set(c) # convert to a set
- dict(c) # convert to a regular dictionary
- c.items() # convert to a list of (elem, c
- Counter(dict(list_of_pairs)) # convert from a list of (elem, c
- c.most_common()[:,-n:-1] # n least common elements
- c += Counter() # remove zero and negative coun
Several mathematical operations are provided for combining `Counter` objects to produce multisets (counters that have counts greater than zero). Addition and subtraction combine counters by adding or subtracting the counts of corresponding elements. Intersection and union return the minimum and maximum of corresponding counts. Each operation can accept inputs with signed counts, but the output will exclude results with counts of zero or less.

```python
>>> c = Counter(a=3, b=1)
>>> d = Counter(a=1, b=2)
>>> c + d
Counter({'a': 4, 'b': 3})  # add two counters together: c[x] + d[x]
>>> c - d
Counter({'a': 2})  # subtract (keeping only positive counts)
>>> c & d
Counter({'a': 1, 'b': 1})  # intersection: min(c[x], d[x])
>>> c | d
Counter({'a': 3, 'b': 2})  # union: max(c[x], d[x])
```

**Note:** Counters were primarily designed to work with positive integers to represent running counts; however, care was taken to not unnecessarily preclude use cases needing other types or negative values. To help with those use cases, this section documents the minimum range and type restrictions.

- The `Counter` class itself is a dictionary subclass with no restrictions on its keys and values. The values are intended to be numbers representing counts, but you could store anything in the value field.
- The `most_common()` method requires only that the values be orderable.
- For in-place operations such as `c[key] += 1`, the value type need only support addition and subtraction. So fractions, floats, and decimals would work and negative values are supported. The same is also true for `update()` and `subtract()` which allow negative and zero values for both inputs and
The multiset methods are designed only for use cases with positive values. The inputs may be negative or zero, but only outputs with positive values are created. There are no type restrictions, but the value type needs to support support addition, subtraction, and comparison.

- The `elements()` method requires integer counts. It ignores zero and negative counts.

- To enumerate all distinct multisets of a given size over a given set of elements, see `itertools.combinations_withReplacement()`:

```python
map(Counter, combinations_with Replacement('ABC', 2))
-> AA AB AC BB BC CC
```
8.3.3. deque objects

```python
class collections.deque([iterable, maxlen])
```

Returns a new deque object initialized left-to-right (using `append()`) with data from `iterable`. If `iterable` is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced “deck” and is short for “double-ended queue”). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same $O(1)$ performance in either direction.

Though `list` objects support similar operations, they are optimized for fast fixed-length operations and incur $O(n)$ memory movement costs for `pop(0)` and `insert(0, v)` operations which change both the size and position of the underlying data representation.

*New in version 2.4.*

If `maxlen` is not specified or is `None`, deques may grow to an arbitrary length. Otherwise, the deque is bounded to the specified maximum length. Once a bounded length deque is full, when new items are added, a corresponding number of items are discarded from the opposite end. Bounded length deques provide functionality similar to the `tail` filter in Unix. They are also useful for tracking transactions and other pools of data where only the most recent activity is of interest.

*Changed in version 2.6: Added `maxlen` parameter.*

Deque objects support the following methods:
**append**(x)
Add x to the right side of the deque.

**appendleft**(x)
Add x to the left side of the deque.

**clear**()
Remove all elements from the deque leaving it with length 0.

**count**(x)
Count the number of deque elements equal to x.

*New in version 2.7.*

**extend**(iterable)
Extend the right side of the deque by appending elements from the iterable argument.

**extendleft**(iterable)
Extend the left side of the deque by appending elements from iterable. Note, the series of left appends results in reversing the order of elements in the iterable argument.

**pop**()
Remove and return an element from the right side of the deque. If no elements are present, raises an **IndexError**.

**popleft**()
Remove and return an element from the left side of the deque. If no elements are present, raises an **IndexError**.

**remove**(value)
Removed the first occurrence of value. If not found, raises a **ValueError**.

*New in version 2.5.*
**reverse()**

Reverse the elements of the deque in-place and then return None.

*New in version 2.7.*

**rotate(n)**

Rotate the deque n steps to the right. If n is negative, rotate to the left. Rotating one step to the right is equivalent to:

```python
d.appendleft(d.pop())
```

Deque objects also provide one read-only attribute:

**maxlen**

Maximum size of a deque or *None* if unbounded.

*New in version 2.7.*

In addition to the above, deques support iteration, pickling, `len(d)`, `reversed(d)`, `copy.copy(d)`, `copy.deepcopy(d)`, membership testing with the `in` operator, and subscript references such as `d[-1]`. Indexed access is O(1) at both ends but slows to O(n) in the middle. For fast random access, use lists instead.

Example:

```python
>>> from collections import deque
>>> d = deque('ghi')  # make a new deque with three items
>>> for elem in d:   # iterate over the deque's elements
...     print elem.upper()
G
H
I

>>> d.append('j')   # add a new entry to the right side
>>> d.appendleft('f')   # add a new entry to the left side
>>> d               # show the representation
deque(['f', 'g', 'h', 'i', 'j'])
```
8.3.3.1. deque Recipes

This section shows various approaches to working with deques.

Bounded length deques provide functionality similar to the tail filter
in Unix:

```python
def tail(filename, n=10):
    'Return the last n lines of a file'
    return deque(open(filename), n)
```

Another approach to using deques is to maintain a sequence of recently added elements by appending to the right and popping to the left:

```python
def moving_average(iterable, n=3):
    # moving_average([40, 30, 50, 46, 39, 44]) --> 40.0 42.0 45
    # http://en.wikipedia.org/wiki/Moving_average
    it = iter(iterable)
    d = deque(itertools.islice(it, n-1))
    d.appendleft(0)
    s = sum(d)
    for elem in it:
        s += elem - d.popleft()
        d.append(elem)
        yield s / float(n)
```

The `rotate()` method provides a way to implement `deque` slicing and deletion. For example, a pure Python implementation of `del d[n]` relies on the `rotate()` method to position elements to be popped:

```python
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement `deque` slicing, use a similar approach applying `rotate()` to bring a target element to the left side of the deque. Remove old entries with `popleft()`, add new entries with `extend()`, and then reverse the rotation. With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`. 
8.3.4. defaultdict objects

class collections.defaultdict([default_factory[, ...,]])

Returns a new dictionary-like object. defaultdict is a subclass of the built-in dict class. It overrides one method and adds one writable instance variable. The remaining functionality is the same as for the dict class and is not documented here.

The first argument provides the initial value for the default_factory attribute; it defaults to None. All remaining arguments are treated the same as if they were passed to the dict constructor, including keyword arguments.

New in version 2.5.

defaultdict objects support the following method in addition to the standard dict operations:

__missing__(key)

If the default_factory attribute is None, this raises a KeyError exception with the key as argument.

If default_factory is not None, it is called without arguments to provide a default value for the given key, this value is inserted in the dictionary for the key, and returned.

If calling default_factory raises an exception this exception is propagated unchanged.

This method is called by the __getitem__() method of the dict class when the requested key is not found; whatever it returns or raises is then returned or raised by __getitem__().
defaultdict objects support the following instance variable:

**default_factory**

This attribute is used by the `__missing__()` method; it is initialized from the first argument to the constructor, if present, or to `None`, if absent.

### 8.3.4.1. defaultdict Examples

Using `list` as the `default_factory`, it is easy to group a sequence of key-value pairs into a dictionary of lists:

```python
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3), ('blue', 4)
>>> d = defaultdict(list)
>>> for k, v in s:
...    d[k].append(v)
...
>>> d.items()
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the `default_factory` function which returns an empty `list`. The `list.append()` operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally (returning the list for that key) and the `list.append()` operation adds another value to the list. This technique is simpler and faster than an equivalent technique using `dict.setdefault()`:

```python
>>> d = {}
>>> for k, v in s:
...    d.setdefault(k, []).append(v)
...
>>> d.items()
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```
Setting the `default_factory` to `int` makes the `defaultdict` useful for counting (like a bag or multiset in other languages):

```python
>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
...     d[k] += 1
...
>>> d.items()
[('i', 4), ('p', 2), ('s', 4), ('m', 1)]
```

When a letter is first encountered, it is missing from the mapping, so the `default_factory` function calls `int()` to supply a default count of zero. The increment operation then builds up the count for each letter.

The function `int()` which always returns zero is just a special case of constant functions. A faster and more flexible way to create constant functions is to use `itertools.repeat()` which can supply any constant value (not just zero):

```python
>>> def constant_factory(value):
...     return itertools.repeat(value).next

>>> d = defaultdict(constant_factory('<missing>'))
>>> d.update(name='John', action='ran')
>>> '%(name)s %(action)s to %(object)s' % d
'John ran to <missing>'
```

Setting the `default_factory` to `set` makes the `defaultdict` useful for building a dictionary of sets:

```python
>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4), ('red', 1), ('blue', 4)]
>>> d = defaultdict(set)
>>> for k, v in s:
...     d[k].add(v)
...
>>> d.items()
[('blue', set([2, 4])), ('red', set([1, 3]))]
```
8.3.5. `namedtuple()` Factory Function for Tuples with Named Fields

Named tuples assign meaning to each position in a tuple and allow for more readable, self-documenting code. They can be used wherever regular tuples are used, and they add the ability to access fields by name instead of position index.

```python
collections.namedtuple(typename, field_names[, verbose][, rename])
```

Returns a new tuple subclass named `typename`. The new subclass is used to create tuple-like objects that have fields accessible by attribute lookup as well as being indexable and iterable. Instances of the subclass also have a helpful docstring (with typename and field_names) and a helpful `__repr__()` method which lists the tuple contents in a `name=value` format.

The `field_names` are a single string with each fieldname separated by whitespace and/or commas, for example `'x y'` or `'x, y'`. Alternatively, `field_names` can be a sequence of strings such as `['x', 'y']`.

Any valid Python identifier may be used for a fieldname except for names starting with an underscore. Valid identifiers consist of letters, digits, and underscores but do not start with a digit or underscore and cannot be a keyword such as `class`, `for`, `return`, `global`, `pass`, `print`, or `raise`.

If `rename` is true, invalid fieldnames are automatically replaced with positional names. For example, `['abc', 'def', 'ghi', 'abc']` is converted to `['abc', '_1', 'ghi', '_3']`, eliminating the keyword `def` and the duplicate fieldname `abc`. 
If `verbose` is true, the class definition is printed just before being built.

Named tuple instances do not have per-instance dictionaries, so they are lightweight and require no more memory than regular tuples.

New in version 2.6.

Changed in version 2.7: added support for `rename`.

Example:

```python
>>> Point = namedtuple('Point', 'x y', verbose=True)
class Point(tuple):
    'Point(x, y)'
    __slots__ = ()
    _fields = ('x', 'y')
    def __new__(_cls, x, y):
        'Create a new instance of Point(x, y)'
        return _tuple.__new__(_cls, (x, y))

    @classmethod
    def _make(cls, iterable, new=tuple.__new__, len=len):
        'Make a new Point object from a sequence or iterable'
        result = new(cls, iterable)
        if len(result) != 2:
            raise TypeError('Expected 2 arguments, got %d' % len(result))
        return result

def __repr__(self):
    'Return a nicely formatted representation string'
    return 'Point(x=%r, y=%r)' % self

def _asdict(self):
    'Return a new OrderedDict which maps field names to their values'
    return OrderedDict(zip(self._fields, self))

def _replace(_self, **kwds):
    'Return a new Point object replacing specified field values'
    return _make(map(kwds.pop, self._fields, iter(_self)), len=len)```

result = _self._make(map(kwds.pop, ('x', 'y'), _self))
if kwds:
    raise ValueError('Got unexpected field names: %r'
return result

def __getnewargs__(self):
    'Return self as a plain tuple. Used by copy and peturn tuple(self)

    x = _property(_itemgetter(0), doc='Alias for field numb
y = _property(_itemgetter(1), doc='Alias for field numb

>>> p = Point(11, y=22)      # instantiate with positional or ke
>>> p[0] + p[1]              # indexable like the plain tuple (1
33
>>> x, y = p                 # unpack like a regular tuple
>>> x, y                    (11, 22)
>>> p.x + p.y               # fields also accessible by name
33
>>> p                      # readable __repr__ with a name=val
Point(x=11, y=22)

Named tuples are especially useful for assigning field names to
result tuples returned by the csv or sqlite3 modules:

EmployeeRecord = namedtuple('EmployeeRecord', 'name, age, title
import csv
for emp in map(EmployeeRecord._make, csv.reader(open("employees
    print emp.name, emp.title

import sqlite3
conn = sqlite3.connect('/companydata')
cursor = conn.cursor()
cursor.execute('SELECT name, age, title, department, paygrade F
for emp in map(EmployeeRecord._make, cursor.fetchall()):
    print emp.name, emp.title

In addition to the methods inherited from tuples, named tuples
support three additional methods and one attribute. To prevent
conflicts with field names, the method and attribute names start with
an underscore.

somenamedtuple._make(iterable)
Class method that makes a new instance from an existing sequence or iterable.

    >>> t = [11, 22]
    >>> Point._make(t)
    Point(x=11, y=22)

somenamedtuple._asdict()
Return a new OrderedDict which maps field names to their corresponding values:

    >>> p._asdict()
    OrderedDict([('x', 11), ('y', 22)])

    Changed in version 2.7: Returns an OrderedDict instead of a regular dict.

somenamedtuple._replace(kwags)
Return a new instance of the named tuple replacing specified fields with new values:

    >>> p = Point(x=11, y=22)
    >>> p._replace(x=33)
    Point(x=33, y=22)

    >>> for partnum, record in inventory.items():
    ...     inventory[partnum] = record._replace(price=newprices[partnum],
    ...                                           timestamp=time.now())

somenamedtuple._fields
Tuple of strings listing the field names. Useful for introspection and for creating new named tuple types from existing named tuples.

    >>> p._fields          # view the field names
('x', 'y')

```python
>>> Color = namedtuple('Color', 'red green blue')
>>> Pixel = namedtuple('Pixel', Point._fields + Color._fields)
>>> Pixel(11, 22, 128, 255, 0)
Pixel(x=11, y=22, red=128, green=255, blue=0)
```

To retrieve a field whose name is stored in a string, use the `getattr()` function:

```python
>>> getattr(p, 'x')
11
```

To convert a dictionary to a named tuple, use the double-star-operator (as described in *Unpacking Argument Lists*):

```python
>>> d = {'x': 11, 'y': 22}
>>> Point(**d)
Point(x=11, y=22)
```

Since a named tuple is a regular Python class, it is easy to add or change functionality with a subclass. Here is how to add a calculated field and a fixed-width print format:

```python
>> class Point(namedtuple('Point', 'x y')):
...     __slots__ = ()
...     @property
...     def hypot(self):
...         return (self.x ** 2 + self.y ** 2) ** 0.5
...     def __str__(self):
...         return 'Point: x=%6.3f y=%6.3f hypot=%6.3f' % (self.x, self.y, self.hypot)
```

```python
>>> for p in Point(3, 4), Point(14, 5/7.):
...     print(p)
Point: x= 3.000 y= 4.000 hypot= 5.000
Point: x=14.000 y= 0.714 hypot=14.018
```

The subclass shown above sets `__slots__` to an empty tuple. This helps keep memory requirements low by preventing the creation of
Subclassing is not useful for adding new, stored fields. Instead, simply create a new named tuple type from the _fields attribute:

```python
giriPoint3D = namedtuple('Point3D', Point._fields + ('z',))
```

Default values can be implemented by using _replace() to customize a prototype instance:

```python
giriAccount = namedtuple('Account', 'owner balance transaction_count')
giriAccount = Account('<owner name>', 0.0, 0)  # default account
johns_account = default_account._replace(owner='John')
```

Enumerated constants can be implemented with named tuples, but it is simpler and more efficient to use a simple class declaration:

```python
giriStatus = namedtuple('Status', 'open pending closed')._make(range(3))
giriStatus.open, giriStatus.pending, giriStatus.closed = range(3)
class Status:
    ...  open, pending, closed = range(3)
```

See also: [Named tuple recipe](adapted for Python 2.4)
Ordered dictionaries are just like regular dictionaries but they remember the order that items were inserted. When iterating over an ordered dictionary, the items are returned in the order their keys were first added.

```
class collections.OrderedDict([items])
```

Return an instance of a dict subclass, supporting the usual `dict` methods. An `OrderedDict` is a dict that remembers the order that keys were first inserted. If a new entry overwrites an existing entry, the original insertion position is left unchanged. Deleting an entry and reinserting it will move it to the end.

*New in version 2.7.*

```
OrderedDict.popitem(last=True)
```

The `popitem()` method for ordered dictionaries returns and removes a (key, value) pair. The pairs are returned in LIFO order if `last` is true or FIFO order if false.

In addition to the usual mapping methods, ordered dictionaries also support reverse iteration using `reversed()`.

Equality tests between `OrderedDict` objects are order-sensitive and are implemented as `list(od1.items())==list(od2.items())`. Equality tests between `OrderedDict` objects and other `Mapping` objects are order-insensitive like regular dictionaries. This allows `OrderedDict` objects to be substituted anywhere a regular dictionary is used.

The `OrderedDict` constructor and `update()` method both accept keyword arguments, but their order is lost because Python’s function
call semantics pass-in keyword arguments using a regular unordered dictionary.

**See also:** Equivalent OrderedDict recipe that runs on Python 2.4 or later.

Since an ordered dictionary remembers its insertion order, it can be used in conjunction with sorting to make a sorted dictionary:

```python
>>> # regular unsorted dictionary
>>> d = {'banana': 3, 'apple': 4, 'pear': 1, 'orange': 2}

>>> # dictionary sorted by key
>>> OrderedDict(sorted(d.items(), key=lambda t: t[0]))
OrderedDict([('apple', 4), ('banana', 3), ('orange', 2), ('pear', 1)])

>>> # dictionary sorted by value
>>> OrderedDict(sorted(d.items(), key=lambda t: t[1]))
OrderedDict([('pear', 1), ('orange', 2), ('banana', 3), ('apple', 4)])

>>> # dictionary sorted by length of the key string
>>> OrderedDict(sorted(d.items(), key=lambda t: len(t[0])))
OrderedDict([('pear', 1), ('apple', 4), ('orange', 2), ('banana', 3)])
```

The new sorted dictionaries maintain their sort order when entries are deleted. But when new keys are added, the keys are appended to the end and the sort is not maintained.
8.4. `heapq` — Heap queue algorithm

New in version 2.3.

This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are arrays for which `heap[k] <= heap[2*k+1]` and `heap[k] <= heap[2*k+2]` for all `k`, counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that `heap[0]` is always its smallest element.

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our `pop` method returns the smallest item, not the largest (called a “min heap” in textbooks; a “max heap” is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: `heap[0]` is the smallest item, and `heap.sort()` maintains the heap invariant!

To create a heap, use a list initialized to [], or you can transform a populated list into a heap via function `heapify()`.

The following functions are provided:

`heapq.heappush(heap, item)`

Push the value `item` onto the `heap`, maintaining the heap invariant.
heapq. **heappop**(heap)

Pop and return the smallest item from the heap, maintaining the heap invariant. If the heap is empty, `IndexError` is raised.

heapq. **heappushpop**(heap, item)

Push *item* on the heap, then pop and return the smallest item from the heap. The combined action runs more efficiently than `heappush()` followed by a separate call to `heappop()`.

*New in version 2.6.*

heapq. **heappify**(x)

Transform list *x* into a heap, in-place, in linear time.

heapq. **heappushreplace**(heap, item)

Pop and return the smallest item from the heap, and also push the new *item*. The heap size doesn’t change. If the heap is empty, `IndexError` is raised. This is more efficient than `heappop()` followed by `heappush()`, and can be more appropriate when using a fixed-size heap. Note that the value returned may be larger than *item*! That constrains reasonable uses of this routine unless written as part of a conditional replacement:

```python
if item > heap[0]:
    item = heappushreplace(heap, item)
```
Using a heap to insert items at the correct place in a priority queue:

```python
>>> heap = []
>>> data = [(1, 'J'), (4, 'N'), (3, 'H'), (2, 'O')]
>>> for item in data:
...     heappush(heap, item)
...
>>> while heap:
...     print heappop(heap)[1]
J
O
H
N
```

The module also offers three general purpose functions based on heaps.

`heapq.merge(*iterables)`

Merge multiple sorted inputs into a single sorted output (for example, merge timestamped entries from multiple log files). Returns an *iterator* over the sorted values.

Similar to `sorted(itertools.chain(*iterables))` but returns an iterable, does not pull the data into memory all at once, and assumes that each of the input streams is already sorted (smallest to largest).

*New in version 2.6.*

`heapq.nlargest(n, iterable[, key])`

Return a list with the `n` largest elements from the dataset defined by `iterable`. `key`, if provided, specifies a function of one argument

that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key, reverse=True)[:-n]`

*New in version 2.4.*

*Changed in version 2.5:* Added the optional `key` argument.

```python
heapq.nsmallest(n, iterable[, key])
```

Return a list with the `n` smallest elements from the dataset defined by `iterable`. `key`, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key)[:-n]`

*New in version 2.4.*

*Changed in version 2.5:* Added the optional `key` argument.

The latter two functions perform best for smaller values of `n`. For larger values, it is more efficient to use the `sorted()` function. Also, when `n==1`, it is more efficient to use the built-in `min()` and `max()` functions.
8.4.1. Theory

(This explanation is due to François Pinard. The Python code for this module was contributed by Kevin O’Connor.)

Heaps are arrays for which \( a[k] \leq a[2*k+1] \) and \( a[k] \leq a[2*k+2] \) for all \( k \), counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that \( a[0] \) is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are \( k \), not \( a[k] \):

</table>

In the tree above, each cell \( k \) is topping \( 2*k+1 \) and \( 2*k+2 \). In an usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell “wins” over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the overall winner. The simplest algorithmic way to remove it and find the
“next” winner is to move some loser (let’s say cell 30 in the diagram above) into the 0 position, and then percolate this new 0 down the tree, exchanging values, until the invariant is re-established. This is clearly logarithmic on the total number of items in the tree. By iterating over all items, you get an O(n log n) sort.

A nice feature of this sort is that you can efficiently insert new items while the sort is going on, provided that the inserted items are not “better” than the last 0'th element you extracted. This is especially useful in simulation contexts, where the tree holds all incoming events, and the “win” condition means the smallest scheduled time. When an event schedule other events for execution, they are scheduled into the future, so they can easily go into the heap. So, a heap is a good structure for implementing schedulers (this is what I used for my MIDI sequencer :-).  

Various structures for implementing schedulers have been extensively studied, and heaps are good for this, as they are reasonably speedy, the speed is almost constant, and the worst case is not much different than the average case. However, there are other representations which are more efficient overall, yet the worst cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all know that a big sort implies producing “runs” (which are pre-sorted sequences, which size is usually related to the amount of CPU memory), followed by a merging passes for these runs, which merging is often very cleverly organised [1]. It is very important that the initial sort produces the longest runs possible. Tournaments are a good way to that. If, using all the memory available to hold a tournament, you replace and percolate items that happen to fit the current run, you'll produce runs which are twice the size of the memory for random input, and much better for input fuzzily ordered.

Moreover, if you output the 0'th item on disk and get an input which
may not fit in the current tournament (because the value “wins” over the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a ‘heap’ module around. :-)

Footnotes

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had to be very clever to ensure (far in advance) that each tape movement will be the most effective possible (that is, will best participate at “progressing” the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)

[1]
This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called `bisect` because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

```python
bisect.bisect_left(list, item[, lo[, hi]])
```
Locate the proper insertion point for `item` in `list` to maintain sorted order. The parameters `lo` and `hi` may be used to specify a subset of the list which should be considered; by default the entire list is used. If `item` is already present in `list`, the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to `list.insert()`. This assumes that `list` is already sorted.

*New in version 2.1.*

```python
bisect.bisect_right(list, item[, lo[, hi]])
```
Similar to `bisect_left()`, but returns an insertion point which comes after (to the right of) any existing entries of `item` in `list`.

*New in version 2.1.*

```python
bisect.bisect(...)
```
Alias for `bisect_right()`. 
bisect.**insort_left**(list, item[, lo[, hi]])

Insert *item* in *list* in sorted order. This is equivalent to
list.insert(bisect.bisect_left(list, item, lo, hi), item).
This assumes that *list* is already sorted.

*New in version 2.1.*

bisect.**insort_right**(list, item[, lo[, hi]])

Similar to *insort_left()*, but inserting *item* in *list* after any
existing entries of *item*.

*New in version 2.1.*

bisect.**insort**(...)

Alias for *insort_right().*
8.5.1. Examples

The `bisect()` function is generally useful for categorizing numeric data. This example uses `bisect()` to look up a letter grade for an exam total (say) based on a set of ordered numeric breakpoints: 85 and up is an ‘A’, 75..84 is a ‘B’, etc.

```python
>>> grades = "FEDCBA"
>>> breakpoints = [30, 44, 66, 75, 85]
>>> from bisect import bisect
>>> def grade(total):
...     return grades[bisect(breakpoints, total)]
... >>> grade(66)
'C'
>>> map(grade, [33, 99, 77, 44, 12, 88])
['E', 'A', 'B', 'D', 'F', 'A']
```

Unlike the `sorted()` function, it does not make sense for the `bisect()` functions to have key or reversed arguments because that would lead to an inefficient design (successive calls to bisect functions would not “remember” all of the previous key lookups).

Instead, it is better to search a list of precomputed keys to find the index of the record in question:

```python
>>> data = [('red', 5), ('blue', 1), ('yellow', 8), ('black', 0)
>>> data.sort(key=lambda r: r[1])
>>> keys = [r[1] for r in data]          # precomputed list of k
>>> data[bisect_left(keys, 0)]
('black', 0)
>>> data[bisect_left(keys, 1)]
('blue', 1)
>>> data[bisect_left(keys, 5)]
('red', 5)
>>> data[bisect_left(keys, 8)]
('yellow', 8)
```
This module defines an object type which can compactly represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a type code, which is a single character. The following type codes are defined:

<table>
<thead>
<tr>
<th>Type code</th>
<th>C Type</th>
<th>Python Type</th>
<th>Minimum size in bytes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'c'</td>
<td>char</td>
<td>character</td>
<td>1</td>
</tr>
<tr>
<td>'b'</td>
<td>signed char</td>
<td>int</td>
<td>1</td>
</tr>
<tr>
<td>'B'</td>
<td>unsigned char</td>
<td>int</td>
<td>1</td>
</tr>
<tr>
<td>'u'</td>
<td>Py_UNICODE</td>
<td>Unicode character</td>
<td>2 (see note)</td>
</tr>
<tr>
<td>'h'</td>
<td>signed short</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'H'</td>
<td>unsigned short</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'i'</td>
<td>signed int</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'I'</td>
<td>unsigned int</td>
<td>long</td>
<td>2</td>
</tr>
<tr>
<td>'l'</td>
<td>signed long</td>
<td>int</td>
<td>4</td>
</tr>
<tr>
<td>'L'</td>
<td>unsigned long</td>
<td>long</td>
<td>4</td>
</tr>
<tr>
<td>'f'</td>
<td>float</td>
<td>float</td>
<td>4</td>
</tr>
<tr>
<td>'d'</td>
<td>double</td>
<td>float</td>
<td>8</td>
</tr>
</tbody>
</table>

Note: The 'u' typecode corresponds to Python’s unicode character. On narrow Unicode builds this is 2-bytes, on wide builds this is 4-bytes.

The actual representation of values is determined by the machine
architecture (strictly speaking, by the C implementation). The actual size can be accessed through the `itemsize` attribute. The values stored for 'L' and 'I' items will be represented as Python long integers when retrieved, because Python's plain integer type cannot represent the full range of C's unsigned (long) integers.

The module defines the following type:

```python
class array.array(typecode[, initializer])
```

A new array whose items are restricted by `typecode`, and initialized from the optional `initializer` value, which must be a list, string, or iterable over elements of the appropriate type.

*Changed in version 2.4:* Formerly, only lists or strings were accepted.

If given a list or string, the initializer is passed to the new array's `fromlist()`, `fromstring()`, or `fromunicode()` method (see below) to add initial items to the array. Otherwise, the iterable initializer is passed to the `extend()` method.

`array.ArrayType`

Obsolete alias for `array`.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, `TypeError` is raised. Array objects also implement the buffer interface, and may be used wherever buffer objects are supported.

The following data items and methods are also supported:

`array.typecode`

The `typecode` character used to create the array.
array.itemsize
The length in bytes of one array item in the internal representation.

array.append(x)
Append a new item with value x to the end of the array.

array.buffer_info()
Return a tuple (address, length) giving the current memory address and the length in elements of the buffer used to hold array's contents. The size of the memory buffer in bytes can be computed as array.buffer_info()[1] * array.itemsize. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain ioctl() operations. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.

Note: When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code.

array.byteswap()
“Byteswap” all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, RuntimeError is raised. It is useful when reading data from a file written on a machine with a different byte order.

array.count(x)
Return the number of occurrences of x in the array.

array.extend(iterable)
Append items from \textit{iterable} to the end of the array. If \textit{iterable} is another array, it must have \textit{exactly} the same type code; if not, \texttt{TypeError} will be raised. If \textit{iterable} is not an array, it must be iterable and its elements must be the right type to be appended to the array.

\textit{Changed in version 2.4:} Formerly, the argument could only be another array.

\texttt{array.fromfile(\textit{f}, \textit{n})}
Read \textit{n} items (as machine values) from the file object \textit{f} and append them to the end of the array. If less than \textit{n} items are available, \texttt{EOFError} is raised, but the items that were available are still inserted into the array. \textit{f} must be a real built-in file object; something else with a \texttt{read()} method won't do.

\texttt{array.fromlist(\textit{list})}
Append items from the list. This is equivalent to \texttt{for \textit{x} in \textit{list}: a.append(\textit{x})} except that if there is a type error, the array is unchanged.

\texttt{array.fromstring(\textit{s})}
Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the \texttt{fromfile()} method).

\texttt{array.fromunicode(\textit{s})}
Extends this array with data from the given unicode string. The array must be a type \texttt{'u'} array; otherwise a \texttt{ValueError} is raised. Use \texttt{array.fromstring(unicodestring.encode(\texttt{enc}))} to append Unicode data to an array of some other type.

\texttt{array.index(\textit{x})}
Return the smallest \textit{i} such that \textit{i} is the index of the first
occurrence of \( x \) in the array.

\texttt{array.insert(i, x)}

Insert a new item with value \( x \) in the array before position \( i \). Negative values are treated as being relative to the end of the array.

\texttt{array.pop([i])}

Removes the item with the index \( i \) from the array and returns it. The optional argument defaults to \( -1 \), so that by default the last item is removed and returned.

\texttt{array.read(f, n)}

\texttt{Deprecate since version 1.5.1: Use the fromfile() method.}

Read \( n \) items (as machine values) from the file object \( f \) and append them to the end of the array. If less than \( n \) items are available, \texttt{EOFError} is raised, but the items that were available are still inserted into the array. \( f \) must be a real built-in file object; something else with a \texttt{read()} method won’t do.

\texttt{array.remove(x)}

Remove the first occurrence of \( x \) from the array.

\texttt{array.reverse()}

Reverse the order of the items in the array.

\texttt{array.tofile(f)}

Write all items (as machine values) to the file object \( f \).

\texttt{array.tolist()}

Convert the array to an ordinary list with the same items.

\texttt{array.tostring()}
Convert the array to an array of machine values and return the string representation (the same sequence of bytes that would be written to a file by the `tofile()` method.)

```python
array.tounicode()
```

Convert the array to a unicode string. The array must be a type 'u' array; otherwise a `ValueError` is raised. Use `array.tostring().decode(enc)` to obtain a unicode string from an array of some other type.

```python
array.write(f)
```

`Deprecated since version 1.5.1: Use the tofile() method.`

Write all items (as machine values) to the file object `f`.

When an array object is printed or converted to a string, it is represented as `array(typecode, initializer)`. The `initializer` is omitted if the array is empty, otherwise it is a string if the `typecode` is 'c', otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using `eval()`, so long as the `array()` function has been imported using `from array import array`. Examples:

```python
array('l')
array('c', 'hello world')
array('u', u'hello \u2641')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
```

8.7. sets — Unordered collections of unique elements

New in version 2.3.

Deprecated since version 2.6: The built-in set/frozenset types replace this module.

The sets module provides classes for constructing and manipulating unordered collections of unique elements. Common uses include membership testing, removing duplicates from a sequence, and computing standard math operations on sets such as intersection, union, difference, and symmetric difference.

Like other collections, sets support \( \text{x in set, len(set), and for x in set} \). Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

Most set applications use the Set class which provides every set method except for \( \_	ext{hash}\_() \). For advanced applications requiring a hash method, the ImmutableSet class adds a \( \_	ext{hash}\_() \) method but omits methods which alter the contents of the set. Both Set and ImmutableSet derive from BaseSet, an abstract class useful for determining whether something is a set: \( \text{isinstance(obj, BaseSet)} \).

The set classes are implemented using dictionaries. Accordingly, the requirements for set elements are the same as those for dictionary keys; namely, that the element defines both \( \_	ext{eq}\_() \) and \( \_	ext{hash}\_() \). As a result, sets cannot contain mutable elements such as lists or dictionaries. However, they can contain immutable
collections such as tuples or instances of \texttt{ImmutableSet}. For convenience in implementing sets of sets, inner sets are automatically converted to immutable form, for example, 
\texttt{Set([Set(['dog'])])} is transformed to 
\texttt{Set([ImmutableSet(['dog'])])}.

\texttt{class sets.Set([iterable])}

Constructs a new empty \texttt{set} object. If the optional \texttt{iterable} parameter is supplied, updates the set with elements obtained from iteration. All of the elements in \texttt{iterable} should be immutable or be transformable to an immutable using the protocol described in section \textit{Protocol for automatic conversion to immutable}.

\texttt{class sets.ImmutableSet([iterable])}

Constructs a new empty \texttt{ImmutableSet} object. If the optional \texttt{iterable} parameter is supplied, updates the set with elements obtained from iteration. All of the elements in \texttt{iterable} should be immutable or be transformable to an immutable using the protocol described in section \textit{Protocol for automatic conversion to immutable}.

Because \texttt{ImmutableSet} objects provide a \texttt{__hash__()} method, they can be used as set elements or as dictionary keys. \texttt{ImmutableSet} objects do not have methods for adding or removing elements, so all of the elements must be known when the constructor is called.
8.7.1. Set Objects

Instances of `Set` and `ImmutableSet` both provide the following operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>len(s)</code></td>
<td></td>
<td>cardinality of set s</td>
</tr>
<tr>
<td><code>x in s</code></td>
<td></td>
<td>test x for membership in s</td>
</tr>
<tr>
<td><code>x not in s</code></td>
<td></td>
<td>test x for non-membership in s</td>
</tr>
<tr>
<td><code>s.issubset(t)</code></td>
<td><code>s &lt;= t</code></td>
<td>test whether every element in s is in t</td>
</tr>
<tr>
<td><code>s.issuperset(t)</code></td>
<td><code>s &gt;= t</code></td>
<td>test whether every element in t is in s</td>
</tr>
<tr>
<td><code>s.union(t)</code></td>
<td>`s</td>
<td>t`</td>
</tr>
<tr>
<td><code>s.intersection(t)</code></td>
<td><code>s &amp; t</code></td>
<td>new set with elements common to s and t</td>
</tr>
<tr>
<td><code>s.difference(t)</code></td>
<td><code>s - t</code></td>
<td>new set with elements in s but not in t</td>
</tr>
<tr>
<td><code>s.symmetric_difference(t)</code></td>
<td><code>s ^ t</code></td>
<td>new set with elements in either s or t but not both</td>
</tr>
<tr>
<td><code>s.copy()</code></td>
<td></td>
<td>new set with a shallow copy of s</td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `union()`, `intersection()`, `difference()`, and `symmetric_difference()` will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `Set('abc') & 'cbs'` in favor of the more readable `Set('abc').intersection('cbs')`.

*Changed in version 2.3.1:* Formerly all arguments were required to
be sets.

In addition, both `Set` and `ImmutableSet` support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so all of the following return `False`: `a<b`, `a==b`, or `a>b`. Accordingly, sets do not implement the `__cmp__()` method.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

The following table lists operations available in `ImmutableSet` but not found in `Set`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>hash(s)</code></td>
<td>returns a hash value for <code>s</code></td>
</tr>
</tbody>
</table>

The following table lists operations available in `Set` but not found in `ImmutableSet`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>s.update(t)</code></td>
<td>`s</td>
<td>= t`</td>
</tr>
<tr>
<td><code>s.intersection_update(t)</code></td>
<td><code>s &amp;= t</code></td>
<td>return set <code>s</code> keeping only elements also</td>
</tr>
<tr>
<td>Method</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>---------------------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td></td>
</tr>
<tr>
<td><code>s.difference_update(t)</code></td>
<td><code>s -= t</code> return set <code>s</code> after removing elements found in <code>t</code></td>
<td></td>
</tr>
<tr>
<td><code>s.symmetric_difference_update(t)</code></td>
<td><code>s ^= t</code> return set <code>s</code> with elements from <code>s</code> or <code>t</code> but not both</td>
<td></td>
</tr>
<tr>
<td><code>s.add(x)</code></td>
<td>add element <code>x</code> to set <code>s</code></td>
<td></td>
</tr>
<tr>
<td><code>s.remove(x)</code></td>
<td>remove <code>x</code> from set <code>s</code>; raises <code>KeyError</code> if not present</td>
<td></td>
</tr>
<tr>
<td><code>s.discard(x)</code></td>
<td>removes <code>x</code> from set <code>s</code> if present</td>
<td></td>
</tr>
<tr>
<td><code>s.pop()</code></td>
<td>remove and return an arbitrary element from <code>s</code>; raises <code>KeyError</code> if empty</td>
<td></td>
</tr>
<tr>
<td><code>s.clear()</code></td>
<td>remove all elements from set <code>s</code></td>
<td></td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `update()`, `intersection_update()`, `difference_update()`, and `symmetric_difference_update()` will accept any iterable as an argument.

*Changed in version 2.3.1:* Formerly all arguments were required to be sets.

Also note, the module also includes a `union_update()` method which is an alias for `update()`. The method is included for backwards compatibility. Programmers should prefer the `update()` method because it is supported by the built-in `set()` and `frozenset()` types.
8.7.2. Example

```python
>>> from sets import Set
>>> engineers = Set(['John', 'Jane', 'Jack', 'Janice'])
>>> programmers = Set(['Jack', 'Sam', 'Susan', 'Janice'])
>>> managers = Set(['Jane', 'Jack', 'Susan', 'Zack'])
>>> employees = engineers | programmers | managers  #
>>> engineering_management = engineers & managers  #
>>> fulltime_management = managers - engineers - programmers #
>>> engineers.add('Marvin')  #
>>> print engineers # doctest: +SKIP
Set(['Jane', 'Marvin', 'Janice', 'John', 'Jack'])
>>> employees.issuperset(engineers)  # superset test
False
>>> employees.update(engineers)  # update from another s
>>> employees.issuperset(engineers)
True
>>> for group in [engineers, programmers, managers, employees]:
...				group.discard('Susan')  # unconditionally remov
...				print group
...
Set(['Jane', 'Marvin', 'Janice', 'John', 'Jack'])
Set(['Janice', 'Jack', 'Sam'])
Set(['Jane', 'Zack', 'Jack'])
Set(['Jack', 'Sam', 'Jane', 'Marvin', 'Janice', 'John', 'Zack'])
```
8.7.3. Protocol for automatic conversion to immutable

Sets can only contain immutable elements. For convenience, mutable `Set` objects are automatically copied to an `ImmutableSet` before being added as a set element.

The mechanism is to always add a `hashable` element, or if it is not hashable, the element is checked to see if it has an `__as_immutable__()` method which returns an immutable equivalent.

Since `Set` objects have a `__as_immutable__()` method returning an instance of `ImmutableSet`, it is possible to construct sets of sets.

A similar mechanism is needed by the `__contains__()` and `remove()` methods which need to hash an element to check for membership in a set. Those methods check an element for hashability and, if not, check for a `__as_temporarily_immutable__()` method which returns the element wrapped by a class that provides temporary methods for `__hash__()`, `__eq__()`, and `__ne__()`.

The alternate mechanism spares the need to build a separate copy of the original mutable object.

`Set` objects implement the `__as_temporarily_immutable__()` method which returns the `Set` object wrapped by a new class `_TemporarilyImmutableSet`.

The two mechanisms for adding hashability are normally invisible to the user; however, a conflict can arise in a multi-threaded environment where one thread is updating a set while another has temporarily wrapped it in `_TemporarilyImmutableSet`. In other words,
sets of mutable sets are not thread-safe.
8.7.4. Comparison to the built-in set types

The built-in \texttt{set} and \texttt{frozenset} types were designed based on lessons learned from the \texttt{sets} module. The key differences are:

- \texttt{Set} and \texttt{ImmutableSet} were renamed to \texttt{set} and \texttt{frozenset}.
- There is no equivalent to \texttt{BaseSet}. Instead, use \texttt{isinstance(x, (set, frozenset))}.
- The hash algorithm for the built-ins performs significantly better (fewer collisions) for most datasets.
- The built-in versions have more space efficient pickles.
- The built-in versions do not have a \texttt{union_update()} method. Instead, use the \texttt{update()} method which is equivalent.
- The built-in versions do not have a \texttt{_repr(sorted=True)} method. Instead, use the built-in \texttt{repr()} and \texttt{sorted()} functions: \texttt{repr(sorted(s))}.
- The built-in version does not have a protocol for automatic conversion to immutable. Many found this feature to be confusing and no one in the community reported having found real uses for it.
The Python Standard Library » 8. Data Types »
The `sched` module defines a class which implements a general purpose event scheduler:

```python
class sched.scheduler(timefunc, delayfunc)
```

The `scheduler` class defines a generic interface to scheduling events. It needs two functions to actually deal with the “outside world” — `timefunc` should be callable without arguments, and return a number (the “time”, in any units whatsoever). The `delayfunc` function should be callable with one argument, compatible with the output of `timefunc`, and should delay that many time units. `delayfunc` will also be called with the argument 0 after each event is run to allow other threads an opportunity to run in multi-threaded applications.

Example:

```python
>>> import sched, time
>>> s = sched.scheduler(time.time, time.sleep)
>>> def print_time(): print "From print_time", time.time()
...
>>> def print_some_times():
...     print time.time()
...     s.enter(5, 1, print_time, ())
...     s.enter(10, 1, print_time, ())
...     s.run()
...     print time.time()
...
>>> print_some_times()
930343690.257
From print_time 930343695.274
From print_time 930343700.273
930343700.276
```

In multi-threaded environments, the `scheduler` class has limitations with respect to thread-safety, inability to insert a new task before the
one currently pending in a running scheduler, and holding up the main thread until the event queue is empty. Instead, the preferred approach is to use the `threading.Timer` class instead.

Example:

```python
>>> import time
>>> from threading import Timer
>>> def print_time():
...     print "From print_time", time.time()

From print_time 930343700.273
301
```
8.8.1. Scheduler Objects

scheduler instances have the following methods and attributes:

scheduler.**enterabs**(time, priority, action, argument)
Schedule a new event. The *time* argument should be a numeric type compatible with the return value of the *timedelay* function passed to the constructor. Events scheduled for the same *time* will be executed in the order of their *priority*.

Executing the event means executing `action(*argument)`.
*argument* must be a sequence holding the parameters for *action*.

Return value is an event which may be used for later cancellation of the event (see `cancel()`).

scheduler.**enter**(delay, priority, action, argument)
Schedule an event for *delay* more time units. Other than the relative time, the other arguments, the effect and the return value are the same as those for `enterabs()`.

scheduler.**cancel**(event)
Remove the event from the queue. If *event* is not an event currently in the queue, this method will raise a `ValueError`.

scheduler.**empty**()
Return true if the event queue is empty.

scheduler.**run**()
Run all scheduled events. This function will wait (using the *delayfunc* function passed to the constructor) for the next event, then execute it and so on until there are no more scheduled events.
Either *action* or *delayfunc* can raise an exception. In either case, the scheduler will maintain a consistent state and propagate the exception. If an exception is raised by *action*, the event will not be attempted in future calls to *run()*.

If a sequence of events takes longer to run than the time available before the next event, the scheduler will simply fall behind. No events will be dropped; the calling code is responsible for canceling events which are no longer pertinent.

**scheduler.queue**

Read-only attribute returning a list of upcoming events in the order they will be run. Each event is shown as a *named tuple* with the following fields: time, priority, action, argument.

*New in version 2.6.*
8.9. mutex — Mutual exclusion support

*Deprecated since version 2.6:* The mutex module has been removed in Python 3.0.

The mutex module defines a class that allows mutual-exclusion via acquiring and releasing locks. It does not require (or imply) threading or multi-tasking, though it could be useful for those purposes.

The mutex module defines the following class:

```python
class mutex

Create a new (unlocked) mutex.

A mutex has two pieces of state — a “locked” bit and a queue. When the mutex is not locked, the queue is empty. Otherwise, the queue contains zero or more (function, argument) pairs representing functions (or methods) waiting to acquire the lock. When the mutex is unlocked while the queue is not empty, the first queue entry is removed and its function(argument) pair called, implying it now has the lock.

Of course, no multi-threading is implied — hence the funny interface for `lock()`, where a function is called once the lock is acquired.
8.9.1. Mutex Objects

mutex objects have following methods:

mutex.test()

    Check whether the mutex is locked.

mutex.testandset()

    “Atomic” test-and-set, grab the lock if it is not set, and return True, otherwise, return False.

mutex.lock(function, argument)

    Execute function(argument), unless the mutex is locked. In the case it is locked, place the function and argument on the queue. See unlock() for explanation of when function(argument) is executed in that case.

mutex.unlock()

    Unlock the mutex if queue is empty, otherwise execute the first element in the queue.
8.10. queue — A synchronized queue class

**Note:** The `queue` module has been renamed to `queue` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

The `queue` module implements multi-producer, multi-consumer queues. It is especially useful in threaded programming when information must be exchanged safely between multiple threads. The `Queue` class in this module implements all the required locking semantics. It depends on the availability of thread support in Python; see the `threading` module.

Implements three types of queue whose only difference is the order that the entries are retrieved. In a FIFO queue, the first tasks added are the first retrieved. In a LIFO queue, the most recently added entry is the first retrieved (operating like a stack). With a priority queue, the entries are kept sorted (using the `heapq` module) and the lowest valued entry is retrieved first.

The `queue` module defines the following classes and exceptions:

```python
class Queue.Queue(maxsize=0)
    Constructor for a FIFO queue. `maxsize` is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If `maxsize` is less than or equal to zero, the queue size is infinite.

class Queue.LifoQueue(maxsize=0)
    Constructor for a LIFO queue. `maxsize` is an integer that sets the
```
upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \texttt{maxsize} is less than or equal to zero, the queue size is infinite.

\textit{New in version 2.6.}

\texttt{class Queue.\texttt{PriorityQueue}(maxsize=0)}

Constructor for a priority queue. \texttt{maxsize} is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \texttt{maxsize} is less than or equal to zero, the queue size is infinite.

The lowest valued entries are retrieved first (the lowest valued entry is the one returned by \texttt{sorted(list(entries))[0]}). A typical pattern for entries is a tuple in the form: \texttt{(priority\_number, data)}.

\textit{New in version 2.6.}

\texttt{exception Queue.\texttt{Empty}}

Exception raised when non-blocking \texttt{get()} (or \texttt{get\_nowait()}) is called on a \texttt{Queue} object which is empty.

\texttt{exception Queue.\texttt{Full}}

Exception raised when non-blocking \texttt{put()} (or \texttt{put\_nowait()}) is called on a \texttt{Queue} object which is full.

\texttt{See also: collections.deque} is an alternative implementation of unbounded queues with fast atomic \texttt{append()} and \texttt{popleft()} operations that do not require locking.
8.10.1. Queue Objects

Queue objects (Queue, LifoQueue, or PriorityQueue) provide the public methods described below.

Queue.qsize()
Return the approximate size of the queue. Note, qsize() > 0 doesn't guarantee that a subsequent get() will not block, nor will qsize() < maxsize guarantee that put() will not block.

Queue.empty()
Return True if the queue is empty, False otherwise. If empty() returns True it doesn't guarantee that a subsequent call to put() will not block. Similarly, if empty() returns False it doesn't guarantee that a subsequent call to get() will not block.

Queue.full()
Return True if the queue is full, False otherwise. If full() returns True it doesn't guarantee that a subsequent call to get() will not block. Similarly, if full() returns False it doesn't guarantee that a subsequent call to put() will not block.

Queue.put(item[, block[, timeout]])
Put item into the queue. If optional args block is true and timeout is None (the default), block if necessary until a free slot is available. If timeout is a positive number, it blocks at most timeout seconds and raises the Full exception if no free slot was available within that time. Otherwise (block is false), put an item on the queue if a free slot is immediately available, else raise the Full exception (timeout is ignored in that case).

New in version 2.3: The timeout parameter.
Queue. **put_nowait**(item)

Equivalent to `put(item, False)`.

Queue. **get**(blk[, timeout])

Remove and return an item from the queue. If optional args `block` is true and `timeout` is None (the default), block if necessary until an item is available. If `timeout` is a positive number, it blocks at most `timeout` seconds and raises the `Empty` exception if no item was available within that time. Otherwise (`block` is false), return an item if one is immediately available, else raise the `Empty` exception (`timeout` is ignored in that case).

*New in version 2.3:* The `timeout` parameter.

Queue. **get_nowait**()

Equivalent to `get(False)`.

Two methods are offered to support tracking whether enqueued tasks have been fully processed by daemon consumer threads.

Queue. **task_done**()

Indicate that a formerly enqueued task is complete. Used by queue consumer threads. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

Raises a `ValueError` if called more times than there were items placed in the queue.

*New in version 2.5.*
Queue. `join()`
Blocks until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

*New in version 2.5.*

Example of how to wait for enqueued tasks to be completed:

```python
def worker():
    while True:
        item = q.get()
        do_work(item)
        q.task_done()

def worker():
for i in range(num_worker_threads):
t = Thread(target=worker)
t.daemon = True
t.start()

for item in source():
    q.put(item)

q.join()  # block until all tasks are done
```
Standard Library » 8. Data Types »
New in version 2.1.

The `weakref` module allows the Python programmer to create weak references to objects.

In the following, the term `referent` means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, garbage collection is free to destroy the referent and reuse its memory for something else. A primary use for weak references is to implement caches or mappings holding large objects, where it's desired that a large object not be kept alive solely because it appears in a cache or mapping.

For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The `WeakKeyDictionary` and `WeakValueDictionary` classes supplied by the `weakref` module are an alternative, using weak references to construct mappings that don’t keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a `WeakValueDictionary`, then when the last remaining references to that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

`WeakKeyDictionary` and `WeakValueDictionary` use weak references in their implementation, setting up callback functions on the weak
references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. Most programs should find that using one of these weak dictionary types is all they need – it's not usually necessary to create your own weak references directly. The low-level machinery used by the weak dictionary implementations is exposed by the `weakref` module for the benefit of advanced uses.

**Note:** Weak references to an object are cleared before the object's `__del__()`, to ensure that the weak reference callback (if any) finds the object still alive.

Not all objects can be weakly referenced; those objects which can include class instances, functions written in Python (but not in C), methods (both bound and unbound), sets, frozensets, file objects, `generator`s, type objects, `DBcursor` objects from the `bsddb` module, sockets, arrays, deques, regular expression pattern objects, and code objects.  

*Changed in version 2.4:* Added support for files, sockets, arrays, and patterns.

*Changed in version 2.7:* Added support for `thread.lock`, `threading.Lock`, and code objects.

Several built-in types such as `list` and `dict` do not directly support weak references but can add support through subclassing:

```
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3)  # this object is weak referenceable
```

**CPython implementation detail:** Other built-in types such as
tuple and long do not support weak references even when subclassed.

```
class weakref.ref(object[, callback])
```

Return a weak reference to object. The original object can be retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause None to be returned. If callback is provided and not None, and the returned weakref object is still alive, the callback will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object's __del__() method.

Weak references are hashable if the object is hashable. They will maintain their hash value even after the object was deleted. If hash() is called the first time only after the object was deleted, the call will raise TypeError.

Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their referents (regardless of the callback). If either referent has been deleted, the references are equal only if the reference objects are the same object.
Changed in version 2.4: This is now a subclassable type rather than a factory function; it derives from \texttt{object}.

\begin{verbatim}
weakref.proxy(object[, callback])
\end{verbatim}

Return a proxy to \texttt{object} which uses a weak reference. This supports use of the proxy in most contexts instead of requiring the explicit dereferencing used with weak reference objects. The returned object will have a type of either \texttt{ProxyType} or \texttt{CallableProxyType}, depending on whether \texttt{object} is callable. Proxy objects are not \texttt{hashable} regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevent their use as dictionary keys. \texttt{callback} is the same as the parameter of the same name to the \texttt{ref()} function.

\begin{verbatim}
weakref.getweakrefcount(object)
\end{verbatim}

Return the number of weak references and proxies which refer to \texttt{object}.

\begin{verbatim}
weakref.getweakrefs(object)
\end{verbatim}

Return a list of all weak reference and proxy objects which refer to \texttt{object}.

\begin{verbatim}
class weakref.WeakKeyDictionary([dict])
\end{verbatim}

Mapping class that references keys weakly. Entries in the dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

\begin{verbatim}
Note: Caution: Because a WeakKeyDictionary is built on top of a Python dictionary, it must not change size when iterating over
\end{verbatim}
it. This can be difficult to ensure for a **WeakKeyDictionary** because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

**WeakKeyDictionary** objects have the following additional methods. These expose the internal references directly. The references are not guaranteed to be “live” at the time they are used, so the result of calling the references needs to be checked before being used. This can be used to avoid creating references that will cause the garbage collector to keep the keys around longer than needed.

**WeakKeyDictionary**. `iterkeyrefs()`

Return an *iterator* that yields the weak references to the keys.

*New in version 2.5.*

**WeakKeyDictionary**. `keyrefs()`

Return a list of weak references to the keys.

*New in version 2.5.*

**class** `weakref.WeakValueDictionary([dict])`

Mapping class that references values weakly. Entries in the dictionary will be discarded when no strong reference to the value exists any more.

**Note:** Caution: Because a **WeakValueDictionary** is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a **WeakValueDictionary** because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).
WeakValueDictionary objects have the following additional methods. These methods have the same issues as the iterkeyrefs() and keyrefs() methods of WeakKeyDictionary objects.

WeakValueDictionary. itervaluerefs()
Return an iterator that yields the weak references to the values.

    New in version 2.5.

WeakValueDictionary. valuerefs()
Return a list of weak references to the values.

    New in version 2.5.

class weakref. WeakSet([elements])
Set class that keeps weak references to its elements. An element will be discarded when no strong reference to it exists any more.

    New in version 2.7.

weakref. ReferenceType
The type object for weak references objects.

weakref. ProxyType
The type object for proxies of objects which are not callable.

weakref. CallableProxyType
The type object for proxies of callable objects.

weakref. ProxyTypes
Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

exception weakref. ReferenceError
Exception raised when a proxy object is used but the underlying
object has been collected. This is the same as the standard `ReferenceError` exception.

See also:

**PEP 0205 - Weak References**

The proposal and rationale for this feature, including links to earlier implementations and information about similar features in other languages.
8.11.1. Weak Reference Objects

Weak reference objects have no attributes or methods, but do allow the referent to be obtained, if it still exists, by calling it:

```python
>>> import weakref
>>> class Object:
...     pass
...
>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns `None`:

```python
>>> del o, o2
>>> print r()
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```python
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print "Object has been deallocated; can't frobnicate."
else:
    print "Object is still live!"
    o.do_something_useful()
```

Using a separate test for “liveness” creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom
shown above is safe in threaded applications as well as single-threaded applications.

Specialized versions of `ref` objects can be created through subclassing. This is used in the implementation of the `WeakValueDictionary` to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert additional processing on calls to retrieve the referent.

This example shows how a subclass of `ref` can be used to store additional information about an object and affect the value that's returned when the referent is accessed:

```python
import weakref
class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, **annotations):
        super(ExtendedRef, self).__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.iteritems():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the number of times the reference has been called."
        ob = super(ExtendedRef, self).__call__()
        if ob is not None:
            self.__counter += 1
            ob = (ob, self.__counter)
        return ob
```
This simple example shows how an application can use objects IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```python
import weakref

_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```
8.12. **UserDict** — Class wrapper for dictionary objects

The module defines a mixin, **DictMixin**, defining all dictionary methods for classes that already have a minimum mapping interface. This greatly simplifies writing classes that need to be substitutable for dictionaries (such as the shelve module).

This module also defines a class, **UserDict**, that acts as a wrapper around dictionary objects. The need for this class has been largely supplanted by the ability to subclass directly from `dict` (a feature that became available starting with Python version 2.2). Prior to the introduction of `dict`, the **UserDict** class was used to create dictionary-like sub-classes that obtained new behaviors by overriding existing methods or adding new ones.

The **UserDict** module defines the **UserDict** class and **DictMixin**:

```python
class UserDict.

UserDict([initialdata])
```

Class that simulates a dictionary. The instance's contents are kept in a regular dictionary, which is accessible via the `data` attribute of **UserDict** instances. If `initialdata` is provided, `data` is initialized with its contents; note that a reference to `initialdata` will not be kept, allowing it be used for other purposes.

**Note:** For backward compatibility, instances of **UserDict** are not iterable.

```python
class UserDict.

IterableUserDict([initialdata])
```

Subclass of **UserDict** that supports direct iteration (e.g. `for key in myDict`).
In addition to supporting the methods and operations of mappings (see section *Mapping Types — dict*), `UserDict` and `IterableUserDict` instances provide the following attribute:

`IterableUserDict.data`

A real dictionary used to store the contents of the `UserDict` class.

```python
class UserDict.DictMixin
    Mixin defining all dictionary methods for classes that already have a minimum dictionary interface including `__getitem__()`, `__setitem__()`, `__delitem__()`, and `keys()`.
```

This mixin should be used as a superclass. Adding each of the above methods adds progressively more functionality. For instance, defining all but `__delitem__()` will preclude only `pop()` and `popitem()` from the full interface.

In addition to the four base methods, progressively more efficiency comes with defining `__contains__()`, `__iter__()`, and `iteritems()`.

Since the mixin has no knowledge of the subclass constructor, it does not define `__init__()` or `copy()`.

Starting with Python version 2.6, it is recommended to use `collections.MutableMapping` instead of `DictMixin`. 
8.13. **UserList** — Class wrapper for list objects

**Note:** This module is available for backward compatibility only. If you are writing code that does not need to work with versions of Python earlier than Python 2.2, please consider subclassing directly from the built-in `list` type.

This module defines a class that acts as a wrapper around list objects. It is a useful base class for your own list-like classes, which can inherit from them and override existing methods or add new ones. In this way one can add new behaviors to lists.

The **UserList** module defines the **UserList** class:

```python
class UserList(UserList([list]))
    Class that simulates a list. The instance’s contents are kept in a regular list, which is accessible via the `data` attribute of **UserList** instances. The instance’s contents are initially set to a copy of `list`, defaulting to the empty list `[]`. `list` can be any iterable, e.g. a real Python list or a **UserList** object.
```

**Note:** The **UserList** class has been moved to the **collections** module in Python 3.0. The **2to3** tool will automatically adapt imports when converting your sources to 3.0.

In addition to supporting the methods and operations of mutable sequences (see section *Sequence Types — str, unicode, list, tuple, buffer, xrange*), **UserList** instances provide the following attribute:

**UserList.data**

A real Python list object used to store the contents of the
**UserList** class.

**Subclassing requirements:** Subclasses of **UserList** are expect to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.

If a derived class does not wish to comply with this requirement, all of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided in that case.

*Changed in version 2.0:* Python versions 1.5.2 and 1.6 also required that the constructor be callable with no parameters, and offer a mutable **data** attribute. Earlier versions of Python did not attempt to create instances of the derived class.
### 8.14. UserString — Class wrapper for string objects

**Note:** This `UserString` class from this module is available for backward compatibility only. If you are writing code that does not need to work with versions of Python earlier than Python 2.2, please consider subclassing directly from the built-in `str` type instead of using `UserString` (there is no built-in equivalent to `MutableString`).

This module defines a class that acts as a wrapper around string objects. It is a useful base class for your own string-like classes, which can inherit from them and override existing methods or add new ones. In this way one can add new behaviors to strings.

It should be noted that these classes are highly inefficient compared to real string or Unicode objects; this is especially the case for `MutableString`.

The `UserString` module defines the following classes:

```python
class UserString.

UserString([sequence] )
```

Class that simulates a string or a Unicode string object. The instance's content is kept in a regular string or Unicode string object, which is accessible via the `data` attribute of `UserString` instances. The instance's contents are initially set to a copy of `sequence`. `sequence` can be either a regular Python string or Unicode string, an instance of `UserString` (or a subclass) or an arbitrary sequence which can be converted into a string using the built-in `str()` function.
class UserString.MutableString(sequence)

This class is derived from the UserString above and redefines strings to be mutable. Mutable strings can't be used as dictionary keys, because dictionaries require immutable objects as keys. The main intention of this class is to serve as an educational example for inheritance and necessity to remove (override) the __hash__() method in order to trap attempts to use a mutable object as dictionary key, which would be otherwise very error prone and hard to track down.

**Deprecated since version 2.6:** The MutableString class has been removed in Python 3.0.

In addition to supporting the methods and operations of string and Unicode objects (see section String Methods), UserString instances provide the following attribute:

MutableString.data

A real Python string or Unicode object used to store the content of the UserString class.
8.15. *types* — Names for built-in types

This module defines names for some object types that are used by the standard Python interpreter, but not for the types defined by various extension modules. Also, it does not include some of the types that arise during processing such as the *listiterator* type. It is safe to use `from types import *` — the module does not export any names besides the ones listed here. New names exported by future versions of this module will all end in `Type`.

Typical use is for functions that do different things depending on their argument types, like the following:

```python
from types import *
def delete(mylist, item):
    if type(item) is IntType:
        del mylist[item]
    else:
        mylist.remove(item)
```

Starting in Python 2.2, built-in factory functions such as `int()` and `str()` are also names for the corresponding types. This is now the preferred way to access the type instead of using the `types` module. Accordingly, the example above should be written as follows:

```python
def delete(mylist, item):
    if isinstance(item, int):
        del mylist[item]
    else:
        mylist.remove(item)
```

The module defines the following names:

*types*. **NoneType**
The type of None.

types. **TypeType**
The type of type objects (such as returned by `type()`); alias of the built-in `type`.

types. **BooleanType**
The type of the bool values `True` and `False`; alias of the built-in `bool`.

*New in version 2.3.*

types. **IntType**
The type of integers (e.g. `1`); alias of the built-in `int`.

types. **LongType**
The type of long integers (e.g. `1L`); alias of the built-in `long`.

types. **FloatType**
The type of floating point numbers (e.g. `1.0`); alias of the built-in `float`.

types. **ComplexType**
The type of complex numbers (e.g. `1.0j`). This is not defined if Python was built without complex number support.

types. **StringType**
The type of character strings (e.g. `'Spam'`); alias of the built-in `str`.

types. **UnicodeType**
The type of Unicode character strings (e.g. `u'Spam'`). This is not defined if Python was built without Unicode support. It's an alias of the built-in `unicode`.

types. **TupleType**
The type of tuples (e.g. `(1, 2, 3, 'Spam')`); alias of the built-in `tuple`.

types. **ListType**
The type of lists (e.g. `[0, 1, 2, 3]`); alias of the built-in `list`.

types. **DictType**
The type of dictionaries (e.g. `{ 'Bacon': 1, 'Ham': 0 }`); alias of the built-in `dict`.

types. **DictionaryType**
An alternate name for `DictType`.

types. **FunctionType**
types. **LambdaType**
The type of user-defined functions and functions created by `lambda` expressions.

types. **GeneratorType**
The type of `generator`-iterator objects, produced by calling a generator function.

*New in version 2.2.*

types. **CodeType**
The type for code objects such as returned by `compile()`.

types. **ClassType**
The type of user-defined old-style classes.

types. **InstanceType**
The type of instances of user-defined classes.

types. **MethodType**
The type of methods of user-defined class instances.

types. **UnboundMethodType**
An alternate name for `MethodType`.

types. `BuiltinFunctionType`

The type of built-in functions like `len()` or `sys.exit()`, and methods of built-in classes. (Here, the term “built-in” means “written in C”.)

types. `ModuleType`

The type of modules.

types. `FileType`

The type of open file objects such as `sys.stdout`; alias of the built-in `file`.

types. `XRangeType`

The type of range objects returned by `xrange()`; alias of the built-in `xrange`.

types. `SliceType`

The type of objects returned by `slice()`; alias of the built-in `slice`.

types. `EllipsisType`

The type of `Ellipsis`.

types. `TracebackType`

The type of traceback objects such as found in `sys.exc_traceback`.

types. `FrameType`

The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

types. `BufferType`

The type of buffer objects created by the `buffer()` function.
types.DictProxyType
The type of dict proxies, such as `TypeType.__dict__`.

types.NotImplementedType
The type of `NotImplemented`

types.GetSetDescriptorType
The type of objects defined in extension modules with `PyGetSetDef`, such as `FrameType.f_locals` or `array.array.typecode`. This type is used as descriptor for object attributes; it has the same purpose as the `property` type, but for classes defined in extension modules.

New in version 2.5.

types.MemberDescriptorType
The type of objects defined in extension modules with `PyMemberDef`, such as `datetime.timedelta.days`. This type is used as descriptor for simple C data members which use standard conversion functions; it has the same purpose as the `property` type, but for classes defined in extension modules.

CPython implementation detail: In other implementations of Python, this type may be identical to `GetSetDescriptorType`.

New in version 2.5.

types.StringTypes
A sequence containing `StringType` and `UnicodeType` used to facilitate easier checking for any string object. Using this is more portable than using a sequence of the two string types constructed elsewhere since it only contains `UnicodeType` if it has been built in the running version of Python. For example: `isinstance(s, types.StringTypes)`. 
New in version 2.2.
8.16. **new** — Creation of runtime internal objects

*Deprecated since version 2.6:* The `new` module has been removed in Python 3.0. Use the `types` module’s classes instead.

The `new` module allows an interface to the interpreter object creation functions. This is for use primarily in marshal-type functions, when a new object needs to be created “magically” and not by using the regular creation functions. This module provides a low-level interface to the interpreter, so care must be exercised when using this module. It is possible to supply non-sensical arguments which crash the interpreter when the object is used.

The `new` module defines the following functions:

`new.instance(class[, dict])`

This function creates an instance of `class` with dictionary `dict` without calling the `__init__()` constructor. If `dict` is omitted or `None`, a new, empty dictionary is created for the new instance. Note that there are no guarantees that the object will be in a consistent state.

`newinstancemethod(function, instance, class)`

This function will return a method object, bound to `instance`, or unbound if `instance` is `None`. `function` must be callable.

`new.function(code, globals[, name[, argdefs[, closure]]]])`

Returns a (Python) function with the given code and globals. If `name` is given, it must be a string or `None`. If it is a string, the function will have the given name, otherwise the function name
will be taken from `code.co_name`. If `argdefs` is given, it must be a tuple and will be used to determine the default values of parameters. If `closure` is given, it must be `None` or a tuple of cell objects containing objects to bind to the names in `code.co_freevars`.

```python
code(argcount, nlocals, stacksize, flags, codestring, constants, names, varnames, filename, name, firstlineno, lnotab)
```

This function is an interface to the `PyCode_New()` C function.

```python
module(name[, doc])
```

This function returns a new module object with name `name`. `name` must be a string. The optional `doc` argument can have any type.

```python
classobj(name, baseclasses, dict)
```

This function returns a new class object, with name `name`, derived from `baseclasses` (which should be a tuple of classes) and with namespace `dict`. 
This module provides generic (shallow and deep) copying operations.

Interface summary:

**copy**. `copy(x)`

Return a shallow copy of `x`.

**copy**. `deepcopy(x)`

Return a deep copy of `x`.

**exception** `copy.error`

Raised for module specific errors.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A *shallow copy* constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A *deep copy* constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don't exist with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies *everything* it may copy too much,
e.g., administrative data structures that should be shared even between copies.

The `deepcopy()` function avoids these problems by:

- keeping a “memo” dictionary of objects already copied during
  the current copying pass; and
- letting user-defined classes override the copying operation or
  the set of components copied.

This module does not copy types like module, method, stack trace,
stack frame, file, socket, window, array, or any similar types. It does
“copy” functions and classes (shallow and deeply), by returning the
original object unchanged; this is compatible with the way these are
treated by the `pickle` module.

Shallow copies of dictionaries can be made using `dict.copy()`, and
of lists by assigning a slice of the entire list, for example,

```python
copied_list = original_list[:]
```

*Changed in version 2.5: Added copying functions.*

Classes can use the same interfaces to control copying that they use
to control pickling. See the description of module `pickle` for
information on these methods. The `copy` module does not use the
`copy_reg` registration module.

In order for a class to define its own copy implementation, it can
define special methods `__copy__()` and `__deepcopy__()`. The former
is called to implement the shallow copy operation; no additional
arguments are passed. The latter is called to implement the deep
copy operation; it is passed one argument, the memo dictionary. If
the `__deepcopy__()` implementation needs to make a deep copy of a
component, it should call the `deepcopy()` function with the
component as first argument and the memo dictionary as second argument.

**See also:**

**Module pickle**
Discussion of the special methods used to support object state retrieval and restoration.
The `pprint` module provides a capability to “pretty-print” arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets, classes, or instances are included, as well as many other built-in objects which are not representable as Python constants.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don’t fit within the allowed width. Construct `PrettyPrinter` objects explicitly if you need to adjust the width constraint.

*Changed in version 2.5:* Dictionaries are sorted by key before the display is computed; before 2.5, a dictionary was sorted only if its display required more than one line, although that wasn’t documented.

*Changed in version 2.6:* Added support for `set` and `frozenset`.

The `pprint` module defines one class:

```python
class pprint.PrettyPrinter(...)
```

Construct a `PrettyPrinter` instance. This constructor understands several keyword parameters. An output stream may be set using the `stream` keyword; the only method used on the stream object is the file protocol’s `write()` method. If not specified, the `PrettyPrinter` adopts `sys.stdout`. Three additional parameters may be used to control the formatted representation. The keywords are `indent`, `depth`, and `width`. The amount of indentation added for each recursive level is specified by `indent`;

the default is one. Other values can cause output to look a little odd, but can make nesting easier to spot. The number of levels which may be printed is controlled by depth; if the data structure being printed is too deep, the next contained level is replaced by ...

By default, there is no constraint on the depth of the objects being formatted. The desired output width is constrained using the width parameter; the default is 80 characters. If a structure cannot be formatted within the constrained width, a best effort will be made.

```python
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
>>> stuff.insert(0, stuff[:])
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
[  ['spam', 'eggs', 'lumberjack', 'knights', 'ni'],
   'spam',
   'eggs',
   'lumberjack',
   'knights',
   'ni']
>>> tup = ('spam', ('eggs', ('lumberjack', ('knights', ('ni', (... ('parrot', ('fresh fruit',))))))))
>>> pp = pprint.PrettyPrinter(depth=6)
>>> pp.pprint(tup)
('spam', ('eggs', ('lumberjack', ('knights', ('ni', ('dead',

The **PrettyPrinter** class supports several derivative functions:

```
pprint.pformat(object[, indent[, width[, depth]]]])
```

Return the formatted representation of object as a string. indent, width and depth will be passed to the **PrettyPrinter** constructor as formatting parameters.

*Changed in version 2.4:* The parameters indent, width and depth were added.

```
pprint.pprint(object[, stream[, indent[, width[, depth]]]])
```
Prints the formatted representation of `object` on `stream`, followed by a newline. If `stream` is omitted, `sys.stdout` is used. This may be used in the interactive interpreter instead of a `print` statement for inspecting values. `indent`, `width` and `depth` will be passed to the `PrettyPrinter` constructor as formatting parameters.

```python
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=...>, 'spam', 'eggs', 'lumberjack', 'knights', 'ni']
```

*Changed in version 2.4:* The parameters `indent`, `width` and `depth` were added.

`pprint.isreadable(object)`

Determine if the formatted representation of `object` is “readable,” or can be used to reconstruct the value using `eval()`. This always returns `False` for recursive objects.

```python
>>> pprint.isreadable(stuff)
False
```

`pprint.isrecursive(object)`

Determine if `object` requires a recursive representation.

One more support function is also defined:

`pprint.saferepr(object)`

Return a string representation of `object`, protected against recursive data structures. If the representation of `object` exposes a recursive entry, the recursive reference will be represented as
<Recursion on typename with id=number>. The representation is not otherwise formatted.

```python
>>> pprint.saferepr(stuff)
"[<Recursion on list with id=...>, 'spam', 'eggs', 'lumberjack', 'ni']"
```
8.18.1. PrettyPrinter Objects

PrettyPrinter instances have the following methods:

PrettyPrinter.\texttt{pformat}(\texttt{object})
Return the formatted representation of \texttt{object}. This takes into account the options passed to the \texttt{PrettyPrinter} constructor.

PrettyPrinter.\texttt{pprint}(\texttt{object})
Print the formatted representation of \texttt{object} on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new \texttt{PrettyPrinter} objects don’t need to be created.

PrettyPrinter.\texttt{isreadable}(\texttt{object})
Determine if the formatted representation of the object is “readable,” or can be used to reconstruct the value using \texttt{eval()}. Note that this returns \texttt{False} for recursive objects. If the \texttt{depth} parameter of the \texttt{PrettyPrinter} is set and the object is deeper than allowed, this returns \texttt{False}.

PrettyPrinter.\texttt{isrecursive}(\texttt{object})
Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the \texttt{saferepr()} implementation.

PrettyPrinter.\texttt{format}(\texttt{object}, \texttt{context}, \texttt{maxlevels}, \texttt{level})
Returns three values: the formatted version of \texttt{object} as a string,
a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the id() of objects that are part of the current presentation context (direct and indirect containers for object that are affecting the presentation) as the keys; if an object needs to be presented which is already represented in context, the third return value should be True. Recursive calls to the format() method should add additional entries for containers to this dictionary. The third argument, maxlevels, gives the requested limit to recursion; this will be 0 if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, level, gives the current level; recursive calls should be passed a value less than that of the current call.

New in version 2.3.
This example demonstrates several uses of the `pprint()` function and its parameters.

```python
>>> import pprint
>>> tup = ('spam', ('eggs', ('lumberjack', ('knights', ('ni', (...
          ('parrot', ('fresh fruit',))))))))
>>> stuff = ['a' * 10, tup, ['a' * 30, 'b' * 30], ['c' * 20, 'd
>>> pprint.pprint(stuff)
['aaaaaaaaaa',
 ('spam',
  ('eggs',
   ('lumberjack',
    ('knights', ('ni', ('dead', ('parrot', ('fresh fruit',)))))))))
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaa', 'bbbbbbbbbbbbbbbbbbbbbbbbbb
 ['cccbbbbbbbbbbbbbbbbbbbbbbbbbb
 ['cccccccccbbbbbbbbbbbbbb
 ['ddddddddddeeeeedddddd']
>>> pprint.pprint(stuff, depth=3)
['aaaaaaaaaa',
 ('spam', ('eggs', (...)) ),
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaa', 'bbbbbbbbbbbbbbbbbbbbbbbbbb
 ['cccccccccbbbbbbbbbbbbbb
 ['cccccccccbbbbbbbbbbbbbb
 ['ddddddddddeeeeedddddd']
>>> pprint.pprint(stuff, width=60)
['aaaaaaaaaa',
 ('spam',
  ('eggs',
   ('lumberjack',
    ('knights',
     ('ni', ('dead', ('parrot', ('fresh fruit',)))))))))
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaa',
  'bbbbbbbbbbbbbbbbbbbbbbbbbbbb',
 ['cccccccccbbbbbbbbbbbbbb
 ['cccccccccbbbbbbbbbbbbbb
 ['ddddddddddeeeeedddddd']
```
8.19. repr — Alternate repr() implementation

**Note:** The `repr` module has been renamed to `reprlib` in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The `repr` module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

```python
class repr.Repr
    Class which provides formatting services useful in implementing functions similar to the built-in `repr()`; size limits for different object types are added to avoid the generation of representations which are excessively long.

repr.aRepr
    This is an instance of `Repr` which is used to provide the `repr()` function described below. Changing the attributes of this object will affect the size limits used by `repr()` and the Python debugger.

repr.repr(obj)
    This is the `repr()` method of `aRepr`. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.
8.19.1. Repr Objects

Repr instances provide several members which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

Repr. **maxlevel**

Depth limit on the creation of recursive representations. The default is 6.

Repr. **maxdict**

Repr. **maxlist**

Repr. **maxtuple**

Repr. **maxset**

Repr. **maxfrozenset**

Repr. **maxdeque**

Repr. **maxarray**

Limits on the number of entries represented for the named object type. The default is 4 for maxdict, 5 for maxarray, and 6 for the others.

*New in version 2.4:* maxset, maxfrozenset, and set.

Repr. **maxlong**

Maximum number of characters in the representation for a long integer. Digits are dropped from the middle. The default is 40.

Repr. **maxstring**

Limit on the number of characters in the representation of the string. Note that the “normal” representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is 30.

Repr. **maxother**
This limit is used to control the size of object types for which no specific formatting method is available on the `Repr` object. It is applied in a similar manner as `maxstring`. The default is 20.

Repr. **`repr(obj)`**

The equivalent to the built-in `repr()` that uses the formatting imposed by the instance.

Repr. **`repr1(obj, level)`**

Recursive implementation used by `repr()`. This uses the type of `obj` to determine which formatting method to call, passing it `obj` and `level`. The type-specific methods should call `repr1()` to perform recursive formatting, with `level - 1` for the value of `level` in the recursive call.

Repr. **`repr_TYPE(obj, level)`**

Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, `TYPE` is replaced by `string.join(string.split(type(obj).__name__, '_'))`. Dispatch to these methods is handled by `repr1()`. Type-specific methods which need to recursively format a value should call `self.repr1(subobj, level - 1)`. 
The use of dynamic dispatching by `Repr.repr1()` allows subclasses of `Repr` to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```python
import repr as reprlib
import sys

class MyRepr(reprlib.Repr):
    def repr_file(self, obj, level):
        if obj.name in ['<stdin>', '<stdout>', '<stderr>']:
            return obj.name
        else:
            return repr(obj)

aRepr = MyRepr()
print aRepr.repr(sys.stdin)    # prints '<stdin>'
```
The modules described in this chapter provide numeric and math-related functions and data types. The `numbers` module defines an abstract hierarchy of numeric types. The `math` and `cmath` modules contain various mathematical functions for floating-point and complex numbers. For users more interested in decimal accuracy than in speed, the `decimal` module supports exact representations of decimal numbers.

The following modules are documented in this chapter:

- **9.1. `numbers` — Numeric abstract base classes**
  - 9.1.1. The numeric tower
  - 9.1.2. Notes for type implementors
    - 9.1.2.1. Adding More Numeric ABCs
    - 9.1.2.2. Implementing the arithmetic operations
- **9.2. `math` — Mathematical functions**
  - 9.2.1. Number-theoretic and representation functions
  - 9.2.2. Power and logarithmic functions
  - 9.2.3. Trigonometric functions
  - 9.2.4. Angular conversion
  - 9.2.5. Hyperbolic functions
  - 9.2.6. Special functions
  - 9.2.7. Constants
- **9.3. `cmath` — Mathematical functions for complex numbers**
  - 9.3.1. Conversions to and from polar coordinates
  - 9.3.2. Power and logarithmic functions
  - 9.3.3. Trigonometric functions
  - 9.3.4. Hyperbolic functions
  - 9.3.5. Classification functions
9.3.6. Constants

9.4. `decimal` — Decimal fixed point and floating point arithmetic
   9.4.1. Quick-start Tutorial
   9.4.2. Decimal objects
      9.4.2.1. Logical operands
   9.4.3. Context objects
   9.4.4. Signals
   9.4.5. Floating Point Notes
      9.4.5.1. Mitigating round-off error with increased precision
      9.4.5.2. Special values
   9.4.6. Working with threads
   9.4.7. Recipes
   9.4.8. Decimal FAQ

9.5. `fractions` — Rational numbers

9.6. `random` — Generate pseudo-random numbers

9.7. `itertools` — Functions creating iterators for efficient looping
   9.7.1. Itertool functions
   9.7.2. Recipes

9.8. `functools` — Higher order functions and operations on callable objects
   9.8.1. `partial` Objects

9.9. `operator` — Standard operators as functions
   9.9.1. Mapping Operators to Functions
9.1. numbers — Numeric abstract base classes

New in version 2.6.

The numbers module (PEP 3141) defines a hierarchy of numeric abstract base classes which progressively define more operations. None of the types defined in this module can be instantiated.

class numbers. Number
    The root of the numeric hierarchy. If you just want to check if an argument x is a number, without caring what kind, use isinstance(x, Number).
9.1.1. The numeric tower

*class* numbers. **Complex**

Subclasses of this type describe complex numbers and include the operations that work on the built-in `complex` type. These are: conversions to `complex` and `bool`, `real`, `imag`, `+`, `-`, `*`, `/`, `abs()`, `conjugate()`, `==`, and `!=`. All except `-` and `!=` are abstract.

**real**

Abstract. Retrieves the real component of this number.

**imag**

Abstract. Retrieves the imaginary component of this number.

**conjugate()**

Abstract. Returns the complex conjugate. For example, `(1+3j).conjugate() == (1-3j).

*class* numbers. **Real**

To Complex, Real adds the operations that work on real numbers.

In short, those are: a conversion to `float`, `trunc()`, `round()`, `math.floor()`, `math.ceil()`, `divmod()`, `//`, `%`, `<`, `<=`, `>`, and `>=`.

Real also provides defaults for `complex()`, `real`, `imag`, and `conjugate()`.

*class* numbers. **Rational**

Subtypes Real and adds `numerator` and `denominator` properties, which should be in lowest terms. With these, it provides a default for `float()`.

**numerator**

Abstract.
class numbers. **Integral**

Subtypes **Rational** and adds a conversion to **int**. Provides defaults for **float()**, **numerator**, and **denominator**, and bit-string operations: `<<`, `>>`, `&`, `^`, `|`, `~`. 
9.1.2. Notes for type implementors

Implementors should be careful to make equal numbers equal and hash them to the same values. This may be subtle if there are two different extensions of the real numbers. For example, `fractions.Fraction` implements `hash()` as follows:

```python
def __hash__(self):
    if self.denominator == 1:
        # Get integers right.
        return hash(self.numerator)
    # Expensive check, but definitely correct.
    if self == float(self):
        return hash(float(self))
    else:
        # Use tuple's hash to avoid a high collision rate on
        # simple fractions.
        return hash((self.numerator, self.denominator))
```

9.1.2.1. Adding More Numeric ABCs

There are, of course, more possible ABCs for numbers, and this would be a poor hierarchy if it precluded the possibility of adding those. You can add `MyFoo` between `Complex` and `Real` with:

```python
class MyFoo(Complex): ...
MyFoo.register(Real)
```

9.1.2.2. Implementing the arithmetic operations

We want to implement the arithmetic operations so that mixed-mode operations either call an implementation whose author knew about the types of both arguments, or convert both to the nearest built in type and do the operation there. For subtypes of `Integral`, this means that `__add__()` and `__radd__()` should be defined as:
class MyIntegral(Integral):
    def __add__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(self, other)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(self, other)
        else:
            return NotImplemented
    def __radd__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(other, self)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(other, self)
        elif isinstance(other, Integral):
            return int(other) + int(self)
        elif isinstance(other, Real):
            return float(other) + float(self)
        elif isinstance(other, Complex):
            return complex(other) + complex(self)
        else:
            return NotImplemented

There are 5 different cases for a mixed-type operation on subclasses of Complex. I'll refer to all of the above code that doesn't refer to MyIntegral and OtherTypeIKnowAbout as “boilerplate”. a will be an instance of A, which is a subtype of Complex (a : A <: Complex), and b : B <: Complex. I'll consider a + b:

1. If A defines an __add__() which accepts b, all is well.
2. If A falls back to the boilerplate code, and it were to return a value from __add__(), we’d miss the possibility that B defines a more intelligent __radd__(), so the boilerplate should return NotImplemented from __add__(). (Or A may not implement __add__() at all.)
3. Then B's __radd__() gets a chance. If it accepts a, all is well.
4. If it falls back to the boilerplate, there are no more possible
methods to try, so this is where the default implementation should live.

5. If $B <: A$, Python tries $B.__radd__$ before $A.__add__$. This is ok, because it was implemented with knowledge of $A$, so it can handle those instances before delegating to $\texttt{Complex}$.

If $A <: \texttt{Complex}$ and $B <: \texttt{Real}$ without sharing any other knowledge, then the appropriate shared operation is the one involving the built in $\texttt{complex}$, and both $\texttt{__radd__()}$s land there, so $a+b == b+a$.

Because most of the operations on any given type will be very similar, it can be useful to define a helper function which generates the forward and reverse instances of any given operator. For example, $\texttt{fractions.Fraction}$ uses:

```python
def _operator_fallbacks(monomorphic_operator, fallback_operator):
    def forward(a, b):
        if isinstance(b, (int, long, Fraction)):
            return monomorphic_operator(a, b)
        elif isinstance(b, float):
            return fallback_operator(float(a), b)
        elif isinstance(b, complex):
            return fallback_operator(complex(a), b)
        else:
            return NotImplemented
    forward.__name__ = '__' + fallback_operator.__name__ + '__'
    forward.__doc__ = monomorphic_operator.__doc__

    def reverse(b, a):
        if isinstance(a, Rational):
            # Includes ints.
            return monomorphic_operator(a, b)
        elif isinstance(a, numbers.Real):
            return fallback_operator(float(a), float(b))
        elif isinstance(a, numbers.Complex):
            return fallback_operator(complex(a), complex(b))
        else:
            return NotImplemented
    reverse.__name__ = '__r' + fallback_operator.__name__ + '__'
    reverse.__doc__ = monomorphic_operator.__doc__
```
def __add__(a, b):
    """a + b""
    return Fraction(a.numerator * b.denominator +
                     b.numerator * a.denominator,
                     a.denominator * b.denominator)

__add__, __radd__ = operator_fallbacks(__add__, operator.add)
This module is always available. It provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the `cmath` module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don’t is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.
9.2.1. Number-theoretic and representation functions

**math.ceil(x)**

Return the ceiling of $x$ as a float, the smallest integer value greater than or equal to $x$.

**math.copysign(x, y)**

Return $x$ with the sign of $y$. On a platform that supports signed zeros, `copysign(1.0, -0.0)` returns `-1.0`.

*New in version 2.6.*

**math.fabs(x)**

Return the absolute value of $x$.

**math.factorial(x)**

Return $x$ factorial. Raises `ValueError` if $x$ is not integral or is negative.

*New in version 2.6.*

**math.floor(x)**

Return the floor of $x$ as a float, the largest integer value less than or equal to $x$.

**math.fmod(x, y)**

Return `fmod(x, y)`, as defined by the platform C library. Note that the Python expression `x % y` may not return the same result. The intent of the C standard is that `fmod(x, y)` be exactly (mathematically; to infinite precision) equal to $x - n\times y$ for some integer $n$ such that the result has the same sign as $x$ and
magnitude less than abs(y). Python’s x % y returns a result with the sign of y instead, and may not be exactly computable for float arguments. For example, fmod(-1e-100, 1e100) is -1e-100, but the result of Python’s -1e-100 % 1e100 is 1e100-1e-100, which cannot be represented exactly as a float, and rounds to the surprising 1e100. For this reason, function fmod() is generally preferred when working with floats, while Python’s x % y is preferred when working with integers.

math.frexp(x)
Return the mantissa and exponent of x as the pair (m, e). m is a float and e is an integer such that x == m * 2**e exactly. If x is zero, returns (0.0, 0), otherwise 0.5 <= abs(m) < 1. This is used to “pick apart” the internal representation of a float in a portable way.

math.fsum(iterable)
Return an accurate floating point sum of values in the iterable. Avoids loss of precision by tracking multiple intermediate partial sums:

```python
>>> sum([.1, .1, .1, .1, .1, .1, .1, .1])
0.9999999999999999
>>> fsum([.1, .1, .1, .1, .1, .1, .1, .1])
1.0
```

The algorithm’s accuracy depends on IEEE-754 arithmetic guarantees and the typical case where the rounding mode is half-even. On some non-Windows builds, the underlying C library uses extended precision addition and may occasionally double-round an intermediate sum causing it to be off in its least significant bit.

For further discussion and two alternative approaches, see the ASPN cookbook recipes for accurate floating point summation.
New in version 2.6.

```
math.isinf(x)
```

Check if the float \( x \) is positive or negative infinity.

New in version 2.6.

```
math.isnan(x)
```

Check if the float \( x \) is a NaN (not a number). For more information on NaNs, see the IEEE 754 standards.

New in version 2.6.

```
math.ldexp(x, i)
```

Return \( x \times (2^{\ast}i) \). This is essentially the inverse of function `frexp()`.

```
math.modf(x)
```

Return the fractional and integer parts of \( x \). Both results carry the sign of \( x \) and are floats.

```
math.trunc(x)
```

Return the Real value \( x \) truncated to an Integral (usually a long integer). Uses the `__trunc__` method.

New in version 2.6.

Note that `frexp()` and `modf()` have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an ‘output parameter’ (there is no such thing in Python).

For the `ceil()`, `floor()`, and `modf()` functions, note that all floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the
same as the platform C double type), in which case any float x with \( \text{abs}(x) \geq 2^{**52} \) necessarily has no fractional bits.
9.2.2. Power and logarithmic functions

**Math.exp(x)**
Return $e^x$.

**Math.expm1(x)**
Return $e^x - 1$. For small floats $x$, the subtraction in $\exp(x) - 1$ can result in a significant loss of precision; the `expm1()` function provides a way to compute this quantity to full precision:

```python
>>> from math import exp, expm1
>>> exp(1e-5) - 1  # gives result accurate to 11 places 1.0000050000069649e-05
>>> expm1(1e-5)    # result accurate to full precision 1.0000050000166668e-05
```

*New in version 2.7.*

**Math.log(x[, base])**
With one argument, return the natural logarithm of $x$ (to base $e$).

With two arguments, return the logarithm of $x$ to the given `base`, calculated as $\log(x)/\log(base)$.

*Changed in version 2.3: base argument added.*

**Math.log1p(x)**
Return the natural logarithm of $1+x$ (base $e$). The result is calculated in a way which is accurate for $x$ near zero.

*New in version 2.6.*

**Math.log10(x)**
Return the base-10 logarithm of $x$. This is usually more accurate
than $\log(x, 10)$.

**math. `pow(x, y)`**

Return $x$ raised to the power $y$. Exceptional cases follow Annex ‘F’ of the C99 standard as far as possible. In particular, `pow(1.0, x)` and `pow(x, 0.0)` always return 1.0, even when $x$ is a zero or a NaN. If both $x$ and $y$ are finite, $x$ is negative, and $y$ is not an integer then `pow(x, y)` is undefined, and raises `ValueError`.

*Changed in version 2.6:* The outcome of $1^{\text{nan}}$ and $\text{nan}^{0}$ was undefined.

**math. `sqrt(x)`**

Return the square root of $x$. 
9.2.3. Trigonometric functions

math. $\text{acos}(x)$
Return the arc cosine of $x$, in radians.

math. $\text{asin}(x)$
Return the arc sine of $x$, in radians.

math. $\text{atan}(x)$
Return the arc tangent of $x$, in radians.

math. $\text{atan2}(y, x)$
Return $\text{atan}(y / x)$, in radians. The result is between $-\pi$ and $\pi$. The vector in the plane from the origin to point $(x, y)$ makes this angle with the positive X axis. The point of $\text{atan2}()$ is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, $\text{atan}(1)$ and $\text{atan2}(1, 1)$ are both $\pi/4$, but $\text{atan2}(-1, -1)$ is $-3\pi/4$.

math. $\text{cos}(x)$
Return the cosine of $x$ radians.

math. $\text{hypot}(x, y)$
Return the Euclidean norm, $\sqrt{x^2 + y^2}$. This is the length of the vector from the origin to point $(x, y)$.

math. $\text{sin}(x)$
Return the sine of $x$ radians.

math. $\text{tan}(x)$
Return the tangent of $x$ radians.
9.2.4. Angular conversion

```
math.degrees(x)
    Converts angle x from radians to degrees.

math.radians(x)
    Converts angle x from degrees to radians.
```
9.2.5. Hyperbolic functions

\texttt{math.acosh(x)}

Return the inverse hyperbolic cosine of $x$.  

\textit{New in version 2.6.}

\texttt{math.asinh(x)}

Return the inverse hyperbolic sine of $x$.  

\textit{New in version 2.6.}

\texttt{math.atanh(x)}

Return the inverse hyperbolic tangent of $x$.  

\textit{New in version 2.6.}

\texttt{math.cosh(x)}

Return the hyperbolic cosine of $x$. 

\texttt{math.sinh(x)}

Return the hyperbolic sine of $x$. 

\texttt{math.tanh(x)}

Return the hyperbolic tangent of $x$. 
9.2.6. Special functions

\texttt{math.\texttt{erf}(x)}

Return the error function at \( x \).

\textit{New in version 2.7.}

\texttt{math.\texttt{erfc}(x)}

Return the complementary error function at \( x \).

\textit{New in version 2.7.}

\texttt{math.\texttt{gamma}(x)}

Return the Gamma function at \( x \).

\textit{New in version 2.7.}

\texttt{math.\texttt{lgamma}(x)}

Return the natural logarithm of the absolute value of the Gamma function at \( x \).

\textit{New in version 2.7.}
### 9.2.7. Constants

**math.pi**

The mathematical constant $\pi = 3.141592...$, to available precision.

**math.e**

The mathematical constant $e = 2.718281...$, to available precision.

**CPython implementation detail:** The `math` module consists mostly of thin wrappers around the platform C math library functions. Behavior in exceptional cases follows Annex F of the C99 standard where appropriate. The current implementation will raise `ValueError` for invalid operations like `sqrt(-1.0)` or `log(0.0)` (where C99 Annex F recommends signaling invalid operation or divide-by-zero), and `OverflowError` for results that overflow (for example, `exp(1000.0)`). A NaN will not be returned from any of the functions above unless one or more of the input arguments was a NaN; in that case, most functions will return a NaN, but (again following C99 Annex F) there are some exceptions to this rule, for example `pow(float('nan'), 0.0)` or `hypot(float('nan'), float('inf'))`.

Note that Python makes no effort to distinguish signaling NaNs from quiet NaNs, and behavior for signaling NaNs remains unspecified. Typical behavior is to treat all NaNs as though they were quiet.

*Changed in version 2.6:* Behavior in special cases now aims to follow C99 Annex F. In earlier versions of Python the behavior in special cases was loosely specified.
See also:

**Module `cmath`**
Complex number versions of many of these functions.
This module is always available. It provides access to mathematical functions for complex numbers. The functions in this module accept integers, floating-point numbers or complex numbers as arguments. They will also accept any Python object that has either a \_\_complex\_\_() or a \_\_float\_\_() method: these methods are used to convert the object to a complex or floating-point number, respectively, and the function is then applied to the result of the conversion.

**Note:** On platforms with hardware and system-level support for signed zeros, functions involving branch cuts are continuous on both sides of the branch cut: the sign of the zero distinguishes one side of the branch cut from the other. On platforms that do not support signed zeros the continuity is as specified below.
9.3.1. Conversions to and from polar coordinates

A Python complex number $z$ is stored internally using rectangular or Cartesian coordinates. It is completely determined by its real part $z\text{.real}$ and its imaginary part $z\text{.imag}$. In other words:

$$z == z\text{.real} + z\text{.imag}\times1j$$

Polar coordinates give an alternative way to represent a complex number. In polar coordinates, a complex number $z$ is defined by the modulus $r$ and the phase angle $\phi$. The modulus $r$ is the distance from $z$ to the origin, while the phase $\phi$ is the counterclockwise angle, measured in radians, from the positive $x$-axis to the line segment that joins the origin to $z$.

The following functions can be used to convert from the native rectangular coordinates to polar coordinates and back.

cmath.\texttt{phase(x)}

Return the phase of $x$ (also known as the argument of $x$), as a float. \texttt{phase(x)} is equivalent to \texttt{math.atan2(x.imag, x.real)}. The result lies in the range $[-\pi, \pi]$, and the branch cut for this operation lies along the negative real axis, continuous from above. On systems with support for signed zeros (which includes most systems in current use), this means that the sign of the result is the same as the sign of $x\text{.imag}$, even when $x\text{.imag}$ is zero:

```python
>>> phase(complex(-1.0, 0.0))
3.1415926535897931
>>> phase(complex(-1.0, -0.0))
-3.1415926535897931
```
New in version 2.6.

**Note:** The modulus (absolute value) of a complex number $x$ can be computed using the built-in `abs()` function. There is no separate `cmath` module function for this operation.

```python
cmath.polar(x)
```
Return the representation of $x$ in polar coordinates. Returns a pair $(r, \phi)$ where $r$ is the modulus of $x$ and $\phi$ is the phase of $x$. `polar(x)` is equivalent to `(abs(x), phase(x))`.

New in version 2.6.

```python
cmath.rect(r, phi)
```
Return the complex number $x$ with polar coordinates $r$ and $\phi$. Equivalent to $r * (\text{math.cos(\phi)} + \text{math.sin(\phi)}*\text{1j})$.

New in version 2.6.
9.3.2. Power and logarithmic functions

cmath. \( \texttt{exp}(x) \)
Return the exponential value \( e^{**x} \).

cmath. \( \texttt{log}(x[, \text{base}]) \)
Returns the logarithm of \( x \) to the given \textit{base}. If the \textit{base} is not specified, returns the natural logarithm of \( x \). There is one branch cut, from 0 along the negative real axis to \(-\infty\), continuous from above.

\textit{Changed in version 2.4: base argument added.}

cmath. \( \texttt{log10}(x) \)
Return the base-10 logarithm of \( x \). This has the same branch cut as \( \texttt{log}() \).

cmath. \( \texttt{sqrt}(x) \)
Return the square root of \( x \). This has the same branch cut as \( \texttt{log}() \).
9.3.3. Trigonometric functions

**cmath.acos(x)**
Return the arc cosine of $x$. There are two branch cuts: One extends right from 1 along the real axis to $\infty$, continuous from below. The other extends left from -1 along the real axis to $-\infty$, continuous from above.

**cmath.asin(x)**
Return the arc sine of $x$. This has the same branch cuts as `acos()`.

**cmath.atan(x)**
Return the arc tangent of $x$. There are two branch cuts: One extends from $1j$ along the imaginary axis to $\infty j$, continuous from the right. The other extends from $-1j$ along the imaginary axis to $-\infty j$, continuous from the left.

*Changed in version 2.6:* direction of continuity of upper cut reversed

**cmath.cos(x)**
Return the cosine of $x$.

**cmath.sin(x)**
Return the sine of $x$.

**cmath.tan(x)**
Return the tangent of $x$. 

9.3.4. Hyperbolic functions

`cmath.acosh(x)`
Return the hyperbolic arc cosine of \( x \). There is one branch cut, extending left from 1 along the real axis to \(-\infty\), continuous from above.

`cmath.asinh(x)`
Return the hyperbolic arc sine of \( x \). There are two branch cuts: One extends from \( 1j \) along the imaginary axis to \( \infty j \), continuous from the right. The other extends from \(-1j \) along the imaginary axis to \(-\infty j \), continuous from the left.

*Changed in version 2.6:* branch cuts moved to match those recommended by the C99 standard

`cmath.atanh(x)`
Return the hyperbolic arc tangent of \( x \). There are two branch cuts: One extends from 1 along the real axis to \( \infty \), continuous from below. The other extends from -1 along the real axis to \(-\infty \), continuous from above.

*Changed in version 2.6:* direction of continuity of right cut reversed

`cmath.cosh(x)`
Return the hyperbolic cosine of \( x \).

`cmath.sinh(x)`
Return the hyperbolic sine of \( x \).

`cmath.tanh(x)`
Return the hyperbolic tangent of \( x \).
9.3.5. Classification functions

cmath.\texttt{isinf}(x)

Return \textit{True} if the real or the imaginary part of \( x \) is positive or negative infinity.

\textit{New in version 2.6.}

cmath.\texttt{isnan}(x)

Return \textit{True} if the real or imaginary part of \( x \) is not a number (NaN).

\textit{New in version 2.6.}
### 9.3.6. Constants

**cmath.pi**

The mathematical constant $\pi$, as a float.

**cmath.e**

The mathematical constant $e$, as a float.

Note that the selection of functions is similar, but not identical, to that in module `math`. The reason for having two modules is that some users aren’t interested in complex numbers, and perhaps don’t even know what they are. They would rather have `math.sqrt(-1)` raise an exception than return a complex number. Also note that the functions defined in `cmath` always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

9.4. `decimal` — Decimal fixed point and floating point arithmetic

New in version 2.4.

The `decimal` module provides support for decimal floating point arithmetic. It offers several advantages over the `float` datatype:

- Decimal “is based on a floating-point model which was designed with people in mind, and necessarily has a paramount guiding principle – computers must provide an arithmetic that works in the same way as the arithmetic that people learn at school.” – excerpt from the decimal arithmetic specification.

- Decimal numbers can be represented exactly. In contrast, numbers like 1.1 and 2.2 do not have an exact representations in binary floating point. End users typically would not expect 1.1 + 2.2 to display as 3.3000000000000003 as it does with binary floating point.

- The exactness carries over into arithmetic. In decimal floating point, 0.1 + 0.1 + 0.1 - 0.3 is exactly equal to zero. In binary floating point, the result is 5.5511151231257827e-017. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal is preferred in accounting applications which have strict equality invariants.

- The decimal module incorporates a notion of significant places so that 1.30 + 1.20 is 2.50. The trailing zero is kept to indicate significance. This is the customary presentation for monetary applications. For multiplication, the “schoolbook” approach uses all the figures in the multiplicands. For instance, 1.3 * 1.2 gives
1.56 while 1.30 * 1.20 gives 1.5600.

- Unlike hardware based binary floating point, the decimal module has a user alterable precision (defaulting to 28 places) which can be as large as needed for a given problem:

  >>> getcontext().prec = 6
  >>> Decimal(1) / Decimal(7)
  Decimal('0.142857')
  >>> getcontext().prec = 28
  >>> Decimal(1) / Decimal(7)
  Decimal('0.1428571428571428571428571429')

- Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling. This includes an option to enforce exact arithmetic by using exceptions to block any inexact operations.

- The decimal module was designed to support “without prejudice, both exact unrounded decimal arithmetic (sometimes called fixed-point arithmetic) and rounded floating-point arithmetic.” – excerpt from the decimal arithmetic specification.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not truncate trailing zeros. Decimals also include special values such as \(\text{Infinity}\), \(-\text{Infinity}\), and \(\text{NaN}\). The standard also differentiates \(-0\) from \(+0\).

The context for arithmetic is an environment specifying precision, rounding rules, limits on exponents, flags indicating the results of
operations, and trap enablers which determine whether signals are
treated as exceptions. Rounding options include \texttt{ROUND_CEILING},
\texttt{ROUND_DOWN}, \texttt{ROUND_FLOOR}, \texttt{ROUND_HALF_DOWN}, \texttt{ROUND_HALF_EVEN},
\texttt{ROUND_HALF_UP}, \texttt{ROUND_UP}, and \texttt{ROUND_05UP}.

Signals are groups of exceptional conditions arising during the
course of computation. Depending on the needs of the application,
signals may be ignored, considered as informational, or treated as
exceptions. The signals in the decimal module are: \texttt{Clamped},
\texttt{InvalidOperation}, \texttt{DivisionByZero}, \texttt{Inexact}, \texttt{Rounded}, \texttt{Subnormal},
\texttt{Overflow}, and \texttt{Underflow}.

For each signal there is a flag and a trap enabler. When a signal is
encountered, its flag is set to one, then, if the trap enabler is set to
one, an exception is raised. Flags are sticky, so the user needs to
reset them before monitoring a calculation.

\textbf{See also:}

- IBM's General Decimal Arithmetic Specification, \textit{The General
  Decimal Arithmetic Specification}.
9.4.1. Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with `getcontext()` and, if necessary, setting new values for precision, rounding, or enabled traps:

```
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999, capitals=1, flags=[], traps=[Overflow, DivisionByZero, InvalidOperation])
```

```
>>> getcontext().prec = 7          # Set a new precision
```

Decimal instances can be constructed from integers, strings, floats, or tuples. Construction from an integer or a float performs an exact conversion of the value of that integer or float. Decimal numbers include special values such as `NaN` which stands for “Not a number”, positive and negative `Infinity`, and `-0`.

```
>>> getcontext().prec = 28
>>> Decimal(10)
Decimal('10')
>>> Decimal('3.14')
Decimal('3.14')
>>> Decimal(3.14)
Decimal('3.14')
>>> Decimal((0, (3, 1, 4), -2))
Decimal('3.14')
>>> Decimal(str(2.0 ** 0.5))
Decimal('1.41421356237')
>>> Decimal(2) ** Decimal('0.5')
Decimal('1.414213562373095048801688724')
>>> Decimal('NaN')
Decimal('NaN')
>>> Decimal('-Infinity')
Decimal('-Infinity')
```
The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come into play during arithmetic operations.

```python
g>>> getcontext().prec = 6
g>>> Decimal('3.0')
Decimal('3.0')
g>>> Decimal('3.1415926535')
Decimal('3.1415926535')
g>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85987')
g>>> getcontext().rounding = ROUND_UP

g>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85988')
```

Decimals interact well with much of the rest of Python. Here is a small decimal floating point flying circus:

```python
g>>> data = map(Decimal, '1.34 1.87 3.45 2.35 1.00 0.03 9.25'.split())
g>>> max(data)
Decimal('9.25')
g>>> min(data)
Decimal('0.03')
g>>> sorted(data)
[Decimal('0.03'), Decimal('1.00'), Decimal('1.34'), Decimal('1.87'), Decimal('2.35'), Decimal('3.45'), Decimal('9.25')]
g>>> sum(data)
Decimal('19.29')
g>>> a,b,c = data[:3]
g>>> str(a)
'1.34'
g>>> float(a)
1.34
g>>> round(a, 1)  # round() first converts to binary floating point
1.3
g>>> int(a)
1
g>>> a * 5
Decimal('6.70')
g>>> a * b
Decimal('2.5058')
g>>> c % a
Decimal('0.77')
```
And some mathematical functions are also available to Decimal:

```python
>>> getcontext().prec = 28
>>> Decimal(2).sqrt()
Decimal('1.414213562373095048801688724')
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal('10').ln()
Decimal('2.302585092994045684017991455')
>>> Decimal('10').log10()
Decimal('1')
```

The `quantize()` method rounds a number to a fixed exponent. This method is useful for monetary applications that often round results to a fixed number of places:

```python
>>> Decimal('7.325').quantize(Decimal('.01'), rounding=ROUND_DOWN)
Decimal('7.32')
>>> Decimal('7.325').quantize(Decimal('1.'), rounding=ROUND_UP)
Decimal('8')
```

As shown above, the `getcontext()` function accesses the current context and allows the settings to be changed. This approach meets the needs of most applications.

For more advanced work, it may be useful to create alternate contexts using the `Context()` constructor. To make an alternate active, use the `setcontext()` function.

In accordance with the standard, the `Decimal` module provides two ready to use standard contexts, `BasicContext` and `ExtendedContext`. The former is especially useful for debugging because many of the traps are enabled:

```python
>>> myothercontext = Context(prec=60, rounding=ROUND_HALF_DOWN)
>>> setcontext(myothercontext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857142857142857142857142857142857142857142857142857142857')
```
>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999,
capitals=1, flags=[], traps=[])  
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857143')
>>> Decimal(42) / Decimal(0)
Decimal('Infinity')

>>> setcontext(BasicContext)
>>> Decimal(42) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#143>", line 1, in -toplevel-
    Decimal(42) / Decimal(0)
DivisionByZero: x / 0

Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the `clear_flags()` method.

>>> setcontext(ExtendedContext)
>>> getcontext().clear_flags()
>>> Decimal(355) / Decimal(113)
Decimal('3.14159292')
>>> getcontext()
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999,
capitals=1, flags=[Rounded, Inexact], traps=[])  

The `flags` entry shows that the rational approximation to \( \pi \) was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the `traps` field of a context:

>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(0)
Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to `Decimal` with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.
9.4.2. Decimal objects

```python
class decimal.Decimal([value[, context]])
```
Construct a new `Decimal` object based from `value`.

`value` can be an integer, string, tuple, float, or another `Decimal` object. If no `value` is given, returns `Decimal('0')`. If `value` is a string, it should conform to the decimal numeric string syntax after leading and trailing whitespace characters are removed:

```
sign      ::= '+' | '-'
digit     ::= '0' | '1' | '2' | '3' | '4' | '5' | '6'
indicator ::= 'e' | 'E'
digits    ::= digit [digit]...
decimal-part ::= digits '.' [digits] | ['.' ] digits
exponent-part ::= indicator [sign] digits
infinity   ::= 'Infinity' | 'Inf'
nan        ::= 'NaN' [digits] | 'sNaN' [digits]
numeric-value ::= decimal-part [exponent-part] | infinity
numeric-string ::= [sign] numeric-value | [sign] nan
```

If `value` is a unicode string then other Unicode decimal digits are also permitted where `digit` appears above. These include decimal digits from various other alphabets (for example, Arabic-Indic and Devanāgarī digits) along with the fullwidth digits `u'\uff10' through `u'\uff19'.

If `value` is a `tuple`, it should have three components, a sign (0 for positive or 1 for negative), a `tuple` of digits, and an integer exponent. For example, `Decimal((0, (1, 4, 1, 4), -3))` returns `Decimal('1.414')`.

If `value` is a `float`, the binary floating point value is losslessly converted to its exact decimal equivalent. This conversion can
often require 53 or more digits of precision. For example, `Decimal(float('1.1'))` converts to `Decimal('1.100000000000000088817841970012523233890533447265625')`

The context precision does not affect how many digits are stored. That is determined exclusively by the number of digits in value. For example, `Decimal('3.00000')` records all five zeros even if the context precision is only three.

The purpose of the context argument is determining what to do if value is a malformed string. If the context traps `InvalidOperation`, an exception is raised; otherwise, the constructor returns a new Decimal with the value of NaN.

Once constructed, `Decimal` objects are immutable.

*Changed in version 2.6*: leading and trailing whitespace characters are permitted when creating a Decimal instance from a string.

*Changed in version 2.7*: The argument to the constructor is now permitted to be a `float` instance.

Decimal floating point objects share many properties with the other built-in numeric types such as `float` and `int`. All of the usual math operations and special methods apply. Likewise, decimal objects can be copied, pickled, printed, used as dictionary keys, used as set elements, compared, sorted, and coerced to another type (such as `float` or `long`).

Decimal objects cannot generally be combined with floats in arithmetic operations: an attempt to add a `Decimal` to a `float`, for example, will raise a `TypeError`. There’s one exception to this rule: it’s possible to use Python’s comparison operators to
compare a float instance $x$ with a Decimal instance $y$. Without this exception, comparisons between Decimal and float instances would follow the general rules for comparing objects of different types described in the Expressions section of the reference manual, leading to confusing results.

*Changed in version 2.7:* A comparison between a float instance $x$ and a Decimal instance $y$ now returns a result based on the values of $x$ and $y$. In earlier versions $x < y$ returned the same (arbitrary) result for any Decimal instance $x$ and any float instance $y$.

In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

**adjusted()**
Return the adjusted exponent after shifting out the coefficient’s rightmost digits until only the lead digit remains: `Decimal('321e+5').adjusted()` returns seven. Used for determining the position of the most significant digit with respect to the decimal point.

**as_tuple()**
Return a named tuple representation of the number: `DecimalTuple(sign, digits, exponent)`.

*Changed in version 2.6:* Use a named tuple.

**canonical()**
Return the canonical encoding of the argument. Currently, the encoding of a Decimal instance is always canonical, so this operation returns its argument unchanged.

*New in version 2.6.*
**compare**(other[, context])

Compare the values of two Decimal instances. This operation behaves in the same way as the usual comparison method __cmp__(), except that compare() returns a Decimal instance rather than an integer, and if either operand is a NaN then the result is a NaN:

<table>
<thead>
<tr>
<th>Condition</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>a or b is a NaN</td>
<td>Decimal('NaN')</td>
</tr>
<tr>
<td>a &lt; b</td>
<td>Decimal('-1')</td>
</tr>
<tr>
<td>a == b</td>
<td>Decimal('0')</td>
</tr>
<tr>
<td>a &gt; b</td>
<td>Decimal('1')</td>
</tr>
</tbody>
</table>

**compare_signal**(other[, context])

This operation is identical to the compare() method, except that all NaNs signal. That is, if neither operand is a signaling NaN then any quiet NaN operand is treated as though it were a signaling NaN.

*New in version 2.6.*

**compare_total**(other)

Compare two operands using their abstract representation rather than their numerical value. Similar to the compare() method, but the result gives a total ordering on Decimal instances. Two Decimal instances with the same numeric value but different representations compare unequal in this ordering:

>>> Decimal('12.0').compare_total(Decimal('12'))
Decimal('-1')

Quiet and signaling NaNs are also included in the total ordering. The result of this function is Decimal('0') if both operands have the same representation, Decimal('-1') if the first operand is lower in the total order than the second, and
Decimal('1') if the first operand is higher in the total order than the second operand. See the specification for details of the total order.

*New in version 2.6.*

**compare_total_mag(other)**

Compare two operands using their abstract representation rather than their value as in `compare_total()`, but ignoring the sign of each operand. `x.compare_total_mag(y)` is equivalent to `x.copy_abs().compare_total(y.copy_abs())`.

*New in version 2.6.*

**conjugate()**

Just returns self, this method is only to comply with the Decimal Specification.

*New in version 2.6.*

**copy_abs()**

Return the absolute value of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

*New in version 2.6.*

**copy_negate()**

Return the negation of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

*New in version 2.6.*

**copy_sign(other)**
Return a copy of the first operand with the sign set to be the same as the sign of the second operand. For example:

```python
>>> Decimal('2.3').copy_sign(Decimal('-1.5'))
Decimal('-2.3')
```

This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

*New in version 2.6.*

**exp(context)**

Return the value of the (natural) exponential function \( e^x \) at the given number. The result is correctly rounded using the \texttt{ROUND_HALF_EVEN} rounding mode.

```python
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal(321).exp()
Decimal('2.561702493119680037517373933E+139')
```

*New in version 2.6.*

**from_float(f)**

Classmethod that converts a float to a decimal number, exactly.

Note \texttt{Decimal.from_float(0.1)} is not the same as \texttt{Decimal('0.1')} . Since 0.1 is not exactly representable in binary floating point, the value is stored as the nearest representable value which is \( 0x1.9999999999999ap-4 \). That equivalent value in decimal is \( 0.1000000000000000555111512312578270211815834045410 \).

**Note:** From Python 2.7 onwards, a \texttt{Decimal} instance can also be constructed directly from a \texttt{float}. 

```python
>>> Decimal.from_float(0.1)
Decimal('0.1000000000000000055511151231257827021181583404541015625')
>>> Decimal.from_float(float('nan'))
Decimal('NaN')
>>> Decimal.from_float(float('inf'))
Decimal('Infinity')
>>> Decimal.from_float(float('-inf'))
Decimal('-Infinity')
```

New in version 2.7.

**fma(other, third[, context])**

Fused multiply-add. Return self*other+third with no rounding of the intermediate product self*other.

```python
>>> Decimal(2).fma(3, 5)
Decimal('11')
```

New in version 2.6.

**is_canonical()**

Return `True` if the argument is canonical and `False` otherwise. Currently, a `Decimal` instance is always canonical, so this operation always returns `True`.

New in version 2.6.

**is_finite()**

Return `True` if the argument is a finite number, and `False` if the argument is an infinity or a NaN.

New in version 2.6.

**is_infinite()**

Return `True` if the argument is either positive or negative infinity and `False` otherwise.
New in version 2.6.

**is_nan()**
Return **True** if the argument is a (quiet or signaling) NaN and **False** otherwise.

New in version 2.6.

**is_normal()**
Return **True** if the argument is a normal finite non-zero number with an adjusted exponent greater than or equal to \( E_{\min} \). Return **False** if the argument is zero, subnormal, infinite or a NaN. Note, the term *normal* is used here in a different sense with the `normalize()` method which is used to create canonical values.

New in version 2.6.

**is_qnan()**
Return **True** if the argument is a quiet NaN, and **False** otherwise.

New in version 2.6.

**is_signed()**
Return **True** if the argument has a negative sign and **False** otherwise. Note that zeros and NaNs can both carry signs.

New in version 2.6.

**is_snan()**
Return **True** if the argument is a signaling NaN and **False** otherwise.

New in version 2.6.
**is_subnormal()**
Return **True** if the argument is subnormal, and **False** otherwise. A number is subnormal if it is nonzero, finite, and has an adjusted exponent less than $E_{min}$.

*New in version 2.6.*

**is_zero()**
Return **True** if the argument is a (positive or negative) zero and **False** otherwise.

*New in version 2.6.*

**ln([context])**
Return the natural (base e) logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

*New in version 2.6.*

**log10([context])**
Return the base ten logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

*New in version 2.6.*

**logb([context])**
For a nonzero number, return the adjusted exponent of its operand as a **Decimal** instance. If the operand is a zero then **Decimal('-Infinity')** is returned and the **DivisionByZero** flag is raised. If the operand is an infinity then **Decimal('Infinity')** is returned.

*New in version 2.6.*
logical_and(other[, context])

`logical_and()` is a logical operation which takes two logical operands (see Logical operands). The result is the digit-wise and of the two operands.

*New in version 2.6.*

logical_invert([context])

`logical_invert()` is a logical operation. The result is the digit-wise inversion of the operand.

*New in version 2.6.*

logical_or(other[, context])

`logical_or()` is a logical operation which takes two logical operands (see Logical operands). The result is the digit-wise or of the two operands.

*New in version 2.6.*

logical_xor(other[, context])

`logical_xor()` is a logical operation which takes two logical operands (see Logical operands). The result is the digit-wise exclusive or of the two operands.

*New in version 2.6.*

max(other[, context])

Like `max(self, other)` except that the context rounding rule is applied before returning and that `NaN` values are either signaled or ignored (depending on the context and whether they are signaling or quiet).
\texttt{max\_mag}(\texttt{other[, context]})

Similar to the \texttt{max()} method, but the comparison is done using the absolute values of the operands.

\textit{New in version 2.6.}

\texttt{min}(\texttt{other[, context]})

Like \texttt{min(self, other)} except that the context rounding rule is applied before returning and that \texttt{NaN} values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

\texttt{min\_mag}(\texttt{other[, context]})

Similar to the \texttt{min()} method, but the comparison is done using the absolute values of the operands.

\textit{New in version 2.6.}

\texttt{next\_minus}(\texttt{context})

Return the largest number representable in the given context (or in the current thread's context if no context is given) that is smaller than the given operand.

\textit{New in version 2.6.}

\texttt{next\_plus}(\texttt{context})

Return the smallest number representable in the given context (or in the current thread's context if no context is given) that is larger than the given operand.

\textit{New in version 2.6.}

\texttt{next\_toward}(\texttt{other[, context]})

If the two operands are unequal, return the number closest to
the first operand in the direction of the second operand. If both operands are numerically equal, return a copy of the first operand with the sign set to be the same as the sign of the second operand.

*New in version 2.6.*

**normalize([context])**

Normalize the number by stripping the rightmost trailing zeros and converting any result equal to `Decimal('0')` to `Decimal('0e0')`. Used for producing canonical values for members of an equivalence class. For example, `Decimal('32.100')` and `Decimal('0.321000e+2')` both normalize to the equivalent value `Decimal('32.1')`.

**number_class([context])**

Return a string describing the class of the operand. The returned value is one of the following ten strings.

- "-Infinity", indicating that the operand is negative infinity.
- "-Normal", indicating that the operand is a negative normal number.
- "-Subnormal", indicating that the operand is negative and subnormal.
- "-Zero", indicating that the operand is a negative zero.
- "+Zero", indicating that the operand is a positive zero.
- "+Subnormal", indicating that the operand is positive and subnormal.
- "+Normal", indicating that the operand is a positive normal number.
- "+Infinity", indicating that the operand is positive infinity.
- "NaN", indicating that the operand is a quiet NaN (Not a Number).
- "sNaN", indicating that the operand is a signaling NaN.

*New in version 2.6.*

`quantize(exp[, rounding[, context[, watchexp]]])`

Return a value equal to the first operand after rounding and having the exponent of the second operand.

```python
>>> Decimal('1.41421356').quantize(Decimal('1.000'))
Decimal('1.414')
```

Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an `InvalidOperation` is signaled. This guarantees that, unless there is an error condition, the quantized exponent is always equal to that of the right-hand operand.

Also unlike other operations, quantize never signals Underflow, even if the result is subnormal and inexact.

If the exponent of the second operand is larger than that of the first then rounding may be necessary. In this case, the rounding mode is determined by the `rounding` argument if given, else by the given `context` argument; if neither argument is given the rounding mode of the current thread's context is used.

If `watchexp` is set (default), then an error is returned whenever the resulting exponent is greater than `Emax` or less than `Etiny`.

`radix()`

Return `Decimal(10)`, the radix (base) in which the `Decimal` class does all its arithmetic. Included for compatibility with the
specification.

New in version 2.6.

**remainder_near**(other[, context])

Compute the modulo as either a positive or negative value depending on which is closest to zero. For instance, `Decimal(10).remainder_near(6)` returns `Decimal('-2')` which is closer to zero than `Decimal('4')`.

If both are equally close, the one chosen will have the same sign as `self`.

**rotate**(other[, context])

Return the result of rotating the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to rotate. If the second operand is positive then rotation is to the left; otherwise rotation is to the right. The coefficient of the first operand is padded on the left with zeros to length precision if necessary. The sign and exponent of the first operand are unchanged.

New in version 2.6.

**same_quantum**(other[, context])

Test whether self and other have the same exponent or whether both are NaN.

**scaleb**(other[, context])

Return the first operand with exponent adjusted by the second. Equivalently, return the first operand multiplied by `10**other`. The second operand must be an integer.
New in version 2.6.

**shift(other[, context])**
Return the result of shifting the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range \(-\text{precision}\) through \(\text{precision}\). The absolute value of the second operand gives the number of places to shift. If the second operand is positive then the shift is to the left; otherwise the shift is to the right. Digits shifted into the coefficient are zeros. The sign and exponent of the first operand are unchanged.

New in version 2.6.

**sqrt([context])**
Return the square root of the argument to full precision.

**to_eng_string([context])**
Convert to an engineering-type string.

Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts `Decimal('123E+1')` to `Decimal('1.23E+3')`

**to_integral([rounding[, context]]))**
Identical to the `to_integral_value()` method. The `to_integral` name has been kept for compatibility with older versions.

**to_integral_exact([rounding[, context]]))**
Round to the nearest integer, signaling `Inexact` or `Rounded` as appropriate if rounding occurs. The rounding mode is determined by the `rounding` parameter if given, else by the given `context`. If neither parameter is given then the rounding
mode of the current context is used.

*New in version 2.6.*

**`to_integral_value([rounding[, context]])`**

Round to the nearest integer without signaling **Inexact** or **Rounded**. If given, applies `rounding`; otherwise, uses the rounding method in either the supplied `context` or the current context.

*Changed in version 2.6:* renamed from `to_integral` to `to_integral_value`. The old name remains valid for compatibility.

### 9.4.2.1. Logical operands

The `logical_and()`, `logical_invert()`, `logical_or()`, and `logical_xor()` methods expect their arguments to be **logical operands**. A **logical operand** is a **Decimal** instance whose exponent and sign are both zero, and whose digits are all either 0 or 1.
9.4.3. Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the `getcontext()` and `setcontext()` functions:

```python
decimal.getcontext()
    Return the current context for the active thread.

decimal.setcontext(c)
    Set the current context for the active thread to c.
```

Beginning with Python 2.5, you can also use the `with` statement and the `localcontext()` function to temporarily change the active context.

```python
decimal.localcontext([c])
    Return a context manager that will set the current context for the active thread to a copy of c on entry to the with-statement and restore the previous context when exiting the with-statement. If no context is specified, a copy of the current context is used.

    New in version 2.5.
```

For example, the following code sets the current decimal precision to 42 places, performs a calculation, and then automatically restores the previous context:

```python
from decimal import localcontext

with localcontext() as ctx:
    ctx.prec = 42  # Perform a high precision calculation
    s = calculate_something()
```
New contexts can also be created using the `Context` constructor described below. In addition, the module provides three pre-made contexts:

### `class` `decimal.BasicContext`
This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_UP`. All flags are cleared. All traps are enabled (treated as exceptions) except `Inexact`, `Rounded`, and `Subnormal`.

Because many of the traps are enabled, this context is useful for debugging.

### `class` `decimal.ExtendedContext`
This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_EVEN`. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the traps are disabled, this context is useful for applications that prefer to have result value of `NaN` or `Infinity` instead of raising exceptions. This allows an application to complete a run in the presence of conditions that would otherwise halt the program.

### `class` `decimal.DefaultContext`
This context is used by the `Context` constructor as a prototype for new contexts. Changing a field (such a precision) has the effect of changing the default for new contexts created by the `Context` constructor.

This context is most useful in multi-threaded environments.
Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are precision=28, rounding=ROUND_HALF_EVEN, and enabled traps for Overflow, InvalidOperation, and DivisionByZero.

In addition to the three supplied contexts, new contexts can be created with the `Context` constructor.

```python
class decimal.Context(prec=None, rounding=None, traps=None, flags=None, Emin=None, Emax=None, capitals=1)
```

Creates a new context. If a field is not specified or is `None`, the default values are copied from the `DefaultContext`. If the `flags` field is not specified or is `None`, all flags are cleared.

The `prec` field is a positive integer that sets the precision for arithmetic operations in the context.

The `rounding` option is one of:

- `ROUND_CEILING` (towards `Infinity`),
- `ROUND_DOWN` (towards zero),
- `ROUND_FLOOR` (towards `-Infinity`),
- `ROUND_HALF_DOWN` (to nearest with ties going towards zero),
- `ROUND_HALF_EVEN` (to nearest with ties going to nearest even integer),
- `ROUND_HALF_UP` (to nearest with ties going away from zero), or
• **ROUND_UP** (away from zero).
• **ROUND_05UP** (away from zero if last digit after rounding towards zero would have been 0 or 5; otherwise towards zero)

The *traps* and *flags* fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.

The *Emin* and *Emax* fields are integers specifying the outer limits allowable for exponents.

The *capitals* field is either 0 or 1 (the default). If set to 1, exponents are printed with a capital E; otherwise, a lowercase e is used: `Decimal('6.02e+23')`.

*Changed in version 2.6:* The **ROUND_05UP** rounding mode was added.

The *Context* class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context. In addition, for each of the *Decimal* methods described above (with the exception of the `adjusted()` and `as_tuple()` methods) there is a corresponding *Context* method. For example, for a *Context* instance `c` and *Decimal* instance `x`, `c.exp(x)` is equivalent to `x.exp(context=c)`. Each *Context* method accepts a Python integer (an instance of `int` or `long`) anywhere that a Decimal instance is accepted.

```python
clear_flags()
    Resets all of the flags to 0.

copy()
    Return a duplicate of the context.

copy_decimal(num)
```
Return a copy of the Decimal instance num.

**create_decimal(num)**

Creates a new Decimal instance from `num` but using `self` as context. Unlike the Decimal constructor, the context precision, rounding method, flags, and traps are applied to the conversion.

This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:

```
>>> getcontext().prec = 3
>>> Decimal('3.4445') + Decimal('1.0023')
Decimal('4.45')
>>> Decimal('3.4445') + Decimal(0) + Decimal('1.0023')
Decimal('4.44')
```

This method implements the to-number operation of the IBM specification. If the argument is a string, no leading or trailing whitespace is permitted.

**create_decimal_from_float(f)**

Creates a new Decimal instance from a float `f` but rounding using `self` as the context. Unlike the `Decimal.from_float()` class method, the context precision, rounding method, flags, and traps are applied to the conversion.

```
>>> context = Context(prec=5, rounding=ROUND_DOWN)
>>> context.create_decimal_from_float(math.pi)
Decimal('3.1415')
>>> context = Context(prec=5, traps=[Inexact])
>>> context.create_decimal_from_float(math.pi)
Traceback (most recent call last):
  ...
New in version 2.7.

**Etiny()**

Returns a value equal to $E_{\text{min}} - \text{prec} + 1$ which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to Etiny.

**Etop()**

Returns a value equal to $E_{\text{max}} - \text{prec} + 1$.

The usual approach to working with decimals is to create Decimal instances and then apply arithmetic operations which take place within the current context for the active thread. An alternative approach is to use context methods for calculating within a specific context. The methods are similar to those for the Decimal class and are only briefly recounted here.

**abs**($x$)

Returns the absolute value of $x$.

**add**($x$, $y$)

Return the sum of $x$ and $y$.

**canonical**($x$)

Returns the same Decimal object $x$.

**compare**($x$, $y$)

Compares $x$ and $y$ numerically.

**compare_signal**($x$, $y$)

Compares the values of the two operands numerically.

**compare_total**($x$, $y$)

Compares two operands using their abstract representation.
**compare_total_mag**(*x, y*)

Compares two operands using their abstract representation, ignoring sign.

**copy_abs**(*x*)

Returns a copy of *x* with the sign set to 0.

**copy_negate**(*x*)

Returns a copy of *x* with the sign inverted.

**copy_sign**(*x, y*)

Copies the sign from *y* to *x*.

**divide**(*x, y*)

Return *x* divided by *y*.

**divide_int**(*x, y*)

Return *x* divided by *y*, truncated to an integer.

**divmod**(*x, y*)

Divides two numbers and returns the integer part of the result.

**exp**(*x*)

Returns $e^x$.

**fma**(*x, y, z*)

Returns *x* multiplied by *y*, plus *z*.

**is_canonical**(*x*)

Returns True if *x* is canonical; otherwise returns False.

**is_finite**(*x*)

Returns True if *x* is finite; otherwise returns False.

**is_infinite**(*x*)

Returns True if *x* is infinite; otherwise returns False.
is_nan(x)
Returns True if x is a qNaN or sNaN; otherwise returns False.

is_normal(x)
Returns True if x is a normal number; otherwise returns False.

is_qnan(x)
Returns True if x is a quiet NaN; otherwise returns False.

is_signed(x)
Returns True if x is negative; otherwise returns False.

is_snan(x)
Returns True if x is a signaling NaN; otherwise returns False.

is_subnormal(x)
Returns True if x is subnormal; otherwise returns False.

is_zero(x)
Returns True if x is a zero; otherwise returns False.

ln(x)
Returns the natural (base e) logarithm of x.

log10(x)
Returns the base 10 logarithm of x.

logb(x)
Returns the exponent of the magnitude of the operand's MSD.

logical_and(x, y)
Applies the logical operation and between each operand's digits.

logical_invert(x)
Invert all the digits in x.
\texttt{logical\_or}(x, y)
\hspace{1em} Applies the logical operation \textit{or} between each operand's digits.

\texttt{logical\_xor}(x, y)
\hspace{1em} Applies the logical operation \textit{xor} between each operand's digits.

\texttt{max}(x, y)
\hspace{1em} Compares two values numerically and returns the maximum.

\texttt{max\_mag}(x, y)
\hspace{1em} Compares the values numerically with their sign ignored.

\texttt{min}(x, y)
\hspace{1em} Compares two values numerically and returns the minimum.

\texttt{min\_mag}(x, y)
\hspace{1em} Compares the values numerically with their sign ignored.

\texttt{minus}(x)
\hspace{1em} Minus corresponds to the unary prefix minus operator in Python.

\texttt{multiply}(x, y)
\hspace{1em} Return the product of \textit{x} and \textit{y}.

\texttt{next\_minus}(x)
\hspace{1em} Returns the largest representable number smaller than \textit{x}.

\texttt{next\_plus}(x)
\hspace{1em} Returns the smallest representable number larger than \textit{x}.

\texttt{next\_toward}(x, y)
\hspace{1em} Returns the number closest to \textit{x}, in direction towards \textit{y}.

\texttt{normalize}(x)
Reduces $x$ to its simplest form.

**number_class($x$)**

Returns an indication of the class of $x$.

**plus($x$)**

Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is not an identity operation.

**power($x$, $y$, [modulo])**

Return $x$ to the power of $y$, reduced modulo modulo if given.

With two arguments, compute $x^{**}y$. If $x$ is negative then $y$ must be integral. The result will be inexact unless $y$ is integral and the result is finite and can be expressed exactly in 'precision' digits. The result should always be correctly rounded, using the rounding mode of the current thread's context.

With three arguments, compute $(x^{**}y) \%$ modulo. For the three argument form, the following restrictions on the arguments hold:

- all three arguments must be integral
- $y$ must be nonnegative
- at least one of $x$ or $y$ must be nonzero
- modulo must be nonzero and have at most 'precision' digits

The value resulting from `Context.power(x, y, modulo)` is equal to the value that would be obtained by computing $(x^{**}y) \%$ modulo with unbounded precision, but is computed more efficiently. The exponent of the result is zero, regardless
of the exponents of \(x\), \(y\), and modulo. The result is always exact.

*Changed in version 2.6:* \(y\) may now be nonintegral in \(x**y\). Stricter requirements for the three-argument version.

**quantize**(\(x, y\))

Returns a value equal to \(x\) (rounded), having the exponent of \(y\).

**radix**()

Just returns 10, as this is Decimal, :)

**remainder**(\(x, y\))

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the original dividend.

**remainder_near**(\(x, y\))

Returns \(x - y \times n\), where \(n\) is the integer nearest the exact value of \(x / y\) (if the result is 0 then its sign will be the sign of \(x\)).

**rotate**(\(x, y\))

Returns a rotated copy of \(x, y\) times.

**same_quantum**(\(x, y\))

Returns True if the two operands have the same exponent.

**scaleb**(\(x, y\))

Returns the first operand after adding the second value its exp.

**shift**(\(x, y\))

Returns a shifted copy of \(x, y\) times.
\[ \sqrt{x} \]  
Square root of a non-negative number to context precision.

\[ \text{subtract}(x, y) \]  
Return the difference between \( x \) and \( y \).

\[ \text{to_eng_string}(x) \]  
Converts a number to a string, using scientific notation.

\[ \text{to_integral_exact}(x) \]  
Rounds to an integer.

\[ \text{to_sci_string}(x) \]  
Converts a number to a string using scientific notation.
9.4.4. Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is set whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context's trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the `DivisionByZero` trap is set, then a `DivisionByZero` exception is raised upon encountering the condition.

```python
class decimal.Clamped
    Altered an exponent to fit representation constraints.

    Typically, clamping occurs when an exponent falls outside the
    context's Emin and Emax limits. If possible, the exponent is
    reduced to fit by adding zeros to the coefficient.

class decimal.DecimalException
    Base class for other signals and a subclass of ArithmeticError.

class decimal.DivisionByZero
    Signals the division of a non-infinite number by zero.

    Can occur with division, modulo division, or when raising a
    number to a negative power. If this signal is not trapped, returns
    Infinity or -Infinity with the sign determined by the inputs to
    the calculation.
```
**class** decimal. **Inexact**
Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.

**class** decimal. **InvalidOperation**
An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns *NaN*. Possible causes include:

```plaintext
Infinity - Infinity
0 * Infinity
Infinity / Infinity
x % 0
Infinity % x
x._rescale( non-integer )
sqrt(-x) and x > 0
0 ** 0
x ** (non-integer)
x ** Infinity
```

**class** decimal. **Overflow**
Numerical overflow.

Indicates the exponent is larger than *E_max* after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to *Infinity*. In either case, **Inexact** and **Rounded** are also signaled.

**class** decimal. **Rounded**
Rounding occurred though possibly no information was lost.

Signaled whenever rounding discards digits; even if those digits
are zero (such as rounding 5.00 to 5.0). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

```python
class decimal.Subnormal
    Exponent was lower than Emin prior to rounding.

    Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.
```

```python
class decimal.Underflow
    Numerical underflow with result rounded to zero.

    Occurs when a subnormal result is pushed to zero by rounding. **Inexact** and **Subnormal** are also signaled.
```

The following table summarizes the hierarchy of signals:

```
exceptions.ArithmeticError(exceptions.StandardError)
    DecimalException
        Clamped
        DivisionByZero(DecimalException, exceptions.ZeroDivisionError)
        Inexact
            Overflow(Inexact, Rounded)
            Underflow(Inexact, Rounded, Subnormal)
    InexactOperation
        Rounded
        Subnormal
```

9.4.5. Floating Point Notes

9.4.5.1. Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent $0.1$ exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```python
# Examples from Seminumerical Algorithms, Section 4.2.2.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7.51111111')
>>> (u + v) + w
Decimal('9.5111111')
>>> u + (v + w)
Decimal('10')

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.01')
>>> u * (v+w)
Decimal('0.0060000')
```

The `decimal` module makes it possible to restore the identities by expanding the precision sufficiently to avoid loss of significance:
9.4.5.2. Special values

The number system for the decimal module provides special values including \texttt{NaN}, \texttt{sNaN}, \texttt{-Infinity}, \texttt{Infinity}, and two zeros, \texttt{+0} and \texttt{-0}.

Infinities can be constructed directly with: \texttt{Decimal('Infinity')}. Also, they can arise from dividing by zero when the \texttt{DivisionByZero} signal is not trapped. Likewise, when the \texttt{Overflow} signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return \texttt{NaN}, or if the \texttt{InvalidOperation} signal is trapped, raise an exception. For example, \texttt{0/0} returns \texttt{NaN} which means “not a number”. This variety of \texttt{NaN} is quiet and, once created, will flow through other computations always resulting in another \texttt{NaN}. This behavior can be useful for a series of computations that occasionally have missing inputs — it allows the calculation to proceed while flagging specific results as invalid.
A variant is **sNaN** which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The behavior of Python’s comparison operators can be a little surprising where a **NaN** is involved. A test for equality where one of the operands is a quiet or signaling **NaN** always returns **False** (even when doing `Decimal('NaN')==Decimal('NaN')`), while a test for inequality always returns **True**. An attempt to compare two Decimals using any of the `<`, `<=`, `>` or `>=` operators will raise the `InvalidOperation` signal if either operand is a **NaN**, and return **False** if this signal is not trapped. Note that the General Decimal Arithmetic specification does not specify the behavior of direct comparisons; these rules for comparisons involving a **NaN** were taken from the IEEE 854 standard (see Table 3 in section 5.7). To ensure strict standards-compliance, use the `compare()` and `compare-signal()` methods instead.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.

In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation returns a value equal to zero:

```python
>>> 1 / Decimal('Infinity')
Decimal('0E-1000000026')
```
9.4.6. Working with threads

The `getcontext()` function accesses a different `Context` object for each thread. Having separate thread contexts means that threads may make changes (such as `getcontext.prec=10`) without interfering with other threads.

Likewise, the `setcontext()` function automatically assigns its target to the current thread.

If `setcontext()` has not been called before `getcontext()`, then `getcontext()` will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called `DefaultContext`. To control the defaults so that each thread will use the same values throughout the application, directly modify the `DefaultContext` object. This should be done before any threads are started so that there won’t be a race condition between threads calling `getcontext()`. For example:

```python
# Set applicationwide defaults for all threads about to be launched
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
T1.start()
T2.start()
T3.start()
...
```

...
9.4.7. Recipes

Here are a few recipes that serve as utility functions and that demonstrate ways to work with the `Decimal` class:

```python
def moneyfmt(value, places=2, curr='', sep=',', dp='.', pos='', neg='-', trailneg=''):    ""
    Convert Decimal to a money formatted string.
    
    places: required number of places after the decimal point
    curr: optional currency symbol before the sign (may be blank)
    sep: optional grouping separator (comma, period, space, etc.)
    dp: decimal point indicator (comma or period)
        only specify as blank when places is zero
    pos: optional sign for positive numbers: '+', space or blank
    neg: optional sign for negative numbers: '-', '(', space
    trailneg:optional trailing minus indicator: ' -', ')', space

    >>> d = Decimal('-1234567.8901')
    >>> moneyfmt(d, curr='$')
    '$-1,234,567.89'
    >>> moneyfmt(d, places=0, sep='.', dp='', neg='', trailneg='-')
    '1.234.568-'
    >>> moneyfmt(d, curr='$', neg='(', trailneg=')')
    '($1,234,567.89)'
    >>> moneyfmt(Decimal(123456789), sep='	')
    '123	456	789.00'
    >>> moneyfmt(Decimal('-0.02'), neg='<', trailneg=')')
    '<0.02>'
    
    ""
    q = Decimal(10) ** -places        # 2 places --> '0.01'
    sign, digits, exp = value.quantize(q).as_tuple()
    result = []
    digits = map(str, digits)
    build, next = result.append, digits.pop
    if sign:
        build(trailneg)
    for i in range(places):
        build(next() if digits else '0')
    build(dp)
    if not digits:
        build('0')
```

i = 0
while digits:
    build(next())
    i += 1
    if i == 3 and digits:
        i = 0
        build(sep)
    build(curr)
build(neg if sign else pos)
return ''.join(reversed(result))

def pi():
    """Compute Pi to the current precision."

    >>> print pi()
    3.141592653589793238462643383
    ""
    getcontext().prec += 2  # extra digits for intermediate steps
    three = Decimal(3)  # substitute "three=3.0" for regular floats
    lasts, t, s, n, na, d, da = 0, three, 3, 1, 0, 0, 24
    while s != lasts:
        lasts = s
        n, na = n+na, na+8
        d, da = d+da, da+32
        t = (t * n) / d
        s += t
    getcontext().prec -= 2
    return +s  # unary plus applies the new precision

def exp(x):
    """Return e raised to the power of x. Result type matches
    ""
    >>> print exp(Decimal(1))
    2.718281828459045235360287471
    >>> print exp(Decimal(2))
    7.389056098930650227230427461
    >>> print exp(2.0)
    7.38905609893
    >>> print exp(2+0j)
    (7.38905609893+0j)
    ""
    getcontext().prec += 2
    i, lasts, s, fact, num = 0, 0, 1, 1, 1
    while s != lasts:
        lasts = s
i += 1
fact *= i
num *= x
s += num / fact
getcontext().prec -= 2
return +s

def cos(x):
    """Return the cosine of x as measured in radians."

    >>> print cos(Decimal('0.5'))
    0.8775825618903727161162815826
    >>> print cos(0.5)
    0.87758256189
    >>> print cos(0.5+0j)
    (0.87758256189+0j)
    """
    getcontext().prec += 2
    i, lasts, s, fact, num, sign = 0, 0, 1, 1, 1, 1
    while s != lasts:
        lasts = s
        i += 2
        fact *= i * (i-1)
        num *= x * x
        sign *= -1
        s += num / fact * sign
    getcontext().prec -= 2
    return +s

def sin(x):
    """Return the sine of x as measured in radians."

    >>> print sin(Decimal('0.5'))
    0.4794255386042030002732879352
    >>> print sin(0.5)
    0.479425538604
    >>> print sin(0.5+0j)
    (0.479425538604+0j)
    """
    getcontext().prec += 2
    i, lasts, s, fact, num, sign = 1, 0, x, 1, x, 1
    while s != lasts:
        lasts = s
        i += 2
        fact *= i * (i-1)
num *= x * x
sign *= -1
s += num / fact * sign
getcontext().prec -= 2
return +s
9.4.8. Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5')`. Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```python
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal('4.68')
```

Q. In a fixed-point application with two decimal places, some inputs have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The `quantize()` method rounds to a fixed number of decimal places. If the `Inexact` trap is set, it is also useful for validation:

```python
>>> TWOPLACES = Decimal(10) ** -2  # same as Decimal('0.01')

>>> # Round to two places
>>> Decimal('3.214').quantize(TWOPLACES)
Decimal('3.21')

>>> # Validate that a number does not exceed two places
>>> Decimal('3.21').quantize(TWOPLACES, context=Context(traps=[Inexact]))
Decimal('3.21')
```

Q. Once I have valid two place inputs, how do I maintain that
invariant throughout an application?

A. Some operations like addition, subtraction, and multiplication by an integer will automatically preserve fixed point. Others operations, like division and non-integer multiplication, will change the number of decimal places and need to be followed-up with a `quantize()` step:

```python
>>> a = Decimal('102.72')  # Initial fixed-point value
>>> b = Decimal('3.17')  # Addition preserves fixed-point
>>> a + b
Decimal('105.89')
>>> a - b
Decimal('99.55')
>>> a * b
Decimal('4314.24')
>>> (a * b).quantize(TWOPLACES)  # Must quantize non-integer multiplication
Decimal('325.62')
>>> (b / a).quantize(TWOPLACES)  # And quantize division
Decimal('0.03')
```

In developing fixed-point applications, it is convenient to define functions to handle the `quantize()` step:

```python
>>> def mul(x, y, fp=TWOPLACES):
...     return (x * y).quantize(fp)
>>> def div(x, y, fp=TWOPLACES):
...     return (x / y).quantize(fp)
```

Q. There are many ways to express the same value. The numbers `200`, `200.000`, `2E2`, and `02E+4` all have the same value at various precisions. Is there a way to transform them to a single recognizable canonical value?
A. The `normalize()` method maps all equivalent values to a single representative:

```python
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split())
>>> [v.normalize() for v in values]
[Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2')]
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing 5.0E+3 as 5000 keeps the value constant but cannot show the original’s two-place significance.

If an application does not care about tracking significance, it is easy to remove the exponent and trailing zeros, losing significance, but keeping the value unchanged:

```python
def remove_exponent(d):
    '''Remove exponent and trailing zeros.'''
    >>> remove_exponent(Decimal('5E+3'))
    Decimal('5000')

    return d.quantize(Decimal(1)) if d == d.to_integral() else
    return d.normalize()
```

Q. Is there a way to convert a regular float to a `Decimal`?

A. Yes, any binary floating point number can be exactly expressed as a Decimal though an exact conversion may take more precision than intuition would suggest:

```python
>>> Decimal(math.pi)
Decimal('3.14159265358979311599763468544185161590576171875')
```
Q. Within a complex calculation, how can I make sure that I haven’t gotten a spurious result because of insufficient precision or rounding anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that “what you type is what you get”. A disadvantage is that the results can look odd if you forget that the inputs haven’t been rounded:

```python
>>> getcontext().prec = 3
>>> Decimal('3.104') + Decimal('2.104')
Decimal('5.21')
>>> Decimal('3.104') + Decimal('0.000') + Decimal('2.104')
Decimal('5.20')
```

The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```python
>>> getcontext().prec = 3
>>> +Decimal('1.23456789')  # unary plus triggers rounding
Decimal('1.23')
```

Alternatively, inputs can be rounded upon creation using the `Context.create_decimal()` method:

```python
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal('1.2345'
```
The *fractions* module provides support for rational number arithmetic.

A Fraction instance can be constructed from a pair of integers, from another rational number, or from a string.

```python
class fractions.Fraction(numerator=0, denominator=1)
class fractions.Fraction(other_fraction)
class fractions.Fraction(float)
class fractions.Fraction(decimal)
class fractions.Fraction(string)
```

The first version requires that `numerator` and `denominator` are instances of `numbers.Rational` and returns a new `Fraction` instance with value `numerator/denominator`. If `denominator` is 0, it raises a `ZeroDivisionError`. The second version requires that `other_fraction` is an instance of `numbers.Rational` and returns a `Fraction` instance with the same value. The next two versions accept either a `float` or a `decimal.Decimal` instance, and return a `Fraction` instance with exactly the same value. Note that due to the usual issues with binary floating-point (see *Floating Point Arithmetic: Issues and Limitations*), the argument to `Fraction(1.1)` is not exactly equal to 11/10, and so `Fraction(1.1)` does *not* return `Fraction(11, 10)` as one might expect. (But see the documentation for the `limit_denominator()` method below.) The last version of the constructor expects a string or unicode instance. The usual form for this instance is:

```
[sign] numerator ['/' denominator]
```
where the optional `sign` may be either '+' or '-' and `numerator` and `denominator` (if present) are strings of decimal digits. In addition, any string that represents a finite value and is accepted by the `float` constructor is also accepted by the `Fraction` constructor. In either form the input string may also have leading and/or trailing whitespace. Here are some examples:

```python
>>> from fractions import Fraction
>>> Fraction(16, -10)
Fraction(-8, 5)
>>> Fraction(123)
Fraction(123, 1)
>>> Fraction()
Fraction(0, 1)
>>> Fraction('3/7')
Fraction(3, 7)
[40794 refs]
>>> Fraction(' -3/7 ')
Fraction(-3, 7)
>>> Fraction('1.414213 \t\n')
Fraction(1414213, 1000000)
>>> Fraction('- .125')
Fraction(-1, 8)
>>> Fraction('7e-6')
Fraction(7, 1000000)
>>> Fraction(2.25)
Fraction(9, 4)
>>> Fraction(1.1)
Fraction(2476979795053773, 2251799813685248)
>>> from decimal import Decimal
>>> Fraction(Decimal('1.1'))
Fraction(11, 10)
```

The `Fraction` class inherits from the abstract base class `numbers.Rational`, and implements all of the methods and operations from that class. `Fraction` instances are hashable, and should be treated as immutable. In addition, `Fraction` has the following methods:

*Changed in version 2.7:* The `Fraction` constructor now accepts
float and decimal.Decimal instances.

from_float(flt)
This class method constructs a Fraction representing the exact value of flt, which must be a float. Beware that Fraction.from_float(0.3) is not the same value as Fraction(3, 10)

Note: From Python 2.7 onwards, you can also construct a Fraction instance directly from a float.

from_decimal(dec)
This class method constructs a Fraction representing the exact value of dec, which must be a decimal.Decimal.

Note: From Python 2.7 onwards, you can also construct a Fraction instance directly from a decimal.Decimal instance.

limit_denominator(max_denominator=1000000)
Finds and returns the closest Fraction to self that has denominator at most max_denominator. This method is useful for finding rational approximations to a given floating-point number:

```python
>>> from fractions import Fraction
>>> Fraction('3.1415926535897932').limit_denominator(1000)
Fraction(355, 113)
```

or for recovering a rational number that's represented as a float:

```python
>>> from math import pi, cos
>>> Fraction(cos(pi/3))
Fraction(4503599627370497, 9007199254740992)
```
fractions. \textbf{gcd}(a, b)

Return the greatest common divisor of the integers \(a\) and \(b\). If either \(a\) or \(b\) is nonzero, then the absolute value of \(\text{gcd}(a, b)\) is the largest integer that divides both \(a\) and \(b\). \(\text{gcd}(a, b)\) has the same sign as \(b\) if \(b\) is nonzero; otherwise it takes the sign of \(a\). \(\text{gcd}(0, 0)\) returns 0.

\textbf{Module} numbers

The abstract base classes making up the numeric tower.
9.6. random — Generate pseudo-random numbers

This module implements pseudo-random number generators for various distributions.

For integers, uniform selection from a range. For sequences, uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function `random()`, which generates a random float uniformly in the semi-open range [0.0, 1.0). Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of $2^{19937}-1$. The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the `random.Random` class. You can instantiate your own instances of `Random` to get generators that don't share state. This is especially useful for multi-threaded programs, creating a different instance of `Random` for each thread, and using the `jumpahead()` method to make it likely that the generated sequences seen by each thread don't overlap.
Class `Random` can also be subclassed if you want to use a different basic generator of your own devising: in that case, override the `random()`, `seed()`, `getstate()`, `setstate()` and `jumpahead()` methods. Optionally, a new generator can supply a `getrandbits()` method — this allows `randrange()` to produce selections over an arbitrarily large range.

*New in version 2.4:* the `getrandbits()` method.

As an example of subclassing, the `random` module provides the `WichmannHill` class that implements an alternative generator in pure Python. The class provides a backward compatible way to reproduce results from earlier versions of Python, which used the Wichmann-Hill algorithm as the core generator. Note that this Wichmann-Hill generator can no longer be recommended: its period is too short by contemporary standards, and the sequence generated is known to fail some stringent randomness tests. See the references below for a recent variant that repairs these flaws.

*Changed in version 2.3:* MersenneTwister replaced Wichmann-Hill as the default generator.

The `random` module also provides the `SystemRandom` class which uses the system function `os.urandom()` to generate random numbers from sources provided by the operating system.

Bookkeeping functions:

`random.seed([x])`

Initialize the basic random number generator. Optional argument `x` can be any `hashable` object. If `x` is omitted or `None`, current system time is used; current system time is also used to initialize the generator when the module is first imported. If randomness sources are provided by the operating system, they are used
instead of the system time (see the `os.urandom()` function for details on availability).

*Changed in version 2.4:* formerly, operating system resources were not used.

If `x` is not `None` or an int or long, `hash(x)` is used instead. If `x` is an int or long, `x` is used directly.

```python
random.getstate()
```

Return an object capturing the current internal state of the generator. This object can be passed to `setstate()` to restore the state.

*New in version 2.1.*

*Changed in version 2.6:* State values produced in Python 2.6 cannot be loaded into earlier versions.

```python
random.setstate(state)
```

`state` should have been obtained from a previous call to `getstate()`, and `setstate()` restores the internal state of the generator to what it was at the time `setstate()` was called.

*New in version 2.1.*

```python
random.jumpahead(n)
```

Change the internal state to one different from and likely far away from the current state. `n` is a non-negative integer which is used to scramble the current state vector. This is most useful in multi-threaded programs, in conjunction with multiple instances of the `Random` class: `setstate()` or `seed()` can be used to force all instances into the same internal state, and then `jumpahead()` can be used to force the instances’ states far apart.
New in version 2.1.

Changed in version 2.3: Instead of jumping to a specific state, \( n \) steps ahead, \texttt{jumpahead}(n) jumps to another state likely to be separated by many steps.

\texttt{random.getrandbits}(k)

Returns a python \texttt{long} int with \( k \) random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, \texttt{getrandbits()} enables \texttt{randrange()} to handle arbitrarily large ranges.

New in version 2.4.

Functions for integers:

\texttt{random.randint}(a, b)

Return a random integer \( N \) such that \( a \leq N \leq b \).

Functions for sequences:

\texttt{random.choice}(seq)

Return a random element from the non-empty sequence \( \texttt{seq} \). If \( \texttt{seq} \) is empty, raises \texttt{IndexError}.

\texttt{random.shuffle}(x[, random])
Shuffle the sequence \( x \) in place. The optional argument \( \text{random} \) is a 0-argument function returning a random float in \([0.0, 1.0)\); by default, this is the function \( \text{random()} \).

Note that for even rather small \( \text{len}(x) \), the total number of permutations of \( x \) is larger than the period of most random number generators; this implies that most permutations of a long sequence can never be generated.

random. \texttt{sample}(\textit{population}, \textit{k})

Return a \( k \) length list of unique elements chosen from the population sequence. Used for random sampling without replacement.

\textit{New in version 2.3.}

Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the subslices).

Members of the population need not be \textit{hashable} or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

To choose a sample from a range of integers, use an \texttt{xrange()} object as an argument. This is especially fast and space efficient for sampling from a large population: \texttt{sample(xrange(10000000), 60)}.

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution’s equation, as used in common mathematical practice; most of these equations can be found in any statistics text.
random.\texttt{random}()

Return the next random floating point number in the range [0.0, 1.0).

random.\texttt{uniform}(a, b)

Return a random floating point number \(N\) such that \(a \leq N \leq b\)
for \(a \leq b\) and \(b \leq N \leq a\) for \(b < a\).

The end-point value \(b\) may or may not be included in the range depending on floating-point rounding in the equation \(a + (b-a) \times \texttt{random}()\).

random.\texttt{triangular}(low, high, mode)

Return a random floating point number \(N\) such that \(\text{low} \leq N \leq \text{high}\) and with the specified \textit{mode} between those bounds. The \textit{low} and \textit{high} bounds default to zero and one. The \textit{mode} argument defaults to the midpoint between the bounds, giving a symmetric distribution.

\textit{New in version 2.6.}

random.\texttt{betavariate}(alpha, beta)

Beta distribution. Conditions on the parameters are \(\text{alpha} > 0\) and \(\text{beta} > 0\). Returned values range between 0 and 1.

random.\texttt{expovariate}(\textit{lambd})

Exponential distribution. \(\textit{lambd}\) is 1.0 divided by the desired mean. It should be nonzero. (The parameter would be called “\textit{lambda}”, but that is a reserved word in Python.) Returned values range from 0 to positive infinity if \(\textit{lambd}\) is positive, and from negative infinity to 0 if \(\textit{lambd}\) is negative.

random.\texttt{gammavariate}(alpha, beta)

Gamma distribution. (\textit{Not} the gamma function!) Conditions on the
parameters are \( \alpha > 0 \) and \( \beta > 0 \).

\texttt{random. gauss(mu, sigma)}

Gaussian distribution. \( mu \) is the mean, and \( sigma \) is the standard deviation. This is slightly faster than the \texttt{normalvariate()} function defined below.

\texttt{random. lognormvariate(mu, sigma)}

Log normal distribution. If you take the natural logarithm of this distribution, you'll get a normal distribution with mean \( mu \) and standard deviation \( sigma \). \( mu \) can have any value, and \( sigma \) must be greater than zero.

\texttt{random. normalvariate(mu, sigma)}

Normal distribution. \( mu \) is the mean, and \( sigma \) is the standard deviation.

\texttt{random. vonmisesvariate(mu, kappa)}

\( mu \) is the mean angle, expressed in radians between 0 and 2\(\pi\), and \( kappa \) is the concentration parameter, which must be greater than or equal to zero. If \( kappa \) is equal to zero, this distribution reduces to a uniform random angle over the range 0 to 2\(\pi\).

\texttt{random. paretovariate(alpha)}

Pareto distribution. \( alpha \) is the shape parameter.

\texttt{random. weibullvariate(alpha, beta)}

Weibull distribution. \( alpha \) is the scale parameter and \( beta \) is the shape parameter.

Alternative Generators:

\texttt{class random. WichmannHill([seed])}

Class that implements the Wichmann-Hill algorithm as the core
generator. Has all of the same methods as `Random` plus the `whseed()` method described below. Because this class is implemented in pure Python, it is not threadsafe and may require locks between calls. The period of the generator is 6,953,607,871,644 which is small enough to require care that two independent random sequences do not overlap.

`random.whseed([x])`

This is obsolete, supplied for bit-level compatibility with versions of Python prior to 2.1. See `seed()` for details. `whseed()` does not guarantee that distinct integer arguments yield distinct internal states, and can yield no more than about $2^{24}$ distinct internal states in all.

`class random.SystemRandom([seed])`

Class that uses the `os.urandom()` function for generating random numbers from sources provided by the operating system. Not available on all systems. Does not rely on software state and sequences are not reproducible. Accordingly, the `seed()` and `jumpahead()` methods have no effect and are ignored. The `getstate()` and `setstate()` methods raise `NotImplementedError` if called.

*New in version 2.4.*

Examples of basic usage:

```python
>>> random.random()  # Random float x, 0.0 <= x < 1.0
0.37444887175646646
>>> random.uniform(1, 10)  # Random float x, 1.0 <= x < 10.0
1.1800146073117523
>>> random.randint(1, 10)  # Integer from 1 to 10, endpoints included
7
>>> random.randrange(0, 101, 2)  # Even integer from 0 to 100
26
>>> random.choice('abcdefghij')  # Choose a random element
```
'c'

```python
>>> items = [1, 2, 3, 4, 5, 6, 7]
>>> random.shuffle(items)
>>> items
[7, 3, 2, 5, 6, 4, 1]
>>> random.sample([1, 2, 3, 4, 5], 3)  # Choose 3 elements
[4, 1, 5]
```

**Complementary-Multiply-with-Carry recipe** for a compatible alternative random number generator with a long period and comparatively simple update operations.
9.7. `itertools` — Functions creating iterators for efficient looping

New in version 2.3.

This module implements a number of iterator building blocks inspired by constructs from APL, Haskell, and SML. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Together, they form an “iterator algebra” making it possible to construct specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence `f(0), f(1), ...`. The same effect can be achieved in Python by combining `imap()` and `count()` to form `imap(f, count())`.

These tools and their built-in counterparts also work well with the high-speed functions in the `operator` module. For example, the multiplication operator can be mapped across two vectors to form an efficient dot-product: `sum(imap(operator.mul, vector1, vector2)).`

### Infinite Iterators:

<table>
<thead>
<tr>
<th>Iterator</th>
<th>Arguments</th>
<th>Results</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>count()</code></td>
<td>start, [step]</td>
<td>start, start+step, start+2*step, ...</td>
<td><code>count(10) --&gt; 10 11 12 13 14 ...</code></td>
</tr>
<tr>
<td><code>cycle()</code></td>
<td>p</td>
<td>p0, p1, ... plast, p0, p1, ...</td>
<td><code>cycle('ABCD') --&gt; A B C D A B C D ...</code></td>
</tr>
<tr>
<td><code>repeat()</code></td>
<td>elem [,n]</td>
<td>elem, elem, elem, ... endlessly or up to n</td>
<td><code>repeat(10, 3) --&gt;</code></td>

<td></td>
<td></td>
</tr>
</tbody>
</table>
The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

**itertools.** **chain(** iterables **)**
Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Equivalent to:

```python
def chain(*iterables):
    # chain('ABC', 'DEF') --> A B C D E F
    for it in iterables:
        for element in it:
            yield element
```

**itertools.chain.** **from_iterable(iterable)**
Alternate constructor for chain(). Gets chained inputs from a single iterable argument that is evaluated lazily. Equivalent to:

```python
@classmethod
def from_iterable(iterables):
    # chain.from_iterable(['ABC', 'DEF']) --> A B C D E F
    for it in iterables:
        for element in it:
            yield element
```

*New in version 2.6.*

**itertools.** **combinations**( iterable, r )
Return r length subsequences of elements from the input iterable.

Combinations are emitted in lexicographic sort order. So, if the input iterable is sorted, the combination tuples will be produced in
Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each combination.

Equivalent to:

```python
def combinations(iterable, r):
    # combinations('ABCD', 2) --> AB AC AD BC BD CD
    # combinations(range(4), 3) --> 012 013 023 123
    pool = tuple(iterable)
    n = len(pool)
    if r > n:
        return
    indices = range(r)
    yield tuple(pool[i] for i in indices)
    while True:
        for i in reversed(range(r)):
            if indices[i] != i + n - r:
                break
        else:
            return
        indices[i] += 1
        for j in range(i+1, r):
            indices[j] = indices[j-1] + 1
        yield tuple(pool[i] for i in indices)
```

The code for `combinations()` can be also expressed as a subsequence of `permutations()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```python
def combinations(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in permutations(range(n), r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)
```

The number of items returned is \( \frac{n!}{r! \cdot (n-r)!} \) when \( 0 \leq r \leq n \).
<= n or zero when r > n.

*New in version 2.6.*

`itertools.combinations_with_replacement(iterable, r)`

Return `r` length subsequences of elements from the input `iterable` allowing individual elements to be repeated more than once.

Combinations are emitted in lexicographic sort order. So, if the input `iterable` is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, the generated combinations will also be unique.

Equivalent to:

```python
def combinations_with_replacement(iterable, r):
    # combinations_with_replacement('ABC', 2) --> AA AB AC B
    pool = tuple(iterable)
    n = len(pool)
    if not n and r:
        return
    indices = [0] * r
    yield tuple(pool[i] for i in indices)
    while True:
        for i in reversed(range(r)):
            if indices[i] != n - 1:
                break
        else:
            return
        indices[i:] = [indices[i] + 1] * (r - i)
    yield tuple(pool[i] for i in indices)
```

The code for `combinations_with_replacement()` can be also expressed as a subsequence of `product()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):
def combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in product(range(n), repeat=r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)

The number of items returned is \((n+r-1)! / r! / (n-1)!\) when \(n > 0\).

*New in version 2.7.*

**itertools.compress(data, selectors)**

Make an iterator that filters elements from `data` returning only those that have a corresponding element in `selectors` that evaluates to `True`. Stops when either the `data` or `selectors` iterables has been exhausted. Equivalent to:

```python
def compress(data, selectors):
    # compress('ABCDEF', [1,0,1,0,1,1]) --> A C E F
    return (d for d, s in izip(data, selectors) if s)
```

*New in version 2.7.*

**itertools.count(start=0, step=1)**

Make an iterator that returns evenly spaced values starting with \(n\). Often used as an argument to `imap()` to generate consecutive data points. Also, used with `izip()` to add sequence numbers. Equivalent to:

```python
def count(start=0, step=1):
    # count(10) --> 10 11 12 13 14 ...
    # count(2.5, 0.5) --> 3.5 3.0 4.5 ...
    n = start
    while True:
        yield n
        n += step
```
When counting with floating point numbers, better accuracy can sometimes be achieved by substituting multiplicative code such as: *(start + step * i for i in count()).*

*Changed in version 2.7: added step argument and allowed non-integer arguments.*

**itertools.**`cycle(iterable)`

Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Equivalent to:

```python
def cycle(iterable):
    # cycle('ABCD') --> A B C D A B C D A B C D ...
    saved = []
    for element in iterable:
        yield element
        saved.append(element)
    while saved:
        for element in saved:
            yield element
```

Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

**itertools.**`dropwhile(predicate, iterable)`

Make an iterator that drops elements from the iterable as long as the predicate is true; afterwards, returns every element. Note, the iterator does not produce any output until the predicate first becomes false, so it may have a lengthy start-up time. Equivalent to:

```python
def dropwhile(predicate, iterable):
    # dropwhile(lambda x: x<5, [1,4,6,4,1]) --> 6 4 1
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
        break
```
for x in iterable:
    yield x

```
for x in iterable:
    yield x
```

**itertools.groupby(iterable[, key])**

Make an iterator that returns consecutive keys and groups from the *iterable*. The *key* is a function computing a key value for each element. If not specified or is *None*, *key* defaults to an identity function and returns the element unchanged. Generally, the iterable needs to already be sorted on the same key function.

The operation of `groupby()` is similar to the `uniq` filter in Unix. It generates a break or new group every time the value of the key function changes (which is why it is usually necessary to have sorted the data using the same key function). That behavior differs from SQL’s GROUP BY which aggregates common elements regardless of their input order.

The returned group is itself an iterator that shares the underlying iterable with `groupby()`. Because the source is shared, when the `groupby()` object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```
groups = []
uniquekeys = []
data = sorted(data, key=keyfunc)
for k, g in groupby(data, keyfunc):
    groups.append(list(g))  # Store group iterator as a
    uniquekeys.append(k)
```

`groupby()` is equivalent to:

```
class groupby(object):
    # [k for k, g in groupby('AAAAABBBCCDAABBB')] --> A B C D
    # [list(g) for k, g in groupby('AAAAABBBCCD')] --> AAAA B
    def __init__(self, iterable, key=None):
        if key is None:
New in version 2.4.

**itertools.ifilter**(predicate, iterable)

Make an iterator that filters elements from iterable returning only those for which the predicate is True. If predicate is None, return the items that are true. Equivalent to:

```python
def ifilter(predicate, iterable):
    # ifilter(lambda x: x%2, range(10)) --> 1 3 5 7 9
    if predicate is None:
        predicate = bool
    for x in iterable:
        if predicate(x):
            yield x
```

**itertools.ifilterfalse**(predicate, iterable)

Make an iterator that filters elements from iterable returning only those for which the predicate is False. If predicate is None, return the items that are false. Equivalent to:

```python
def ifilterfalse(predicate, iterable):
    # ifilterfalse(lambda x: x%2, range(10)) --> 0 2 4 6 8
    if predicate is None:
```
```python
def imap(function, *iterables):
    # imap(pow, (2,3,10), (5,2,3)) --> 32 9 1000
    iterables = map(iter, iterables)
    while True:
        args = [next(it) for it in iterables]
        if function is None:
            yield tuple(args)
        else:
            yield function(*args)
```

**itertools.** `imap(function, *iterables)`

Make an iterator that computes the function using arguments from each of the iterables. If `function` is set to `None`, then `imap()` returns the arguments as a tuple. Like `map()` but stops when the shortest iterable is exhausted instead of filling in `None` for shorter iterables. The reason for the difference is that infinite iterator arguments are typically an error for `map()` (because the output is fully evaluated) but represent a common and useful way of supplying arguments to `imap()`. Equivalent to:

```
predicate = bool
for x in iterable:
    if not predicate(x):
        yield x
```

**itertools.** `islice(iterable[, start], stop[, step])`

Make an iterator that returns selected elements from the iterable. If `start` is non-zero, then elements from the iterable are skipped until start is reached. Afterward, elements are returned consecutively unless `step` is set higher than one which results in items being skipped. If `stop` is `None`, then iteration continues until the iterator is exhausted, if at all; otherwise, it stops at the specified position. Unlike regular slicing, `islice()` does not support negative values for `start`, `stop`, or `step`. Can be used to extract related fields from data where the internal structure has been flattened (for example, a multi-line report may list a name
def islice(iterable, *args):
    # islice('ABCDEFG', 2) --> A B
    # islice('ABCDEFG', 2, 4) --> C D
    # islice('ABCDEFG', 2, None) --> C D E F G
    # islice('ABCDEFG', 0, None, 2) --> A C E G
    s = slice(*args)
    it = iter(xrange(s.start or 0, s.stop or sys.maxint, s.step or 1))
    nexti = next(it)
    for i, element in enumerate(iterable):
        if i == nexti:
            yield element
        nexti = next(it)

If start is None, then iteration starts at zero. If step is None, then
the step defaults to one.

*Changed in version 2.5:* accept None values for default start and step.

```
itertools.izip(*iterables)
```

Make an iterator that aggregates elements from each of the
iterables. Like `zip()` except that it returns an iterator instead of a
list. Used for lock-step iteration over several iterables at a time.
Equivalent to:

```
def izip(*iterables):
    # izip('ABCD', 'xy') --> Ax By
    iterables = map(iter, iterables)
    while iterables:
        yield tuple(map(next, iterables))
```

*Changed in version 2.4:* When no iterables are specified, returns
a zero length iterator instead of raising a TypeError exception.

The left-to-right evaluation order of the iterables is guaranteed.
This makes possible an idiom for clustering a data series into n-
length groups using `izip(*[iter(s)]*n)`.

`izip()` should only be used with unequal length inputs when you don’t care about trailing, unmatched values from the longer iterables. If those values are important, use `izip_longest()` instead.

**itertools.izip_longest(*iterables[, fillvalue])**

Make an iterator that aggregates elements from each of the iterables. If the iterables are of uneven length, missing values are filled-in with `fillvalue`. Iteration continues until the longest iterable is exhausted. Equivalent to:

```python
def izip_longest(*args, **kwds):
    # izip_longest('ABCD', 'xy', fillvalue='-') --> Ax By C-
    fillvalue = kwds.get('fillvalue')
    def sentinel(counter = ([fillvalue]*(len(args)-1)).pop):
        yield counter()  # yields the fillvalue, or raises IndexError
    fillers = repeat(fillvalue)
    iters = [chain(it, sentinel(), fillers) for it in args]
    try:
        for tup in izip(*iters):
            yield tup
    except IndexError:
        pass
```

If one of the iterables is potentially infinite, then the `izip_longest()` function should be wrapped with something that limits the number of calls (for example `islice()` or `takewhile()`). If not specified, `fillvalue` defaults to `None`.

*New in version 2.6.*

**itertools.permutations(iterable[, r])**

Return successive `r` length permutations of elements in the `iterable`. 
If \( r \) is not specified or is \texttt{None}, then \( r \) defaults to the length of the \texttt{iterable} and all possible full-length permutations are generated.

Permutations are emitted in lexicographic sort order. So, if the input \texttt{iterable} is sorted, the permutation tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each permutation.

Equivalent to:

```python
def permutations(iterable, r=None):
    # permutations('ABCD', 2) --> AB AC AD BA BC BD CA CB CD
    # permutations(range(3)) --> 012 021 102 120 201 210
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    if r > n:
        return
    indices = range(n)
    cycles = range(n, n-r, -1)
    yield tuple(pool[i] for i in indices[:r])
    while n:
        for i in reversed(range(r)):
            cycles[i] -= 1
            if cycles[i] == 0:
                indices[i:] = indices[i+1:] + indices[i:i+1]
                cycles[i] = n - i
            else:
                j = cycles[i]
                indices[i], indices[-j] = indices[-j], indices[i]
                yield tuple(pool[i] for i in indices[:r])
        else:
            break
    else:
        return
```

The code for \texttt{permutations()} can be also expressed as a subsequence of \texttt{product()}, filtered to exclude entries with
repeated elements (those from the same position in the input pool):

```python
def permutations(iterable, r=None):
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    for indices in product(range(n), repeat=r):
        if len(set(indices)) == r:
            yield tuple(pool[i] for i in indices)
```

The number of items returned is $n! / (n-r)!$ when $0 \leq r \leq n$ or zero when $r > n$.

*New in version 2.6.*

`itertools.product(*iterables[, repeat])`

Cartesian product of input iterables.

Equivalent to nested for-loops in a generator expression. For example, `product(A, B)` returns the same as `((x,y) for x in A for y in B)`.

The nested loops cycle like an odometer with the rightmost element advancing on every iteration. This pattern creates a lexicographic ordering so that if the input's iterables are sorted, the product tuples are emitted in sorted order.

To compute the product of an iterable with itself, specify the number of repetitions with the optional `repeat` keyword argument. For example, `product(A, repeat=4)` means the same as `product(A, A, A, A)`.

This function is equivalent to the following code, except that the actual implementation does not build up intermediate results in memory:
def product(*args, **kwds):
    # product('ABCD', 'xy') --> Ax Ay Bx Cy Dx Dy
    # product(range(2), repeat=3) --> 000 001 010 011 100 101
    pools = map(tuple, args) * kwds.get('repeat', 1)
    result = [[]]
    for pool in pools:
        result = [x+[y] for x in result for y in pool]
    for prod in result:
        yield tuple(prod)

New in version 2.6.

itertools.repeat(object[, times])

Make an iterator that returns object over and over again. Runs indefinitely unless the times argument is specified. Used as argument to imap() for invariant function parameters. Also used with izip() to create constant fields in a tuple record. Equivalent to:

def repeat(object, times=None):
    # repeat(10, 3) --> 10 10 10
    if times is None:
        while True:
            yield object
    else:
        for i in xrange(times):
            yield object

itertools.starmap(function, iterable)

Make an iterator that computes the function using arguments obtained from the iterable. Used instead of imap() when argument parameters are already grouped in tuples from a single iterable (the data has been “pre-zipped”). The difference between imap() and starmap() parallels the distinction between function(a,b) and function(*c). Equivalent to:

def starmap(function, iterable):
    # starmap(pow, [(2,5), (3,2), (10,3)]) --> 32 9 1000
for args in iterable:
    yield function(*args)

*Changed in version 2.6:* Previously, `starmap()` required the function arguments to be tuples. Now, any iterable is allowed.

**itertools.** **takewhile** *(predicate, iterable)*

Make an iterator that returns elements from the iterable as long as the predicate is true. Equivalent to:

```python
def takewhile(predicate, iterable):
    # takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1 4
    for x in iterable:
        if predicate(x):
            yield x
        else:
            break
```

**itertools.** **tee** *(iterable[, n=2])*  

Return *n* independent iterators from a single iterable. Equivalent to:

```python
def tee(iterable, n=2):
    it = iter(iterable)
    deques = [collections.deque() for i in range(n)]
    def gen(mydeque):
        while True:
            if not mydeque:  # when the local deque is empty
                newval = next(it)  # fetch a new value
            for d in deques:  # load it to all the deques
                d.append(newval)
            yield mydeque.popleft()
    return tuple(gen(d) for d in deques)
```

Once `tee()` has made a split, the original `iterable` should not be used anywhere else; otherwise, the `iterable` could get advanced without the tee objects being informed.

This itertool may require significant auxiliary storage (depending
on how much temporary data needs to be stored). In general, if one iterator uses most or all of the data before another iterator starts, it is faster to use \texttt{list()} instead of \texttt{tee()}.

\textit{New in version 2.4.}
9.7.2. Recipes

This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The extended tools offer the same high performance as the underlying toolset. The superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring “vectorized” building blocks over the use of for-loops and generators which incur interpreter overhead.

```python
def take(n, iterable):
    "Return first n items of the iterable as a list"
    return list(islice(iterable, n))

def tabulate(function, start=0):
    "Return function(0), function(1), ...
    return imap(function, count(start))

def consume(iterator, n):
    "Advance the iterator n-steps ahead. If n is none, consume
    # Use functions that consume iterators at C speed.
    if n is None:
        # feed the entire iterator into a zero-length deque
        collections.deque(iterator, maxlen=0)
    else:
        # advance to the empty slice starting at position n
        next(islice(iterator, n, n), None)

def nth(iterable, n, default=None):
    "Returns the nth item or a default value"
    return next(islice(iterable, n, None), default)

def quantify(iterable, pred=bool):
    "Count how many times the predicate is true"
    return sum(imap(pred, iterable))
```
def padnone(iterable):
    """Returns the sequence elements and then returns None indefinitely. Useful for emulating the behavior of the built-in map() function."""
    return chain(iterable, repeat(None))

def ncycles(iterable, n):
    "Returns the sequence elements n times"
    return chain.from_iterable(repeat(tuple(iterable), n))

def dotproduct(vec1, vec2):
    return sum(imap(operator.mul, vec1, vec2))

def flatten(listOfLists):
    "Flatten one level of nesting"
    return chain.from_iterable(listOfLists)

def repeatfunc(func, times=None, *args):
    "Repeat calls to func with specified arguments."
    if times is None:
        return starmap(func, repeat(args))
    return starmap(func, repeat(args, times))

def pairwise(iterable):
    "s -> (s0,s1), (s1,s2), (s2, s3), ...
    a, b = tee(iterable)
    next(b, None)
    return izip(a, b)

def grouper(n, iterable, fillvalue=None):
    "grouper(3, 'ABCDEFG', 'x') --> ABC DEF Gxx"
    args = [iter(iterable)] * n
    return izip_longest(fillvalue=fillvalue, *args)

def roundrobin(*iterables):
    "roundrobin('ABC', 'D', 'EF') --> A D E B F C"
    # Recipe credited to George Sakkis
    pending = len(iterables)
    nexts = cycle(iter(it).next for it in iterables)
    while pending:
        try:
            for next in nexts:
                yield next()
```python
def powerset(iterable):
    "powerset([1,2,3]) --> () (1,) (2,) (3,) (1,2) (1,3) (2,3)
    s = list(iterable)
    return chain.from_iterable(combinations(s, r) for r in range(len(s) + 1))

def unique_everseen(iterable, key=None):
    "List unique elements, preserving order. Remember all elements ever seen."
    seen = set()
    seen_add = seen.add
    if key is None:
        for element in ifilterfalse(seen.__contains__, iterable):
            seen_add(element)
            yield element
    else:
        for element in iterable:
            k = key(element)
            if k not in seen:
                seen_add(k)
                yield element

def unique_justseen(iterable, key=None):
    "List unique elements, preserving order. Remember only the element just seen."
    return imap(next, imap(itemgetter(1), groupby(iterable, key)))

def iter_except(func, exception, first=None):
    """Call a function repeatedly until an exception is raised
    Converts a call-until-exception interface to an iterator interface
    Like __builtin__.iter(func, sentinel) but uses an exception to end the loop.
    Examples:
    bsddbiter = iter_except(db.next, bsddb.error, db.first)
    heapiter = iter_except(functools.partial(heappop, h), IndexError)
    dictiter = iter_except(d.popitem, KeyError)
    dequeiter = iter_except(d.popleft, IndexError)
    queueiter = iter_except(q.get_nowait, Queue.Empty)
    setiter = iter_except(s.pop, KeyError)"
except StopIteration:
    pending -= 1
nexts = cycle(islice(nexts, pending))
```
try:
    if first is not None:
        yield first()
    while 1:
        yield func()
except exception:
    pass

def random_product(*args, **kwds):
    "Random selection from itertools.product(*args, **kwds)"
    pools = map(tuple, args) * kwds.get('repeat', 1)
    return tuple(random.choice(pool) for pool in pools)

def random_permutation(iterable, r=None):
    "Random selection from itertools.permutations(iterable, r)"
    pool = tuple(iterable)
    r = len(pool) if r is None else r
    return tuple(random.sample(pool, r))

def random_combination(iterable, r):
    "Random selection from itertools.combinations(iterable, r)"
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.sample(xrange(n), r))
    return tuple(pool[i] for i in indices)

def random_combination_with_replacement(iterable, r):
    "Random selection from itertools.combinations_with_replacement(iterable, r)"
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.randrange(n) for i in xrange(r))
    return tuple(pool[i] for i in indices)

Note, many of the above recipes can be optimized by replacing global lookups with local variables defined as default values. For example, the dotproduct recipe can be written as:

def dotproduct(vec1, vec2, sum=sum, imap=imap, mul=operator.mul):
    return sum(imap(mul, vec1, vec2))
9.8. functools — Higher order functions and operations on callable objects

New in version 2.5.

The functools module is for higher-order functions: functions that act on or return other functions. In general, any callable object can be treated as a function for the purposes of this module.

The functools module defines the following functions:

functools.\texttt{cmp\_to\_key(func)}

Transform an old-style comparison function to a key-function. Used with tools that accept key functions (such as \texttt{sorted()}, \texttt{min()}, \texttt{max()}, \texttt{heapq.nlargest()}, \texttt{heapq.nsmallest()}, \texttt{itertools.groupby()}). This function is primarily used as a transition tool for programs being converted to Py3.x where comparison functions are no longer supported.

A compare function is any callable that accept two arguments, compares them, and returns a negative number for less-than, zero for equality, or a positive number for greater-than. A key function is a callable that accepts one argument and returns another value that indicates the position in the desired collation sequence.

Example:

\begin{verbatim}
sorted(iterable, key=cmp_to_key(locale.strcoll))  # locale-aware sort order
\end{verbatim}
functools.**total_ordering**(cls)

Given a class defining one or more rich comparison ordering methods, this class decorator supplies the rest. This simplifies the effort involved in specifying all of the possible rich comparison operations:

The class must define one of **__lt__()**, **__le__()**, **__gt__()**, or **__ge__()**. In addition, the class should supply an **__eq__()** method.

For example:

```python
@total_ordering
class Student:
    def __eq__(self, other):
        return ((self.lastname.lower(), self.firstname.lower())
                 == (other.lastname.lower(), other.firstname.lower()))
    def __lt__(self, other):
        return ((self.lastname.lower(), self.firstname.lower())
                 < (other.lastname.lower(), other.firstname.lower()))
```

functools.**reduce**(function, iterable[, initializer])

This is the same function as **reduce()**. It is made available in this module to allow writing code more forward-compatible with Python 3.

functools.**partial**(func[, *args][, **keywords]])

Return a new **partial** object which when called will behave like **func** called with the positional arguments **args** and keyword arguments **keywords**. If more arguments are supplied to the call,
they are appended to *args. If additional keyword arguments are supplied, they extend and override *keywords. Roughly equivalent to:

```python
def partial(func, *args, **keywords):
    def newfunc(*fargs, **fkeywords):
        newkeywords = keywords.copy()
        newkeywords.update(fkeywords)
        return func(*(args + fargs), **newkeywords)
    newfunc.func = func
    newfunc.args = args
    newfunc.keywords = keywords
    return newfunc
```

The `partial()` is used for partial function application which “freezes” some portion of a function’s arguments and/or keywords resulting in a new object with a simplified signature. For example, `partial()` can be used to create a callable that behaves like the `int()` function where the base argument defaults to two:

```python
>>> from functools import partial
>>> basetwo = partial(int, base=2)
>>> basetwo.__doc__ = 'Convert base 2 string to an int.'
>>> basetwo('10010')
18
```

`functools.update_wrapper(wrapper, wrapped[, assigned][, updated])`

Update a `wrapper` function to look like the `wrapped` function. The optional arguments are tuples to specify which attributes of the original function are assigned directly to the matching attributes on the wrapper function and which attributes of the wrapper function are updated with the corresponding attributes from the original function. The default values for these arguments are the module level constants `WRAPPER_ASSIGNMENTS` (which assigns to the wrapper function’s `__name__`, `__module__` and
The main intended use for this function is in decorator functions which wrap the decorated function and return the wrapper. If the wrapper function is not updated, the metadata of the returned function will reflect the wrapper definition rather than the original function definition, which is typically less than helpful.

**functools.wraps(wrapped[, assigned][, updated])**

This is a convenience function for invoking partial(update_wrapper, wrapped=wrapped, assigned=assigned, updated=updated) as a function decorator when defining a wrapper function. For example:

```python
>>> from functools import wraps
>>> def my_decorator(f):
...     @wraps(f)
...     def wrapper(*args, **kwds):
...         print 'Calling decorated function'
...         return f(*args, **kwds)
...     return wrapper
...
>>> @my_decorator
... def example():
...     """Docstring""
...     print 'Called example function'
...
>>> example()
Calling decorated function
Called example function
```

Without the use of this decorator factory, the name of the example function would have been 'wrapper', and the docstring

__doc__, the documentation string) and WRAPPER_UPDATES (which updates the wrapper function's __dict__, i.e. the instance dictionary).
of the original example() would have been lost.
9.8.1. partial Objects

`partial` objects are callable objects created by `partial()`. They have three read-only attributes:

`partial.func`
A callable object or function. Calls to the `partial` object will be forwarded to `func` with new arguments and keywords.

`partial.args`
The leftmost positional arguments that will be prepended to the positional arguments provided to a `partial` object call.

`partial.keywords`
The keyword arguments that will be supplied when the `partial` object is called.

`partial` objects are like `function` objects in that they are callable, weak referencable, and can have attributes. There are some important differences. For instance, the `__name__` and `__doc__` attributes are not created automatically. Also, `partial` objects defined in classes behave like static methods and do not transform into bound methods during instance attribute look-up.
9.9. operator — Standard operators as functions

The `operator` module exports a set of functions implemented in C corresponding to the intrinsic operators of Python. For example, `operator.add(x, y)` is equivalent to the expression `x+y`. The function names are those used for special class methods; variants without leading and trailing `__` are also provided for convenience.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations, sequence operations, and abstract type tests.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

- `operator.lt(a, b)`
- `operator.le(a, b)`
- `operator.eq(a, b)`
- `operator.ne(a, b)`
- `operator.ge(a, b)`
- `operator.gt(a, b)`
- `operator.__lt__(a, b)`
- `operator.__le__(a, b)`
- `operator.__eq__(a, b)`
- `operator.__ne__(a, b)`
- `operator.__ge__(a, b)`
- `operator.__gt__(a, b)`

Perform “rich comparisons” between `a` and `b`. Specifically, `lt(a, b)` is equivalent to `a < b`, `le(a, b)` is equivalent to `a <= b`, `eq(a, b)` is equivalent to `a == b`, `ne(a, b)` is equivalent to `a != b`, `gt(a, b)` is equivalent to `a > b` and `ge(a, b)` is equivalent to `a >= b`. 
Note that unlike the built-in \texttt{cmp()}, these functions can return any value, which may or may not be interpretable as a Boolean value. See \textit{Comparisons} for more information about rich comparisons.

\textit{New in version 2.2.}

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

\begin{verbatim}
operator.\texttt{not}(obj)
operator.\texttt{__not__}(obj)
\end{verbatim}

Return the outcome of \texttt{not obj}. (Note that there is no \texttt{__not__()} method for object instances; only the interpreter core defines this operation. The result is affected by the \texttt{__nonzero__()} and \texttt{__len__()} methods.)

\begin{verbatim}
operator.\texttt{truth}(obj)
\end{verbatim}

Return \texttt{True} if \texttt{obj} is true, and \texttt{False} otherwise. This is equivalent to using the \texttt{bool} constructor.

\begin{verbatim}
operator.\texttt{is_}(a, b)
\end{verbatim}

Return \texttt{a is b}. Tests object identity.

\textit{New in version 2.3.}

\begin{verbatim}
operator.\texttt{is_not}(a, b)
\end{verbatim}

Return \texttt{a is not b}. Tests object identity.

\textit{New in version 2.3.}

The mathematical and bitwise operations are the most numerous:

\begin{verbatim}
operator.\texttt{abs}(obj)
operator.\texttt{__abs__}(obj)
\end{verbatim}

Return the absolute value of \texttt{obj}.
operator.\texttt{add}(a, b)
operator.\texttt{__add__}(a, b)

Return $a + b$, for $a$ and $b$ numbers.

operator.\texttt{and_}(a, b)
operator.\texttt{__and__}(a, b)

Return the bitwise and of $a$ and $b$.

operator.\texttt{div}(a, b)
operator.\texttt{__div__}(a, b)

Return $a / b$ when\texttt{__future__.division} is not in effect. This is also known as “classic” division.

operator.\texttt{floordiv}(a, b)
operator.\texttt{__floordiv__}(a, b)

Return $a \div b$.

\textit{New in version 2.2.}

operator.\texttt{index}(a)
operator.\texttt{__index__}(a)

Return $a$ converted to an integer. Equivalent to $a.\texttt{__index__()}$.

\textit{New in version 2.5.}

operator.\texttt{inv}(obj)
operator.\texttt{invert}(obj)
operator.\texttt{__inv__}(obj)
operator.\texttt{__invert__}(obj)

Return the bitwise inverse of the number $obj$. This is equivalent to $-obj$.

\textit{New in version 2.0:} The names \texttt{invert()} and \texttt{__invert__()}. 
operator.\texttt{\_lshift\_}(a, b)
operator.\texttt{\_lshift\_}(a, b)

    Return a shifted left by \texttt{b}.

operator.\texttt{\_mod\_}(a, b)
operator.\texttt{\_mod\_}(a, b)

    Return \texttt{a \% b}.

operator.\texttt{\_mul\_}(a, b)
operator.\texttt{\_mul\_}(a, b)

    Return a \texttt{* b}, for \texttt{a} and \texttt{b} numbers.

operator.\texttt{\_neg\_}(obj)
operator.\texttt{\_neg\_}(obj)

    Return \texttt{obj} negated (-\texttt{obj}).

operator.\texttt{\_or\_}(a, b)
operator.\texttt{\_or\_}(a, b)

    Return the bitwise or of \texttt{a} and \texttt{b}.

operator.\texttt{\_pos\_}(obj)
operator.\texttt{\_pos\_}(obj)

    Return \texttt{obj} positive (+\texttt{obj}).

operator.\texttt{\_pow\_}(a, b)
operator.\texttt{\_pow\_}(a, b)

    Return a \texttt{** b}, for \texttt{a} and \texttt{b} numbers.

    \textit{New in version 2.3.}

operator.\texttt{\_rshift\_}(a, b)
operator.\texttt{\_rshift\_}(a, b)

    Return a shifted right by \texttt{b}. 
operator.\texttt{sub}(a, b)
operator.\texttt{\_\_sub\_}(a, b)

Return \( a - b \).

operator.\texttt{truediv}(a, b)
operator.\texttt{\_\_truediv\_}(a, b)

Return \( a / b \) when \texttt{\_\_future\_.division} is in effect. This is also known as “true” division.

\textit{New in version 2.2.}

operator.\texttt{xor}(a, b)
operator.\texttt{\_\_xor\_}(a, b)

Return the bitwise exclusive or of \( a \) and \( b \).

Operations which work with sequences (some of them with mappings too) include:

operator.\texttt{concat}(a, b)
operator.\texttt{\_\_concat\_}(a, b)

Return \( a + b \) for \( a \) and \( b \) sequences.

operator.\texttt{contains}(a, b)
operator.\texttt{\_\_contains\_}(a, b)

Return the outcome of the test \( b \text{ in } a \). Note the reversed operands.

\textit{New in version 2.0: The name \texttt{\_\_contains\_}().}

operator.\texttt{countOf}(a, b)

Return the number of occurrences of \( b \) in \( a \).

operator.\texttt{delitem}(a, b)
operator.\texttt{\_\_delitem\_}(a, b)
Remove the value of `a` at index `b`.

```python
operator.delslice(a, b, c)
operator.__delslice__(a, b, c)
```

Delete the slice of `a` from index `b` to index `c-1`.

*Deprecated since version 2.6:* This function is removed in Python 3.x. Use `delitem()` with a slice index.

```python
operatorgetitem(a, b)
operator.__getitem__(a, b)
```

Return the value of `a` at index `b`.

```python
operator.getslice(a, b, c)
operator.__getslice__(a, b, c)
```

Return the slice of `a` from index `b` to index `c-1`.

*Deprecated since version 2.6:* This function is removed in Python 3.x. Use `getitem()` with a slice index.

```python
operator.indexOf(a, b)
```

Return the index of the first occurrence of `b` in `a`.

```python
operator.repeat(a, b)
operator.__repeat__(a, b)
```

*Deprecated since version 2.7:* Use `__mul__()` instead.

Return `a * b` where `a` is a sequence and `b` is an integer.

```python
operator.sequenceIncludes(...)
```

*Deprecated since version 2.0:* Use `contains()` instead.
Alias for `contains()`.

```python
operator.setitem(a, b, c)
operator.__setitem__(a, b, c)
```
Set the value of `a` at index `b` to `c`.

```python
operator.setslice(a, b, c, v)
operator.__setslice__(a, b, c, v)
```
Set the slice of `a` from index `b` to index `c-1` to the sequence `v`.

**Deprecated since version 2.6:** This function is removed in Python 3.x. Use `setitem()` with a slice index.

Example use of operator functions:

```python
>>> # Elementwise multiplication
>>> map(mul, [0, 1, 2, 3], [10, 20, 30, 40])
[0, 20, 60, 120]

>>> # Dot product
>>> sum(map(mul, [0, 1, 2, 3], [10, 20, 30, 40]))
200
```

Many operations have an “in-place” version. The following functions provide a more primitive access to in-place operators than the usual syntax does; for example, the statement `x += y` is equivalent to `x = operator.iadd(x, y)`. Another way to put it is to say that `z = operator.iadd(x, y)` is equivalent to the compound statement `z = x; z += y`.

```python
operator.iadd(a, b)
operator.__iadd__(a, b)
```

`a = iadd(a, b)` is equivalent to `a += b`.

**New in version 2.5.**
operator. **iand**(a, b)
operator. **__iand__**(a, b)
    a = iand(a, b) is equivalent to a &= b.

*New in version 2.5.*

operator. **iconcat**(a, b)
operator. **__iconcat__**(a, b)
    a = iconcat(a, b) is equivalent to a += b for a and b sequences.

*New in version 2.5.*

operator. **idiv**(a, b)
operator. **__idiv__**(a, b)
    a = idiv(a, b) is equivalent to a /= b when __future__.division is not in effect.

*New in version 2.5.*

operator. **ifloordiv**(a, b)
operator. **__ifloordiv__**(a, b)
    a = ifloordiv(a, b) is equivalent to a //= b.

*New in version 2.5.*

operator. **ilshift**(a, b)
operator. **__ilshift__**(a, b)
    a = ilshift(a, b) is equivalent to a <<= b.

*New in version 2.5.*

operator. **imod**(a, b)
operator. **__imod__**(a, b)
    a = imod(a, b) is equivalent to a %= b.
New in version 2.5.

operator.\texttt{imul}(a, b)
operator.\_\_\texttt{imul}\_\_(a, b)
\begin{align*}
a &= \texttt{imul}(a, b) \text{ is equivalent to } a *= b.
\end{align*}

New in version 2.5.

operator.\texttt{ior}(a, b)
operator.\_\_\texttt{ior}\_\_(a, b)
\begin{align*}
a &= \texttt{ior}(a, b) \text{ is equivalent to } a |= b.
\end{align*}

New in version 2.5.

operator.\texttt{ipow}(a, b)
operator.\_\_\texttt{ipow}\_\_(a, b)
\begin{align*}
a &= \texttt{ipow}(a, b) \text{ is equivalent to } a **= b.
\end{align*}

New in version 2.5.

operator.\texttt{irepeat}(a, b)
operator.\_\_\texttt{irepeat}\_\_(a, b)
\begin{align*}
a &= \texttt{irepeat}(a, b) \text{ is equivalent to } a *= b \text{ where } a \text{ is a sequence and } b \text{ is an integer.}
\end{align*}

New in version 2.5.

operator.\texttt{irshift}(a, b)
operator.\_\_\texttt{irshift}\_\_(a, b)
\begin{align*}
a &= \texttt{irshift}(a, b) \text{ is equivalent to } a >>= b.
\end{align*}
operator.\texttt{isub}\(a, b\)
operator.\texttt{\_\_isub\_}\(a, b\)

\[
\texttt{a} = \texttt{isub}(a, b) \text{ is equivalent to } \texttt{a} -= \texttt{b}.
\]

\textit{New in version 2.5.}

operator.\texttt{itruediv}\(a, b\)
operator.\texttt{\_\_itruediv\_}\(a, b\)

\[
\texttt{a} = \texttt{itruediv}(a, b) \text{ is equivalent to } \texttt{a} /= \texttt{b} \text{ when } \texttt{\_\_future\_.\_\_division} \text{ is in effect.}
\]

\textit{New in version 2.5.}

operator.\texttt{ixor}\(a, b\)
operator.\texttt{\_\_ixor\_}\(a, b\)

\[
\texttt{a} = \texttt{ixor}(a, b) \text{ is equivalent to } \texttt{a} ^= \texttt{b}.
\]

\textit{New in version 2.5.}

The \texttt{operator} module also defines a few predicates to test the type of objects; however, these are not all reliable. It is preferable to test abstract base classes instead (see \texttt{collections} and \texttt{numbers} for details).

operator.\texttt{isCallable}(\texttt{obj})

\begin{tabular}{|l|}
\hline
\texttt{Deprecated since version 2.0: Use } \texttt{isinstance(x, collections.Callable)} \texttt{instead.} \\
\hline
\end{tabular}

Returns true if the object \texttt{obj} can be called like a function, otherwise it returns false. True is returned for functions, bound and unbound methods, class objects, and instance objects which support the \texttt{\_\_call\_()} method.

operator.\texttt{isMappingType}(\texttt{obj})
Returns true if the object obj supports the mapping interface. This is true for dictionaries and all instance objects defining `__getitem__()`.

**operator.isNumberType(obj)**

Returns true if the object obj represents a number. This is true for all numeric types implemented in C.

**operator.isSequenceType(obj)**

Returns true if the object obj supports the sequence protocol. This returns true for all objects which define sequence methods in C, and for all instance objects defining `__getitem__()`.

The operator module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for `map()`, `sorted()`, `itertools.groupby()`, or other functions that expect a function argument.

**operator.attrgetter(attr[, args...])**

Return a callable object that fetches attr from its operand. If more than one attribute is requested, returns a tuple of attributes. After, \( f = \text{attrgetter('name')} \), the call \( f(b) \) returns \( b.name \). After, \( f = \text{attrgetter('name', 'date')} \), the call \( f(b) \) returns \((b.name,\)
b.date).

The attribute names can also contain dots; after \( f = \text{attrgetter('date.month')} \), the call \( f(b) \) returns \( b.date.month \).

*New in version 2.4.*

*Changed in version 2.5:* Added support for multiple attributes.

*Changed in version 2.6:* Added support for dotted attributes.

```
operator.itemgetter(item[, args...])
```

Return a callable object that fetches \( item \) from its operand using the operand's \( \text{__getitem__}() \) method. If multiple items are specified, returns a tuple of lookup values. Equivalent to:

```python
def itemgetter(*items):
    if len(items) == 1:
        item = items[0]
        def g(obj):
            return obj[item]
    else:
        def g(obj):
            return tuple(obj[item] for item in items)
    return g
```

The items can be any type accepted by the operand's \( \text{__getitem__}() \) method. Dictionaries accept any hashable value. Lists, tuples, and strings accept an index or a slice:

```
>>> itemgetter(1)('ABCDEFG')
'B'
>>> itemgetter(1,3,5)('ABCDEFG')
('B', 'D', 'F')
>>> itemgetter(slice(2,None))('ABCDEFG')
'CDEFG'
```

*New in version 2.4.*
*Changed in version 2.5:* Added support for multiple item extraction.

Example of using `itemgetter()` to retrieve specific fields from a tuple record:

```python
>>> inventory = [\('apple', 3\), \('banana', 2\), \('pear', 5\), \('orange', 1\)]
>>> getcount = itemgetter(1)
>>> map(getcount, inventory)
[3, 2, 5, 1]
>>> sorted(inventory, key=getcount)
[\('orange', 1\), \('banana', 2\), \('apple', 3\), \('pear', 5\)]
```

operator.`methodcaller`(name[, args...])

Return a callable object that calls the method `name` on its operand. If additional arguments and/or keyword arguments are given, they will be given to the method as well. After `f = methodcaller('name')`, the call `f(b)` returns `b.name()`. After `f = methodcaller('name', 'foo', bar=1)`, the call `f(b)` returns `b.name('foo', bar=1).

*New in version 2.6.*
9.9.1. Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the `operator` module.

<table>

10. File and Directory Access

The modules described in this chapter deal with disk files and directories. For example, there are modules for reading the properties of files, manipulating paths in a portable way, and creating temporary files. The full list of modules in this chapter is:

- **10.1. os.path** — Common pathname manipulations
- **10.2. fileinput** — Iterate over lines from multiple input streams
- **10.3. stat** — Interpreting \texttt{stat()} results
- **10.4. statvfs** — Constants used with \texttt{os.statvfs()}
- **10.5. filecmp** — File and Directory Comparisons
  - **10.5.1. The \texttt{dircmp} class**
- **10.6. tempfile** — Generate temporary files and directories
- **10.7. glob** — Unix style pathname pattern expansion
- **10.8. fnmatch** — Unix filename pattern matching
- **10.9. linecache** — Random access to text lines
- **10.10. shutil** — High-level file operations
  - **10.10.1. Directory and files operations**
    - **10.10.1.1. copytree example**
  - **10.10.2. Archives operations**
    - **10.10.2.1. Archiving example**
- **10.11. dircache** — Cached directory listings

See also:

**Section File Objects**
A description of Python’s built-in file objects.

**Module os**
Operating system interfaces, including functions to work with files at a lower level than the built-in file object.
Standard Library » 10. File and Directory Access »
10.1. os.path — Common pathname manipulations

This module implements some useful functions on pathnames. To read or write files see `open()`, and for accessing the filesystem see the `os` module.

**Note:** On Windows, many of these functions do not properly support UNC pathnames. `splitunc()` and `ismount()` do handle them correctly.

**Note:** Since different operating systems have different path name conventions, there are several versions of this module in the standard library. The `os.path` module is always the path module suitable for the operating system Python is running on, and therefore usable for local paths. However, you can also import and use the individual modules if you want to manipulate a path that is always in one of the different formats. They all have the same interface:

- `posixpath` for UNIX-style paths
- `ntpath` for Windows paths
- `macpath` for old-style MacOS paths
- `os2emxpath` for OS/2 EMX paths

`os.path.abspath(path)`

Return a normalized absolutized version of the pathname `path`. On most platforms, this is equivalent to `normpath(join(os.getcwd(), path))`.

*New in version 1.5.2.*
os.path.basename(path)
Return the base name of pathname path. This is the second half of the pair returned by split(path). Note that the result of this function is different from the Unix basename program; where basename for '/foo/bar/' returns 'bar', the basename() function returns an empty string ('').

os.path.commonprefix(list)
Return the longest path prefix (taken character-by-character) that is a prefix of all paths in list. If list is empty, return the empty string (''). Note that this may return invalid paths because it works a character at a time.

os.path.dirname(path)
Return the directory name of pathname path. This is the first half of the pair returned by split(path).

os.path.exists(path)
Return True if path refers to an existing path. Returns False for broken symbolic links. On some platforms, this function may return False if permission is not granted to execute os.stat() on the requested file, even if the path physically exists.

os.path.lexists(path)
Return True if path refers to an existing path. Returns True for broken symbolic links. Equivalent to exists() on platforms lacking os.lstat().

New in version 2.4.

os.path.expanduser(path)
On Unix and Windows, return the argument with an initial component of ~ or ~user replaced by that user's home directory.
On Unix, an initial ~ is replaced by the environment variable HOME if it is set; otherwise the current user’s home directory is looked up in the password directory through the built-in module pwd. An initial ~user is looked up directly in the password directory.

On Windows, HOME and USERPROFILE will be used if set, otherwise a combination of HOMEPATH and HOMEDRIVE will be used. An initial ~user is handled by stripping the last directory component from the created user path derived above.

If the expansion fails or if the path does not begin with a tilde, the path is returned unchanged.

os.path.expandvars(path)
Return the argument with environment variables expanded. Substrings of the form $name or ${name} are replaced by the value of environment variable name. Malformed variable names and references to non-existing variables are left unchanged.

On Windows, %name% expansions are supported in addition to $name and ${name}.

os.path.getatime(path)
Return the time of last access of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise os.error if the file does not exist or is inaccessible.

New in version 1.5.2.

Changed in version 2.3: If os.stat_float_times() returns True, the result is a floating point number.

os.path.getmtime(path)
Return the time of last modification of \textit{path}. The return value is a number giving the number of seconds since the epoch (see the \texttt{time} module). Raise \texttt{os.error} if the file does not exist or is inaccessible.

\textit{New in version 1.5.2.}

\textit{Changed in version 2.3}: If \texttt{os.stat_float_times()} returns True, the result is a floating point number.

\texttt{os.path.getctime(path)}
Return the system’s ctime which, on some systems (like Unix) is the time of the last change, and, on others (like Windows), is the creation time for \textit{path}. The return value is a number giving the number of seconds since the epoch (see the \texttt{time} module). Raise \texttt{os.error} if the file does not exist or is inaccessible.

\textit{New in version 2.3.}

\texttt{os.path.getsize(path)}
Return the size, in bytes, of \textit{path}. Raise \texttt{os.error} if the file does not exist or is inaccessible.

\textit{New in version 1.5.2.}

\texttt{os.path.isabs(path)}
Return \texttt{True} if \textit{path} is an absolute pathname. On Unix, that means it begins with a slash, on Windows that it begins with a (back)slash after chopping off a potential drive letter.

\texttt{os.path.isfile(path)}
Return \texttt{True} if \textit{path} is an existing regular file. This follows symbolic links, so both \texttt{islink()} and \texttt{isfile()} can be true for the same path.
os.path.isdir(path)
Return True if path is an existing directory. This follows symbolic links, so both islink() and isdir() can be true for the same path.

os.path.islink(path)
Return True if path refers to a directory entry that is a symbolic link. Always False if symbolic links are not supported.

os.path.ismount(path)
Return True if pathname path is a mount point: a point in a file system where a different file system has been mounted. The function checks whether path's parent, path/.., is on a different device than path, or whether path/.. and path point to the same i-node on the same device — this should detect mount points for all Unix and POSIX variants.

os.path.join(path1[, path2[, ...]])
Join one or more path components intelligently. If any component is an absolute path, all previous components (on Windows, including the previous drive letter, if there was one) are thrown away, and joining continues. The return value is the concatenation of path1, and optionally path2, etc., with exactly one directory separator (os.sep) inserted between components, unless path2 is empty. Note that on Windows, since there is a current directory for each drive, os.path.join("c:\", "foo") represents a path relative to the current directory on drive c: (c:foo), not c:\foo.

os.path.normcase(path)
Normalize the case of a pathname. On Unix and Mac OS X, this returns the path unchanged; on case-insensitive filesystems, it converts the path to lowercase. On Windows, it also converts
forward slashes to backward slashes.

**os.path.normpath(path)**

Normalize a pathname. This collapses redundant separators and up-level references so that A//B, A/./B and A/foo/../B all become A/B. It does not normalize the case (use normcase() for that). On Windows, it converts forward slashes to backward slashes. It should be understood that this may change the meaning of the path if it contains symbolic links!

**os.path.realpath(path)**

Return the canonical path of the specified filename, eliminating any symbolic links encountered in the path (if they are supported by the operating system).

*New in version 2.2.*

**os.path.relp ath(path[, start])**

Return a relative filepath to path either from the current directory or from an optional start point.

* start defaults to os.curdir.

Availability: Windows, Unix.

*New in version 2.6.*

**os.path.samefile(path1, path2)**

Return True if both pathname arguments refer to the same file or directory (as indicated by device number and i-node number). Raise an exception if a os.stat() call on either pathname fails.

Availability: Unix.

**os.path.sameopenfile(fp1, fp2)**
Return `True` if the file descriptors `fp1` and `fp2` refer to the same file.

Availability: Unix.

`os.path.samestat(stat1, stat2)`

Return `True` if the stat tuples `stat1` and `stat2` refer to the same file. These structures may have been returned by `fstat()`, `lstat()`, or `stat()`. This function implements the underlying comparison used by `samefile()` and `sameopenfile()`.

Availability: Unix.

`os.path.split(path)`

Split the pathname `path` into a pair, `(head, tail)` where `tail` is the last pathname component and `head` is everything leading up to that. The `tail` part will never contain a slash; if `path` ends in a slash, `tail` will be empty. If there is no slash in `path`, `head` will be empty. If `path` is empty, both `head` and `tail` are empty. Trailing slashes are stripped from `head` unless it is the root (one or more slashes only). In nearly all cases, `join(head, tail)` equals `path` (the only exception being when there were multiple slashes separating `head` from `tail`).

`os.path.splitdrive(path)`

Split the pathname `path` into a pair `(drive, tail)` where `drive` is either a drive specification or the empty string. On systems which do not use drive specifications, `drive` will always be the empty string. In all cases, `drive + tail` will be the same as `path`.

*New in version 1.3.*

`os.path.splitext(path)`

Split the pathname `path` into a pair `(root, ext)` such that `root` +
ext == path, and ext is empty or begins with a period and contains at most one period. Leading periods on the basename are ignored; `splitext('.cshrc')` returns `('.cshrc', '')`.

*Changed in version 2.6:* Earlier versions could produce an empty root when the only period was the first character.

**os.path.splitunc(path)**
Split the pathname path into a pair (unc, rest) so that unc is the UNC mount point (such as `r'\host\mount'`), if present, and rest the rest of the path (such as `r'\path\file.ext'`). For paths containing drive letters, unc will always be the empty string.

*Availability:* Windows.

**os.path.walk(path, visit, arg)**
Calls the function visit with arguments (arg, dirname, names) for each directory in the directory tree rooted at path (including path itself, if it is a directory). The argument dirname specifies the visited directory, the argument names lists the files in the directory (gotten from `os.listdir(dirname)`). The visit function may modify names to influence the set of directories visited below dirname, e.g. to avoid visiting certain parts of the tree. (The object referred to by names must be modified in place, using `del` or slice assignment.)

**Note:** Symbolic links to directories are not treated as subdirectories, and that `walk()` therefore will not visit them. To visit linked directories you must identify them with `os.path.islink(file)` and `os.path.isdir(file)`, and invoke `walk()` as necessary.

**Note:** This function is deprecated and has been removed in
3.0 in favor of `os.walk()`.

`os.path.supports_unicode_filenames`
True if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system), and if `os.listdir()` returns Unicode strings for a Unicode argument.

*New in version 2.3.*
10.2. fileinput — Iterate over lines from multiple input streams

This module implements a helper class and functions to quickly write a loop over standard input or a list of files. If you just want to read or write one file see open().

The typical use is:

```python
import fileinput
for line in fileinput.input():
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is `'-',` it is also replaced by `sys.stdin`. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode by default, but you can override this by specifying the `mode` parameter in the call to `input()` or `FileInput()`. If an I/O error occurs during opening or reading a file, `IOError` is raised.

If `sys.stdin` is used more than once, the second and further use will return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using `sys.stdin.seek(0)`).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last file opened is empty.

Lines are returned with any newlines intact, which means that the
last line in a file may not have one.

You can control how files are opened by providing an opening hook via the `openhook` parameter to `fileinput.input()` or `FileInput()`. The hook must be a function that takes two arguments, `filename` and `mode`, and returns an accordingly opened file-like object. Two useful hooks are already provided by this module.

The following function is the primary interface of this module:

```python
fileinput.input([files[, inplace[, backup[, mode[, openhook]]]]])
```

Create an instance of the `FileInput` class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the `FileInput` class.

*Changed in version 2.5:* Added the `mode` and `openhook` parameters.

The following functions use the global state created by `fileinput.input()`; if there is no active state, `RuntimeError` is raised.

```python
fileinput.filename()
```

Return the name of the file currently being read. Before the first line has been read, returns `None`.

```python
fileinput.fileno()
```

Return the integer “file descriptor” for the current file. When no file is opened (before the first line and between files), returns `-1`.

*New in version 2.5.*

```python
fileinput.lineno()
```

Return the cumulative line number of the line that has just been read. Before the first line has been read, returns `0`. After the last
line of the last file has been read, returns the line number of that line.

fileinput.filelineno()
Return the line number in the current file. Before the first line has been read, returns 0. After the last line of the last file has been read, returns the line number of that line within the file.

fileinput.isfirstline()
Returns true if the line just read is the first line of its file, otherwise returns false.

fileinput.isstdin()
Returns true if the last line was read from sys.stdin, otherwise returns false.

fileinput.nextfile()
Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

fileinput.close()
Close the sequence.

The class which implements the sequence behavior provided by the module is available for subclassing as well:

class fileinput.FileInput([files[, inplace[, backup[, mode[, openhook]]]]]])
Class FileInput is the implementation; its methods filename(),
fileno(), lineno(), filelineno(), isfirstline(), isstdin(), nextfile() and close() correspond to the functions of the same name in the module. In addition it has a readline() method which returns the next input line, and a __getitem__() method which implements the sequence behavior. The sequence must be accessed in strictly sequential order; random access and readline() cannot be mixed.

With mode you can specify which file mode will be passed to open(). It must be one of 'r', 'rU', 'u' and 'rb'.

The openhook, when given, must be a function that takes two arguments, filename and mode, and returns an accordingly opened file-like object. You cannot use inplace and openhook together.

Changed in version 2.5: Added the mode and openhook parameters.

Optional in-place filtering: if the keyword argument inplace=1 is passed to fileinput.input() or to the FileInput constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the backup parameter is given (typically as backup='.<some extension>'), it specifies the extension for the backup file, and the backup file remains around; by default, the extension is '.bak' and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

Note: The current implementation does not work for MS-DOS 8+3 filesystems.

The two following opening hooks are provided by this module:
fileinput.\texttt{hook\_compressed}(filename, mode)

Transparencyly opens files compressed with gzip and bzip2 (recognized by the extensions '.gz' and '.bz2') using the \texttt{gzip} and \texttt{bz2} modules. If the filename extension is not '.gz' or '.bz2', the file is opened normally (ie, using \texttt{open()} without any decompression).

Usage example: \begin{verbatim}
fi = fileinput.FileInput(openhook=fileinput.hook\_compressed)
\end{verbatim}

\textit{New in version 2.5.}

fileinput.\texttt{hook\_encoded}(encoding)

Returns a hook which opens each file with \texttt{codecs.open()}, using the given \texttt{encoding} to read the file.

Usage example: \begin{verbatim}
fi = fileinput.FileInput(openhook=fileinput.hook\_encoded("iso-8859-1"))
\end{verbatim}

\begin{quote}
\textbf{Note:} With this hook, \texttt{FileInput} might return Unicode strings depending on the specified \texttt{encoding}.
\end{quote}

\textit{New in version 2.5.}
10.3. stat — Interpreting stat() results

The `stat` module defines constants and functions for interpreting the results of `os.stat()`, `os.fstat()` and `os.lstat()` (if they exist). For complete details about the `stat()`, `fstat()` and `lstat()` calls, consult the documentation for your system.

The `stat` module defines the following functions to test for specific file types:

- `stat.S_ISDIR(mode)`
  Return non-zero if the mode is from a directory.

- `stat.S_ISCHR(mode)`
  Return non-zero if the mode is from a character special device file.

- `stat.S_ISBLK(mode)`
  Return non-zero if the mode is from a block special device file.

- `stat.S_ISREG(mode)`
  Return non-zero if the mode is from a regular file.

- `stat.S_ISFIFO(mode)`
  Return non-zero if the mode is from a FIFO (named pipe).

- `stat.S_ISLNK(mode)`
  Return non-zero if the mode is from a symbolic link.

- `stat.S_ISSOCK(mode)`
  Return non-zero if the mode is from a socket.
Two additional functions are defined for more general manipulation of the file's mode:

\[ \text{stat.} \mathbf{S \_IMODE}(\text{mode}) \]
Return the portion of the file's mode that can be set by \texttt{os.chmod}—that is, the file's permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

\[ \text{stat.} \mathbf{S \_IFMT}(\text{mode}) \]
Return the portion of the file's mode that describes the file type (used by the \texttt{s_is*()} functions above).

Normally, you would use the \texttt{os.path.is*()} functions for testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the \texttt{stat()} system call for each test. These are also useful when checking for information about a file that isn't handled by \texttt{os.path}, like the tests for block and character devices.

All the variables below are simply symbolic indexes into the 10-tuple returned by \texttt{os.stat()}, \texttt{os.fstat()} or \texttt{os.lstat()}.

\[ \text{stat.} \mathbf{ST \_MODE} \]
Inode protection mode.

\[ \text{stat.} \mathbf{ST \_INO} \]
Inode number.

\[ \text{stat.} \mathbf{ST \_DEV} \]
Device inode resides on.

\[ \text{stat.} \mathbf{ST \_NLINK} \]
Number of links to the inode.

\[ \text{stat.} \mathbf{ST \_UID} \]
User id of the owner.
**stat.ST_GID**

Group id of the owner.

**stat.ST_SIZE**

Size in bytes of a plain file; amount of data waiting on some special files.

**stat.ST_ATIME**

Time of last access.

**stat.ST_MTIME**

Time of last modification.

**stat.ST_CTIME**

The “ctime” as reported by the operating system. On some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of “file size” changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of Unix (including Linux in particular), the “size” is the number of bytes waiting to be read at the time of the call to `os.stat()`, `os.fstat()`, or `os.lstat()`; this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the underlying system call.

The variables below define the flags used in the **ST_MODE** field.

Use of the functions above is more portable than use of the first set of flags:

**stat.S_IFMT**

Bit mask for the file type bit bit fields.
stat. **S_IFSOCK**
Socket.

stat. **S_IFLNK**
Symbolic link.

stat. **S_IFREG**
Regular file.

stat. **S_IFBLK**
Block device.

stat. **S_IFDIR**
Directory.

stat. **S_IFCHR**
Character device.

stat. **S_IFIFO**
FIFO.

The following flags can also be used in the *mode* argument of `os.chmod()`:

stat. **S_ISUID**
Set UID bit.

stat. **S_ISGID**
Set-group-ID bit. This bit has several special uses. For a directory it indicates that BSD semantics is to be used for that directory: files created there inherit their group ID from the directory, not from the effective group ID of the creating process, and directories created there will also get the **S_ISGID** bit set. For a file that does not have the group execution bit (**S_IXGRP**) set, the set-group-ID bit indicates mandatory file/record locking (see also **S_ENFMT**).
stat. **S_ISVTX**
Sticky bit. When this bit is set on a directory it means that a file in that directory can be renamed or deleted only by the owner of the file, by the owner of the directory, or by a privileged process.

stat. **S_IRWXU**
Mask for file owner permissions.

stat. **S_IRUSR**
Owner has read permission.

stat. **S_IWUSR**
Owner has write permission.

stat. **S_IXUSR**
Owner has execute permission.

stat. **S_IRWXG**
Mask for group permissions.

stat. **S_IRGRP**
Group has read permission.

stat. **S_IWGRP**
Group has write permission.

stat. **S_IXGRP**
Group has execute permission.

stat. **S_IRWXO**
Mask for permissions for others (not in group).

stat. **S_IROTH**
Others have read permission.

stat. **S_IWOTH**
Others have write permission.
stat. **S_IEXEC**

Others have execute permission.

stat. **S_ENFMT**

System V file locking enforcement. This flag is shared with **S_ISGID**: file/record locking is enforced on files that do not have the group execution bit (**S_IXGRP**) set.

stat. **S_IWRITE**

Unix V7 synonym for **S_IWUSR**.

stat. **S_IWRITE**

Unix V7 synonym for **S_IWUSR**.

stat. **S_IXUSR**

Unix V7 synonym for **S_IXUSR**.

Example:

```python
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted at top, calling the callback function for each regular file'''

    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.stat(pathname)[ST_MODE]
        if S_ISDIR(mode):
            # It's a directory, recurse into it
            walktree(pathname, callback)
        elif S_ISREG(mode):
            # It's a file, call the callback function
            callback(pathname)
        else:
            # Unknown file type, print a message
            print 'Skipping %s' % pathname

def visitfile(file):
    print 'visiting', file
```
if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)
10.4. statvfs — Constants used with os.statvfs()

*Deprecated since version 2.6:* The `statvfs` module has been deprecated for removal in Python 3.0.

The `statvfs` module defines constants so interpreting the result of `os.statvfs()`, which returns a tuple, can be made without remembering “magic numbers.” Each of the constants defined in this module is the index of the entry in the tuple returned by `os.statvfs()` that contains the specified information.

- `statvfs.F_BSIZE`  
  Preferred file system block size.

- `statvfs.F_FRSIZE`  
  Fundamental file system block size.

- `statvfs.F_BLOCKS`  
  Total number of blocks in the filesystem.

- `statvfs.F_BFREE`  
  Total number of free blocks.

- `statvfs.F_BAVAIL`  
  Free blocks available to non-super user.

- `statvfs.F_FILES`  
  Total number of file nodes.

- `statvfs.F_FFREE`  
  Total number of free file nodes.

- `statvfs.F_FAVAIL`
Free nodes available to non-super user.

\texttt{statvfs.\texttt{F\_FLAG}}

Flags. System dependent: see \texttt{statvfs()} man page.

\texttt{statvfs.\texttt{F\_NAMEMAX}}

Maximum file name length.
10.5. filecmp — File and Directory Comparisons

The filecmp module defines functions to compare files and directories, with various optional time/correctness trade-offs. For comparing files, see also the difflib module.

The filecmp module defines the following functions:

```python
filecmp.cmp(f1, f2[, shallow])
```

Compare the files named $f1$ and $f2$, returning True if they seem equal, False otherwise.

Unless shallow is given and is false, files with identical os.stat() signatures are taken to be equal.

Files that were compared using this function will not be compared again unless their os.stat() signature changes.

Note that no external programs are called from this function, giving it portability and efficiency.

```python
filecmp.cmpfiles(dir1, dir2, common[, shallow])
```

Compare the files in the two directories $dir1$ and $dir2$ whose names are given by common.

Returns three lists of file names: match, mismatch, errors. match contains the list of files that match, mismatch contains the names of those that don’t, and errors lists the names of files which could not be compared. Files are listed in errors if they don’t exist in one of the directories, the user lacks permission to read them or if the comparison could not be done for some other reason.
The *shallow* parameter has the same meaning and default value as for *filecmp.cmp()*.

For example, *cmpfiles('a', 'b', ['c', 'd/e'])* will compare *a/c* with *b/c* and *a/d/e* with *b/d/e*. *'c'* and *'d/e'* will each be in one of the three returned lists.

Example:

```python
>>> import filecmp
>>> filecmp.cmp('undoc.rst', 'undoc.rst')
True
>>> filecmp.cmp('undoc.rst', 'index.rst')
False
```
10.5.1. The `dircmp` class

dircmp instances are built using this constructor:

```python
class filecmp.dircmp(a, b[, ignore[, hide]])
```

Construct a new directory comparison object, to compare the directories `a` and `b`. `ignore` is a list of names to ignore, and defaults to `['RCS', 'CVS', 'tags']`. `hide` is a list of names to hide, and defaults to `[os.curdir, os.pardir]`.

The `dircmp` class provides the following methods:

```python
report()
```

Print (to `sys.stdout`) a comparison between `a` and `b`.

```python
report_partial_closure()
```

Print a comparison between `a` and `b` and common immediate subdirectories.

```python
report_full_closure()
```

Print a comparison between `a` and `b` and common subdirectories (recursively).

The `dircmp` offers a number of interesting attributes that may be used to get various bits of information about the directory trees being compared.

Note that via `__getattr__()` hooks, all attributes are computed lazily, so there is no speed penalty if only those attributes which are lightweight to compute are used.

```python
left_list
```

Files and subdirectories in `a`, filtered by `hide` and `ignore`. 
right_list
Files and subdirectories in \textit{b}, filtered by \textit{hide} and \textit{ignore}.

common
Files and subdirectories in both \textit{a} and \textit{b}.

left_only
Files and subdirectories only in \textit{a}.

right_only
Files and subdirectories only in \textit{b}.

common_dirs
Subdirectories in both \textit{a} and \textit{b}.

common_files
Files in both \textit{a} and \textit{b}.

common_funny
Names in both \textit{a} and \textit{b}, such that the type differs between the directories, or names for which \texttt{os.stat()} reports an error.

same_files
Files which are identical in both \textit{a} and \textit{b}.

diff_files
Files which are in both \textit{a} and \textit{b}, whose contents differ.

funny_files
Files which are in both \textit{a} and \textit{b}, but could not be compared.

subdirs
A dictionary mapping names in \textit{common_dirs} to \texttt{dircmp} objects.
This module generates temporary files and directories. It works on all supported platforms.

In version 2.3 of Python, this module was overhauled for enhanced security. It now provides three new functions, `NamedTemporaryFile()`, `mkstemp()`, and `mkdtemp()`, which should eliminate all remaining need to use the insecure `mktemp()` function. Temporary file names created by this module no longer contain the process ID; instead a string of six random characters is used.

Also, all the user-callable functions now take additional arguments which allow direct control over the location and name of temporary files. It is no longer necessary to use the global `tempdir` and `template` variables. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable functions:

```python
tempfile.TemporaryFile([mode='w+b', bufsize=-1, suffix='', prefix='tmp', dir=None])
```

Return a file-like object that can be used as a temporary storage area. The file is created using `mkstemp()`. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under Unix, the directory entry for the file is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function having or not having a visible name in the file system.
The *mode* parameter defaults to '*w+b*' so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. *bufsize* defaults to -1, meaning that the operating system default is used.

The *dir*, *prefix* and *suffix* parameters are passed to *mkstemp()*.

The returned object is a true file object on POSIX platforms. On other platforms, it is a file-like object whose *file* attribute is the underlying true file object. This file-like object can be used in a *with* statement, just like a normal file.

```
from tempfile import NamedTemporaryFile

NamedTemporaryFile([mode='w+b', bufsize=-1, suffix='', prefix='tmp', dir=None, delete=True])
```

This function operates exactly as *TemporaryFile()* does, except that the file is guaranteed to have a visible name in the file system (on Unix, the directory entry is not unlinked). That name can be retrieved from the *name* member of the file object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on Unix; it cannot on Windows NT or later). If *delete* is true (the default), the file is deleted as soon as it is closed.

The returned object is always a file-like object whose *file* attribute is the underlying true file object. This file-like object can be used in a *with* statement, just like a normal file.

*New in version 2.3.*

*New in version 2.6:* The *delete* parameter.

```
from tempfile import SpooledTemporaryFile

SpooledTemporaryFile([max_size=0, mode='w+b', bufsize=-1, suffix='', prefix='tmp', dir=None])
```
This function operates exactly as `TemporaryFile()` does, except that data is spooled in memory until the file size exceeds `max_size`, or until the file's `fileno()` method is called, at which point the contents are written to disk and operation proceeds as with `TemporaryFile()`.

The resulting file has one additional method, `rollover()`, which causes the file to roll over to an on-disk file regardless of its size.

The returned object is a file-like object whose `_file` attribute is either a `StringIO` object or a true file object, depending on whether `rollover()` has been called. This file-like object can be used in a `with` statement, just like a normal file.

*New in version 2.6.*

```python
tempfile.mkstemp(suffix='', prefix='tmp', dir=None, text=False)
```

Creates a temporary file in the most secure manner possible. There are no race conditions in the file's creation, assuming that the platform properly implements the `os.O_EXCL` flag for `os.open()`. The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike `TemporaryFile()`, the user of `mkstemp()` is responsible for deleting the temporary file when done with it.

If `suffix` is specified, the file name will end with that suffix, otherwise there will be no suffix. `mkstemp()` does not put a dot between the file name and the suffix; if you need one, put it at the beginning of `suffix`. 
If `prefix` is specified, the file name will begin with that prefix; otherwise, a default prefix is used.

If `dir` is specified, the file will be created in that directory; otherwise, a default directory is used. The default directory is chosen from a platform-dependent list, but the user of the application can control the directory location by setting the `TMPDIR`, `TEMP` or `TMP` environment variables. There is thus no guarantee that the generated filename will have any nice properties, such as not requiring quoting when passed to external commands via `os.popen()`.

If `text` is specified, it indicates whether to open the file in binary mode (the default) or text mode. On some platforms, this makes no difference.

`mkstemp()` returns a tuple containing an OS-level handle to an open file (as would be returned by `os.open()`) and the absolute pathname of that file, in that order.

*New in version 2.3.*

`tempfile.mkdtemp([suffix='', prefix='tmp', dir=None])`

Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory’s creation. The directory is readable, writable, and searchable only by the creating user ID.

The user of `mkdtemp()` is responsible for deleting the temporary directory and its contents when done with it.

The `prefix`, `suffix`, and `dir` arguments are the same as for `mkstemp()`.

`mkdtemp()` returns the absolute pathname of the new directory.
New in version 2.3.

tempfile.mktemp([\texttt{suffix=''}, \texttt{prefix='tmp'}, \texttt{dir=None}])

\textit{Deprecated since version 2.3: Use \texttt{mkstemp()} instead.}

Return an absolute pathname of a file that did not exist at the time the call is made. The \texttt{prefix}, \texttt{suffix}, and \texttt{dir} arguments are the same as for \texttt{mkstemp()}.

\textbf{Warning:} Use of this function may introduce a security hole in your program. By the time you get around to doing anything with the file name it returns, someone else may have beaten you to the punch. \texttt{mktemp()} usage can be replaced easily with \texttt{NamedTemporaryFile()}, passing it the \texttt{delete=False} parameter:

\begin{verbatim}
>>> f = NamedTemporaryFile(delete=False)
>>> f
<open file '<fdopen>', mode 'w+b' at 0x384698>
>>> f.name
'/var/folders/5q/5qTPn6xq2RaWqk+1Ytw3-U+++TI/-Tmp-/tmpG7V1Y0'
>>> f.write("Hello World!\n")
>>> f.close()
>>> os.unlink(f.name)
>>> os.path.exists(f.name)
False
\end{verbatim}

The module uses two global variables that tell it how to construct a temporary name. They are initialized at the first call to any of the functions above. The caller may change them, but this is discouraged; use the appropriate function arguments, instead.

tempfile.\texttt{tempdir}

When set to a value other than \texttt{None}, this variable defines the default value for the \texttt{dir} argument to all the functions defined in this module.
If `tempdir` is unset or `None` at any call to any of the above functions, Python searches a standard list of directories and sets `tempdir` to the first one which the calling user can create files in. The list is:

1. The directory named by the `TMPDIR` environment variable.
2. The directory named by the `TEMP` environment variable.
3. The directory named by the `TMP` environment variable.
4. A platform-specific location:
   - On RiscOS, the directory named by the `Wimp$ScrapDir` environment variable.
   - On Windows, the directories `C:\TEMP`, `C:\TMP`, `\TEMP`, and `\TMP`, in that order.
   - On all other platforms, the directories `/tmp`, `/var/tmp`, and `/usr/tmp`, in that order.
5. As a last resort, the current working directory.

tempfile.gettempdir()

Return the directory currently selected to create temporary files in. If `tempdir` is not `None`, this simply returns its contents; otherwise, the search described above is performed, and the result returned.

*New in version 2.3.*

tempfile.template

*Deprecated since version 2.0: Use `gettempprefix()` instead.*

When set to a value other than `None`, this variable defines the prefix of the final component of the filenames returned by `mktemp()`. A string of six random letters and digits is appended to the prefix to make the filename unique. The default prefix is `tmp`. 
Older versions of this module used to require that `template` be set to `None` after a call to `os.fork()`; this has not been necessary since version 1.5.2.

`tempfile.gettempprefix()`

Return the filename prefix used to create temporary files. This does not contain the directory component. Using this function is preferred over reading the `template` variable directly.

*New in version 1.5.2.*
10.7. `glob` — Unix style pathname pattern expansion

The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the Unix shell. No tilde expansion is done, but *, ?, and character ranges expressed with [] will be correctly matched. This is done by using the `os.listdir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

```
glob.glob(pathname)
```

Return a possibly-empty list of path names that match `pathname`, which must be a string containing a path specification. `pathname` can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../Tools/*/*.gif`), and can contain shell-style wildcards. Broken symlinks are included in the results (as in the shell).

```
glob.iglob(pathname)
```

Return an iterator which yields the same values as `glob()` without actually storing them all simultaneously.

*New in version 2.5.*

For example, consider a directory containing only the following files: `1.gif`, `2.txt`, and `card.gif`. `glob()` will produce the following results. Notice how any leading components of the path are preserved.

```
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
>>> glob.glob('*.gif')
```
See also:

**Module fnmatch**

Shell-style filename (not path) expansion
10.8. fnmatch — Unix filename pattern matching

This module provides support for Unix shell-style wildcards, which are *not* the same as regular expressions (which are documented in the *re* module). The special characters used in shell-style wildcards are:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>matches everything</td>
</tr>
<tr>
<td>?</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[seq]</td>
<td>matches any character in seq</td>
</tr>
<tr>
<td>[!seq]</td>
<td>matches any character not in seq</td>
</tr>
</tbody>
</table>

Note that the filename separator ("/' on Unix) is *not* special to this module. See module *glob* for pathname expansion (*glob* uses *fnmatch()* to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the * and ? patterns.

*fnmatch*. fnmatch(*filename, pattern*)

Test whether the *filename* string matches the *pattern* string, returning *True* or *False*. If the operating system is case-insensitive, then both parameters will be normalized to all lower- or upper-case before the comparison is performed. *fnmatchcase()* can be used to perform a case-sensitive comparison, regardless of whether that’s standard for the operating system.

This example will print all file names in the current directory with the extension .txt:
import fnmatch
import os

for file in os.listdir('.):
    if fnmatch.fnmatch(file, '*.txt'):
        print file

fnmatch.fnmatchcase(filename, pattern)
Test whether filename matches pattern, returning True or False; the comparison is case-sensitive.

fnmatch.filter(names, pattern)
Return the subset of the list of names that match pattern. It is the same as [n for n in names if fnmatch(n, pattern)], but implemented more efficiently.

New in version 2.2.

fnmatch.translate(pattern)
Return the shell-style pattern converted to a regular expression.

Example:

>>> import fnmatch, re
>>> regex = fnmatch.translate('*.txt')
>>> regex
'.*\.txt$'
>>> reobj = re.compile(regex)
>>> reobj.match('foobar.txt')
<_sre.SRE_Match object at 0x...>

See also:

Module glob
Unix shell-style path expansion.
10.9. linecache — Random access to text lines

The linecache module allows one to get any line from any file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the traceback module to retrieve source lines for inclusion in the formatted traceback.

The linecache module defines the following functions:

```python
linecache.getline(filename, lineno[, module_globals])
```

Get line lineno from file named filename. This function will never throw an exception — it will return '' on errors (the terminating newline character will be included for lines that are found).

If a file named filename is not found, the function will look for it in the module search path, sys.path, after first checking for a PEP 302 __loader__ in module_globals, in case the module was imported from a zipfile or other non-filesystem import source.

New in version 2.5: The module_globals parameter was added.

```python
linecache.clearcache()
```

Clear the cache. Use this function if you no longer need lines from files previously read using getline().

```python
linecache.checkcache([filename])
```

Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If filename is omitted, it will check all the entries in the cache.
Example:

```python
>>> import linecache
>>> linecache.getline('/etc/passwd', 4)
'sys:x:3:3:sys:/dev:/bin/sh\n'
```
The `shutil` module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal. For operations on individual files, see also the `os` module.

**Warning:** Even the higher-level file copying functions (`copy()`, `copy2()`) can’t copy all file metadata.

On POSIX platforms, this means that file owner and group are lost as well as ACLs. On Mac OS, the resource fork and other metadata are not used. This means that resources will be lost and file type and creator codes will not be correct. On Windows, file owners, ACLs and alternate data streams are not copied.
10.10.1. Directory and files operations

**shutil.copyfileobj**\( (fsrc, fdst[, length]) \)

Copy the contents of the file-like object \( fsrc \) to the file-like object \( fdst \). The integer \( length \), if given, is the buffer size. In particular, a negative \( length \) value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption. Note that if the current file position of the \( fsrc \) object is not 0, only the contents from the current file position to the end of the file will be copied.

**shutil.copyfile**\( (src, dst) \)

Copy the contents (no metadata) of the file named \( src \) to a file named \( dst \). \( dst \) must be the complete target file name; look at **copy()** for a copy that accepts a target directory path. If \( src \) and \( dst \) are the same files, **Error** is raised. The destination location must be writable; otherwise, an **IOError** exception will be raised. If \( dst \) already exists, it will be replaced. Special files such as character or block devices and pipes cannot be copied with this function. \( src \) and \( dst \) are path names given as strings.

**shutil.copymode**\( (src, dst) \)

Copy the permission bits from \( src \) to \( dst \). The file contents, owner, and group are unaffected. \( src \) and \( dst \) are path names given as strings.

**shutil.copystat**\( (src, dst) \)

Copy the permission bits, last access time, last modification time, and flags from \( src \) to \( dst \). The file contents, owner, and group are unaffected. \( src \) and \( dst \) are path names given as strings.

**shutil.copy**\( (src, dst) \)
Copy the file src to the file or directory dst. If dst is a directory, a file with the same basename as src is created (or overwritten) in the directory specified. Permission bits are copied. src and dst are path names given as strings.

`shutil.copy2(src, dst)`
Similar to `copy()`, but metadata is copied as well – in fact, this is just `copy()` followed by `copystat()`. This is similar to the Unix command `cp -p`.

`shutil.ignore_patterns(*patterns)`
This factory function creates a function that can be used as a callable for `copytree()`'s `ignore` argument, ignoring files and directories that match one of the glob-style `patterns` provided. See the example below.

*New in version 2.6.*

`shutil.copytree(src, dst[, symlinks=False[, ignore=None]])`
Recursively copy an entire directory tree rooted at src. The destination directory, named by dst, must not already exist; it will be created as well as missing parent directories. Permissions and times of directories are copied with `copystat()`, individual files are copied using `copy2()`.

If symlinks is true, symbolic links in the source tree are represented as symbolic links in the new tree; if false or omitted, the contents of the linked files are copied to the new tree.

If ignore is given, it must be a callable that will receive as its arguments the directory being visited by `copytree()`, and a list of its contents, as returned by `os.listdir()`. Since `copytree()` is called recursively, the `ignore` callable will be called once for each directory that is copied. The callable must return a sequence of
directory and file names relative to the current directory (i.e. a subset of the items in its second argument); these names will then be ignored in the copy process. `ignore_patterns()` can be used to create such a callable that ignores names based on glob-style patterns.

If exception(s) occur, an `Error` is raised with a list of reasons.

The source code for this should be considered an example rather than the ultimate tool.

*Changed in version 2.3:* `Error` is raised if any exceptions occur during copying, rather than printing a message.

*Changed in version 2.5:* Create intermediate directories needed to create `dst`, rather than raising an error. Copy permissions and times of directories using `copystat()`.

*Changed in version 2.6:* Added the `ignore` argument to be able to influence what is being copied.

```python
shutil.rmtree(path[, ignore_errors[, onerror]])
```

Delete an entire directory tree; `path` must point to a directory (but not a symbolic link to a directory). If `ignore_errors` is true, errors resulting from failed removals will be ignored; if false or omitted, such errors are handled by calling a handler specified by `onerror` or, if that is omitted, they raise an exception.

If `onerror` is provided, it must be a callable that accepts three parameters: `function`, `path`, and `excinfo`. The first parameter, `function`, is the function which raised the exception; it will be `os.path.islink()`, `os.listdir()`, `os.remove()` or `os.rmdir()`. The second parameter, `path`, will be the path name passed to `function`. The third parameter, `excinfo`, will be the exception information return by `sys.exc_info()`. Exceptions raised by
onerror will not be caught.

*Changed in version 2.6:* Explicitly check for path being a symbolic link and raise OSError in that case.

**shutil.move** *(src, dst)*

Recursively move a file or directory to another location.

If the destination is on the current filesystem, then simply use rename. Otherwise, copy src (with copy2()) to the dst and then remove src.

*New in version 2.3.*

**exception** *shutil.Error*

This exception collects exceptions that raised during a multi-file operation. For copytree(), the exception argument is a list of 3-tuples *(srcname, dstname, exception)*.

*New in version 2.3.*

### 10.10.1.1. copytree example

This example is the implementation of the *copytree()* function, described above, with the docstring omitted. It demonstrates many of the other functions provided by this module.

```python
def copytree(src, dst, symlinks=False, ignore=None):
    names = os.listdir(src)
    if ignore is not None:
        ignored_names = ignore(src, names)
    else:
        ignored_names = set()

    os.makedirs(dst)
    errors = []
    for name in names:
        if name in ignored_names:
```
Another example that uses the `ignore_patterns()` helper:

```python
from shutil import copytree, ignore_patterns

copytree(source, destination, ignore=ignore_patterns('*.pyc', 'tmp'))
```

This will copy everything except `.pyc` files and files or directories whose name starts with `tmp`.

Another example that uses the `ignore` argument to add a logging call:

```python
from shutil import copytree
```
import logging

def _logpath(path, names):
    logging.info('Working in %s' % path)
    return []  # nothing will be ignored

copytree(source, destination, ignore=_logpath)
## 10.10.2. Archives operations

**shutil.make_archive**(*base_name*, *format*, *root_dir*, *base_dir*, *verbose*, *dry_run*, *owner*, *group*, *logger*)

Create an archive file (eg. zip or tar) and returns its name.

*base_name* is the name of the file to create, including the path, minus any format-specific extension. *format* is the archive format: one of “zip”, “tar”, “bztar” or “gztar”.

*root_dir* is a directory that will be the root directory of the archive; ie. we typically chdir into *root_dir* before creating the archive.

*base_dir* is the directory where we start archiving from; ie. *base_dir* will be the common prefix of all files and directories in the archive.

*root_dir* and *base_dir* both default to the current directory.

*owner* and *group* are used when creating a tar archive. By default, uses the current owner and group.

New in version 2.7.

**shutil.get_archive_formats**()

Returns a list of supported formats for archiving. Each element of the returned sequence is a tuple *(name, description)*

By default **shutil** provides these formats:

- *gztar*: gzip’ed tar-file
- *bztar*: bzip2’ed tar-file
- *tar*: uncompressed tar file
- *zip*: ZIP file
You can register new formats or provide your own archiver for any existing formats, by using `register_archive_format()`.

*New in version 2.7.*

```python
shutil.register_archive_format(name, function[, extra_args[, description]])
```

Registers an archiver for the format `name`. `function` is a callable that will be used to invoke the archiver.

If given, `extra_args` is a sequence of `(name, value)` that will be used as extra keywords arguments when the archiver callable is used.

`description` is used by `get_archive_formats()` which returns the list of archivers. Defaults to an empty list.

*New in version 2.7.*

```python
shutil.unregister_archive_format(name)
```

Remove the archive format `name` from the list of supported formats.

*New in version 2.7.*

### 10.10.2.1. Archiving example

In this example, we create a gzip'ed tar-file archive containing all files found in the `.ssh` directory of the user:

```python
>>> from shutil import make_archive
>>> import os
>>> archive_name = os.path.expanduser(os.path.join('~', 'myarchive'))
>>> root_dir = os.path.expanduser(os.path.join('~', '.ssh'))
>>> make_archive(archive_name, 'gztar', root_dir)
'/Users/tarek/myarchive.tar.gz'
```
The resulting archive contains:

```bash
$ tar -tzvf /Users/tarek/myarchive.tar.gz
```

```
drwx------ tarek/staff 0 2010-02-01 16:23:40 ./
-rw-r--r-- tarek/staff 609 2008-06-09 13:26:54 ./authorized_keys

-rw-r--r-- tarek/staff 37192 2010-02-06 18:23:10 ./known_hosts
```
The Python Standard Library » 10. File and Directory Access »
**10.11. dircache — Cached directory listings**

*Deprecated since version 2.6:* The `dircache` module has been removed in Python 3.0.

The `dircache` module defines a function for reading directory listing using a cache, and cache invalidation using the `mtime` of the directory. Additionally, it defines a function to annotate directories by appending a slash.

The `dircache` module defines the following functions:

- **`dircache.reset()`**
  - Resets the directory cache.

- **`dircache.listdir(path)`**
  - Return a directory listing of `path`, as gotten from `os.listdir()`. Note that unless `path` changes, further call to `listdir()` will not re-read the directory structure.
    - Note that the list returned should be regarded as read-only. (Perhaps a future version should change it to return a tuple?)

- **`dircache.opendir(path)`**
  - Same as `listdir()`. Defined for backwards compatibility.

- **`dircache.annotate(head, list)`**
  - Assume `list` is a list of paths relative to `head`, and append, in place, a `'/ '` to each path which points to a directory.

```python
>>> import dircache
>>> a = dircache.listdir('/')
```
```python
>>> a = a[:]  # Copy the return value so we can change 'a'
>>> a
['bin', 'boot', 'cdrom', 'dev', 'etc', 'floppy', 'home', 'initrd', 'mnt', 'proc', 'root', 'sbin', 'tmp', 'usr', 'var', 'vmlinuz']
>>> dircache.annotate('/', a)
>>> a
['bin/', 'boot/', 'cdrom/', 'dev/', 'etc/', 'floppy/', 'home/', 'initrd/', 'mnt/', 'proc/', 'root/', 'sbin/', 'tmp/', 'usr/', 'vmlinuz']
```
11. Data Persistence

The modules described in this chapter support storing Python data in a persistent form on disk. The pickle and marshal modules can turn many Python data types into a stream of bytes and then recreate the objects from the bytes. The various DBM-related modules support a family of hash-based file formats that store a mapping of strings to other strings. The bsddb module also provides such disk-based string-to-string mappings based on hashing, and also supports B-Tree and record-based formats.

The list of modules described in this chapter is:

- **11.1. pickle** — Python object serialization
  - 11.1.1. Relationship to other Python modules
  - 11.1.2. Data stream format
  - 11.1.3. Usage
  - 11.1.4. What can be pickled and unpickled?
  - 11.1.5. The pickle protocol
    - 11.1.5.1. Pickling and unpickling normal class instances
    - 11.1.5.2. Pickling and unpickling extension types
    - 11.1.5.3. Pickling and unpickling external objects
  - 11.1.6. Subclassing Unpicklers
  - 11.1.7. Example
- **11.2. cPickle** — A faster pickle
- **11.3. copy_reg** — Register pickle support functions
- **11.4. shelve** — Python object persistence
  - 11.4.1. Restrictions
  - 11.4.2. Example
- **11.5. marshal** — Internal Python object serialization
- **11.6. anydbm** — Generic access to DBM-style databases
- **11.7. whichdb** — Guess which DBM module created a database
• 11.8. **dbhash** — DBM-style interface to the BSD database library
  ○ 11.8.1. Database Objects

• 11.9. **dumbdbm** — Portable DBM implementation
  ○ 11.9.1. Dumbdbm Objects

• 11.10. **sqlite3** — DB-API 2.0 interface for SQLite databases
  ○ 11.10.1. Module functions and constants
  ○ 11.10.2. Connection Objects
  ○ 11.10.3. Cursor Objects
  ○ 11.10.4. Row Objects
  ○ 11.10.5. SQLite and Python types
    ■ 11.10.5.1. Introduction
    ■ 11.10.5.2. Using adapters to store additional Python types in SQLite databases
      ■ 11.10.5.2.1. Letting your object adapt itself
      ■ 11.10.5.2.2. Registering an adapter callable
    ■ 11.10.5.3. Converting SQLite values to custom Python types
    ■ 11.10.5.4. Default adapters and converters
  ○ 11.10.6. Controlling Transactions
  ○ 11.10.7. Using **sqlite3** efficiently
    ■ 11.10.7.1. Using shortcut methods
    ■ 11.10.7.2. Accessing columns by name instead of by index
    ■ 11.10.7.3. Using the connection as a context manager
The `pickle` module implements a fundamental, but powerful algorithm for serializing and de-serializing a Python object structure. “Pickling” is the process whereby a Python object hierarchy is converted into a byte stream, and “unpickling” is the inverse operation, whereby a byte stream is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as “serialization”, “marshalling,” [1] or “flattening”, however, to avoid confusion, the terms used here are “pickling” and “unpickling”.

This documentation describes both the `pickle` module and the `cPickle` module.
11.1.1. Relationship to other Python modules

The pickle module has an optimized cousin called the cPickle module. As its name implies, cPickle is written in C, so it can be up to 1000 times faster than pickle. However it does not support subclassing of the Pickler() and Unpickler() classes, because in cPickle these are functions, not classes. Most applications have no need for this functionality, and can benefit from the improved performance of cPickle. Other than that, the interfaces of the two modules are nearly identical; the common interface is described in this manual and differences are pointed out where necessary. In the following discussions, we use the term “pickle” to collectively describe the pickle and cPickle modules.

The data streams the two modules produce are guaranteed to be interchangeable.

Python has a more primitive serialization module called marshal, but in general pickle should always be the preferred way to serialize Python objects. marshal exists primarily to support Python’s .pyc files.

The pickle module differs from marshal several significant ways:

- The pickle module keeps track of the objects it has already serialized, so that later references to the same object won’t be serialized again. marshal doesn’t do this.

This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by marshal, and in fact,
attempting to marshal recursive objects will crash your Python interpreter. Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. pickle stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- **marshal** cannot be used to serialize user-defined classes and their instances. pickle can save and restore class instances transparently, however the class definition must be importable and live in the same module as when the object was stored.

- The **marshal** serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support `.pyc` files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The **pickle** serialization format is guaranteed to be backwards compatible across Python releases.

**Warning:** The **pickle** module is not intended to be secure against erroneous or maliciously constructed data. Never unpickle data received from an untrusted or unauthenticated source.

Note that serialization is a more primitive notion than persistence; although **pickle** reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The **pickle** module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send
them across a network or store them in a database. The module `shelve` provides a simple interface to pickle and unpickle objects on DBM-style database files.
11.1.2. Data stream format

The data format used by pickle is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as XDR (which can't represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the pickle data format uses a printable ASCII representation. This is slightly more voluminous than a binary representation. The big advantage of using printable ASCII (and of some other characteristics of pickle's representation) is that for debugging or recovery purposes it is possible for a human to read the pickled file with a standard text editor.

There are currently 3 different protocols which can be used for pickling.

- Protocol version 0 is the original ASCII protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is the old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of new-style classes.

Refer to PEP 307 for more information.

If a protocol is not specified, protocol 0 is used. If protocol is specified as a negative value or HIGHEST_PROTOCOL, the highest protocol version available will be used.

*Changed in version 2.3:* Introduced the protocol parameter.

A binary format, which is slightly more efficient, can be chosen by
specifying a *protocol* version $\geq 1$. 
11.1.3. Usage

To serialize an object hierarchy, you first create a pickler, then you call the pickler’s `dump()` method. To de-serialize a data stream, you first create an unpickler, then you call the unpickler’s `load()` method. The `pickle` module provides the following constant:

`pickle.HIGHEST_PROTOCOL`

The highest protocol version available. This value can be passed as a `protocol` value.

*New in version 2.3.*

**Note:** Be sure to always open pickle files created with protocols >= 1 in binary mode. For the old ASCII-based pickle protocol 0 you can use either text mode or binary mode as long as you stay consistent.

A pickle file written with protocol 0 in binary mode will contain lone linefeeds as line terminators and therefore will look “funny” when viewed in Notepad or other editors which do not support this format.

The `pickle` module provides the following functions to make the pickling process more convenient:

`pickle.dump(obj, file[, protocol])`

Write a pickled representation of `obj` to the open file object `file`. This is equivalent to `Pickler(file, protocol).dump(obj)`.

If the `protocol` parameter is omitted, protocol 0 is used. If `protocol` is specified as a negative value or `HIGHEST_PROTOCOL`, the highest
protocol version will be used.

*Changed in version 2.3:* Introduced the `protocol` parameter.

*file* must have a `write()` method that accepts a single string argument. It can thus be a file object opened for writing, a `StringIO` object, or any other custom object that meets this interface.

**pickle.** `load`(*file*)

Read a string from the open file object *file* and interpret it as a pickle data stream, reconstructing and returning the original object hierarchy. This is equivalent to `Unpickler(file).load()`.

*file* must have two methods, a `read()` method that takes an integer argument, and a `readline()` method that requires no arguments. Both methods should return a string. Thus *file* can be a file object opened for reading, a `StringIO` object, or any other custom object that meets this interface.

This function automatically determines whether the data stream was written in binary mode or not.

**pickle.** `dumps`(*obj[, protocol]*)

Return the pickled representation of the object as a string, instead of writing it to a file.

If the `protocol` parameter is omitted, protocol 0 is used. If `protocol` is specified as a negative value or `HIGHEST_PROTOCOL`, the highest protocol version will be used.

*Changed in version 2.3:* The `protocol` parameter was added.

**pickle.** `loads`(*string*)

Read a pickled object hierarchy from a string. Characters in the
string past the pickled object’s representation are ignored.

The pickle module also defines three exceptions:

**exception** pickle. **PickleError**
A common base class for the other exceptions defined below. This inherits from Exception.

**exception** pickle. **PicklingError**
This exception is raised when an unpicklable object is passed to the `dump()` method.

**exception** pickle. **UnpicklingError**
This exception is raised when there is a problem unpickling an object. Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) `AttributeError`, `EOFError`, `ImportError`, and `IndexError`.

The pickle module also exports two callables [2], Pickler and Unpickler:

**class** pickle. **Pickler**(`file`, `protocol`)
This takes a file-like object to which it will write a pickle data stream.

If the `protocol` parameter is omitted, protocol 0 is used. If `protocol` is specified as a negative value or `HIGHEST_PROTOCOL`, the highest protocol version will be used.

*Changed in version 2.3:* Introduced the `protocol` parameter.

`file` must have a `write()` method that accepts a single string argument. It can thus be an open file object, a `StringIO` object, or any other custom object that meets this interface.
**Pickler** objects define one (or two) public methods:

\[ \text{dump}(\text{obj}) \]
Write a pickled representation of \textit{obj} to the open file object given in the constructor. Either the binary or ASCII format will be used, depending on the value of the \textit{protocol} argument passed to the constructor.

\[ \text{clear.memo}() \]
Clears the pickler’s “memo”. The memo is the data structure that remembers which objects the pickler has already seen, so that shared or recursive objects pickled by reference and not by value. This method is useful when re-using picklers.

**Note:** Prior to Python 2.3, \text{clear.memo}() was only available on the picklers created by \texttt{cPickle}. In the \texttt{pickle} module, picklers have an instance variable called \texttt{memo} which is a Python dictionary. So to clear the memo for a \texttt{pickle} module pickler, you could do the following:

\begin{verbatim}
mypickler.memo.clear()
\end{verbatim}

Code that does not need to support older versions of Python should simply use \text{clear.memo}().

It is possible to make multiple calls to the \text{dump()} method of the same \texttt{Pickler} instance. These must then be matched to the same number of calls to the \text{load()} method of the corresponding \texttt{Unpickler} instance. If the same object is pickled by multiple \text{dump()} calls, the \text{load()} will all yield references to the same object. \[3\]

**Unpickler** objects are defined as:
class pickle. **Unpickler**(*file*)

This takes a file-like object from which it will read a pickle data stream. This class automatically determines whether the data stream was written in binary mode or not, so it does not need a flag as in the **Pickler** factory.

*file* must have two methods, a **read()** method that takes an integer argument, and a **readline()** method that requires no arguments. Both methods should return a string. Thus *file* can be a file object opened for reading, a **StringIO** object, or any other custom object that meets this interface.

**Unpickler** objects have one (or two) public methods:

**load()**

Read a pickled object representation from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein.

This method automatically determines whether the data stream was written in binary mode or not.

**noload()**

This is just like **load()** except that it doesn’t actually create any objects. This is useful primarily for finding what’s called “persistent ids” that may be referenced in a pickle data stream. See section *The pickle protocol* below for more details.

**Note:** the **noload()** method is currently only available on **Unpickler** objects created with the **cPickle** module. **pickle** module **Unpicklers** do not have the **noload()** method.
11.1.4. What can be pickled and unpickled?

The following types can be pickled:

- None, True, and False
- integers, long integers, floating point numbers, complex numbers
- normal and Unicode strings
- tuples, lists, sets, and dictionaries containing only picklable objects
- functions defined at the top level of a module
- built-in functions defined at the top level of a module
- classes that are defined at the top level of a module
- instances of such classes whose __dict__ or __setstate__() is picklable (see section The pickle protocol for details)

Attempts to pickle unpicklable objects will raise the PicklingError exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a RuntimeError will be raised in this case. You can carefully raise this limit with sys.setrecursionlimit().

Note that functions (built-in and user-defined) are pickled by “fully qualified” name reference, not by value. This means that only the function name is pickled, along with the name of module the function is defined in. Neither the function’s code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised. [4]

Similarly, classes are pickled by named reference, so the same restrictions in the unpickling environment apply. Note that none of
the class's code or data is pickled, so in the following example the class attribute `attr` is not restored in the unpickling environment:

```python
class Foo:
    attr = 'a class attr'

picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined in the top level of a module.

Similarly, when class instances are pickled, their class's code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class's `__setstate__()` method.
11.1.5. The pickle protocol

This section describes the “pickling protocol” that defines the interface between the pickler/unpickler and the objects that are being serialized. This protocol provides a standard way for you to define, customize, and control how your objects are serialized and deserialized. The description in this section doesn't cover specific customizations that you can employ to make the unpickling environment slightly safer from untrusted pickle data streams; see section Subclassing Unpicklers for more details.

11.1.5.1. Pickling and unpickling normal class instances

object.__getinitargs__()  
When a pickled class instance is unpickled, its __init__() method is normally not invoked. If it is desirable that the __init__() method be called on unpickling, an old-style class can define a method __getinitargs__(), which should return a tuple containing the arguments to be passed to the class constructor (__init__() for example). The __getinitargs__() method is called at pickle time; the tuple it returns is incorporated in the pickle for the instance.

object.__getnewargs__()  
New-style types can provide a __getnewargs__() method that is used for protocol 2. Implementing this method is needed if the type establishes some internal invariants when the instance is created, or if the memory allocation is affected by the values passed to the __new__() method for the type (as it is for tuples and strings). Instances of a new-style class c are created using
obj = C.__new__(C, *args)

where args is the result of calling __getnewargs__() on the original object; if there is no __getnewargs__(), an empty tuple is assumed.

object.__getstate__()

Classes can further influence how their instances are pickled; if the class defines the method __getstate__(), it is called and the return state is pickled as the contents for the instance, instead of the contents of the instance’s dictionary. If there is no __getstate__() method, the instance’s __dict__ is pickled.

object.__setstate__()

Upon unpickling, if the class also defines the method __setstate__(), it is called with the unpickled state. [5] If there is no __setstate__() method, the pickled state must be a dictionary and its items are assigned to the new instance’s dictionary. If a class defines both __getstate__() and __setstate__(), the state object needn’t be a dictionary and these methods can do what they want. [6]

**Note:** For new-style classes, if __getstate__() returns a false value, the __setstate__() method will not be called.

**Note:** At unpickling time, some methods like __getattr__(), __getattribute__(), or __setattr__() may be called upon the instance. In case those methods rely on some internal invariant being true, the type should implement either __getinitargs__() or __getnewargs__() to establish such an invariant; otherwise, neither __new__() nor __init__() will be called.
object.__reduce__()  

When the Pickler encounters an object of a type it knows nothing about — such as an extension type — it looks in two places for a hint of how to pickle it. One alternative is for the object to implement a __reduce__() method. If provided, at pickling time __reduce__() will be called with no arguments, and it must return either a string or a tuple.

If a string is returned, it names a global variable whose contents are pickled as normal. The string returned by __reduce__() should be the object’s local name relative to its module; the pickle module searches the module namespace to determine the object’s module.

When a tuple is returned, it must be between two and five elements long. Optional elements can either be omitted, or None can be provided as their value. The contents of this tuple are pickled as normal and used to reconstruct the object at unpickling time. The semantics of each element are:

- A callable object that will be called to create the initial version of the object. The next element of the tuple will provide arguments for this callable, and later elements provide additional state information that will subsequently be used to fully reconstruct the pickled data.

In the unpickling environment this object must be either a class, a callable registered as a “safe constructor” (see below), or it must have an attribute __safe_for_unpickling__ with a true value. Otherwise, an UnpicklingError will be raised in the unpickling environment. Note that as usual, the callable itself is pickled by name.
• A tuple of arguments for the callable object.

  Changed in version 2.5: Formerly, this argument could also be None.

• Optionally, the object's state, which will be passed to the object's __setstate__() method as described in section
  Pickling and unpickling normal class instances. If the object has no __setstate__() method, then, as above, the value
  must be a dictionary and it will be added to the object's __dict__.

• Optionally, an iterator (and not a sequence) yielding successive list items. These list items will be pickled, and
  appended to the object using either obj.append(item) or obj.extend(list_of_items). This is primarily used for list
  subclasses, but may be used by other classes as long as they have append() and extend() methods with the
  appropriate signature. (Whether append() or extend() is used depends on which pickle protocol version is used as
  well as the number of items to append, so both must be supported.)

• Optionally, an iterator (not a sequence) yielding successive dictionary items, which should be tuples of the form (key,
  value). These items will be pickled and stored to the object using obj[key] = value. This is primarily used for dictionary
  subclasses, but may be used by other classes as long as they implement __setitem__().

object.__reduce_ex__(protocol)

  It is sometimes useful to know the protocol version when implementing __reduce__() method. This can be done by implementing a
  method named __reduce_ex__() instead of __reduce__().
`__reduce_ex__()` method will be called with a single integer argument, the protocol version.

The object class implements both `__reduce__()` and `__reduce_ex__()`; however, if a subclass overrides `__reduce__()` but not `__reduce_ex__()`, the `__reduce_ex__()` implementation detects this and calls `__reduce__()`.

An alternative to implementing a `__reduce__()` method on the object to be pickled, is to register the callable with the `copy_reg` module. This module provides a way for programs to register “reduction functions” and constructors for user-defined types. Reduction functions have the same semantics and interface as the `__reduce__()` method described above, except that they are called with a single argument, the object to be pickled.

The registered constructor is deemed a “safe constructor” for purposes of unpickling as described above.

### 11.1.5.3. Pickling and unpickling external objects

For the benefit of object persistence, the `pickle` module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a “persistent id”, which is just an arbitrary string of printable ASCII characters. The resolution of such names is not defined by the `pickle` module; it will delegate this resolution to user defined functions on the pickler and unpickler. [7]

To define external persistent id resolution, you need to set the `persistent_id` attribute of the pickler object and the `persistent_load` attribute of the unpickler object.
To pickle objects that have an external persistent id, the pickler must have a custom `persistent_id()` method that takes an object as an argument and returns either `None` or the persistent id for that object. When `None` is returned, the pickler simply pickles the object as normal. When a persistent id string is returned, the pickler will pickle that string, along with a marker so that the unpickler will recognize the string as a persistent id.

To unpickle external objects, the unpickler must have a custom `persistent_load()` function that takes a persistent id string and returns the referenced object.

Here's a silly example that *might* shed more light:

```python
import pickle
from cStringIO import StringIO

src = StringIO()
p = pickle.Pickler(src)

def persistent_id(obj):
    if hasattr(obj, 'x'):
        return 'the value %d' % obj.x
    else:
        return None

p.persistent_id = persistent_id

class Integer:
    def __init__(self, x):
        self.x = x
    def __str__(self):
        return 'My name is integer %d' % self.x

i = Integer(7)
print i
p.dump(i)
datastream = src.getvalue()
print repr(datastream)
dst = StringIO(datastream)
```

In the `cPickle` module, the unpickler’s `persistent_load` attribute can also be set to a Python list, in which case, when the unpickler reaches a persistent id, the persistent id string will simply be appended to this list. This functionality exists so that a pickle data stream can be “sniffed” for object references without actually instantiating all the objects in a pickle. [8] Setting `persistent_load` to a list is usually used in conjunction with the `noload()` method on the Unpickler.
11.1.6. Subclassing Unpicklers

By default, unpickling will import any class that it finds in the pickle data. You can control exactly what gets unpickled and what gets called by customizing your unpickler. Unfortunately, exactly how you do this is different depending on whether you’re using pickle or cPickle. [9]

In the pickle module, you need to derive a subclass from Unpickler, overriding the load_global() method. load_global() should read two lines from the pickle data stream where the first line will the name of the module containing the class and the second line will be the name of the instance’s class. It then looks up the class, possibly importing the module and digging out the attribute, then it appends what it finds to the unpickler’s stack. Later on, this class will be assigned to the __class__ attribute of an empty class, as a way of magically creating an instance without calling its class’s __init__(). Your job (should you choose to accept it), would be to have load_global() push onto the unpickler’s stack, a known safe version of any class you deem safe to unpickle. It is up to you to produce such a class. Or you could raise an error if you want to disallow all unpickling of instances. If this sounds like a hack, you’re right. Refer to the source code to make this work.

Things are a little cleaner with cPickle, but not by much. To control what gets unpickled, you can set the unpickler’s find_global attribute to a function or None. If it is None then any attempts to unpickle instances will raise an UnpicklingError. If it is a function, then it should accept a module name and a class name, and return the corresponding class object. It is responsible for looking up the class and performing any necessary imports, and it may raise an error to prevent instances of the class from being unpickled.
The moral of the story is that you should be really careful about the source of the strings your application unpickles.
11.1.7. Example

For the simplest code, use the `dump()` and `load()` functions. Note that a self-referencing list is pickled and restored correctly.

```python
import pickle

data1 = {'a': [1, 2.0, 3, 4+6j],
         'b': ('string', u'Unicode string'),
         'c': None}

selfref_list = [1, 2, 3]
selfref_list.append(selfref_list)

output = open('data.pkl', 'wb')
#
# Pickle dictionary using protocol 0.
pickle.dump(data1, output)
#
# Pickle the list using the highest protocol available.
pickle.dump(selfref_list, output, -1)

output.close()
```

The following example reads the resulting pickled data. When reading a pickle-containing file, you should open the file in binary mode because you can't be sure if the ASCII or binary format was used.

```python
import pprint, pickle

pkl_file = open('data.pkl', 'rb')
data1 = pickle.load(pkl_file)
pprint.pprint(data1)

data2 = pickle.load(pkl_file)
pprint.pprint(data2)
pkl_file.close()
```
Here's a larger example that shows how to modify pickling behavior for a class. The TextReader class opens a text file, and returns the line number and line contents each time its readline() method is called. If a TextReader instance is pickled, all attributes except the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The __setstate__() and __getstate__() methods are used to implement this behavior.

```python
#!/usr/local/bin/python

class TextReader:
    """Print and number lines in a text file."""
    def __init__(self, file):
        self.file = file
        self.fh = open(file)
        self.lineno = 0

    def readline(self):
        self.lineno = self.lineno + 1
        line = self.fh.readline()
        if not line:
            return None
        if line.endswith("\n"):
            line = line[:-1]
        return "%d: %s" % (self.lineno, line)

    def __getstate__(self):
        odict = self.__dict__.copy() # copy the dict since we change it
        del odict['fh'] # remove filehandle entry
        return odict

    def __setstate__(self, dict):
        fh = open(dict['file']) # reopen file
        count = dict['lineno'] # read from file...
        while count:
            # until line count is restored
            fh.readline()
            count = count - 1
        self.__dict__.update(dict) # update attributes
        self.fh = fh # save the file object
```
A sample usage might be something like this:

```python
>>> import TextReader
>>> obj = TextReader.TextReader("TextReader.py")
>>> obj.readline()
'1: #!/usr/local/bin/python'
>>> obj.readline()
'2: '
>>> obj.readline()
'3: class TextReader:'
>>> import pickle
>>> pickle.dump(obj, open('save.p', 'wb'))
```

If you want to see that `pickle` works across Python processes, start another Python session, before continuing. What follows can happen from either the same process or a new process.

```python
>>> import pickle
>>> reader = pickle.load(open('save.p', 'rb'))
>>> reader.readline()
'4: """Print and number lines in a text file."""
```

**Module** `copy_reg`

Pickle interface constructor registration for extension types.

**Module** `shelve`

Indexed databases of objects; uses `pickle`.

**Module** `copy`

Shallow and deep object copying.

**Module** `marshal`

High-performance serialization of built-in types.
11.2. cPickle — A faster pickle

The cPickle module supports serialization and de-serialization of Python objects, providing an interface and functionality nearly identical to the pickle module. There are several differences, the most important being performance and subclassability.

First, cPickle can be up to 1000 times faster than pickle because the former is implemented in C. Second, in the cPickle module the callables Pickler() and Unpickler() are functions, not classes. This means that you cannot use them to derive custom pickling and unpickling subclasses. Most applications have no need for this functionality and should benefit from the greatly improved performance of the cPickle module.

The pickle data stream produced by pickle and cPickle are identical, so it is possible to use pickle and cPickle interchangeably with existing pickles. [10]

There are additional minor differences in API between cPickle and pickle, however for most applications, they are interchangeable. More documentation is provided in the pickle module documentation, which includes a list of the documented differences.

Footnotes

[1] Don’t confuse this with the marshal module
In the pickle module these callables are classes, which you could subclass to customize the behavior. However, in the cPickle module these callables are factory functions and so cannot be subclassed. One common reason to subclass is to control what objects can actually be unpickled. See section Subclassing Unpicklers for more details.
**Warning:** this is intended for pickling multiple objects without intervening modifications to the objects or their parts. If you modify an object and then pickle it again using the same [Pickler] instance, the object is not pickled again — a reference to it is pickled and the [Unpickler] will return the old value, not the modified one. There are two problems here: (1) detecting changes, and (2) marshalling a minimal set of changes. Garbage Collection may also become a problem here.

The exception raised will likely be an [ImportError] or an [AttributeError] but it could be something else.

These methods can also be used to implement copying class instances.

This protocol is also used by the shallow and deep copying operations defined in the [copy] module.

The actual mechanism for associating these user defined functions is slightly different for pickle and cPickle. The description given here works the same for both implementations. Users of the pickle module could also use subclassing to effect the same results, overriding the persistent_id() and persistent_load() methods in the derived classes.

We'll leave you with the image of Guido and Jim sitting around sniffing pickles in their living rooms.

A word of caution: the mechanisms described here use internal attributes and methods, which are subject to change in future versions of Python. We intend to someday provide a common interface for controlling this behavior, which will work in either pickle or cPickle.

Since the pickle data format is actually a tiny stack-oriented programming language, and some freedom is taken in the encodings of certain objects, it is possible that the two modules produce different data streams for the same input objects. However it is guaranteed that they will always be able to read each other’s data streams.
11. Data Persistence
11.3. copy_reg — Register pickle support functions

Note: The copy_reg module has been renamed to copyreg in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The copy_reg module provides support for the pickle and cPickle modules. The copy module is likely to use this in the future as well. It provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

copy_reg.constructor(object)
Declares object to be a valid constructor. If object is not callable (and hence not valid as a constructor), raises TypeError.

copy_reg.pickle(type, function[, constructor])
Declares that function should be used as a “reduction” function for objects of type type; type must not be a “classic” class object. (Classic classes are handled differently; see the documentation for the pickle module for details.) function should return either a string or a tuple containing two or three elements.

The optional constructor parameter, if provided, is a callable object which can be used to reconstruct the object when called with the tuple of arguments returned by function at pickling time. TypeError will be raised if object is a class or constructor is not callable.

See the pickle module for more details on the interface expected of function and constructor.
11.4. shelve — Python object persistence

A “shelf” is a persistent, dictionary-like object. The difference with “dbm” databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects — anything that the pickle module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

\[
\text{shelve.open}(\text{filename}[\text{, flag='c'[, protocol=None[, writeback=False]]]})
\]

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional flag parameter has the same interpretation as the flag parameter of anydbm.open().

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the protocol parameter.

*Changed in version 2.3:* The protocol parameter was added.

Because of Python semantics, a shelf cannot know when a mutable persistent-dictionary entry is modified. By default modified objects are written only when assigned to the shelf (see Example). If the optional writeback parameter is set to True, all entries accessed are also cached in memory, and written back on sync() and close(); this can make it handier to mutate mutable entries in the persistent dictionary, but, if many entries are
accessed, it can consume vast amounts of memory for the cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were actually mutated).

**Note:** Do not rely on the shelf being closed automatically; always call `close()` explicitly when you don’t need it any more, or use a `with` statement with `contextlib.closing()`.

Shelf objects support all methods supported by dictionaries. This eases the transition from dictionary based scripts to those requiring persistent storage.

Two additional methods are supported:

**Shelf.sync()**
Write back all entries in the cache if the shelf was opened with `writeback` set to `True`. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with `close()`.

**Shelf.close()**
Synchronize and close the persistent `dict` object. Operations on a closed shelf will fail with a `ValueError`.

**See also:** Persistent dictionary recipe with widely supported storage formats and having the speed of native dictionaries.
11.4.1. Restrictions

- The choice of which database package will be used (such as `dbm`, `gdbm` or `bsddb`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used — this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.

- The `shelve` module does not support concurrent read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. Unix file locking can be used to solve this, but this differs across Unix versions and requires knowledge about the database implementation used.

```python
class shelve.Shelf(dict[, protocol=None[, writeback=False]])
```
A subclass of `UserDict.DictMixin` which stores pickled values in the `dict` object.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the `protocol` parameter. See the `pickle` documentation for a discussion of the pickle protocols.

*Changed in version 2.3:* The `protocol` parameter was added.

If the `writeback` parameter is `True`, the object will hold a cache of all entries accessed and write them back to the `dict` at sync and close times. This allows natural operations on mutable entries, but can consume much more memory and make sync and close
take a long time.

class shelve.BsdDbShelf(dict[, protocol=None[, writeback=False]])
A subclass of Shelf which exposes first(), next(), previous(), last() and set_location() which are available in the bsddb module but not in other database modules. The dict object passed to the constructor must support those methods. This is generally accomplished by calling one of bsddb.hashopen(), bsddb.btopen() or bsddb.rnopen(). The optional protocol and writeback parameters have the same interpretation as for the Shelf class.

class shelve.DbfilenameShelf(filename[, flag='c'[, protocol=None[, writeback=False]])]
A subclass of Shelf which accepts a filename instead of a dict-like object. The underlying file will be opened using anydbm.open(). By default, the file will be created and opened for both read and write. The optional flag parameter has the same interpretation as for the open() function. The optional protocol and writeback parameters have the same interpretation as for the Shelf class.
11.4.2. Example

To summarize the interface (**key** is a string, **data** is an arbitrary object):

```python
import shelve

d = shelve.open(filename)  # open -- file may get suffix added by library

d[key] = data  # store data at key (overwrites old data if using an existing key)
data = d[key]  # retrieve a COPY of data at key (raise KeyError if such key)
del d[key]  # delete data stored at key (raises KeyError if no such key)
flag = d.has_key(key)  # true if the key exists
klist = d.keys()  # a list of all existing keys (slow!)

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = range(4)  # this works as expected, but...
d['xx'].append(5)  # *this doesn't!* -- d['xx'] is STILL range

# having opened d without writeback=True, you need to code carefully:
temp = d['xx']  # extracts the copy
temp.append(5)  # mutates the copy
d['xx'] = temp  # stores the copy right back, to persist it

# or, d=shelve.open(filename,writeback=True) would let you just
# d['xx'].append(5) and have it work as expected, BUT it would
# consume more memory and make the d.close() operation slower.

d.close()  # close it
```

**Module** `anydbm`

Generic interface to `dbm-style databases`.

**Module** `bsddb`
BSD `db` database interface.

**Module `dbhash`**
Thin layer around the `bsddb` which provides an `open()` function like the other database modules.

**Module `dbm`**
Standard Unix database interface.

**Module `dumbdbm`**
Portable implementation of the `dbm` interface.

**Module `gdbm`**
GNU database interface, based on the `dbm` interface.

**Module `pickle`**
Object serialization used by `shelve`.

**Module `cPickle`**
High-performance version of `pickle`.
This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does). \[1\]

This is not a general “persistence” module. For general persistence and transfer of Python objects through RPC calls, see the modules pickle and shelve. The marshal module exists mainly to support reading and writing the “pseudo-compiled” code for Python modules of .pyc files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you’re serializing and de-serializing Python objects, use the pickle module instead – the performance is comparable, version independence is guaranteed, and pickle supports a substantially wider range of objects than marshal.

**Warning:** The marshal module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: booleans, integers, long integers, floating point numbers, complex numbers, strings, Unicode objects, tuples, lists, sets, frozensets, dictionaries, and code objects, where it should be
understood that tuples, lists, sets, frozensets and dictionaries are only supported as long as the values contained therein are themselves supported; and recursive lists, sets and dictionaries should not be written (they will cause infinite loops). The singletons None, Ellipsis and StopIteration can also be marshalled and unmarshalled.

**Warning:** On machines where C's `long int` type has more than 32 bits (such as the DEC Alpha), it is possible to create plain Python integers that are longer than 32 bits. If such an integer is marshaled and read back in on a machine where C's `long int` type has only 32 bits, a Python long integer object is returned instead. While of a different type, the numeric value is the same. (This behavior is new in Python 2.2. In earlier versions, all but the least-significant 32 bits of the value were lost, and a warning message was printed.)

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

```
marshal.dump(value, file[, version])
```

Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `os.popen()`. It must be opened in binary mode (`'wb'` or `'w+b'`).

If the value has (or contains an object that has) an unsupported type, a `ValueError` exception is raised — but garbage data will also be written to the file. The object will not be properly read back by `load()`.

*New in version 2.4:* The `version` argument indicates the data
format that `dump` should use (see below).

**marshal.load(file)**

Read one value from the open file and return it. If no valid value is read (e.g. because the data has a different Python version's incompatible marshal format), raise `EOFError`, `ValueError` or `TypeError`. The file must be an open file object opened in binary mode (`'rb'` or `'r+b'`).

**Note:** If an object containing an unsupported type was marshalled with `dump()`, `load()` will substitute `None` for the unmarshallable type.

**marshal.dumps(value[, version])**

Return the string that would be written to a file by `dump(value, file)`. The value must be a supported type. Raise a `ValueError` exception if value has (or contains an object that has) an unsupported type.

*New in version 2.4:* The `version` argument indicates the data format that `dumps` should use (see below).

**marshal.loads(string)**

Convert the string to a value. If no valid value is found, raise `EOFError`, `ValueError` or `TypeError`. Extra characters in the string are ignored.

In addition, the following constants are defined:

**marshal.version**

Indicates the format that the module uses. Version 0 is the historical format, version 1 (added in Python 2.4) shares interned strings and version 2 (added in Python 2.5) uses a binary format
for floating point numbers. The current version is 2.

New in version 2.4.

Footnotes

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term “marshalling” for shipping of data around in a self-contained form. Strictly speaking, “to marshal” means to convert some data from internal to external form (in an RPC buffer for instance) and “unmarshalling” for the reverse process.
11.6. anydbm — Generic access to DBM-style databases

**Note:** The `anydbm` module has been renamed to `dbm` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

`anydbm` is a generic interface to variants of the DBM database — `dbhash` (requires `bsddb`), `gdbm`, or `dbm`. If none of these modules is installed, the slow-but-simple implementation in module `dumbdbm` will be used.

```python
anydbm.open(filename[, flag[, mode]])
```

Open the database file `filename` and return a corresponding object.

If the database file already exists, the `whichdb` module is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is used.

The optional `flag` argument must be one of these values:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn't exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

If not specified, the default value is 'r'.
The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0666 (and will be modified by the prevailing umask).

**exception anydbm.error**

A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception also named *anydbm.error* as the first item — the latter is used when *anydbm.error* is raised.

The object returned by *open()* supports most of the same functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the *has_key()* and *keys()* methods are available. Keys and values must always be strings.

The following example records some hostnames and a corresponding title, and then prints out the contents of the database:

```python
import anydbm

# Open database, creating it if necessary.
db = anydbm.open('cache', 'c')

# Record some values
db['www.python.org'] = 'Python Website'
db['www.cnn.com'] = 'Cable News Network'

# Loop through contents. Other dictionary methods
# such as .keys(), .values() also work.
for k, v in db.iteritems():
    print k, '\t', v

# Storing a non-string key or value will raise an exception (most
# likely a TypeError).
db['www.yahoo.com'] = 4

# Close when done.
db.close()
```

GNU database interface, based on the dbm interface.

Module **shelve**
General object persistence built on top of the Python dbm interface.

Module **whichdb**
Utility module used to determine the type of an existing database.
11.7. whichdb — Guess which DBM module created a database

**Note:** The `whichdb` module’s only function has been put into the `dbm` module in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

The single function in this module attempts to guess which of the several simple database modules available—`dbm`, `gdbm`, or `dbhash`—should be used to open a given file.

`whichdb.whchdb(filename)`

Returns one of the following values: `None` if the file can’t be opened because it’s unreadable or doesn’t exist; the empty string (`''`) if the file’s format can’t be guessed; or a string containing the required module name, such as `'dbm'` or `'gdbm'`.

© Copyright 1990-2013, Python Software Foundation. Please donate. Last updated on May 10, 2013. Found a bug? Created using Sphinx 0.6.3.
11.8. `dbhash` — DBM-style interface to the BSD database library

*Deprecated since version 2.6:* The `dbhash` module has been deprecated for removal in Python 3.0.

The `dbhash` module provides a function to open databases using the BSD `db` library. This module mirrors the interface of the other Python database modules that provide access to DBM-style databases. The `bsddb` module is required to use `dbhash`.

This module provides an exception and a function:

```python
exception dbhash.error
    Exception raised on database errors other than `KeyError`. It is a synonym for `bsddb.error`.

dbhash.open(path[, flag[, mode]])
    Open a `db` database and return the database object. The `path` argument is the name of the database file.
```

The `flag` argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn't exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

For platforms on which the BSD `db` library supports locking, an
'1' can be appended to indicate that locking should be used.

The optional *mode* parameter is used to indicate the Unix permission bits that should be set if a new database must be created; this will be masked by the current umask value for the process.

See also:

**Module anydbm**
Generic interface to *dbm*-style databases.

**Module bsddb**
Lower-level interface to the BSD *db* library.

**Module whichdb**
Utility module used to determine the type of an existing database.
The database objects returned by `open()` provide the methods common to all the DBM-style databases and mapping objects. The following methods are available in addition to the standard methods.

**dbhash.first()**

It's possible to loop over every key/value pair in the database using this method and the `next()` method. The traversal is ordered by the databases internal hash values, and won't be sorted by the key values. This method returns the starting key.

**dbhash.last()**

Return the last key/value pair in a database traversal. This may be used to begin a reverse-order traversal; see `previous()`.

**dbhash.next()**

Returns the key next key/value pair in a database traversal. The following code prints every key in the database `db`, without having to create a list in memory that contains them all:

```python
print db.first()
for i in xrange(1, len(db)):
    print db.next()
```

**dbhash.previous()**

Returns the previous key/value pair in a forward-traversal of the database. In conjunction with `last()`, this may be used to implement a reverse-order traversal.

**dbhash.sync()**

This method forces any unwritten data to be written to the disk.
11.9. **dumbdbm** — Portable DBM implementation

**Note:** The `dumbdbm` module has been renamed to `dbm.dumb` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

**Note:** The `dumbdbm` module is intended as a last resort fallback for the `anydbm` module when no more robust module is available. The `dumbdbm` module is not written for speed and is not nearly as heavily used as the other database modules.

The `dumbdbm` module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as `gdbm` and `bsddb`, no external library is required. As with other persistent mappings, the keys and values must always be strings.

The module defines the following:

```python
exception dumbdbm.error
    Raised on dumbdbm-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

dumbdbm.open(filename[, flag[, mode]])
    Open a dumbdbm database and return a dumbdbm object. The `filename` argument is the basename of the database file (without any specific extensions). When a dumbdbm database is created, files with `.dat` and `.dir` extensions are created.

    The optional `flag` argument is currently ignored; the database is always opened for update, and will be created if it does not exist.
```
The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0666 (and will be modified by the prevailing umask).

*Changed in version 2.2:* The *mode* argument was ignored in earlier versions.

**See also:**

Similar interface to the DBM/NDBM library.

**Module** [gdbm](#)
Similar interface to the GNU GDBM library.

**Module** [shelve](#)
Persistence module which stores non-string data.

**Module** [whichdb](#)
Utility module used to determine the type of an existing database.
11.9.1. Dumbdbm Objects

In addition to the methods provided by the `UserDict.DictMixin` class, `dumbdbm` objects provide the following methods.

```
dumbdbm.sync()
```

Synchronize the on-disk directory and data files. This method is called by the `sync()` method of `shelve` objects.
11.10. sqlite3 — DB-API 2.0 interface for SQLite databases

New in version 2.5.

SQLite is a C library that provides a lightweight disk-based database that doesn’t require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It's also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

sqlite3 was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by PEP 249.

To use the module, you must first create a Connection object that represents the database. Here the data will be stored in the /tmp/example file:

```python
cconn = sqlite3.connect('/tmp/example')
```

You can also supply the special name :memory: to create a database in RAM.

Once you have a Connection, you can create a Cursor object and call its execute() method to perform SQL commands:

```python
c = conn.cursor()
# Create table
c.execute('''create table stocks
     (date text, trans text, symbol text, qty real, price real)'''')
```
Usually your SQL operations will need to use values from Python variables. You shouldn’t assemble your query using Python’s string operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

Instead, use the DB-API’s parameter substitution. Put `?` as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor’s `execute()` method. (Other database modules may use a different placeholder, such as `%s` or `:1`.) For example:

```python
# Never do this -- insecure!
symbol = 'IBM'
c.execute("... where symbol = '%s'" % symbol)

# Do this instead
t = (symbol,)
c.execute('select * from stocks where symbol=?', t)

# Larger example
for t in [('2006-03-28', 'BUY', 'IBM', 1000, 45.00),
          ('2006-04-05', 'BUY', 'MSOFT', 1000, 72.00),
          ('2006-04-06', 'SELL', 'IBM', 500, 53.00),
          ]:
    c.execute('insert into stocks values (?,?,?,?,?)', t)
```

To retrieve data after executing a SELECT statement, you can either treat the cursor as an *iterator*, call the cursor’s `fetchone()` method to retrieve a single matching row, or call `fetchall()` to get a list of the matching rows.
This example uses the iterator form:

```python
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
...     print row
...
(u'2006-01-05', u'BUY', u'RHAT', 100, 35.14)
(u'2006-03-28', u'BUY', u'IBM', 1000, 45.0)
(u'2006-04-06', u'SELL', u'IBM', 500, 53.0)
(u'2006-04-05', u'BUY', u'MSOFT', 1000, 72.0)
>>> 
```

**PEP 249 - Database API Specification 2.0**

PEP written by Marc-André Lemburg.
11.10.1. Module functions and constants

sqlite3.PARSE_DECLTYPES
This constant is meant to be used with the detect_types parameter of the connect() function.

Setting it makes the sqlite3 module parse the declared type for each column it returns. It will parse out the first word of the declared type, i.e. for “integer primary key”, it will parse out “integer”, or for “number(10)” it will parse out “number”. Then for that column, it will look into the converters dictionary and use the converter function registered for that type there.

sqlite3.PARSE_COLNAMES
This constant is meant to be used with the detect_types parameter of the connect() function.

Setting this makes the SQLite interface parse the column name for each column it returns. It will look for a string formed [mytype] in there, and then decide that ‘mytype’ is the type of the column. It will try to find an entry of ‘mytype’ in the converters dictionary and then use the converter function found there to return the value. The column name found in Cursor.description is only the first word of the column name, i.e. if you use something like 'as "x [datetime]"' in your SQL, then we will parse out everything until the first blank for the column name: the column name would simply be “x”.

sqlite3.connect(database[, timeout, isolation_level, detect_types, factory])
Opens a connection to the SQLite database file database. You can use ":memory:" to open a database connection to a database
that resides in RAM instead of on disk.

When a database is accessed by multiple connections, and one of the processes modifies the database, the SQLite database is locked until that transaction is committed. The `timeout` parameter specifies how long the connection should wait for the lock to go away until raising an exception. The default for the timeout parameter is 5.0 (five seconds).

For the `isolation_level` parameter, please see the `Connection.isolation_level` property of `Connection` objects.

SQLite natively supports only the types TEXT, INTEGER, FLOAT, BLOB and NULL. If you want to use other types you must add support for them yourself. The `detect_types` parameter and the using custom `converters` registered with the module-level `register_converter()` function allow you to easily do that.

`detect_types` defaults to 0 (i.e. off, no type detection), you can set it to any combination of `PARSE_DECLTYPES` and `PARSE_COLNAMES` to turn type detection on.

By default, the `sqlite3` module uses its `Connection` class for the `connect` call. You can, however, subclass the `Connection` class and make `connect()` use your class instead by providing your class for the `factory` parameter.

Consult the section `SQLite and Python types` of this manual for details.

The `sqlite3` module internally uses a statement cache to avoid SQL parsing overhead. If you want to explicitly set the number of statements that are cached for the connection, you can set the `cached_statements` parameter. The currently implemented default is to cache 100 statements.
sqlite3. **register_converter**(typename, callable)

Registers a callable to convert a bytestring from the database into a custom Python type. The callable will be invoked for all database values that are of the type `typename`. Confer the parameter `detect_types` of the `connect()` function for how the type detection works. Note that the case of `typename` and the name of the type in your query must match!

sqlite3. **register_adapter**(type, callable)

Registers a callable to convert the custom Python type `type` into one of SQLite's supported types. The callable `callable` accepts as single parameter the Python value, and must return a value of the following types: int, long, float, str (UTF-8 encoded), unicode or buffer.

sqlite3. **complete_statement**(sql)

Returns `True` if the string `sql` contains one or more complete SQL statements terminated by semicolons. It does not verify that the SQL is syntactically correct, only that there are no unclosed string literals and the statement is terminated by a semicolon.

This can be used to build a shell for SQLite, as in the following example:

```python
# A minimal SQLite shell for experiments
import sqlite3
con = sqlite3.connect(':memory:')
con.isolation_level = None
cur = con.cursor()

buffer = ''

print "Enter your SQL commands to execute in sqlite3."
print "Enter a blank line to exit."

while True:
```
line = raw_input()
if line == "":
    break
buffer += line
if sqlite3.complete_statement(buffer):
    try:
        buffer = buffer.strip()
        cur.execute(buffer)
        if buffer.lstrip().upper().startswith("SELECT"):
            print cur.fetchall()
    except sqlite3.Error, e:
        print "An error occurred:", e.args[0]
        buffer = ""
con.close()

sqlite3.enable_callback_tracebacks(flag)
By default you will not get any tracebacks in user-defined functions, aggregates, converters, authorizer callbacks etc. If you want to debug them, you can call this function with flag as True. Afterwards, you will get tracebacks from callbacks on sys.stderr. Use False to disable the feature again.
11.10.2. Connection Objects

class sqlite3.\textbf{Connection}

A SQLite database connection has the following attributes and methods:

Connection.\textbf{isolation\_level}

Get or set the current isolation level. \texttt{None} for autocommit mode or one of “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”. See section \emph{Controlling Transactions} for a more detailed explanation.

Connection.\textbf{cursor}(\texttt{[cursorClass]})

The cursor method accepts a single optional parameter \texttt{cursorClass}. If supplied, this must be a custom cursor class that extends sqlite3.Cursor.

Connection.\textbf{commit()}

This method commits the current transaction. If you don’t call this method, anything you did since the last call to \texttt{commit()} is not visible from from other database connections. If you wonder why you don’t see the data you’ve written to the database, please check you didn’t forget to call this method.

Connection.\textbf{rollback()}

This method rolls back any changes to the database since the last call to \texttt{commit()}.

Connection.\textbf{close()}

This closes the database connection. Note that this does not automatically call \texttt{commit()}. If you just close your database connection without calling \texttt{commit()} first, your changes will be lost!
Connection.execute(sql[, parameters])

This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s execute method with the parameters given.

Connection.executemany(sql[, parameters])

This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s executemany method with the parameters given.

Connection.executescript(sql_script)

This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s executescript method with the parameters given.

Connection.create_function(name, num_params, func)

Creates a user-defined function that you can later use from within SQL statements under the function name name. num_params is the number of parameters the function accepts, and func is a Python callable that is called as the SQL function.

The function can return any of the types supported by SQLite: unicode, str, int, long, float, buffer and None.

Example:

```
import sqlite3
import md5

def md5sum(t):
    return md5.md5(t).hexdigest()

con = sqlite3.connect(':memory:)
con.create_function("md5", 1, md5sum)
cur = con.cursor()
cur.execute("select md5(?), ("foo"),)
print cur.fetchone()[0]
```
Connection. `create_aggregate(name, num_params, aggregate_class)`

Creates a user-defined aggregate function.

The aggregate class must implement a `step` method, which accepts the number of parameters `num_params`, and a `finalize` method which will return the final result of the aggregate.

The `finalize` method can return any of the types supported by SQLite: unicode, str, int, long, float, buffer and None.

Example:

```python
import sqlite3

class MySum:
    def __init__(self):
        self.count = 0

    def step(self, value):
        self.count += value

    def finalize(self):
        return self.count

con = sqlite3.connect(':memory:')
con.create_aggregate('mysum', 1, MySum)
cur = con.cursor()
cur.execute('create table test(i)')
cur.execute('insert into test(i) values (1)')
cur.execute('insert into test(i) values (2)')
cur.execute('select mysum(i) from test')
print cur.fetchone()[0]
```

Connection. `create_collation(name, callable)`

Creates a collation with the specified `name` and `callable`. The callable will be passed two string arguments. It should return -1 if the first is ordered lower than the second, 0 if they are ordered equal and 1 if the first is ordered higher than the second. Note that this controls sorting (ORDER BY in SQL) so your
comparisons don’t affect other SQL operations.

Note that the callable will get its parameters as Python bytestrings, which will normally be encoded in UTF-8.

The following example shows a custom collation that sorts “the wrong way”:

```python
import sqlite3
def collate_reverse(string1, string2):
    return -cmp(string1, string2)

con = sqlite3.connect(':memory:)
con.create_collation('reverse', collate_reverse)

cur = con.cursor()
cur.execute("create table test(x)")
cur.executemany("insert into test(x) values (?)", [("a"), (... 
for row in cur:
    print row
con.close()
```

To remove a collation, call `create_collation` with None as callable:

```python
con.create_collation('reverse', None)
```

`Connection.interrupt()`

You can call this method from a different thread to abort any queries that might be executing on the connection. The query will then abort and the caller will get an exception.

`Connection.set_authorizer(authorizer_callback)`

This routine registers a callback. The callback is invoked for each attempt to access a column of a table in the database. The callback should return `SQLITE_OK` if access is allowed,
**SQLITE_DENY** if the entire SQL statement should be aborted with an error and **SQLITE_IGNORE** if the column should be treated as a NULL value. These constants are available in the *sqlite3* module.

The first argument to the callback signifies what kind of operation is to be authorized. The second and third argument will be arguments or **None** depending on the first argument. The 4th argument is the name of the database ("main", "temp", etc.) if applicable. The 5th argument is the name of the inner-most trigger or view that is responsible for the access attempt or **None** if this access attempt is directly from input SQL code.

Please consult the SQLite documentation about the possible values for the first argument and the meaning of the second and third argument depending on the first one. All necessary constants are available in the *sqlite3* module.

**Connection**. **set_progress_handler**(handler, n)

*New in version 2.6.*

This routine registers a callback. The callback is invoked for every n instructions of the SQLite virtual machine. This is useful if you want to get called from SQLite during long-running operations, for example to update a GUI.

If you want to clear any previously installed progress handler, call the method with **None** for handler.

**Connection**. **enable_load_extension**(enabled)

*New in version 2.7.*

This routine allows/disallows the SQLite engine to load SQLite extensions from shared libraries. SQLite extensions can define new functions, aggregates or whole new virtual table
implementations. One well-known extension is the fulltext-search extension distributed with SQLite.

```python
import sqlite3

con = sqlite3.connect(':memory:)

# enable extension loading
con.enable_load_extension(True)

# Load the fulltext search extension
con.execute("select load_extension('./fts3.so')")

# alternatively you can load the extension using an API call
# con.load_extension('./fts3.so')

# disable extension loading again
con.enable_load_extension(False)

# example from SQLite wiki
con.execute("create virtual table recipe using fts3(name, in
con.executescript(""
    insert into recipe (name, ingredients) values ('broccoli
    insert into recipe (name, ingredients) values ('pumpkin
    insert into recipe (name, ingredients) values ('broccoli
    insert into recipe (name, ingredients) values ('pumpkin
""")

for row in con.execute("select rowid, name, ingredients from
print row
```

**Connection.load_extension(path)**

*New in version 2.7.*

This routine loads a SQLite extension from a shared library. You have to enable extension loading with `enable_load_extension` before you can use this routine.

**Connection.row_factory**

You can change this attribute to a callable that accepts the cursor and the original row as a tuple and will return the real result row. This way, you can implement more advanced ways of returning
results, such as returning an object that can also access columns by name.

Example:

```python
import sqlite3
def dict_factory(cursor, row):
    d = {}
    for idx, col in enumerate(cursor.description):
        d[col[0]] = row[idx]
    return d

con = sqlite3.connect(":memory:"
con.row_factory = dict_factory
cur = con.cursor()
cur.execute("select 1 as a")
print cur.fetchone()['a']
```

If returning a tuple doesn’t suffice and you want name-based access to columns, you should consider setting `row_factory` to the highly-optimized `sqlite3.Row` type. `Row` provides both index-based and case-insensitive name-based access to columns with almost no memory overhead. It will probably be better than your own custom dictionary-based approach or even a `db_row` based solution.

Connection. `text_factory`

Using this attribute you can control what objects are returned for the `TEXT` data type. By default, this attribute is set to `unicode` and the `sqlite3` module will return Unicode objects for `TEXT`. If you want to return bytestrings instead, you can set it to `str`.

For efficiency reasons, there’s also a way to return Unicode objects only for non-ASCII data, and bytestrings otherwise. To activate it, set this attribute to `sqlite3.OptimizedUnicode`.

You can also set it to any other callable that accepts a single
bytestring parameter and returns the resulting object.

See the following example code for illustration:

```python
import sqlite3

con = sqlite3.connect(':memory:)
cur = con.cursor()

# Create the table
con.execute("create table person(lastname, firstname)"

AUSTRIA = u"\xd6sterreich"

# by default, rows are returned as Unicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert row[0] == AUSTRIA

# but we can make sqlite3 always return bytestrings ...
con.text_factory = str
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) == str

# the bytestrings will be encoded in UTF-8, unless you store
# database ...
assert row[0] == AUSTRIA.encode("utf-8")

# we can also implement a custom text_factory ...
# here we implement one that will ignore Unicode characters
# decoded from UTF-8
con.text_factory = lambda x: unicode(x, "utf-8", "ignore")
cur.execute("select ?", ("this is latin1 and would normally" +
    u"\xe4\xf6\xfc".encode("latin1"),))
row = cur.fetchone()
assert type(row[0]) == unicode

# sqlite3 offers a built-in optimized text_factory that will # objects, if the data is in ASCII only, and otherwise return
con.text_factory = sqlite3.OptimizedUnicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) == unicode

cur.execute("select ?", ("Germany",))
row = cur.fetchone()
```
Connection. `total_changes`

Returns the total number of database rows that have been modified, inserted, or deleted since the database connection was opened.

Connection. `iterdump`

Returns an iterator to dump the database in an SQL text format. Useful when saving an in-memory database for later restoration. This function provides the same capabilities as the `.dump` command in the `sqlite3` shell.

*New in version 2.6.*

Example:

```python
# Convert file existing_db.db to SQL dump file dump.sql
import sqlite3, os

con = sqlite3.connect('existing_db.db')
with open('dump.sql', 'w') as f:
    for line in con.iterdump():
        f.write('%s
' % line)
```
11.10.3. Cursor Objects

A Cursor instance has the following attributes and methods:

A SQLite database cursor has the following attributes and methods:

```python
Cursor.execute(sql[, parameters])
```
Executes an SQL statement. The SQL statement may be parametrized (i.e., placeholders instead of SQL literals). The `sqlite3` module supports two kinds of placeholders: question marks (qmark style) and named placeholders (named style).

This example shows how to use parameters with qmark style:

```python
import sqlite3
con = sqlite3.connect("mydb")
cur = con.cursor()
who = "Yeltsin"
age = 72
cur.execute("select name_last, age from people where name_last=? and age=?", (who, age))
print cur.fetchone()
```

This example shows how to use the named style:

```python
import sqlite3
con = sqlite3.connect("mydb")
cur = con.cursor()
who = "Yeltsin"
age = 72
```
execute() will only execute a single SQL statement. If you try to execute more than one statement with it, it will raise a Warning. Use executescript() if you want to execute multiple SQL statements with one call.

Cursor.execute(sql, seq_of_parameters)
Executes an SQL command against all parameter sequences or mappings found in the sequence sql. The sqlite3 module also allows using an iterator yielding parameters instead of a sequence.

```python
import sqlite3

class IterChars:
    def __init__(self):
        self.count = ord('a')

    def __iter__(self):
        return self

    def next(self):
        if self.count > ord('z'):
            raise StopIteration
        self.count += 1
        return (chr(self.count - 1),)  # this is a 1-tuple

con = sqlite3.connect(':memory:)
cur = con.cursor()
cur.execute("create table characters(c)"
theIter = IterChars()
cur.executemany("insert into characters(c) values (?)", theI
cur.execute("select c from characters")
print cur.fetchall()
```
Here's a shorter example using a `generator`:

```python
import sqlite3
def char_generator():
    import string
    for c in string.letters[:26]:
        yield (c,)
con = sqlite3.connect(':memory:)
cur = con.cursor()
cur.execute("create table characters(c)")
cur.executemany("insert into characters(c) values (?)", char
cur.execute("select c from characters")
print cur.fetchall()
```

`Cursor.executescript(sql_script)`

This is a nonstandard convenience method for executing multiple SQL statements at once. It issues a `COMMIT` statement first, then executes the SQL script it gets as a parameter.

`sql_script` can be a bytestring or a Unicode string.

Example:

```python
import sqlite3
con = sqlite3.connect(':memory:)
cur = con.cursor()
cur.executescript(""
cur.executescript(""
    create table person( 
        firstname, 
        lastname, 
        age 
    );

    create table book( 
        title, 
        author, 
        published 
```
```sql
insert into book(title, author, published)
values ('Dirk Gently''s Holistic Detective Agency', 'Douglas Adams', 1987);
```

**Cursor. `fetchone()`**

Fetches the next row of a query result set, returning a single sequence, or `None` when no more data is available.

**Cursor. `fetchmany([size=cursor.arraysize])`**

Fetches the next set of rows of a query result, returning a list. An empty list is returned when no more rows are available.

The number of rows to fetch per call is specified by the `size` parameter. If it is not given, the cursor’s `arraysize` determines the number of rows to be fetched. The method should try to fetch as many rows as indicated by the size parameter. If this is not possible due to the specified number of rows not being available, fewer rows may be returned.

Note there are performance considerations involved with the `size` parameter. For optimal performance, it is usually best to use the `arraysize` attribute. If the `size` parameter is used, then it is best for it to retain the same value from one `fetchmany()` call to the next.

**Cursor. `fetchall()`**

Fetches all (remaining) rows of a query result, returning a list. Note that the cursor’s `arraysize` attribute can affect the performance of this operation. An empty list is returned when no rows are available.

**Cursor. `rowcount`**
Although the Cursor class of the sqlite3 module implements this attribute, the database engine’s own support for the determination of “rows affected”/"rows selected" is quirky.

For **DELETE** statements, SQLite reports **rowcount** as 0 if you make a **DELETE FROM table** without any condition.

For **executemany()** statements, the number of modifications are summed up into **rowcount**.

As required by the Python DB API Spec, the **rowcount** attribute “is -1 in case no **executeXX()** has been performed on the cursor or the rowcount of the last operation is not determinable by the interface”.

This includes **SELECT** statements because we cannot determine the number of rows a query produced until all rows were fetched.

**Cursor. lastrowid**

This read-only attribute provides the rowid of the last modified row. It is only set if you issued a **INSERT** statement using the **execute()** method. For operations other than **INSERT** or when **executemany()** is called, **lastrowid** is set to **None**.

**Cursor. description**

This read-only attribute provides the column names of the last query. To remain compatible with the Python DB API, it returns a 7-tuple for each column where the last six items of each tuple are **None**.

It is set for **SELECT** statements without any matching rows as well.
class sqlite3.Row

A Row instance serves as a highly optimized row_factory for Connection objects. It tries to mimic a tuple in most of its features.

It supports mapping access by column name and index, iteration, representation, equality testing and len().

If two Row objects have exactly the same columns and their members are equal, they compare equal.

Changed in version 2.6: Added iteration and equality (hashability).

keys()

This method returns a tuple of column names. Immediately after a query, it is the first member of each tuple in Cursor.description.

New in version 2.6.

Let’s assume we initialize a table as in the example given above:

```python
cconn = sqlite3.connect(":memory:"
c = conn.cursor()
c.execute(""create table stocks
    (date text, trans text, symbol text,
     qty real, price real)"")
c.execute(""insert into stocks
    values ('2006-01-05','BUY','RHAT',100,35.14)"")
c.conn.commit()
c.close()
```

Now we plug Row in:
>>> conn.row_factory = sqlite3.Row
>>> c = conn.cursor()
>>> c.execute('select * from stocks')
<sqlite3.Cursor object at 0x7f4e7dd8fa80>
>>> r = c.fetchone()
>>> type(r)
<type 'sqlite3.Row'>
>>> r
(u'2006-01-05', u'BUY', u'RHAT', 100.0, 35.14)
>>> len(r)
5
>>> r[2]
u'RHAT'
>>> r.keys()
['date', 'trans', 'symbol', 'qty', 'price']
>>> r['qty']
100.0
>>> for member in r: print member
...
2006-01-05
BUY
RHAT
100.0
35.14
11.10.5. SQLite and Python types

11.10.5.1. Introduction

SQLite natively supports the following types: NULL, INTEGER, REAL, TEXT, BLOB.

The following Python types can thus be sent to SQLite without any problem:

<table>
<thead>
<tr>
<th>Python type</th>
<th>SQLite type</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>NULL</td>
</tr>
<tr>
<td>int</td>
<td>INTEGER</td>
</tr>
<tr>
<td>long</td>
<td>INTEGER</td>
</tr>
<tr>
<td>float</td>
<td>REAL</td>
</tr>
<tr>
<td>str (UTF8-encoded)</td>
<td>TEXT</td>
</tr>
<tr>
<td>unicode</td>
<td>TEXT</td>
</tr>
<tr>
<td>buffer</td>
<td>BLOB</td>
</tr>
</tbody>
</table>

This is how SQLite types are converted to Python types by default:

<table>
<thead>
<tr>
<th>SQLite type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>NULL</td>
<td>None</td>
</tr>
<tr>
<td>INTEGER</td>
<td>int or long, depending on size</td>
</tr>
<tr>
<td>REAL</td>
<td>float</td>
</tr>
<tr>
<td>TEXT</td>
<td>depends on text_factory, unicode by default</td>
</tr>
<tr>
<td>BLOB</td>
<td>buffer</td>
</tr>
</tbody>
</table>

The type system of the sqlite3 module is extensible in two ways: you can store additional Python types in a SQLite database via object adaptation, and you can let the sqlite3 module convert SQLite types to different Python types via converters.
11.10.5.2. Using adapters to store additional Python types in SQLite databases

As described before, SQLite supports only a limited set of types natively. To use other Python types with SQLite, you must adapt them to one of the sqlite3 module’s supported types for SQLite: one of NoneType, int, long, float, str, unicode, buffer.

The sqlite3 module uses Python object adaptation, as described in PEP 246 for this. The protocol to use is PrepareProtocol.

There are two ways to enable the sqlite3 module to adapt a custom Python type to one of the supported ones.

11.10.5.2.1. Letting your object adapt itself

This is a good approach if you write the class yourself. Let’s suppose you have a class like this:

```python
class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y
```

Now you want to store the point in a single SQLite column. First you'll have to choose one of the supported types first to be used for representing the point. Let's just use str and separate the coordinates using a semicolon. Then you need to give your class a method `__conform__(self, protocol)` which must return the converted value. The parameter `protocol` will be `PrepareProtocol`.

```python
import sqlite3

class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y
```
```python
def __conform__(self, protocol):
    if protocol is sqlite3.PrepareProtocol:
        return "%f;%f" % (self.x, self.y)

con = sqlite3.connect(":memory:"
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print cur.fetchone()[0]
```

### 11.10.5.2.2. Registering an adapter callable

The other possibility is to create a function that converts the type to the string representation and register the function with `sqlite3.register_adapter()`.

**Note:** The type/class to adapt must be a *new-style class*, i.e. it must have `object` as one of its bases.

```python
import sqlite3
class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y

    def adapt_point(point):
        return "%f;%f" % (point.x, point.y)

sqlite3.register_adapter(Point, adapt_point)

con = sqlite3.connect(":memory:"
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print cur.fetchone()[0]
```

The `sqlite3` module has two default adapters for Python’s built-in `datetime.date` and `datetime.datetime` types. Now let’s suppose we want to store `datetime.datetime` objects not in ISO representation,
but as a Unix timestamp.

```python
import sqlite3
import datetime, time

def adapt_datetime(ts):
    return time.mktime(ts.timetuple())

sqlite3.register_adapter(datetime.datetime, adapt_datetime)

con = sqlite3.connect(':memory:)
cur = con.cursor()

now = datetime.datetime.now()
cur.execute("select ?", (now,))
print cur.fetchone()[0]
```

### 11.10.5.3. Converting SQLite values to custom Python types

Writing an adapter lets you send custom Python types to SQLite. But to make it really useful we need to make the Python to SQLite to Python roundtrip work.

Enter converters.

Let’s go back to the `Point` class. We stored the x and y coordinates separated via semicolons as strings in SQLite.

First, we’ll define a converter function that accepts the string as a parameter and constructs a `Point` object from it.

**Note:** Converter functions **always** get called with a string, no matter under which data type you sent the value to SQLite.

```python
def convert_point(s):
    x, y = map(float, s.split(";"))
    return Point(x, y)
```
Now you need to make the sqlite3 module know that what you select from the database is actually a point. There are two ways of doing this:

- Implicitly via the declared type
- Explicitly via the column name

Both ways are described in section *Module functions and constants*, in the entries for the constants `PARSE_DECLTYPES` and `PARSE_COLNAMES`.

The following example illustrates both approaches.

```python
import sqlite3

class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __repr__(self):
        return "(%f;%f)" % (self.x, self.y)

def adapt_point(point):
    return "%f;%f" % (point.x, point.y)

def convert_point(s):
    x, y = map(float, s.split(";"))
    return Point(x, y)

# Register the adapter
sqlite3.register_adapter(Point, adapt_point)

# Register the converter
sqlite3.register_converter("point", convert_point)

p = Point(4.0, -3.2)

# 1) Using declared types
con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p point)")
cur.execute("insert into test(p) values (?)", (p,))
```
There are default adapters for the date and datetime types in the datetime module. They will be sent as ISO dates/ISO timestamps to SQLite.

The default converters are registered under the name “date” for \texttt{datetime.date} and under the name “timestamp” for \texttt{datetime.datetime}.

This way, you can use date/timestamps from Python without any additional fiddling in most cases. The format of the adapters is also compatible with the experimental SQLite date/time functions.

The following example demonstrates this.

```python
import sqlite3
import datetime

con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(d date, ts timestamp)")
```
```python
today = datetime.date.today()
now = datetime.datetime.now()

cur.execute("insert into test(d, ts) values (?, ?)", (today, now))
row = cur.fetchone()
print today, ">=", row[0], type(row[0])
print now, ">=", row[1], type(row[1])

cur.execute('select current_date as "d [date]", current_timestamp as "ts [timestamp]"')
row = cur.fetchone()
print "current_date", row[0], type(row[0])
print "current_timestamp", row[1], type(row[1])
```
11.10.6. Controlling Transactions

By default, the `sqlite3` module opens transactions implicitly before a Data Modification Language (DML) statement (i.e. `INSERT/UPDATE/DELETE/REPLACE`), and commits transactions implicitly before a non-DML, non-query statement (i.e. anything other than `SELECT` or the aforementioned).

So if you are within a transaction and issue a command like `CREATE TABLE ...`, `VACUUM`, `PRAGMA`, the `sqlite3` module will commit implicitly before executing that command. There are two reasons for doing that. The first is that some of these commands don’t work within transactions. The other reason is that sqlite3 needs to keep track of the transaction state (if a transaction is active or not).

You can control which kind of `BEGIN` statements sqlite3 implicitly executes (or none at all) via the `isolation_level` parameter to the `connect()` call, or via the `isolation_level` property of connections.

If you want **autocommit mode**, then set `isolation_level` to `None`.

Otherwise leave it at its default, which will result in a plain “BEGIN” statement, or set it to one of SQLite’s supported isolation levels: “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”.

11.10.7. Using sqlite3 efficiently

11.10.7.1. Using shortcut methods

Using the nonstandard `execute()`, `executemany()` and `executescript()` methods of the `Connection` object, your code can be written more concisely because you don’t have to create the (often superfluous) `Cursor` objects explicitly. Instead, the `Cursor` objects are created implicitly and these shortcut methods return the cursor objects. This way, you can execute a `SELECT` statement and iterate over it directly using only a single call on the `Connection` object.

```python
import sqlite3

persons = [  
    ("Hugo", "Boss"),  
    ("Calvin", "Klein")  
]

con = sqlite3.connect(":memory:")

# Create the table
con.execute("create table person(firstname, lastname)")

# Fill the table
con.executemany("insert into person(firstname, lastname) values (?, ?)", persons)

# Print the table contents
for row in con.execute("select firstname, lastname from person"):
    print row

# Using a dummy WHERE clause to not let SQLite take the shortcut
print "I just deleted", con.execute("delete from person where 1")
```

11.10.7.2. Accessing columns by name instead of
One useful feature of the \texttt{sqlite3} module is the built-in \texttt{sqlite3.Row} class designed to be used as a row factory.

Rows wrapped with this class can be accessed both by index (like tuples) and case-insensitively by name:

```python
import sqlite3
con = sqlite3.connect("mydb")
con.row_factory = sqlite3.Row

cur = con.cursor()
cur.execute("select name_last, age from people")
for row in cur:
    assert row[0] == row["name_last"]
    assert row["name_last"] == row["nAmE_lAsT"]
    assert row[1] == row["age"]
    assert row[1] == row["AgE"]
```

### 11.10.7.3. Using the connection as a context manager

\textit{New in version 2.6.}

Connection objects can be used as context managers that automatically commit or rollback transactions. In the event of an exception, the transaction is rolled back; otherwise, the transaction is committed:

```python
import sqlite3
con = sqlite3.connect(":memory:"
con.execute("create table person (id integer primary key, first Leonardo)"
# Successful, con.commit() is called automatically afterwards
with con:
    con.execute("insert into person(firstname) values (?)", ("J
```
# con.rollback() is called after the with block finishes with an exception, the
# exception is still raised and must be caught
try:
    with con:
        con.execute("insert into person(firstname) values (?)",
    except sqlite3.IntegrityError:
        print "couldn't add Joe twice"
12. Data Compression and Archiving

The modules described in this chapter support data compression with the zlib, gzip, and bzip2 algorithms, and the creation of ZIP- and tar-format archives.

- **12.1. zlib** — Compression compatible with [gzip](#)
- **12.2. gzip** — Support for [gzip](#) files
  - 12.2.1. Examples of usage
- **12.3. bzip2** — Compression compatible with [bzip2](#)
  - 12.3.1. (De)compression of files
  - 12.3.2. Sequential (de)compression
  - 12.3.3. One-shot (de)compression
- **12.4. zipfile** — Work with ZIP archives
  - 12.4.1. ZipFile Objects
  - 12.4.2. PyZipFile Objects
  - 12.4.3. ZipInfo Objects
- **12.5. tarfile** — Read and write tar archive files
  - 12.5.1. TarFile Objects
  - 12.5.2. TarInfo Objects
  - 12.5.3. Examples
  - 12.5.4. Supported tar formats
  - 12.5.5. Unicode issues
The Python Standard Library » 12. Data Compression and Archiving »
12.1. zlib — Compression compatible with gzip

For applications that require data compression, the functions in this module allow compression and decompression, using the zlib library. The zlib library has its own home page at http://www.zlib.net. There are known incompatibilities between the Python module and versions of the zlib library earlier than 1.1.3; 1.1.3 has a security vulnerability, so we recommend using 1.1.4 or later.

zlib's functions have many options and often need to be used in a particular order. This documentation doesn’t attempt to cover all of the permutations; consult the zlib manual at http://www.zlib.net/manual.html for authoritative information.

For reading and writing .gz files see the gzip module. For other archive formats, see the bz2, zipfile, and tarfile modules.

The available exception and functions in this module are:

```python
exception zlib.error
    Exception raised on compression and decompression errors.

zlib.adler32(data[, value])
    Computes a Adler-32 checksum of data. (An Adler-32 checksum is almost as reliable as a CRC32 but can be computed much more quickly.) If value is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.
```
This function always returns an integer object.

**Note:** To generate the same numeric value across all Python versions and platforms use adler32(data) & 0xffffffff. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32bit binary representation regardless of sign.

*Changed in version 2.6:* The return value is in the range \([-2^{31}, 2^{31}-1]\) regardless of platform. In older versions the value is signed on some platforms and unsigned on others.

*Changed in version 3.0:* The return value is unsigned and in the range \([0, 2^{32}-1]\) regardless of platform.

**zlib.compress**(string[, level])

Compresses the data in `string`, returning a string contained compressed data. `level` is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. The default value is 6. Raises the `error` exception if any error occurs.

**zlib.compressobj**([level])

Returns a compression object, to be used for compressing data streams that won’t fit into memory at once. `level` is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. The default value is 6.

**zlib.crc32**(data[, value])

Computes a CRC (Cyclic Redundancy Check) checksum of `data`. If `value` is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows
computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

This function always returns an integer object.

**Note:** To generate the same numeric value across all Python versions and platforms use `crc32(data) & 0xffffffff`. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32bit binary representation regardless of sign.

*Changed in version 2.6:* The return value is in the range \([-2^{31}, 2^{31}-1]\) regardless of platform. In older versions the value would be signed on some platforms and unsigned on others.

*Changed in version 3.0:* The return value is unsigned and in the range \([0, 2^{32}-1]\) regardless of platform.

```
zlib.decompress(string[, wbits[, bufsize]])
```

Decompresses the data in `string`, returning a string containing the uncompressed data. The `wbits` parameter controls the size of the window buffer, and is discussed further below. If `bufsize` is given, it is used as the initial size of the output buffer. Raises the `error` exception if any error occurs.

The absolute value of `wbits` is the base two logarithm of the size of the history buffer (the “window size”) used when compressing data. Its absolute value should be between 8 and 15 for the most recent versions of the zlib library, larger values resulting in better compression at the expense of greater memory usage. When decompressing a stream, `wbits` must not be smaller than the size
originally used to compress the stream; using a too-small value will result in an exception. The default value is therefore the highest value, 15. When \texttt{wbits} is negative, the standard \texttt{gzip} header is suppressed.

\textit{bufsize} is the initial size of the buffer used to hold decompressed data. If more space is required, the buffer size will be increased as needed, so you don’t have to get this value exactly right; tuning it will only save a few calls to \texttt{malloc()}. The default size is 16384.

\texttt{zlib.decompressobj([\texttt{wbits}])}

Returns a decompression object, to be used for decompressing data streams that won’t fit into memory at once. The \texttt{wbits} parameter controls the size of the window buffer.

Compression objects support the following methods:

\texttt{Compress.compress(string)}

Compress \textit{string}, returning a string containing compressed data for at least part of the data in \textit{string}. This data should be concatenated to the output produced by any preceding calls to the \texttt{compress()} method. Some input may be kept in internal buffers for later processing.

\texttt{Compress.flush([\texttt{mode}] )}

All pending input is processed, and a string containing the remaining compressed output is returned. \texttt{mode} can be selected from the constants \texttt{Z_SYNC_FLUSH}, \texttt{Z_FULL_FLUSH}, or \texttt{Z_FINISH}, defaulting to \texttt{Z_FINISH}. \texttt{Z_SYNC_FLUSH} and \texttt{Z_FULL_FLUSH} allow compressing further strings of data, while \texttt{Z_FINISH} finishes the compressed stream and prevents compressing any more data. After calling \texttt{flush()} with \texttt{mode} set to \texttt{Z_FINISH}, the \texttt{compress()} method cannot be called again; the only realistic action is to
delete the object.

Compress. **copy()**

Returns a copy of the compression object. This can be used to efficiently compress a set of data that share a common initial prefix.

*New in version 2.5.*

Decompression objects support the following methods, and two attributes:

Decompress. **unused_data**

A string which contains any bytes past the end of the compressed data. That is, this remains "" until the last byte that contains compression data is available. If the whole string turned out to contain compressed data, this is "", the empty string.

The only way to determine where a string of compressed data ends is by actually decompressing it. This means that when compressed data is contained part of a larger file, you can only find the end of it by reading data and feeding it followed by some non-empty string into a decompression object’s **decompress()** method until the **unused_data** attribute is no longer the empty string.

Decompress. **unconsumed_tail**

A string that contains any data that was not consumed by the last decompress() call because it exceeded the limit for the uncompressed data buffer. This data has not yet been seen by the zlib machinery, so you must feed it (possibly with further data concatenated to it) back to a subsequent decompress() method call in order to get correct output.

Decompress. **decompress(string[, max_length])**
Decompress string, returning a string containing the uncompressed data corresponding to at least part of the data in string. This data should be concatenated to the output produced by any preceding calls to the decompress() method. Some of the input data may be preserved in internal buffers for later processing.

If the optional parameter max_length is supplied then the return value will be no longer than max_length. This may mean that not all of the compressed input can be processed; and unconsumed data will be stored in the attribute unconsumed_tail. This string must be passed to a subsequent call to decompress() if decompression is to continue. If max_length is not supplied then the whole input is decompressed, and unconsumed_tail is an empty string.

Decompress. flush([length])

All pending input is processed, and a string containing the remaining uncompressed output is returned. After calling flush(), the decompress() method cannot be called again; the only realistic action is to delete the object.

The optional parameter length sets the initial size of the output buffer.

Decompress.copy()

Returns a copy of the decompression object. This can be used to save the state of the decompressor midway through the data stream in order to speed up random seeks into the stream at a future point.

New in version 2.5.

The zlib manual explains the semantics and usage of the library’s many functions.
12.2. gzip — Support for gzip files

This module provides a simple interface to compress and decompress files just like the GNU programs gzip and gunzip would.

The data compression is provided by the zlib module.

The gzip module provides the GzipFile class which is modeled after Python’s File Object. The GzipFile class reads and writes gzip-format files, automatically compressing or decompressing the data so that it looks like an ordinary file object.

Note that additional file formats which can be decompressed by the gzip and gunzip programs, such as those produced by compress and pack, are not supported by this module.

For other archive formats, see the bz2, zipfile, and tarfile modules.

The module defines the following items:

class gzip.GzipFile([filename[, mode[, compresslevel[, fileobj[, mtime]]]]])

Constructor for the GzipFile class, which simulates most of the methods of a file object, with the exception of the readinto() and truncate() methods. At least one of fileobj and filename must be given a non-trivial value.

The new class instance is based on fileobj, which can be a regular file, a StringIO object, or any other object which simulates a file. It defaults to None, in which case filename is opened to provide a file object.
When `fileobj` is not `None`, the `filename` argument is only used to be included in the `gzip` file header, which may includes the original filename of the uncompressed file. It defaults to the filename of `fileobj`, if discernible; otherwise, it defaults to the empty string, and in this case the original filename is not included in the header.

The `mode` argument can be any of `'r'`, `'rb'`, `'a'`, `'ab'`, `'w'`, or `'wb'`, depending on whether the file will be read or written. The default is the mode of `fileobj` if discernible; otherwise, the default is `'rb'`. If not given, the `b` flag will be added to the mode to ensure the file is opened in binary mode for cross-platform portability.

The `compresslevel` argument is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, and 9 is slowest and produces the most compression. The default is 9.

The `mtime` argument is an optional numeric timestamp to be written to the stream when compressing. All `gzip` compressed streams are required to contain a timestamp. If omitted or `None`, the current time is used. This module ignores the timestamp when decompressing; however, some programs, such as `gunzip`, make use of it. The format of the timestamp is the same as that of the return value of `time.time()` and of the `st_mtime` member of the object returned by `os.stat()`.

Calling a `GzipFile` object’s `close()` method does not close `fileobj`, since you might wish to append more material after the compressed data. This also allows you to pass a `StringIO` object opened for writing as `fileobj`, and retrieve the resulting memory buffer using the `StringIO` object’s `getvalue()` method.
GzipFile supports iteration and the with statement.

Changed in version 2.7: Support for the with statement was added.

Changed in version 2.7: Support for zero-padded files was added.

gzip.open(filename[, mode[, compresslevel]])
This is a shorthand for GzipFile(filename, mode, compresslevel). The filename argument is required; mode defaults to 'rb' and compresslevel defaults to 9.
12.2.1. Examples of usage

Example of how to read a compressed file:

```python
import gzip
f = gzip.open('/home/joe/file.txt.gz', 'rb')
file_content = f.read()
f.close()
```

Example of how to create a compressed GZIP file:

```python
import gzip
content = "Lots of content here"
f = gzip.open('/home/joe/file.txt.gz', 'wb')
f.write(content)
f.close()
```

Example of how to GZIP compress an existing file:

```python
import gzip
f_in = open('/home/joe/file.txt', 'rb')
f_out = gzip.open('/home/joe/file.txt.gz', 'wb')
f_out.writelines(f_in)
f_out.close()
f_in.close()
```

See also:

**Module zlib**
The basic data compression module needed to support the **gzip** file format.
12.3. bz2 — Compression compatible with bzip2

*New in version 2.3.*

This module provides a comprehensive interface for the bz2 compression library. It implements a complete file interface, one-shot (de)compression functions, and types for sequential (de)compression.

For other archive formats, see the `gzip`, `zipfile`, and `tarfile` modules.

Here is a summary of the features offered by the bz2 module:

- **BZ2File** class implements a complete file interface, including `readline()`, `readlines()`, `writelines()`, `seek()`, etc;
- **BZ2File** class implements emulated `seek()` support;
- **BZ2File** class implements universal newline support;
- **BZ2File** class offers an optimized line iteration using the readahead algorithm borrowed from file objects;
- Sequential (de)compression supported by `BZ2Compressor` and `BZ2Decompressor` classes;
- One-shot (de)compression supported by `compress()` and `decompress()` functions;
- Thread safety uses individual locking mechanism.
12.3.1. (De)compression of files

Handling of compressed files is offered by the `BZ2File` class.

```python
class bz2.BZ2File(filename[, mode[, buffering[, compresslevel]]])
```
Open a bz2 file. Mode can be either 'r' or 'w', for reading (default) or writing. When opened for writing, the file will be created if it doesn’t exist, and truncated otherwise. If `buffering` is given, 0 means unbuffered, and larger numbers specify the buffer size; the default is 0. If `compresslevel` is given, it must be a number between 1 and 9; the default is 9. Add a 'u' to mode to open the file for input with universal newline support. Any line ending in the input file will be seen as a '\n' in Python. Also, a file so opened gains the attribute `newlines`; the value for this attribute is one of `None` (no newline read yet), '\r', '\n', '\r\n' or a tuple containing all the newline types seen. Universal newlines are available only when reading. Instances support iteration in the same way as normal `file` instances.

`BZ2File` supports the `with` statement.

*Changed in version 2.7:* Support for the `with` statement was added.

```python
close()
```
Close the file. Sets data attribute `closed` to true. A closed file cannot be used for further I/O operations. `close()` may be called more than once without error.

```python
read([size])
```
Read at most size uncompressed bytes, returned as a string. If the `size` argument is negative or omitted, read until EOF is
reached.

`readline([size])`
Return the next line from the file, as a string, retaining newline. A non-negative size argument limits the maximum number of bytes to return (an incomplete line may be returned then). Return an empty string at EOF.

`readlines([size])`
Return a list of lines read. The optional size argument, if given, is an approximate bound on the total number of bytes in the lines returned.

`xreadlines()`
For backward compatibility. `BZ2File` objects now include the performance optimizations previously implemented in the `xreadlines` module.

```plaintext
Deprecated since version 2.3: This exists only for compatibility with the method by this name on file objects, which is deprecated. Use for line in file instead.
```

`seek(offset[, whence])`
Move to new file position. Argument offset is a byte count. Optional argument whence defaults to `os.SEEK_SET` or 0 (offset from start of file; offset should be >= 0); other values are `os.SEEK_CUR` or 1 (move relative to current position; offset can be positive or negative), and `os.SEEK_END` or 2 (move relative to end of file; offset is usually negative, although many platforms allow seeking beyond the end of a file).

Note that seeking of bz2 files is emulated, and depending on the parameters the operation may be extremely slow.
**tell()**
Return the current file position, an integer (may be a long integer).

**write(data)**
Write string *data* to file. Note that due to buffering, *close()* may be needed before the file on disk reflects the data written.

**writelines(sequence_of_strings)**
Write the sequence of strings to the file. Note that newlines are not added. The sequence can be any iterable object producing strings. This is equivalent to calling write() for each string.
12.3.2. Sequential (de)compression

Sequential compression and decompression is done using the classes `BZ2Compressor` and `BZ2Decompressor`.

```python
class bz2.BZ2Compressor([compresslevel])
    Create a new compressor object. This object may be used to compress data sequentially. If you want to compress data in one shot, use the `compress()` function instead. The `compresslevel` parameter, if given, must be a number between 1 and 9; the default is 9.

    compress(data)
        Provide more data to the compressor object. It will return chunks of compressed data whenever possible. When you've finished providing data to compress, call the `flush()` method to finish the compression process, and return what is left in internal buffers.

    flush()
        Finish the compression process and return what is left in internal buffers. You must not use the compressor object after calling this method.
```

```python
class bz2.BZ2Decompressor
    Create a new decompressor object. This object may be used to decompress data sequentially. If you want to decompress data in one shot, use the `decompress()` function instead.

    decompress(data)
        Provide more data to the decompressor object. It will return chunks of decompressed data whenever possible. If you try to
decompress data after the end of stream is found, `EOFError` will be raised. If any data was found after the end of stream, it'll be ignored and saved in `unused_data` attribute.
12.3.3. One-shot (de)compression

One-shot compression and decompression is provided through the \texttt{compress()} and \texttt{decompress()} functions.

\texttt{bz2.\texttt{compress(data[, compresslevel])}}

Compress \textit{data} in one shot. If you want to compress \textit{data} sequentially, use an instance of \texttt{BZ2Compressor} instead. The \texttt{compresslevel} parameter, if given, must be a number between 1 and 9; the default is 9.

\texttt{bz2.\texttt{decompress(data)}}

Decompress \textit{data} in one shot. If you want to decompress \textit{data} sequentially, use an instance of \texttt{BZ2Decompressor} instead.
12.4. zipfile — Work with ZIP archives

*New in version 1.6.*

The ZIP file format is a common archive and compression standard. This module provides tools to create, read, write, append, and list a ZIP file. Any advanced use of this module will require an understanding of the format, as defined in PKZIP Application Note.

This module does not currently handle multi-disk ZIP files, or ZIP files which have appended comments (although it correctly handles comments added to individual archive members—for which see the *ZipInfo Objects* documentation). It can handle ZIP files that use the ZIP64 extensions (that is ZIP files that are more than 4 GByte in size). It supports decryption of encrypted files in ZIP archives, but it currently cannot create an encrypted file. Decryption is extremely slow as it is implemented in native Python rather than C.

For other archive formats, see the *bz2*, *gzip*, and *tarfile* modules.

The module defines the following items:

*exception* zipfile.*BadZipfile*

   The error raised for bad ZIP files (old name: zipfile.error).

*exception* zipfile.*LargeZipFile*

   The error raised when a ZIP file would require ZIP64 functionality but that has not been enabled.

*class* zipfile.*ZipFile*

   The class for reading and writing ZIP files. See section *ZipFile Objects* for constructor details.
**class zipfile.** **PyZipFile**

Class for creating ZIP archives containing Python libraries.

**class zipfile.** **ZipInfo**([`filename`, `date_time`])

Class used to represent information about a member of an archive. Instances of this class are returned by the `getinfo()` and `infolist()` methods of `ZipFile` objects. Most users of the `zipfile` module will not need to create these, but only use those created by this module. `filename` should be the full name of the archive member, and `date_time` should be a tuple containing six fields which describe the time of the last modification to the file; the fields are described in section `ZipInfo Objects`.

`zipfile. is_zipfile(filename)`

Returns True if `filename` is a valid ZIP file based on its magic number, otherwise returns False. `filename` may be a file or file-like object too. This module does not currently handle ZIP files which have appended comments.

*Changed in version 2.7:* Support for file and file-like objects.

`zipfile. ZIP_STORED`

The numeric constant for an uncompressed archive member.

`zipfile. ZIP_DEFLATED`

The numeric constant for the usual ZIP compression method. This requires the `zlib` module. No other compression methods are currently supported.

**See also:**

**PKZIP Application Note**

Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.
Info-ZIP Home Page

Information about the Info-ZIP project's ZIP archive programs and development libraries.
12.4.1. ZipFile Objects

class zipfile.ZipFile(file[, mode[, compression[, allowZip64]]]])

Open a ZIP file, where file can be either a path to a file (a string) or a file-like object. The mode parameter should be 'r' to read an existing file, 'w' to truncate and write a new file, or 'a' to append to an existing file. If mode is 'a' and file refers to an existing ZIP file, then additional files are added to it. If file does not refer to a ZIP file, then a new ZIP archive is appended to the file. This is meant for adding a ZIP archive to another file (such as python.exe).

Changed in version 2.6: If mode is a and the file does not exist at all, it is created.

compression is the ZIP compression method to use when writing the archive, and should be ZIP_STORED or ZIP_DEFLATED; unrecognized values will cause RuntimeError to be raised. If ZIP_DEFLATED is specified but the zlib module is not available, RuntimeError is also raised. The default is ZIP_STORED. If allowZip64 is True zipfile will create ZIP files that use the ZIP64 extensions when the zipfile is larger than 2 GB. If it is false (the default) zipfile will raise an exception when the ZIP file would require ZIP64 extensions. ZIP64 extensions are disabled by default because the default zip and unzip commands on Unix (the InfoZIP utilities) don’t support these extensions.

ZipFile is also a context manager and therefore supports the with statement. In the example, myzip is closed after the with statement’s suite is finished—even if an exception occurs:

with ZipFile('spam.zip', 'w') as myzip:
myzip.write('eggs.txt')

New in version 2.7: Added the ability to use ZipFile as a context manager.

*ZipFile.*close()  
Close the archive file. You must call close() before exiting your program or essential records will not be written.

*ZipFile.*getinfo(name)  
Return a *ZipInfo* object with information about the archive member name. Calling getinfo() for a name not currently contained in the archive will raise a *KeyError*.

*ZipFile.*infolist()  
Return a list containing a *ZipInfo* object for each member of the archive. The objects are in the same order as their entries in the actual ZIP file on disk if an existing archive was opened.

*ZipFile.*namelist()  
Return a list of archive members by name.

*ZipFile.*open(name[, mode[, pwd]])  
Extract a member from the archive as a file-like object (ZipExtFile). name is the name of the file in the archive, or a *ZipInfo* object. The mode parameter, if included, must be one of the following: 'r' (the default), 'u', or 'ru'. Choosing 'u' or 'ru' will enable universal newline support in the read-only object. pwd is the password used for encrypted files. Calling open() on a closed ZipFile will raise a *RuntimeError*.

**Note:** The file-like object is read-only and provides the following methods: read(), readline(), readlines(),
__iter__(), next().

**Note:** If the ZipFile was created by passing in a file-like object as the first argument to the constructor, then the object returned by open() shares the ZipFile's file pointer. Under these circumstances, the object returned by open() should not be used after any additional operations are performed on the ZipFile object. If the ZipFile was created by passing in a string (the filename) as the first argument to the constructor, then open() will create a new file object that will be held by the ZipExtFile, allowing it to operate independently of the ZipFile.

**Note:** The open(), read() and extract() methods can take a filename or a ZipInfo object. You will appreciate this when trying to read a ZIP file that contains members with duplicate names.

*New in version 2.6.*

```python
ZipFile.extract(member[, path[, pwd]])
```

Extract a member from the archive to the current working directory; *member* must be its full name or a ZipInfo object). Its file information is extracted as accurately as possible. *path* specifies a different directory to extract to. *member* can be a filename or a ZipInfo object. *pwd* is the password used for encrypted files.

*New in version 2.6.*

```python
ZipFile.extractall([path[, members[, pwd]]])
```

Extract all members from the archive to the current working directory. *path* specifies a different directory to extract to. *members* is optional and must be a subset of the list returned by
namelist(). *pwd* is the password used for encrypted files.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of *path*, e.g. members that have absolute filenames starting with "/" or filenames with two dots "..".

*New in version 2.6.*

**ZipFile.** `printdir()`

Print a table of contents for the archive to `sys.stdout`.

**ZipFile.** `setpassword(pwd)`

Set *pwd* as default password to extract encrypted files.

*New in version 2.6.*

**ZipFile.** `read(name[, pwd])`

Return the bytes of the file *name* in the archive. *name* is the name of the file in the archive, or a `ZipInfo` object. The archive must be open for read or append. *pwd* is the password used for encrypted files and, if specified, it will override the default password set with `setpassword()`. Calling `read()` on a closed ZipFile will raise a `RuntimeError`.

*Changed in version 2.6:* *pwd* was added, and *name* can now be a `ZipInfo` object.

**ZipFile.** `testzip()`

Read all the files in the archive and check their CRC's and file headers. Return the name of the first bad file, or else return `None`. Calling `testzip()` on a closed ZipFile will raise a `RuntimeError`.

**ZipFile.** `write(filename[, arcname[, compress_type]])`
Write the file named `filename` to the archive, giving it the archive name `arcname` (by default, this will be the same as `filename`, but without a drive letter and with leading path separators removed). If given, `compress_type` overrides the value given for the `compression` parameter to the constructor for the new entry. The archive must be open with mode `'w'` or `'a'` – calling `write()` on a ZipFile created with mode `'r'` will raise a `RuntimeError`. Calling `write()` on a closed ZipFile will raise a `RuntimeError`.

**Note:** There is no official file name encoding for ZIP files. If you have unicode file names, you must convert them to byte strings in your desired encoding before passing them to `write()`. WinZip interprets all file names as encoded in CP437, also known as DOS Latin.

**Note:** Archive names should be relative to the archive root, that is, they should not start with a path separator.

**Note:** If `arcname` (or `filename`, if `arcname` is not given) contains a null byte, the name of the file in the archive will be truncated at the null byte.

### `ZipFile.writestr(zinfo_or_arcname, bytes[, compress_type])`

Write the string `bytes` to the archive; `zinfo_or_arcname` is either the file name it will be given in the archive, or a `ZipInfo` instance. If it’s an instance, at least the filename, date, and time must be given. If it’s a name, the date and time is set to the current date and time. The archive must be opened with mode `'w'` or `'a'` – calling `writestr()` on a ZipFile created with mode `'r'` will raise a `RuntimeError`. Calling `writestr()` on a closed ZipFile will raise a `RuntimeError`.

If given, `compress_type` overrides the value given for the
compression parameter to the constructor for the new entry, or in the zinfo_or_arcname (if that is a ZipInfo instance).

**Note:** When passing a ZipInfo instance as the zinfo_or_arcname parameter, the compression method used will be that specified in the compress_type member of the given ZipInfo instance. By default, the ZipInfo constructor sets this member to ZIP_STORED.

*Changed in version 2.7:* The compression_type argument.

The following data attributes are also available:

**ZipFile.debug**

The level of debug output to use. This may be set from 0 (the default, no output) to 3 (the most output). Debugging information is written to *sys.stdout*.

**ZipFile.comment**

The comment text associated with the ZIP file. If assigning a comment to a ZipFile instance created with mode ‘a’ or ‘w’, this should be a string no longer than 65535 bytes. Comments longer than this will be truncated in the written archive when ZipFile.close() is called.
12.4.2. PyZipFile Objects

The `PyZipFile` constructor takes the same parameters as the `ZipFile` constructor. Instances have one method in addition to those of `ZipFile` objects.

`PyZipFile.writepy(pathname[, basename])`  
Search for files `*.py` and add the corresponding file to the archive. The corresponding file is a `*.pyo` file if available, else a `*.pyc` file, compiling if necessary. If the pathname is a file, the filename must end with `.py`, and just the (corresponding `*.py[co]`) file is added at the top level (no path information). If the pathname is a file that does not end with `.py`, a `RuntimeError` will be raised. If it is a directory, and the directory is not a package directory, then all the files `*.py[co]` are added at the top level. If the directory is a package directory, then all `*.py[co]` are added under the package name as a file path, and if any subdirectories are package directories, all of these are added recursively. `basename` is intended for internal use only. The `writepy()` method makes archives with file names like this:

```
string.pyc  # Top level name
test/__init__.pyc  # Package directory
test/test_support.pyc  # Module test
test/bogus/__init__.pyc  # Subpackage directory
test/bogus/myfile.pyc  # Submodule test.b
```
12.4.3. ZipInfo Objects

Instances of the `ZipInfo` class are returned by the `getinfo()` and `infolist()` methods of `ZipFile` objects. Each object stores information about a single member of the ZIP archive.

Instances have the following attributes:

**ZipInfo.`filename`**
- Name of the file in the archive.

**ZipInfo.`date_time`**
- The time and date of the last modification to the archive member. This is a tuple of six values:

<table>
<thead>
<tr>
<th>Index</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Year</td>
</tr>
<tr>
<td>1</td>
<td>Month (one-based)</td>
</tr>
<tr>
<td>2</td>
<td>Day of month (one-based)</td>
</tr>
<tr>
<td>3</td>
<td>Hours (zero-based)</td>
</tr>
<tr>
<td>4</td>
<td>Minutes (zero-based)</td>
</tr>
<tr>
<td>5</td>
<td>Seconds (zero-based)</td>
</tr>
</tbody>
</table>

**ZipInfo.`compress_type`**
- Type of compression for the archive member.

**ZipInfo.`comment`**
- Comment for the individual archive member.

**ZipInfo.`extra`**
- Expansion field data. The **PKZIP Application Note** contains some comments on the internal structure of the data contained in this string.
ZipInfo.\texttt{create\_system}
System which created ZIP archive.

ZipInfo.\texttt{create\_version}
PKZIP version which created ZIP archive.

ZipInfo.\texttt{extract\_version}
PKZIP version needed to extract archive.

ZipInfo.\texttt{reserved}
Must be zero.

ZipInfo.\texttt{flag\_bits}
ZIP flag bits.

ZipInfo.\texttt{volume}
Volume number of file header.

ZipInfo.\texttt{internal\_attr}
Internal attributes.

ZipInfo.\texttt{external\_attr}
External file attributes.

ZipInfo.\texttt{header\_offset}
Byte offset to the file header.

ZipInfo.\texttt{CRC}
CRC-32 of the uncompressed file.

ZipInfo.\texttt{compress\_size}
Size of the compressed data.

ZipInfo.\texttt{file\_size}
Size of the uncompressed file.
12.5. tarfile — Read and write tar archive files

New in version 2.3.

The tarfile module makes it possible to read and write tar archives, including those using gzip or bz2 compression. (.zip files can be read and written using the zipfile module.)

Some facts and figures:

- reads and writes gzip and bz2 compressed archives.
- read/write support for the POSIX.1-1988 (ustar) format.
- read/write support for the GNU tar format including longname and longlink extensions, read-only support for the sparse extension.
- read/write support for the POSIX.1-2001 (pax) format.

New in version 2.6.

- handles directories, regular files, hardlinks, symbolic links, fifos, character devices and block devices and is able to acquire and restore file information like timestamp, access permissions and owner.

```
 tarfile.open(name=None, mode='r', fileobj=None, bufsize=10240, **kwargs)
```

Return a TarFile object for the pathname name. For detailed information on TarFile objects and the keyword arguments that are allowed, see TarFile Objects.
*mode* has to be a string of the form `'filemode[:compression]'`, it defaults to `'r'`. Here is a full list of mode combinations:

<table>
<thead>
<tr>
<th>mode</th>
<th>action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r' or 'r:*'</td>
<td>Open for reading with transparent compression (recommended).</td>
</tr>
<tr>
<td>'r:'</td>
<td>Open for reading exclusively without compression.</td>
</tr>
<tr>
<td>'r:gz'</td>
<td>Open for reading with gzip compression.</td>
</tr>
<tr>
<td>'r:bz2'</td>
<td>Open for reading with bzip2 compression.</td>
</tr>
<tr>
<td>'a' or 'a:'</td>
<td>Open for appending with no compression. The file is created if it does not exist.</td>
</tr>
<tr>
<td>'w' or 'w:'</td>
<td>Open for uncompressed writing.</td>
</tr>
<tr>
<td>'w:gz'</td>
<td>Open for gzip compressed writing.</td>
</tr>
<tr>
<td>'w:bz2'</td>
<td>Open for bzip2 compressed writing.</td>
</tr>
</tbody>
</table>

Note that 'a:gz' or 'a:bz2' is not possible. If *mode* is not suitable to open a certain (compressed) file for reading, **ReadError** is raised. Use *mode* `'r'` to avoid this. If a compression method is not supported, **CompressionError** is raised.

If *fileobj* is specified, it is used as an alternative to a file object opened for *name*. It is supposed to be at position 0.

For special purposes, there is a second format for *mode*: `filemode[compression]`. **tarfile.open()** will return a **TarFile** object that processes its data as a stream of blocks. No random seeking will be done on the file. If given, *fileobj* may be any object that has a read() or write() method (depending on the *mode*). *bufsize* specifies the blocksize and defaults to `20 * 512` bytes. Use this variant in combination with e.g. **sys.stdin**, a socket file object or a tape device. However, such a **TarFile** object is limited in that it does not allow to be accessed randomly, see **Examples**. The currently possible modes:
<table>
<thead>
<tr>
<th>Mode</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r</td>
<td>*'</td>
</tr>
<tr>
<td>'r</td>
<td>'</td>
</tr>
<tr>
<td>'r</td>
<td>gz'</td>
</tr>
<tr>
<td>'r</td>
<td>bz2'</td>
</tr>
<tr>
<td>'w</td>
<td>'</td>
</tr>
<tr>
<td>'w</td>
<td>gz'</td>
</tr>
<tr>
<td>'w</td>
<td>bz2'</td>
</tr>
</tbody>
</table>

**class tarfile.TarFile**

Class for reading and writing tar archives. Do not use this class directly, better use `tarfile.open()` instead. See [TarFile Objects](#).

**tarfile.is_tarfile(name)**

Return `True` if `name` is a tar archive file, that the `tarfile` module can read.

**class tarfile.TarFileCompat(filename, mode='r', compression=TAR_PLAIN)**

Class for limited access to tar archives with a `zipfile`-like interface. Please consult the documentation of the `zipfile` module for more details. `compression` must be one of the following constants:

**TAR_PLAIN**

Constant for an uncompressed tar archive.

**TAR_GZIPPED**

Constant for a `gzip` compressed tar archive.

*Deprecated since version 2.6:* The `TarFileCompat` class has been deprecated for removal in Python 3.0.
exception tarfile.TarError
   Base class for all tarfile exceptions.

exception tarfile.ReadError
   Is raised when a tar archive is opened, that either cannot be handled by the tarfile module or is somehow invalid.

exception tarfile.CompressionError
   Is raised when a compression method is not supported or when the data cannot be decoded properly.

exception tarfile.StreamError
   Is raised for the limitations that are typical for stream-like TarFile objects.

exception tarfile.ExtractError
   Is raised for non-fatal errors when using TarFile.extract(), but only if TarFile.errorlevel==2.

exception tarfile.HeaderError
   Is raised by TarInfo.frombuf() if the buffer it gets is invalid.

   New in version 2.6.

Each of the following constants defines a tar archive format that the tarfile module is able to create. See section Supported tar formats for details.

.tarfile.USTAR_FORMAT
   POSIX.1-1988 (ustar) format.

.tarfile.GNU_FORMAT
   GNU tar format.

.tarfile.PAX_FORMAT
   POSIX.1-2001 (pax) format.
tarfile.DEFaulT_FORMAT
The default format for creating archives. This is currently
GNU_FORMAT.

The following variables are available on module level:

tarfile.ENCODING
The default character encoding i.e. the value from either
sys.getfilesystemencoding() or sys.getdefaultencoding().

See also:

Module zipfile
Documentation of the zipfile standard module.

GNU tar manual, Basic Tar Format
Documentation for tar archive files, including GNU tar
extensions.
12.5.1. TarFile Objects

The TarFile object provides an interface to a tar archive. A tar archive is a sequence of blocks. An archive member (a stored file) is made up of a header block followed by data blocks. It is possible to store a file in a tar archive several times. Each archive member is represented by a TarInfo object, see TarInfo Objects for details.

A TarFile object can be used as a context manager in a with statement. It will automatically be closed when the block is completed. Please note that in the event of an exception an archive opened for writing will not be finalized; only the internally used file object will be closed. See the Examples section for a use case.

New in version 2.7: Added support for the context manager protocol.

```python
class tarfile. TarFile(name=None, mode='r', fileobj=None, format=DEFAULT_FORMAT, tarinfo=TarInfo, dereference=False, ignore_zeros=False, encoding=ENCODING, errors=None, pax_headers=None, debug=0, errorlevel=0)
```

All following arguments are optional and can be accessed as instance attributes as well.

name is the pathname of the archive. It can be omitted if fileobj is given. In this case, the file object’s `name` attribute is used if it exists.

mode is either 'r' to read from an existing archive, 'a' to append data to an existing file or 'w' to create a new file overwriting an existing one.

If fileobj is given, it is used for reading or writing data. If it can be determined, mode is overridden by fileobj’s mode. fileobj will be used from position 0.
format controls the archive format. It must be one of the constants USTAR_FORMAT, GNU_FORMAT or PAX_FORMAT that are defined at module level.

New in version 2.6.

The tarinfo argument can be used to replace the default TarInfo class with a different one.

New in version 2.6.

If dereference is False, add symbolic and hard links to the archive. If it is True, add the content of the target files to the archive. This has no effect on systems that do not support symbolic links.

If ignore_zeros is False, treat an empty block as the end of the archive. If it is True, skip empty (and invalid) blocks and try to get as many members as possible. This is only useful for reading concatenated or damaged archives.

debug can be set from 0 (no debug messages) up to 3 (all debug messages). The messages are written to sys.stderr.

If errorlevel is 0, all errors are ignored when using TarFile.extract(). Nevertheless, they appear as error messages in the debug output, when debugging is enabled. If 1, all fatal errors are raised as OSError or IOError exceptions. If 2, all non-fatal errors are raised as TarError exceptions as well.

The encoding and errors arguments control the way strings are converted to unicode objects and vice versa. The default settings
will work for most users. See section *Unicode issues* for in-depth information.

*New in version 2.6.*

The `pax_headers` argument is an optional dictionary of unicode strings which will be added as a pax global header if `format` is `PAX_FORMAT`.

*New in version 2.6.*

**TarFile.open(...)**

Alternative constructor. The `tarfile.open()` function is actually a shortcut to this classmethod.

**TarFile.getmember(name)**

Return a `TarInfo` object for member `name`. If `name` can not be found in the archive, `KeyError` is raised.

**Note:** If a member occurs more than once in the archive, its last occurrence is assumed to be the most up-to-date version.

**TarFile.getmembers()**

Return the members of the archive as a list of `TarInfo` objects. The list has the same order as the members in the archive.

**TarFile.getnames()**

Return the members as a list of their names. It has the same order as the list returned by `getmembers()`.

**TarFile.list(verbosetrue=True)**

Print a table of contents to `sys.stdout`. If `verbose` is `False`, only the names of the members are printed. If it is `True`, output similar to that of `ls -l` is produced.
**TarFile.next()**

Return the next member of the archive as a *TarInfo* object, when *TarFile* is opened for reading. Return *None* if there is no more available.

**TarFile.extractall(path=".", members=None)**

Extract all members from the archive to the current working directory or directory *path*. If optional *members* is given, it must be a subset of the list returned by *getmembers()*.

Directory information like owner, modification time and permissions are set after all members have been extracted. This is done to work around two problems: A directory’s modification time is reset each time a file is created in it. And, if a directory’s permissions do not allow writing, extracting files to it will fail.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of *path*, e.g. members that have absolute filenames starting with "/" or filenames with two dots "..".

*New in version 2.5.*

**TarFile.extract(member, path="")**

Extract a member from the archive to the current working directory, using its full name. Its file information is extracted as accurately as possible. *member* may be a filename or a *TarInfo* object. You can specify a different directory using *path*.

**Note:** The *extract()* method does not take care of several extraction issues. In most cases you should consider using the *extractall()* method.

**Warning:** See the warning for *extractall()*.
**TarFile.**`extractfile(member)`  
Extract a member from the archive as a file object. `member` may be a filename or a `TarInfo` object. If `member` is a regular file, a file-like object is returned. If `member` is a link, a file-like object is constructed from the link’s target. If `member` is none of the above, `None` is returned.

**Note:** The file-like object is read-only. It provides the methods `read()`, `readline()`, `readlines()`, `seek()`, `tell()`, and `close()`, and also supports iteration over its lines.

**TarFile.**`add(name, arcname=None, recursive=True, exclude=None, filter=None)`  
Add the file `name` to the archive. `name` may be any type of file (directory, fifo, symbolic link, etc.). If given, `arcname` specifies an alternative name for the file in the archive. Directories are added recursively by default. This can be avoided by setting `recursive` to `False`. If `exclude` is given it must be a function that takes one filename argument and returns a boolean value. Depending on this value the respective file is either excluded (`True`) or added (`False`). If `filter` is specified it must be a function that takes a `TarInfo` object argument and returns the changed `TarInfo` object. If it instead returns `None` the `TarInfo` object will be excluded from the archive. See `Examples` for an example.

*Changed in version 2.6:* Added the `exclude` parameter.

*Changed in version 2.7:* Added the `filter` parameter.

**Deprecated since version 2.7:** The `exclude` parameter is deprecated, please use the `filter` parameter instead.

**TarFile.**`addfile(tarinfo, fileobj=None)`
Add the `TarInfo` object `tarinfo` to the archive. If `fileobj` is given, `tarinfo.size` bytes are read from it and added to the archive. You can create `TarInfo` objects using `gettarinfo()`.

**Note:** On Windows platforms, `fileobj` should always be opened with mode `'rb'` to avoid irritation about the file size.

```python
TarFile.gettarinfo(name=None, arcname=None, fileobj=None)
```
Create a `TarInfo` object for either the file `name` or the file object `fileobj` (using `os.fstat()` on its file descriptor). You can modify some of the `TarInfo`'s attributes before you add it using `addfile()`. If given, `arcname` specifies an alternative name for the file in the archive.

```python
TarFile.close()
```
Close the `TarFile`. In write mode, two finishing zero blocks are appended to the archive.

```python
TarFile.posix
```
Setting this to `True` is equivalent to setting the `format` attribute to `USTAR_FORMAT`, `False` is equivalent to `GNU_FORMAT`.

*Changed in version 2.4:* `posix` defaults to `False`.

```python
TarFile.pax_headers
```
A dictionary containing key-value pairs of pax global headers.

*New in version 2.6.*
12.5.2. TarInfo Objects

A TarInfo object represents one member in a TarFile. Aside from storing all required attributes of a file (like file type, size, time, permissions, owner etc.), it provides some useful methods to determine its type. It does not contain the file’s data itself.

TarInfo objects are returned by TarFile's methods getmember(), getmembers() and gettarinfo().

class tarfile.TarInfo(name="")
Create a TarInfo object.

TarInfo.frombuf(buf)
Create and return a TarInfo object from string buffer buf.

New in version 2.6: Raises HeaderError if the buffer is invalid..

TarInfo.fromtarfile(tarfile)
Read the next member from the TarFile object tarfile and return it as a TarInfo object.

New in version 2.6.

TarInfo.tobuf(format=DEFAULT_FORMAT, encoding=ENCODING, errors='strict')
Create a string buffer from a TarInfo object. For information on the arguments see the constructor of the TarFile class.

Changed in version 2.6: The arguments were added.

A TarInfo object has the following public data attributes:
TarInfo.name
Name of the archive member.

TarInfo.size
Size in bytes.

TarInfo.mtime
Time of last modification.

TarInfo.mode
Permission bits.

TarInfo.type
File type. type is usually one of these constants: REGTYPE, AREGTYPE, LNKTYPE, SYMTYPE, DIRTYPE, FIFOTYPE, CONTTYPE, CHRTYPE, BLKTYPE, GNUTYPE_SPARSE. To determine the type of a TarInfo object more conveniently, use the is_*() methods below.

TarInfo.linkname
Name of the target file name, which is only present in TarInfo objects of type LNKTYPE and SYMTYPE.

TarInfo.uid
User ID of the user who originally stored this member.

TarInfo.gid
Group ID of the user who originally stored this member.

TarInfo.uname
User name.

TarInfo.gname
Group name.

TarInfo.pax_headers
A dictionary containing key-value pairs of an associated pax
extended header.

*New in version 2.6.*

A `TarInfo` object also provides some convenient query methods:

`TarInfo.isfile()`

Return `True` if the `TarInfo` object is a regular file.

`TarInfo.isreg()`

Same as `isfile()`.

`TarInfo.isdir()`

Return `True` if it is a directory.

`TarInfo.issym()`

Return `True` if it is a symbolic link.

`TarInfo.islnk()`

Return `True` if it is a hard link.

`TarInfo.ischr()`

Return `True` if it is a character device.

`TarInfo.isblk()`

Return `True` if it is a block device.

`TarInfo.isfifo()`

Return `True` if it is a FIFO.

`TarInfo.isdev()`

Return `True` if it is one of character device, block device or FIFO.
12.5.3. Examples

How to extract an entire tar archive to the current working directory:

```python
import tarfile
tar = tarfile.open("sample.tar.gz")
tar.extractall()
tar.close()
```

How to extract a subset of a tar archive with `TarFile.extractall()` using a generator function instead of a list:

```python
import os
import tarfile

def py_files(members):
    for tarinfo in members:
        if os.path.splitext(tarinfo.name)[1] == ".py":
            yield tarinfo

tar = tarfile.open("sample.tar.gz")
tar.extractall(members=py_files(tar))
tar.close()
```

How to create an uncompressed tar archive from a list of filenames:

```python
import tarfile
tar = tarfile.open("sample.tar", "w")
for name in ["foo", "bar", "quux"]:
    tar.add(name)
tar.close()
```

The same example using the `with` statement:

```python
import tarfile
with tarfile.open("sample.tar", "w") as tar:
    for name in ["foo", "bar", "quux"]:
        tar.add(name)
```
How to read a gzip compressed tar archive and display some member information:

```python
import tarfile
tar = tarfile.open("sample.tar.gz", "r:gz")
for tarinfo in tar:
    print tarinfo.name, "is", tarinfo.size, "bytes in size and"
    if tarinfo.isreg():
        print "a regular file."
    elif tarinfo.isdir():
        print "a directory."
    else:
        print "something else."
tar.close()
```

How to create an archive and reset the user information using the `filter` parameter in `TarFile.add()`:

```python
import tarfile
def reset(tarinfo):
    tarinfo.uid = tarinfo.gid = 0
    tarinfo.uname = tarinfo.gname = "root"
    return tarinfo
tar = tarfile.open("sample.tar.gz", "w:gz")
tar.add("foo", filter=reset)
tar.close()
```
12.5.4. Supported tar formats

There are three tar formats that can be created with the `tarfile` module:

- The POSIX.1-1988 ustar format (`USTAR_FORMAT`). It supports filenames up to a length of at best 256 characters and linknames up to 100 characters. The maximum file size is 8 gigabytes. This is an old and limited but widely supported format.

- The GNU tar format (`GNU_FORMAT`). It supports long filenames and linknames, files bigger than 8 gigabytes and sparse files. It is the de facto standard on GNU/Linux systems. `tarfile` fully supports the GNU tar extensions for long names, sparse file support is read-only.

- The POSIX.1-2001 pax format (`PAX_FORMAT`). It is the most flexible format with virtually no limits. It supports long filenames and linknames, large files and stores pathnames in a portable way. However, not all tar implementations today are able to handle pax archives properly.

The `pax` format is an extension to the existing `ustar` format. It uses extra headers for information that cannot be stored otherwise. There are two flavours of pax headers: Extended headers only affect the subsequent file header, global headers are valid for the complete archive and affect all following files. All the data in a pax header is encoded in `UTF-8` for portability reasons.

There are some more variants of the tar format which can be read, but not created:
• The ancient V7 format. This is the first tar format from Unix Seventh Edition, storing only regular files and directories. Names must not be longer than 100 characters, there is no user/group name information. Some archives have miscalculated header checksums in case of fields with non-ASCII characters.
• The SunOS tar extended format. This format is a variant of the POSIX.1-2001 pax format, but is not compatible.
12.5.5. Unicode issues

The tar format was originally conceived to make backups on tape drives with the main focus on preserving file system information. Nowadays tar archives are commonly used for file distribution and exchanging archives over networks. One problem of the original format (that all other formats are merely variants of) is that there is no concept of supporting different character encodings. For example, an ordinary tar archive created on a UTF-8 system cannot be read correctly on a Latin-1 system if it contains non-ASCII characters. Names (i.e. filenames, linknames, user/group names) containing these characters will appear damaged. Unfortunately, there is no way to autodetect the encoding of an archive.

The pax format was designed to solve this problem. It stores non-ASCII names using the universal character encoding UTF-8. When a pax archive is read, these UTF-8 names are converted to the encoding of the local file system.

The details of unicode conversion are controlled by the `encoding` and `errors` keyword arguments of the `TarFile` class.

The default value for `encoding` is the local character encoding. It is deduced from `sys.getfilesystemencoding()` and `sys.getdefaultencoding()`. In read mode, `encoding` is used exclusively to convert unicode names from a pax archive to strings in the local character encoding. In write mode, the use of `encoding` depends on the chosen archive format. In case of `PAX_FORMAT`, input names that contain non-ASCII characters need to be decoded before being stored as UTF-8 strings. The other formats do not make use of `encoding` unless unicode objects are used as input names. These are converted to 8-bit character strings before they are added to the archive.
The `errors` argument defines how characters are treated that cannot be converted to or from `encoding`. Possible values are listed in section *Codec Base Classes*. In read mode, there is an additional scheme `'utf-8'` which means that bad characters are replaced by their *UTF-8* representation. This is the default scheme. In write mode the default value for `errors` is `'strict'` to ensure that name information is not altered unnoticed.
13. File Formats

The modules described in this chapter parse various miscellaneous file formats that aren’t markup languages or are related to e-mail.

- **13.1. csv — CSV File Reading and Writing**
  - 13.1.1. Module Contents
  - 13.1.2. Dialects and Formatting Parameters
  - 13.1.3. Reader Objects
  - 13.1.4. Writer Objects
  - 13.1.5. Examples
- **13.2. ConfigParser — Configuration file parser**
  - 13.2.1. RawConfigParser Objects
  - 13.2.2. ConfigParser Objects
  - 13.2.3. SafeConfigParser Objects
  - 13.2.4. Examples
- **13.3. robotparser — Parser for robots.txt**
- **13.4. netrc — netrc file processing**
  - 13.4.1. netrc Objects
- **13.5. xdrlib — Encode and decode XDR data**
  - 13.5.1. Packer Objects
  - 13.5.2. Unpacker Objects
  - 13.5.3. Exceptions
- **13.6. plistlib — Generate and parse Mac OS X .plist files**
  - 13.6.1. Examples
13. File Formats
13.1. csv — CSV File Reading and Writing

*New in version 2.3.*

The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. There is no “CSV standard”, so the format is operationally defined by the many applications which read and write it. The lack of a standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The `csv` module implements classes to read and write tabular data in CSV format. It allows programmers to say, “write this data in the format preferred by Excel,” or “read data from this file which was generated by Excel,” without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The `csv` module’s `reader` and `writer` objects read and write sequences. Programmers can also read and write data in dictionary form using the `DictReader` and `DictWriter` classes.

**Note:** This version of the `csv` module doesn’t support Unicode input. Also, there are currently some issues regarding ASCII NUL characters. Accordingly, all input should be UTF-8 or printable ASCII to be safe; see the examples in section *Examples*. These
restrictions will be removed in the future.

See also:

**PEP 305 - CSV File API**

The Python Enhancement Proposal which proposed this addition to Python.
The `csv` module defines the following functions:

```python
csv.reader(csvfile[, dialect='excel'][, fmtparam])
```

Return a reader object which will iterate over lines in the given `csvfile`. `csvfile` can be any object which supports the `iterator` protocol and returns a string each time its `next()` method is called — file objects and list objects are both suitable. If `csvfile` is a file object, it must be opened with the ‘b’ flag on platforms where that makes a difference. An optional `dialect` parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects()` function. The other optional `fmtparam` keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`.

Each row read from the csv file is returned as a list of strings. No automatic data type conversion is performed.

A short usage example:

```python
>>> import csv
>>> spamReader = csv.reader(open('eggs.csv'), delimiter=' ',
                         for row in spamReader:
...     print ', '.join(row)
Spam, Spam, Spam, Spam, Spam, Baked Beans
Spam, Lovely Spam, Wonderful Spam
```

*Changed in version 2.5:* The parser is now stricter with respect to multi-line quoted fields. Previously, if a line ended within a quoted
field without a terminating newline character, a newline would be inserted into the returned field. This behavior caused problems when reading files which contained carriage return characters within fields. The behavior was changed to return the field without inserting newlines. As a consequence, if newlines embedded within fields are important, the input should be split into lines in a manner which preserves the newline characters.

```
csv.writer(csvfile[, dialect='excel'][, fmtparam])
```

Return a writer object responsible for converting the user’s data into delimited strings on the given file-like object. `csvfile` can be any object with a `write()` method. If `csvfile` is a file object, it must be opened with the ‘b’ flag on platforms where that makes a difference. An optional `dialect` parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects()` function. The other optional `fmtparam` keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`. To make it as easy as possible to interface with modules which implement the DB API, the value `None` is written as the empty string. While this isn’t a reversible transformation, it makes it easier to dump SQL NULL data values to CSV files without preprocessing the data returned from a `cursor.fetch*` call. All other non-string data are stringified with `str()` before being written.

A short usage example:

```
>>> import csv
>>> spamWriter = csv.writer(open('eggs.csv', 'w'), delimiter='\t',
...                      quotechar='|', quoting=csv.QUOTE_MINIMAL)
>>> spamWriter.writerow(['Spam'] * 5 + ['Baked Beans'])
>>> spamWriter.writerow(['Spam', 'Lovely Spam', 'Wonderful Spam'])
```
```python
csv.register_dialect(name[, dialect][, fmtparam])
```
Associate dialect with name. name must be a string or Unicode object. The dialect can be specified either by passing a sub-class of `Dialect`, or by `fmtparam` keyword arguments, or both, with keyword arguments overriding parameters of the dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`.

```python
csv.unregister_dialect(name)
```
Delete the dialect associated with name from the dialect registry. An `Error` is raised if name is not a registered dialect name.

```python
csv.get_dialect(name)
```
Return the dialect associated with name. An `Error` is raised if name is not a registered dialect name.

*Changed in version 2.5:* This function now returns an immutable `Dialect`. Previously an instance of the requested dialect was returned. Users could modify the underlying class, changing the behavior of active readers and writers.

```python
csv.list_dialects()
```
Return the names of all registered dialects.

```python
csv.field_size_limit([new_limit])
```
Returns the current maximum field size allowed by the parser. If `new_limit` is given, this becomes the new limit.

*New in version 2.5.*

The `csv` module defines the following classes:

```python
class csv.DictReader(csvfile[, fieldnames=None[, restkey=None[,]
```

```python
class csv.DictWriter(csvfile[, fieldnames=None[, restvalue=None[,]
```
Create an object which operates like a regular reader but maps the information read into a dict whose keys are given by the optional `fieldnames` parameter. If the `fieldnames` parameter is omitted, the values in the first row of the `csvfile` will be used as the fieldnames. If the row read has more fields than the fieldnames sequence, the remaining data is added as a sequence keyed by the value of `restkey`. If the row read has fewer fields than the fieldnames sequence, the remaining keys take the value of the optional `restval` parameter. Any other optional or keyword arguments are passed to the underlying `reader` instance.

```python
class csv.DictReader(csvfile, fieldnames=[, restval=None[, dialect='excel'[, *args, **kwds]]]])
```

Create an object which operates like a regular writer but maps dictionaries onto output rows. The `fieldnames` parameter identifies the order in which values in the dictionary passed to the `writerow()` method are written to the `csvfile`. The optional `restval` parameter specifies the value to be written if the dictionary is missing a key in `fieldnames`. If the dictionary passed to the `writerow()` method contains a key not found in `fieldnames`, the optional `extrasaction` parameter indicates what action to take. If it is set to `raise` a `ValueError` is raised. If it is set to `ignore`, extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying `writer` instance.

Note that unlike the `DictReader` class, the `fieldnames` parameter of the `DictWriter` is not optional. Since Python's `dict` objects are not ordered, there is not enough information available to deduce the order in which the row should be written to the `csvfile`. 
class csv.Dialect
    The Dialect class is a container class relied on primarily for its attributes, which are used to define the parameters for a specific reader or writer instance.

class csv.excel
    The excel class defines the usual properties of an Excel-generated CSV file. It is registered with the dialect name 'excel'.

class csv.excel_tab
    The excel_tab class defines the usual properties of an Excel-generated TAB-delimited file. It is registered with the dialect name 'excel-tab'.

class csv.Sniffer
    The Sniffer class is used to deduce the format of a CSV file.

    The Sniffer class provides two methods:

    **sniff(sample[, delimiters=\None])**
    Analyze the given sample and return a Dialect subclass reflecting the parameters found. If the optional delimiters parameter is given, it is interpreted as a string containing possible valid delimiter characters.

    **has_header(sample)**
    Analyze the sample text (presumed to be in CSV format) and return True if the first row appears to be a series of column headers.

An example for Sniffer use:

```python
csvfile = open("example.csv")
dialect = csv.Sniffer().sniff(csvfile.read(1024))
csvfile.seek(0)
```
The **csv** module defines the following constants:

**csv.QUOTE_ALL**

Instructs **writer** objects to quote all fields.

**csv.QUOTE_MINIMAL**

Instructs **writer** objects to only quote those fields which contain special characters such as *delimiter*, *quotechar* or any of the characters in *lineterminator*.

**csv.QUOTE_NONNUMERIC**

Instructs **writer** objects to quote all non-numeric fields.

Instructs the reader to convert all non-quoted fields to type *float*.

**csv.QUOTE_NONE**

Instructs **writer** objects to never quote fields. When the current *delimiter* occurs in output data it is preceded by the current *escapechar* character. If *escapechar* is not set, the writer will raise **Error** if any characters that require escaping are encountered.

Instructs **reader** to perform no special processing of quote characters.

The **csv** module defines the following exception:

**exception** **csv.Error**

Raised by any of the functions when an error is detected.
13.1.2. Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the `Dialect` class having a set of specific methods and a single `validate()` method. When creating `reader` or `writer` objects, the programmer can specify a string or a subclass of the `Dialect` class as the dialect parameter. In addition to, or instead of, the `dialect` parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the `Dialect` class.

Dialects support the following attributes:

**Dialect. delimiter**
A one-character string used to separate fields. It defaults to ",".

**Dialect. doublequote**
Controls how instances of `quotechar` appearing inside a field should be themselves be quoted. When `True`, the character is doubled. When `False`, the `escapechar` is used as a prefix to the `quotechar`. It defaults to `True`.

On output, if `doublequote` is `False` and no `escapechar` is set, `Error` is raised if a `quotechar` is found in a field.

**Dialect. escapechar**
A one-character string used by the writer to escape the `delimiter` if `quoting` is set to `QUOTE_NONE` and the `quotechar` if `doublequote` is `False`. On reading, the `escapechar` removes any special meaning from the following character. It defaults to `None`, which disables escaping.
Dialect. **lineterminator**

The string used to terminate lines produced by the writer. It defaults to `\r\n`.

**Note:** The reader is hard-coded to recognise either `\r` or `\n` as end-of-line, and ignores `lineterminator`. This behavior may change in the future.

Dialect. **quotechar**

A one-character string used to quote fields containing special characters, such as the delimiter or quotechar, or which contain new-line characters. It defaults to `'"'`.

Dialect. **quoting**

Controls when quotes should be generated by the writer and recognised by the reader. It can take on any of the `QUOTE_*` constants (see section *Module Contents*) and defaults to `QUOTE_MINIMAL`.

Dialect. **skipinitialspace**

When True, whitespace immediately following the delimiter is ignored. The default is False.
13.1.3. Reader Objects

Reader objects (DictReader instances and objects returned by the reader() function) have the following public methods:

csvreader.next()
    Return the next row of the reader’s iterable object as a list, parsed according to the current dialect.

Reader objects have the following public attributes:

csvreader.dialect
    A read-only description of the dialect in use by the parser.

csvreader.line_num
    The number of lines read from the source iterator. This is not the same as the number of records returned, as records can span multiple lines.

    New in version 2.5.

DictReader objects have the following public attribute:

csvreader.fieldnames
    If not passed as a parameter when creating the object, this attribute is initialized upon first access or when the first record is read from the file.

    Changed in version 2.6.
### 13.1.4. Writer Objects

**Writer** objects (``DictWriter`` instances and objects returned by the `writer()` function) have the following public methods. A *row* must be a sequence of strings or numbers for **Writer** objects and a dictionary mapping fieldnames to strings or numbers (by passing them through `str()` first) for **DictWriter** objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

- **csvwriter.**`writerow(row)`
  Write the *row* parameter to the writer’s file object, formatted according to the current dialect.

- **csvwriter.**`writerows(rows)`
  Write all the *rows* parameters (a list of *row* objects as described above) to the writer's file object, formatted according to the current dialect.

**Writer** objects have the following public attribute:

- **csvwriter.**`dialect`
  A read-only description of the dialect in use by the writer.

**DictWriter** objects have the following public method:

- **DictWriter.**`writeheader()`
  Write a row with the field names (as specified in the constructor).

  *New in version 2.7.*
13.1.5. Examples

The simplest example of reading a CSV file:

```python
import csv
reader = csv.reader(open("some.csv", "rb"))
for row in reader:
    print row
```

Reading a file with an alternate format:

```python
import csv
reader = csv.reader(open("passwd", "rb"), delimiter=':', quoting=csv.QUOTE_NONE)
for row in reader:
    print row
```

The corresponding simplest possible writing example is:

```python
import csv
writer = csv.writer(open("some.csv", "wb"))
writer.writerows(someiterable)
```

Registering a new dialect:

```python
import csv
csv.register_dialect('unixpwd', delimiter=':', quoting=csv.QUOTE_NONE)
reader = csv.reader(open("passwd", "rb"), 'unixpwd')
```

A slightly more advanced use of the reader — catching and reporting errors:

```python
import csv, sys
filename = "some.csv"
reader = csv.reader(open(filename, "rb"))
try:
```
And while the module doesn’t directly support parsing strings, it can easily be done:

```python
import csv
for row in csv.reader(['one,two,three']):
    print row
```

The `csv` module doesn’t directly support reading and writing Unicode, but it is 8-bit-clean save for some problems with ASCII NUL characters. So you can write functions or classes that handle the encoding and decoding for you as long as you avoid encodings like UTF-16 that use NULs. UTF-8 is recommended.

`unicode_csv_reader()` below is a *generator* that wraps `csv.reader` to handle Unicode CSV data (a list of Unicode strings). `utf_8_encoder()` is a *generator* that encodes the Unicode strings as UTF-8, one string (or row) at a time. The encoded strings are parsed by the CSV reader, and `unicode_csv_reader()` decodes the UTF-8-encoded cells back into Unicode:

```python
import csv
def unicode_csv_reader(unicode_csv_data, dialect=csv.excel, **kwargs):
    # csv.py doesn't do Unicode; encode temporarily as UTF-8:
    csv_reader = csv.reader(utf_8_encoder(unicode_csv_data),
                        dialect=dialect, **kwargs)
    for row in csv_reader:
        # decode UTF-8 back to Unicode, cell by cell:
        yield [unicode(cell, 'utf-8') for cell in row]

def utf_8_encoder(unicode_csv_data):
    for line in unicode_csv_data:
        yield line.encode('utf-8')
```
For all other encodings the following `UnicodeReader` and `UnicodeWriter` classes can be used. They take an additional `encoding` parameter in their constructor and make sure that the data passes the real reader or writer encoded as UTF-8:

```python
import csv, codecs, cStringIO

class UTF8Recoder:
    """
    Iterator that reads an encoded stream and reencodes the input to UTF-8
    """
    def __init__(self, f, encoding):
        self.reader = codecs.getreader(encoding)(f)

    def __iter__(self):
        return self

    def next(self):
        return self.reader.next().encode("utf-8")

class UnicodeReader:
    """
    A CSV reader which will iterate over lines in the CSV file "f", which is encoded in the given encoding.
    """
    def __init__(self, f, dialect=csv.excel, encoding="utf-8", **kwds):
        f = UTF8Recoder(f, encoding)
        self.reader = csv.reader(f, dialect=dialect, **kwds)

    def next(self):
        row = self.reader.next()
        return [unicode(s, "utf-8") for s in row]

    def __iter__(self):
        return self

class UnicodeWriter:
    """
    A CSV writer which will write rows to CSV file "f", which is encoded in the given encoding.
    """
    def __init__(self, f, dialect=csv.excel, encoding="utf-8",
                 **kwds):
        # Redirect output to a queue
```
self.queue = cStringIO.StringIO()
self.writer = csv.writer(self.queue, dialect=dialect, *)
self.stream = f
self.encoder = codecs.getincrementalencoder(encoding)()

def writerow(self, row):
    self.writer.writerow([s.encode("utf-8") for s in row])
    # Fetch UTF-8 output from the queue ...
    data = self.queue.getvalue()
    data = data.decode("utf-8")
    # ... and reencode it into the target encoding
    data = self.encoder.encode(data)
    # write to the target stream
    self.stream.write(data)
    # empty queue
    self.queue.truncate(0)

    def writerows(self, rows):
        for row in rows:
            self.writerow(row)
13.2. ConfigParser — Configuration file parser

Note: The ConfigParser module has been renamed to configparser in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

This module defines the class ConfigParser. The ConfigParser class implements a basic configuration file parser language which provides a structure similar to what you would find on Microsoft Windows INI files. You can use this to write Python programs which can be customized by end users easily.

Note: This library does not interpret or write the value-type prefixes used in the Windows Registry extended version of INI syntax.

The configuration file consists of sections, led by a [section] header and followed by name: value entries, with continuations in the style of RFC 822 (see section 3.1.1, “LONG HEADER FIELDS”); name=value is also accepted. Note that leading whitespace is removed from values. The optional values can contain format strings which refer to other values in the same section, or values in a special DEFAULT section. Additional defaults can be provided on initialization and retrieval. Lines beginning with '#' or ';' are ignored and may be used to provide comments.

For example:

```
[My Section]
foodir: %(dir)s/whatever
dir=frob
long: this value continues
```
would resolve the %\texttt{(dir)s} to the value of \texttt{dir} (\texttt{frob} in this case). All reference expansions are done on demand.

Default values can be specified by passing them into the \texttt{ConfigParser} constructor as a dictionary. Additional defaults may be passed into the \texttt{get()} method which will override all others.

Sections are normally stored in a built-in dictionary. An alternative dictionary type can be passed to the \texttt{ConfigParser} constructor. For example, if a dictionary type is passed that sorts its keys, the sections will be sorted on write-back, as will be the keys within each section.

\begin{verbatim}
class ConfigParser.RawConfigParser([[defaults[, dict_type[, allow_no_value]]]])
  The basic configuration object. When \texttt{defaults} is given, it is initialized into the dictionary of intrinsic defaults. When \texttt{dict_type} is given, it will be used to create the dictionary objects for the list of sections, for the options within a section, and for the default values. When \texttt{allow_no_value} is true (default: \texttt{False}), options without values are accepted; the value presented for these is \texttt{None}.

  This class does not support the magical interpolation behavior.

  \textit{New in version 2.3.}

  \textit{Changed in version 2.6: dict_type was added.}

  \textit{Changed in version 2.7:} The default \texttt{dict_type} is \texttt{collections.OrderedDict}. \texttt{allow_no_value} was added.
\end{verbatim}
Derived class of `RawConfigParser` that implements the magical interpolation feature and adds optional arguments to the `get()` and `items()` methods. The values in `defaults` must be appropriate for the `%(s` string interpolation. Note that `__name__` is an intrinsic default; its value is the section name, and will override any value provided in `defaults`.

All option names used in interpolation will be passed through the `optionxform()` method just like any other option name reference. For example, using the default implementation of `optionxform()` (which converts option names to lower case), the values `foo % (bar)s` and `foo %(BAR)s` are equivalent.

*New in version 2.3.*

*Changed in version 2.6:* `dict_type` was added.

*Changed in version 2.7:* The default `dict_type` is `collections.OrderedDict`. `allow_no_value` was added.

class ConfigParser. SafeConfigParser([[defaults[, [dict_type[, [allow_no_value]]]]]])

Derived class of `ConfigParser` that implements a more-sane variant of the magical interpolation feature. This implementation is more predictable as well. New applications should prefer this version if they don’t need to be compatible with older versions of Python.

*New in version 2.3.*

*Changed in version 2.6:* `dict_type` was added.

*Changed in version 2.7:* The default `dict_type` is
collections.OrderedDict. allow_no_value was added.

exception ConfigParser. NoSectionError
Exception raised when a specified section is not found.

exception ConfigParser. DuplicateSectionError
Exception raised if add_section() is called with the name of a section that is already present.

exception ConfigParser. NoOptionError
Exception raised when a specified option is not found in the specified section.

exception ConfigParser. InterpolationError
Base class for exceptions raised when problems occur performing string interpolation.

exception ConfigParser. InterpolationDepthError
Exception raised when string interpolation cannot be completed because the number of iterations exceeds MAX_INTERPOLATION_DEPTH. Subclass of InterpolationError.

exception ConfigParser. InterpolationMissingOptionError
Exception raised when an option referenced from a value does not exist. Subclass of InterpolationError.

New in version 2.3.

exception ConfigParser. InterpolationSyntaxError
Exception raised when the source text into which substitutions are made does not conform to the required syntax. Subclass of InterpolationError.

New in version 2.3.

exception ConfigParser. MissingSectionHeaderError
Exception raised when attempting to parse a file which has no section headers.

```
exception ConfigParser.ParsingError
Exception raised when errors occur attempting to parse a file.
```

```
ConfigParser.MAX_INTERPOLATION_DEPTH
The maximum depth for recursive interpolation for get() when the raw parameter is false. This is relevant only for the ConfigParser class.
```

See also:

**Module shlex**
Support for a creating Unix shell-like mini-languages which can be used as an alternate format for application configuration files.
13.2.1. RawConfigParser Objects

RawConfigParser instances have the following methods:

RawConfigParser. **defaults()**

Return a dictionary containing the instance-wide defaults.

RawConfigParser. **sections()**

Return a list of the sections available; **DEFAULT** is not included in the list.

RawConfigParser. **add_section(section)**

Add a section named **section** to the instance. If a section by the given name already exists, **DuplicateSectionError** is raised. If the name **DEFAULT** (or any of its case-insensitive variants) is passed, **ValueError** is raised.

RawConfigParser. **has_section(section)**

Indicates whether the named section is present in the configuration. The **DEFAULT** section is not acknowledged.

RawConfigParser. **options(section)**

Returns a list of options available in the specified **section**.

RawConfigParser. **has_option(section, option)**

If the given section exists, and contains the given option, return **True**; otherwise return **False**.

*New in version 1.6.*

RawConfigParser. **read(filenames)**

Attempt to read and parse a list of filenames, returning a list of filenames which were successfully parsed. If **filenames** is a string
or Unicode string, it is treated as a single filename. If a file named in filenames cannot be opened, that file will be ignored. This is designed so that you can specify a list of potential configuration file locations (for example, the current directory, the user’s home directory, and some system-wide directory), and all existing configuration files in the list will be read. If none of the named files exist, the ConfigParser instance will contain an empty dataset. An application which requires initial values to be loaded from a file should load the required file or files using readfp() before calling read() for any optional files:

```python
import ConfigParser, os
config = ConfigParser.ConfigParser()
config.readfp(open('defaults.cfg'))
config.read(["site.cfg", os.path.expanduser('~/myapp.cfg')])
```

*Changed in version 2.4:* Returns list of successfully parsed filenames.

RawConfigParser.**readfp(fp[, filename])**

Read and parse configuration data from the file or file-like object in fp (only the readline() method is used). If filename is omitted and fp has a name attribute, that is used for filename; the default is `???>`.

RawConfigParser.**get(section, option)**

Get an option value for the named section.

RawConfigParser.**getint(section, option)**

A convenience method which coerces the option in the specified section to an integer.

RawConfigParser.**getfloat(section, option)**
A convenience method which coerces the option in the specified section to a floating point number.

RawConfigParser.getboolean(section, option)

A convenience method which coerces the option in the specified section to a Boolean value. Note that the accepted values for the option are "1", "yes", "true", and "on", which cause this method to return True, and "0", "no", "false", and "off", which cause it to return False. These string values are checked in a case-insensitive manner. Any other value will cause it to raise ValueError.

RawConfigParser.items(section)

Return a list of (name, value) pairs for each option in the given section.

RawConfigParser.set(section, option, value)

If the given section exists, set the given option to the specified value; otherwise raise NoSectionError. While it is possible to use RawConfigParser (or ConfigParser with raw parameters set to true) for internal storage of non-string values, full functionality (including interpolation and output to files) can only be achieved using string values.

New in version 1.6.

RawConfigParser.write(fileobject)

Write a representation of the configuration to the specified file object. This representation can be parsed by a future read() call.

New in version 1.6.

RawConfigParser.remove_option(section, option)

Remove the specified option from the specified section. If the
section does not exist, raise **NoSectionError**. If the option existed to be removed, return **True**; otherwise return **False**.

*New in version 1.6.*

**RawConfigParser**. `remove_section(section)`

Remove the specified section from the configuration. If the section in fact existed, return **True**. Otherwise return **False**.

**RawConfigParser**. `optionxform(option)`

Transforms the option name `option` as found in an input file or as passed in by client code to the form that should be used in the internal structures. The default implementation returns a lower-case version of `option`; subclasses may override this or client code can set an attribute of this name on instances to affect this behavior.

You don’t necessarily need to subclass a ConfigParser to use this method, you can also re-set it on an instance, to a function that takes a string argument. Setting it to `str`, for example, would make option names case sensitive:

```python
cfgparser = ConfigParser()
...
cfgparser.optionxform = str
```

Note that when reading configuration files, whitespace around the option names are stripped before `optionxform()` is called.
13.2.2. ConfigParser Objects

The `ConfigParser` class extends some methods of the `RawConfigParser` interface, adding some optional arguments.

`ConfigParser.get(section, option[, raw[, vars]])`

Get an `option` value for the named `section`. All the `'%'` interpolations are expanded in the return values, based on the defaults passed into the constructor, as well as the options `vars` provided, unless the `raw` argument is true.

`ConfigParser.items(section[, raw[, vars]])`

Return a list of `(name, value)` pairs for each option in the given `section`. Optional arguments have the same meaning as for the `get()` method.

`New in version 2.3.`
13.2.3. SafeConfigParser Objects

The `SafeConfigParser` class implements the same extended interface as `ConfigParser`, with the following addition:

```
SafeConfigParser.set(section, option, value)
```

If the given section exists, set the given option to the specified value; otherwise raise `NoSectionError`. `value` must be a string (`str` or `unicode`); if not, `TypeError` is raised.

*New in version 2.4.*
13.2.4. Examples

An example of writing to a configuration file:

```python
import ConfigParser

config = ConfigParser.RawConfigParser()

# When adding sections or items, add them in the reverse order
# how you want them to be displayed in the actual file.
# In addition, please note that using RawConfigParser's and the
# mode of ConfigParser's respective set functions, you can assi
# non-string values to keys internally, but will receive an err
# when attempting to write to a file or when you get it in non-
# mode. SafeConfigParser does not allow such assignments to take
config.add_section('Section1')
config.set('Section1', 'int', '15')
config.set('Section1', 'bool', 'true')
config.set('Section1', 'float', '3.1415')
config.set('Section1', 'baz', 'fun')
config.set('Section1', 'bar', 'Python')
config.set('Section1', 'foo', '%(bar)s is %(baz)s!')

# Writing our configuration file to 'example.cfg'
with open('example.cfg', 'wb') as configfile:
    config.write(configfile)
```

An example of reading the configuration file again:

```python
import ConfigParser

config = ConfigParser.RawConfigParser()
config.read('example.cfg')

# getfloat() raises an exception if the value is not a float
# getint() and getboolean() also do this for their respective t
float = config.getfloat('Section1', 'float')
int = config.getint('Section1', 'int')
print float + int

# Notice that the next output does not interpolate '%(bar)s' or
# This is because we are using a RawConfigParser().
```
if config.getboolean('Section1', 'bool'):
    print config.get('Section1', 'foo')

To get interpolation, you will need to use a ConfigParser or SafeConfigParser:

```python
import ConfigParser
config = ConfigParser.ConfigParser()
cfg.read('example.cfg')

# Set the third, optional argument of get to 1 if you wish to use interpolation and the fourth argument is a dict with members that will take precedence in interpolation.
print config.get('Section1', 'foo', 0, {'bar': 'Documentation', 'baz': 'evil'})

print config.get('Section1', 'foo', 1)  # -> "%(bar)s is %(baz)s!"
```

Defaults are available in all three types of ConfigParsers. They are used in interpolation if an option used is not defined elsewhere.

```python
import ConfigParser

# New instance with 'bar' and 'baz' defaulting to 'Life' and 'hard'
config = ConfigParser.SafeConfigParser({'bar': 'Life', 'baz': 'hard'})
cfg.read('example.cfg')

print config.get('Section1', 'foo')  # -> "Python is fun!"
config.remove_option('Section1', 'bar')
config.remove_option('Section1', 'baz')
print config.get('Section1', 'foo')  # -> "Life is hard!"
```

The function `opt_move` below can be used to move options between sections:

```python
def opt_move(config, section1, section2, option):
    try:
```
Some configuration files are known to include settings without values, but which otherwise conform to the syntax supported by `ConfigParser`. The `allow_no_value` parameter to the constructor can be used to indicate that such values should be accepted:

```python
>>> import ConfigParser
>>> import io

>>> sample_config = ""
... [mysqld]
... user = mysql
... pid-file = /var/run/mysqld/mysqld.pid
... skip-external-locking
... old_passwords = 1
... skip-bdb
... skip-innodb
... ""

>>> config = ConfigParser.RawConfigParser(allow_no_value=True)
>>> config.readfp(io.BytesIO(sample_config))

>>> # Settings with values are treated as before:
>>> config.get("mysqld", "user")
'mysql'

>>> # Settings without values provide None:
>>> config.get("mysqld", "skip-bdb")

>>> # Settings which aren't specified still raise an error:
>>> config.get("mysqld", "does-not-exist")
Traceback (most recent call last):
  ...
ConfigParser.NoOptionError: No option 'does-not-exist' in section: 'mysqld'
```
13.3. robotparser — Parser for robots.txt

**Note:** The `robotparser` module has been renamed `urllib.robotparser` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

This module provides a single class, `RobotFileParser`, which answers questions about whether or not a particular user agent can fetch a URL on the Web site that published the `robots.txt` file. For more details on the structure of `robots.txt` files, see [http://www.robotstxt.org/orig.html](http://www.robotstxt.org/orig.html).

```python
class robotparser.RobotFileParser
    This class provides a set of methods to read, parse and answer questions about a single `robots.txt` file.

    set_url(url)
        Sets the URL referring to a `robots.txt` file.

    read()
        Reads the `robots.txt` URL and feeds it to the parser.

    parse(lines)
        Parses the lines argument.

    can_fetch(useragent, url)
        Returns `True` if the `useragent` is allowed to fetch the `url` according to the rules contained in the parsed `robots.txt` file.

    mtime()
        Returns the time the `robots.txt` file was last fetched. This is
useful for long-running web spiders that need to check for new robots.txt files periodically.

**modified()**

Sets the time the robots.txt file was last fetched to the current time.

The following example demonstrates basic use of the RobotFileParser class.

```python
>>> import robotparser
>>> rp = robotparser.RobotFileParser()
>>> rp.set_url("http://www.musi-cal.com/robots.txt")
>>> rp.read()
>>> rp.can_fetch("*", "http://www.musi-cal.com/cgi-bin/search?city=San+Francisco")
False
>>> rp.can_fetch("*", "http://www.musi-cal.com/")
True
```
13.4. netrc — netrc file processing

New in version 1.5.2.

The netrc class parses and encapsulates the netrc file format used by the Unix ftp program and other FTP clients.

class netrc.netrc([file])

A netrc instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file .netrc in the user’s home directory will be read. Parse errors will raise NetrcParseError with diagnostic information including the file name, line number, and terminating token.

exception netrc.NetrcParseError

Exception raised by the netrc class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: msg is a textual explanation of the error, filename is the name of the source file, and lineno gives the line number on which the error was found.
13.4.1. netrc Objects

A `netrc` instance has the following methods:

`netrc.authenticators(host)`

Return a 3-tuple `(login, account, password)` of authenticators for `host`. If the netrc file did not contain an entry for the given host, return the tuple associated with the 'default' entry. If neither matching host nor default entry is available, return `None`.

`netrc.__repr__()`

Dump the class data as a string in the format of a netrc file. (This discards comments and may reorder the entries.)

Instances of `netrc` have public instance variables:

`netrc.hosts`

Dictionary mapping host names to `(login, account, password)` tuples. The 'default' entry, if any, is represented as a pseudo-host by that name.

`netrc.macros`

Dictionary mapping macro names to string lists.

**Note:** Passwords are limited to a subset of the ASCII character set. Versions of this module prior to 2.3 were extremely limited. Starting with 2.3, all ASCII punctuation is allowed in passwords. However, note that whitespace and non-printable characters are not allowed in passwords. This is a limitation of the way the .netrc file is parsed and may be removed in the future.
13.5. xdrlib — Encode and decode XDR data

The xdrlib module supports the External Data Representation Standard as described in RFC 1014, written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The xdrlib module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

class xdrlib.**Packer**

Packer is the class for packing data into XDR representation. The Packer class is instantiated with no arguments.

class xdrlib.**Unpacker**(data)

Unpacker is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as data.

See also:

**RFC 1014 - XDR: External Data Representation Standard**

This RFC defined the encoding of data which was XDR at the time this module was originally written. It has apparently been obsoleted by RFC 1832.

**RFC 1832 - XDR: External Data Representation Standard**

Newer RFC that provides a revised definition of XDR.
13.5.1. Packer Objects

Packer instances have the following methods:

**Packer**. `get_buffer()`

Returns the current pack buffer as a string.

**Packer**. `reset()`

Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate `pack_type()` method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: `pack_uint()`, `pack_int()`, `pack_enum()`, `pack_bool()`, `pack_uhyper()`, and `pack_hyper()`.

**Packer**. `pack_float(value)`

Packs the single-precision floating point number `value`.

**Packer**. `pack_double(value)`

Packs the double-precision floating point number `value`.

The following methods support packing strings, bytes, and opaque data:

**Packer**. `pack_fstring(n, s)`

Packs a fixed length string, `s`. `n` is the length of the string but it is *not* packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.

**Packer**. `pack_fopaque(n, data)`

Packs a fixed length opaque data stream, similarly to `pack_fstring()`.
Packer. **pack_string(s)**

Packs a variable length string, s. The length of the string is first packed as an unsigned integer, then the string data is packed with `pack_fstring()`.

Packer. **pack_opaque(data)**

Packs a variable length opaque data string, similarly to `pack_string()`.

Packer. **pack_bytes(bytes)**

Packs a variable length byte stream, similarly to `pack_string()`.

The following methods support packing arrays and lists:

Packer. **pack_list(list, pack_item)**

Packs a list of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. `pack_item` is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```python
import xdrlib
p = xdrlib.Packer()
p.pack_list([[1, 2, 3], p.pack_int]
```

Packer. **pack_farray(n, array, pack_item)**

Packs a fixed length list (array) of homogeneous items. n is the length of the list; it is not packed into the buffer, but a `ValueError` exception is raised if `len(array)` is not equal to n. As above, `pack_item` is the function used to pack each element.
Packer. \texttt{pack\_array}(\textit{list, pack\_item})

Packs a variable length \textit{list} of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in \texttt{pack\_farray()} above.
13.5.2. Unpacker Objects

The `Unpacker` class offers the following methods:

**Unpacker. `reset(data)`**
Resets the string buffer with the given `data`.

**Unpacker. `get_position()`**
Returns the current unpack position in the data buffer.

**Unpacker. `set_position(position)`**
Sets the data buffer unpack position to `position`. You should be careful about using `get_position()` and `set_position()`.

**Unpacker. `get_buffer()`**
Returns the current unpack data buffer as a string.

**Unpacker. `done()`**
Indicates unpack completion. Raises an `Error` exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a `Packer`, can be unpacked with an `Unpacker`. Unpacking methods are of the form `unpack_type()`, and take no arguments. They return the unpacked object.

**Unpacker. `unpack_float()`**
Unpacks a single-precision floating point number.

**Unpacker. `unpack_double()`**
Unpacks a double-precision floating point number, similarly to `unpack_float()`.
In addition, the following methods unpack strings, bytes, and opaque data:

**Unpacker.** `unpack_fstring(n)`

Unpacks and returns a fixed length string. *n* is the number of characters expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

**Unpacker.** `unpack_fopaque(n)`

Unpacks and returns a fixed length opaque data stream, similarly to `unpack_fstring()`.

**Unpacker.** `unpack_string()`

Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with `unpack_fstring()`.

**Unpacker.** `unpack_opaque()`

Unpacks and returns a variable length opaque data string, similarly to `unpack_string()`.

**Unpacker.** `unpack_bytes()`

Unpacks and returns a variable length byte stream, similarly to `unpack_string()`.

The following methods support unpacking arrays and lists:

**Unpacker.** `unpack_list(unpack_item)`

Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list. *unpack_item* is the function that is called to unpack the items.
Unpacker. **unpack_farray\((n, \text{unpack\_item})\)**

Unpacks and returns (as a list) a fixed length array of homogeneous items. \(n\) is number of list elements to expect in the buffer. As above, \(\text{unpack\_item}\) is the function used to unpack each element.

Unpacker. **unpack_array\((\text{unpack\_item})\)**

Unpacks and returns a variable length *list* of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is unpacked as in **unpack_farray\()** above.
13.5.3. Exceptions

Exceptions in this module are coded as class instances:

```python
import xdrlib
p = xdrlib.Packer()
try:
    p.pack_double(8.01)
except xdrlib.ConversionError, instance:
    print 'packing the double failed:', instance.msg
```

- **exception xdrlib.Error**
  The base exception class. `Error` has a single public data member `msg` containing the description of the error.

- **exception xdrlib.ConversionError**
  Class derived from `Error`. Contains no additional instance variables.

Here is an example of how you would catch one of these exceptions:
13.6. plistlib — Generate and parse Mac OS X .plist files

Changed in version 2.6: This module was previously only available in the Mac-specific library, it is now available for all platforms.

This module provides an interface for reading and writing the “property list” XML files used mainly by Mac OS X.

The property list (.plist) file format is a simple XML pickle supporting basic object types, like dictionaries, lists, numbers and strings. Usually the top level object is a dictionary.

Values can be strings, integers, floats, booleans, tuples, lists, dictionaries (but only with string keys), Data or datetime.datetime objects. String values (including dictionary keys) may be unicode strings – they will be written out as UTF-8.

The <data> plist type is supported through the Data class. This is a thin wrapper around a Python string. Use Data if your strings contain control characters.

See also:

PList manual page
Apple’s documentation of the file format.

This module defines the following functions:

plistlib.readPlist(pathOrFile)
Read a plist file. pathOrFile may either be a file name or a (readable) file object. Return the unpacked root object (which usually is a dictionary).
The XML data is parsed using the Expat parser from `xml.parsers.expat` – see its documentation for possible exceptions on ill-formed XML. Unknown elements will simply be ignored by the plist parser.

```python
plistlib.writePlist(rootObject, pathOrFile)
```
Write `rootObject` to a plist file. `pathOrFile` may either be a file name or a (writable) file object.

A `TypeError` will be raised if the object is of an unsupported type or a container that contains objects of unsupported types.

```python
plistlib.readPlistFromString(data)
```
Read a plist from a string. Return the root object.

```python
plistlib.writePlistToString(rootObject)
```
Return `rootObject` as a plist-formatted string.

```python
plistlib.readPlistFromResource(path[, restype='plst'[, resid=0]])
```
Read a plist from the resource with type `restype` from the resource fork of `path`. Availability: Mac OS X.

**Note:** In Python 3.x, this function has been removed.

```python
plistlib.writePlistToResource(rootObject, path[, restype='plst'[, resid=0]])
```
Write `rootObject` as a resource with type `restype` to the resource fork of `path`. Availability: Mac OS X.

**Note:** In Python 3.x, this function has been removed.

The following class is available:
class plistlib.Data(data)

Return a “data” wrapper object around the string `data`. This is used in functions converting from/to plists to represent the `<data>` type available in plists.

It has one attribute, `data`, that can be used to retrieve the Python string stored in it.
13.6.1. Examples

Generating a plist:

```python
pl = dict(
    aString="Doodah",
    aList=["A", "B", 12, 32.1, [1, 2, 3]],
    aFloat = 0.1,
    anInt = 728,
    aDict=dict(
        anotherString="<hello & hi there!>",
        aUnicodeValue=u'M̡ëssig, Ma\xdf',
        aTrueValue=True,
        aFalseValue=False,
    ),
    someData = Data("<binary gunk>"),
    someMoreData = Data("<lots of binary gunk>" * 10),
    aDate = datetime.datetime.fromtimestamp(time.mktime(time.gmtime())),
)
# unicode keys are possible, but a little awkward to use:
pl[u'xc5benraa'] = "That was a unicode key."
writePlist(pl, fileName)
```

Parsing a plist:

```python
pl = readPlist(pathOrFile)
print pl["aKey"]
```
14. Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. Here’s an overview:

- 14.1. `hashlib` — Secure hashes and message digests
- 14.2. `hmac` — Keyed-Hashing for Message Authentication
- 14.3. `md5` — MD5 message digest algorithm
- 14.4. `sha` — SHA-1 message digest algorithm

Hardcore cypherpunks will probably find the cryptographic modules written by A.M. Kuchling of further interest; the package contains modules for various encryption algorithms, most notably AES. These modules are not distributed with Python but available separately. See the URL http://www.amk.ca/python/code/crypto.html for more information.
14.1. `hashlib` — Secure hashes and message digests

*New in version 2.5.*

This module implements a common interface to many different secure hash and message digest algorithms. Included are the FIPS secure hash algorithms SHA1, SHA224, SHA256, SHA384, and SHA512 (defined in FIPS 180-2) as well as RSA's MD5 algorithm (defined in Internet RFC 1321). The terms secure hash and message digest are interchangeable. Older algorithms were called message digests. The modern term is secure hash.

**Note:** If you want the adler32 or crc32 hash functions they are available in the `zlib` module.

**Warning:** Some algorithms have known hash collision weaknesses, see the FAQ at the end.

There is one constructor method named for each type of hash. All return a hash object with the same simple interface. For example: use `sha1()` to create a SHA1 hash object. You can now feed this object with arbitrary strings using the `update()` method. At any point you can ask it for the *digest* of the concatenation of the strings fed to it so far using the `digest()` or `hexdigest()` methods.

Constructors for hash algorithms that are always present in this module are `md5()`, `sha1()`, `sha224()`, `sha256()`, `sha384()`, and `sha512()`. Additional algorithms may also be available depending upon the OpenSSL library that Python uses on your platform.

For example, to obtain the digest of the string 'Nobody inspects the
spammish repetition':

```python
>>> import hashlib
>>> m = hashlib.md5()
>>> m.update("Nobody inspects")
>>> m.update(" the spammish repetition")
>>> m.digest()
'xbd\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
>>> m.digest_size
16
>>> m.block_size
64
```

More condensed:

```python
>>> hashlib.sha224("Nobody inspects the spammish repetition").hexdigest()
'a4337bc45a8fc544c03f52dc550cd6e1e87021bc896588bd79e901e2'
```

A generic `new()` constructor that takes the string name of the desired algorithm as its first parameter also exists to allow access to the above listed hashes as well as any other algorithms that your OpenSSL library may offer. The named constructors are much faster than `new()` and should be preferred.

Using `new()` with an algorithm provided by OpenSSL:

```python
>>> h = hashlib.new('ripemd160')
>>> h.update("Nobody inspects the spammish repetition")
>>> h.hexdigest()
'cc4a5ce1b3df48aec5d22d1f16b894a0b894eccc'
```

This module provides the following constant attribute:

`hashlib.algorithms`

A tuple providing the names of the hash algorithms guaranteed to be supported by this module.

*New in version 2.7.*
The following values are provided as constant attributes of the hash objects returned by the constructors:

```python
hash.digest_size
The size of the resulting hash in bytes.
```

```python
hash.block_size
The internal block size of the hash algorithm in bytes.
```

A hash object has the following methods:

```python
hash.update(arg)
Update the hash object with the string arg. Repeated calls are equivalent to a single call with the concatenation of all the arguments: m.update(a); m.update(b) is equivalent to m.update(a+b).

Changed in version 2.7.
```

```python
hash.digest()
Return the digest of the strings passed to the update() method so far. This is a string of digest_size bytes which may contain non-ASCII characters, including null bytes.
```

```python
hash.hexdigest()
Like digest() except the digest is returned as a string of double length, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.
```

```python
hash.copy()
Return a copy ("clone") of the hash object. This can be used to efficiently compute the digests of strings that share a common initial substring.
```
See also:

**Module hmac**
A module to generate message authentication codes using hashes.

**Module base64**
Another way to encode binary hashes for non-binary environments.

The FIPS 180-2 publication on Secure Hash Algorithms.

http://en.wikipedia.org/wiki/Cryptographic_hash_function#Cryptographic_hash_algorithms
Wikipedia article with information on which algorithms have known issues and what that means regarding their use.
14.2. hmac — Keyed-Hashing for Message Authentication

New in version 2.2.

This module implements the HMAC algorithm as described by RFC 2104.

hmac.new([key[, msg[, digestmod]]])

Return a new hmac object. If msg is present, the method call update(msg) is made. digestmod is the digest constructor or module for the HMAC object to use. It defaults to the hashlib.md5() constructor.

Note: The md5 hash has known weaknesses but remains the default for backwards compatibility. Choose a better one for your application.

An HMAC object has the following methods:

hmac.update(msg)

Update the hmac object with the string msg. Repeated calls are equivalent to a single call with the concatenation of all the arguments: m.update(a); m.update(b) is equivalent to m.update(a + b).

hmac.digest()

Return the digest of the strings passed to the update() method so far. This string will be the same length as the digest_size of the digest given to the constructor. It may contain non-ASCII characters, including NUL bytes.
hmac. **hexdigest()**

Like **digest()** except the digest is returned as a string twice the length containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

hmac. **copy()**

Return a copy ("clone") of the hmac object. This can be used to efficiently compute the digests of strings that share a common initial substring.

**See also:**

**Module hashlib**

The Python module providing secure hash functions.
14.3. *md5* — MD5 message digest algorithm

*Deprecated since version 2.5:* Use the *hashlib* module instead.

This module implements the interface to RSA's MD5 message digest algorithm (see also Internet [RFC 1321](https://www.rfc-editor.org/rfc/rfc1321)). Its use is quite straightforward: use `new()` to create an md5 object. You can now feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the `digest` (a strong kind of 128-bit checksum, a.k.a. “fingerprint”) of the concatenation of the strings fed to it so far using the `digest()` method.

For example, to obtain the digest of the string "Nobody inspects the spammish repetition":

```python
>>> import md5
>>> m = md5.new()
>>> m.update("Nobody inspects")
>>> m.update(" the spammish repetition")
>>> m.digest()
'\xbbb\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
```

More condensed:

```python
>>> md5.new("Nobody inspects the spammish repetition").digest()
'\xbbb\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
```

The following values are provided as constants in the module and as attributes of the md5 objects returned by `new()`:

*md5.digest_size*

The size of the resulting digest in bytes. This is always 16.
The md5 module provides the following functions:

\texttt{md5.new([arg])}

Return a new md5 object. If \texttt{arg} is present, the method call \texttt{update(arg)} is made.

\texttt{md5([arg])}

For backward compatibility reasons, this is an alternative name for the \texttt{new()} function.

An md5 object has the following methods:

\texttt{md5.update(arg)}

Update the md5 object with the string \texttt{arg}. Repeated calls are equivalent to a single call with the concatenation of all the arguments: \texttt{m.update(a); m.update(b)} is equivalent to \texttt{m.update(a+b)}.

\texttt{md5.digest()}

Return the digest of the strings passed to the \texttt{update()} method so far. This is a 16-byte string which may contain non-ASCII characters, including null bytes.

\texttt{md5.hexdigest()}

Like \texttt{digest()} except the digest is returned as a string of length 32, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

\texttt{md5.copy()}

Return a copy (“clone”) of the md5 object. This can be used to efficiently compute the digests of strings that share a common initial substring.
See also:

**Module sha**

Similar module implementing the Secure Hash Algorithm (SHA). The SHA algorithm is considered a more secure hash.
14.4. `sha` — SHA-1 message digest algorithm

*Deprecated since version 2.5:* Use the `hashlib` module instead.

This module implements the interface to NIST’s secure hash algorithm, known as SHA-1. SHA-1 is an improved version of the original SHA hash algorithm. It is used in the same way as the `md5` module: use `new()` to create an `sha` object, then feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the `digest` of the concatenation of the strings fed to it so far. SHA-1 digests are 160 bits instead of MD5's 128 bits.

```python
sha.new([string])
```

Return a new `sha` object. If `string` is present, the method call `update(string)` is made.

The following values are provided as constants in the module and as attributes of the `sha` objects returned by `new()`:

```python
sha.blocksize
```

Size of the blocks fed into the hash function; this is always 1. This size is used to allow an arbitrary string to be hashed.

```python
sha.digest_size
```

The size of the resulting digest in bytes. This is always 20.

An `sha` object has the same methods as `md5` objects:

```python
sha.update(arg)
```

Update the `sha` object with the string `arg`. Repeated calls are equivalent to a single call with the concatenation of all the
arguments:  \texttt{m.update(a); m.update(b)} is equivalent to \texttt{m.update(a+b)}.

\texttt{sha.digest()}
Return the digest of the strings passed to the \texttt{update()} method so far. This is a 20-byte string which may contain non-ASCII characters, including null bytes.

\texttt{sha.hexdigest()}
Like \texttt{digest()} except the digest is returned as a string of length 40, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

\texttt{sha.copy()}
Return a copy ("clone") of the sha object. This can be used to efficiently compute the digests of strings that share a common initial substring.

15. Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modeled after the Unix or C interfaces, but they are available on most other systems as well. Here's an overview:

- **15.1. os — Miscellaneous operating system interfaces**
  - 15.1.1. Process Parameters
  - 15.1.2. File Object Creation
  - 15.1.3. File Descriptor Operations
    - 15.1.3.1. `open()` flag constants
  - 15.1.4. Files and Directories
  - 15.1.5. Process Management
  - 15.1.6. Miscellaneous System Information
  - 15.1.7. Miscellaneous Functions
- **15.2. io — Core tools for working with streams**
  - 15.2.1. Module Interface
  - 15.2.2. I/O Base Classes
  - 15.2.3. Raw File I/O
  - 15.2.4. Buffered Streams
  - 15.2.5. Text I/O
- **15.3. time — Time access and conversions**
- **15.4. argparse — Parser for command line options, arguments and sub-commands**
  - 15.4.1. Example
    - 15.4.1.1. Creating a parser
    - 15.4.1.2. Adding arguments
    - 15.4.1.3. Parsing arguments
  - 15.4.2. ArgumentParser objects

15.1. os — Miscellaneous operating system interfaces

This module provides a portable way of using operating system dependent functionality. If you just want to read or write a file see `open()`, if you want to manipulate paths, see the `os.path` module, and if you want to read all the lines in all the files on the command line see the `fileinput` module. For creating temporary files and directories see the `tempfile` module, and for high-level file and directory handling see the `shutil` module.

Notes on the availability of these functions:

- The design of all built-in operating system dependent modules of Python is such that as long as the same functionality is available, it uses the same interface; for example, the function `os.stat(path)` returns stat information about `path` in the same format (which happens to have originated with the POSIX interface).
- Extensions peculiar to a particular operating system are also available through the `os` module, but using them is of course a threat to portability.
- An “Availability: Unix” note means that this function is commonly found on Unix systems. It does not make any claims about its existence on a specific operating system.
- If not separately noted, all functions that claim “Availability: Unix” are supported on Mac OS X, which builds on a Unix core.

**Note:** All functions in this module raise `OSError` in the case of invalid or inaccessible file names and paths, or other arguments that have the correct type, but are not accepted by the operating system.
exception os.error

An alias for the built-in OSError exception.

os.name

The name of the operating system dependent module imported. The following names have currently been registered: 'posix', 'nt', 'os2', 'ce', 'java', 'riscos'.

15.1.1. Process Parameters

These functions and data items provide information and operate on the current process and user.

**os.environ**

A mapping object representing the string environment. For example, `environ['HOME']` is the pathname of your home directory (on some platforms), and is equivalent to `getenv("HOME")` in C.

This mapping is captured the first time the `os` module is imported, typically during Python startup as part of processing `site.py`. Changes to the environment made after this time are not reflected in `os.environ`, except for changes made by modifying `os.environ` directly.

If the platform supports the `putenv()` function, this mapping may be used to modify the environment as well as query the environment. `putenv()` will be called automatically when the mapping is modified.

**Note:** Calling `putenv()` directly does not change `os.environ`, so it's better to modify `os.environ`.

**Note:** On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv()`.

If `putenv()` is not provided, a modified copy of this mapping may be passed to the appropriate process-creation functions to cause child processes to use a modified environment.
If the platform supports the `unsetenv()` function, you can delete items in this mapping to unset environment variables. `unsetenv()` will be called automatically when an item is deleted from `os.environ`, and when one of the `pop()` or `clear()` methods is called.

*Changed in version 2.6:* Also unset environment variables when calling `os.environ.clear()` and `os.environ.pop()`.

```python
os.chdir(path)
o.s.fchdir(fd)
o.s.getcwd()
```

These functions are described in *Files and Directories.*

```python
os.ctermid()
```

Return the filename corresponding to the controlling terminal of the process.

*Availability:* Unix.

```python
os.getegid()
```

Return the effective group id of the current process. This corresponds to the “set id” bit on the file being executed in the current process.

*Availability:* Unix.

```python
os.geteuid()
```

Return the current process’s effective user id.

*Availability:* Unix.

```python
os.getgid()
```

Return the real group id of the current process.
Availability: Unix.

**os.getgroups()**
Return list of supplemental group ids associated with the current process.

Availability: Unix.

**os.initgroups(username, gid)**
Call the system initgroups() to initialize the group access list with all of the groups of which the specified username is a member, plus the specified group id.

Availability: Unix.

*New in version 2.7.*

**os.getlogin()**
Return the name of the user logged in on the controlling terminal of the process. For most purposes, it is more useful to use the environment variable **LOGNAME** to find out who the user is, or `pwd.getpwuid(os.getuid())[0]` to get the login name of the currently effective user id.

Availability: Unix.

**os.getpgid(pid)**
Return the process group id of the process with process id `pid`. If `pid` is 0, the process group id of the current process is returned.

Availability: Unix.

*New in version 2.3.*

**os.getpgrp()**
Return the id of the current process group.
Availability: Unix.

`os.getpid()`
Return the current process id.

Availability: Unix, Windows.

`os.getppid()`
Return the parent’s process id.

Availability: Unix.

`os.getresuid()`
Return a tuple (ruid, euid, suid) denoting the current process’s real, effective, and saved user ids.

Availability: Unix.

*New in version 2.7.*

`os.getresgid()`
Return a tuple (rgid, egid, sgid) denoting the current process’s real, effective, and saved user ids.

Availability: Unix.

*New in version 2.7.*

`os.getuid()`
Return the current process’s user id.

Availability: Unix.

`os.getenv(varname[, value])`
Return the value of the environment variable `varname` if it exists, or `value` if it doesn’t. `value` defaults to `None`. 
Availability: most flavors of Unix, Windows.

**os.putenv(varname, value)**
Set the environment variable named `varname` to the string `value`. Such changes to the environment affect subprocesses started with `os.system()`, `popen()` or `fork()` and `execv()`.

Availability: most flavors of Unix, Windows.

**Note:** On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv`.

When `putenv()` is supported, assignments to items in `os.environ` are automatically translated into corresponding calls to `putenv()`, however, calls to `putenv()` don’t update `os.environ`, so it is actually preferable to assign to items of `os.environ`.

**os.setegid(egid)**
Set the current process’s effective group id.

Availability: Unix.

**os.seteuid(euid)**
Set the current process’s effective user id.

Availability: Unix.

**os.setgid(gid)**
Set the current process’ group id.

Availability: Unix.

**os.setgroups(groups)**
Set the list of supplemental group ids associated with the current
process to *groups*. *groups* must be a sequence, and each element must be an integer identifying a group. This operation is typically available only to the superuser.

*Availability:* Unix.

*New in version 2.2.*

**os. setpgrp()**

Call the system call `setpgrp()` or `setpgrp(0, 0)` depending on which version is implemented (if any). See the Unix manual for the semantics.

*Availability:* Unix.

**os. setpgid(pid, pgrp)**

Call the system call `setpgid()` to set the process group id of the process with id *pid* to the process group with id *pgrp*. See the Unix manual for the semantics.

*Availability:* Unix.

**os. setregid(rgid, egid)**

Set the current process’s real and effective group ids.

*Availability:* Unix.

**os. setresgid(rgid, egid, sgid)**

Set the current process’s real, effective, and saved group ids.

*Availability:* Unix.

*New in version 2.7.*

**os. setresuid(ruid, euid, suid)**

Set the current process’s real, effective, and saved user ids.
Availability: Unix.

New in version 2.7.

```python
os.setreuid(ruid, euid)
```
Set the current process’s real and effective user ids.

Availability: Unix.

```python
os.getsid(pid)
```
Call the system call getsid(). See the Unix manual for the semantics.

Availability: Unix.

New in version 2.4.

```python
os.setsid()
```
Call the system call setsid(). See the Unix manual for the semantics.

Availability: Unix.

```python
os.setuid(uid)
```
Set the current process’s user id.

Availability: Unix.

```python
os.strerror(code)
```
Return the error message corresponding to the error code in code. On platforms where strerror() returns NULL when given an unknown error number, ValueError is raised.

Availability: Unix, Windows.

```python
os.umask(mask)
```
Set the current numeric umask and return the previous umask.

Availability: Unix, Windows.

os.uname()
Return a 5-tuple containing information identifying the current operating system. The tuple contains 5 strings: (sysname, nodename, release, version, machine). Some systems truncate the nodename to 8 characters or to the leading component; a better way to get the hostname is socket.gethostname() or even socket.gethostbyaddr(socket.gethostname()).

Availability: recent flavors of Unix.

os.unsetenv(varname)
Unset (delete) the environment variable named varname. Such changes to the environment affect subprocesses started with os.system(), popen() or fork() and execv().

When unsetenv() is supported, deletion of items in os.environ is automatically translated into a corresponding call to unsetenv(); however, calls to unsetenv() don’t update os.environ, so it is actually preferable to delete items of os.environ.

Availability: most flavors of Unix, Windows.
15.1.2. File Object Creation

These functions create new file objects. (See also `open()`.)

```python
os.fdopen(fd[, mode[, bufsize]])
```

Return an open file object connected to the file descriptor `fd`. The `mode` and `bufsize` arguments have the same meaning as the corresponding arguments to the built-in `open()` function.

Availability: Unix, Windows.

*Changed in version 2.3:* When specified, the `mode` argument must now start with one of the letters `'r'`, `'w'`, or `'a'`, otherwise a `ValueError` is raised.

*Changed in version 2.5:* On Unix, when the `mode` argument starts with `'a'`, the `O_APPEND` flag is set on the file descriptor (which the `fdopen()` implementation already does on most platforms).

```python
os.popen(command[, mode[, bufsize]])
```

Open a pipe to or from `command`. The return value is an open file object connected to the pipe, which can be read or written depending on whether `mode` is `'r'` (default) or `'w'`. The `bufsize` argument has the same meaning as the corresponding argument to the built-in `open()` function. The exit status of the command (encoded in the format specified for `wait()`) is available as the return value of the `close()` method of the file object, except that when the exit status is zero (termination without errors), `None` is returned.

Availability: Unix, Windows.
Deprecated since version 2.6: This function is obsolete. Use the subprocess module. Check especially the Replacing Older Functions with the subprocess Module section.

Changed in version 2.0: This function worked unreliably under Windows in earlier versions of Python. This was due to the use of the _popen() function from the libraries provided with Windows. Newer versions of Python do not use the broken implementation from the Windows libraries.

os.tmpfile()

Return a new file object opened in update mode (w+b). The file has no directory entries associated with it and will be automatically deleted once there are no file descriptors for the file.

Availability: Unix, Windows.

There are a number of different popen*() functions that provide slightly different ways to create subprocesses.

Deprecated since version 2.6: All of the popen*() functions are obsolete. Use the subprocess module.

For each of the popen*() variants, if bufsize is specified, it specifies the buffer size for the I/O pipes. mode, if provided, should be the string 'b' or 't'; on Windows this is needed to determine whether the file objects should be opened in binary or text mode. The default value for mode is 't'.

Also, for each of these variants, on Unix, cmd may be a sequence, in which case arguments will be passed directly to the program without shell intervention (as with os.spawnv()). If cmd is a string it will be
passed to the shell (as with `os.system()`).

These methods do not make it possible to retrieve the exit status from the child processes. The only way to control the input and output streams and also retrieve the return codes is to use the `subprocess` module; these are only available on Unix.

For a discussion of possible deadlock conditions related to the use of these functions, see *Flow Control Issues*.

```python
os.popen2(cmd[, mode[, bufsize]])
```

Execute `cmd` as a sub-process and return the file objects `(child_stdin, child_stdout).

*Deprecated since version 2.6*: This function is obsolete. Use the `subprocess` module. Check especially the *Replacing Older Functions with the subprocess Module* section.

Availability: Unix, Windows.

*New in version 2.0.*

```python
os.popen3(cmd[, mode[, bufsize]])
```

Execute `cmd` as a sub-process and return the file objects `(child_stdin, child_stdout, child_stderr).

*Deprecated since version 2.6*: This function is obsolete. Use the `subprocess` module. Check especially the *Replacing Older Functions with the subprocess Module* section.

Availability: Unix, Windows.

*New in version 2.0.*
os.popen4(cmd[, mode[, bufsize]])

Executecmd as a sub-process and return the file objects (child_stdin, child_stdout_and_stderr).

Deprecated since version 2.6: This function is obsolete. Use the subprocess module. Check especially the Replacing Older Functions with the subprocess Module section.

Availability: Unix, Windows.

New in version 2.0.

(Note that child_stdin, child_stdout, and child_stderr are named from the point of view of the child process, so child_stdin is the child’s standard input.)

This functionality is also available in the popen2 module using functions of the same names, but the return values of those functions have a different order.)
15.1.3. File Descriptor Operations

These functions operate on I/O streams referenced using file descriptors.

File descriptors are small integers corresponding to a file that has been opened by the current process. For example, standard input is usually file descriptor 0, standard output is 1, and standard error is 2. Further files opened by a process will then be assigned 3, 4, 5, and so forth. The name “file descriptor” is slightly deceptive; on Unix platforms, sockets and pipes are also referenced by file descriptors.

The `fileno()` method can be used to obtain the file descriptor associated with a file object when required. Note that using the file descriptor directly will bypass the file object methods, ignoring aspects such as internal buffering of data.

```python
os.close(fd)
```

Close file descriptor `fd`.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `os.open()` or `pipe()`. To close a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, use its `close()` method.

```python
os.closerange(fd_low, fd_high)
```

Close all file descriptors from `fd_low` (inclusive) to `fd_high` (exclusive), ignoring errors. Equivalent to:

```python
for fd in xrange(fd_low, fd_high):
    try:
        os.close(fd)
```

except OSError:
    pass

Availability: Unix, Windows.

*New in version 2.6.*

```python
os.dup(fd)
```

Return a duplicate of file descriptor *fd*.

Availability: Unix, Windows.

```python
os.dup2(fd, fd2)
```

Duplicate file descriptor *fd* to *fd2*, closing the latter first if necessary.

Availability: Unix, Windows.

```python
os.fchmod(fd, mode)
```

Change the mode of the file given by *fd* to the numeric *mode*. See the docs for `chmod()` for possible values of *mode*.

Availability: Unix.

*New in version 2.6.*

```python
os.fchown(fd, uid, gid)
```

Change the owner and group id of the file given by *fd* to the numeric *uid* and *gid*. To leave one of the ids unchanged, set it to -1.

Availability: Unix.

*New in version 2.6.*

```python
os.fdatasync(fd)
```

Force write of file with filedescriptor *fd* to disk. Does not force
update of metadata.

Availability: Unix.

**Note:** This function is not available on MacOS.

```python
os.fpathconf(fd, name)
```

Return system configuration information relevant to an open file. 

*name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the *pathconf_names* dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If *name* is a string and is not known, *ValueError* is raised. If a specific value for *name* is not supported by the host system, even if it is included in *pathconf_names*, an * OSError* is raised with *errno.EINVAL* for the error number.

Availability: Unix.

```python
os.fstat(fd)
```

Return status for file descriptor *fd*, like *stat()*. 

Availability: Unix, Windows.

```python
os.fstatvfs(fd)
```

Return information about the filesystem containing the file associated with file descriptor *fd*, like *statvfs()*. 

Availability: Unix.
**os.fsync(fd)**
Force write of file with filedescriptor *fd* to disk. On Unix, this calls the native `fsync()` function; on Windows, the MS _commit() function.

If you’re starting with a Python file object *f*, first do *f.flush()*, and then do `os.fsync(f.fileno())`, to ensure that all internal buffers associated with *f* are written to disk.

*Availability*: Unix, and Windows starting in 2.2.3.

**os.ftruncate(fd, length)**
Truncate the file corresponding to file descriptor *fd*, so that it is at most *length* bytes in size.

*Availability*: Unix.

**os.isatty(fd)**
Return True if the file descriptor *fd* is open and connected to a tty(-like) device, else False.

*Availability*: Unix.

**os.lseek(fd, pos, how)**
Set the current position of file descriptor *fd* to position *pos*, modified by *how*: SEEK_SET or 0 to set the position relative to the beginning of the file; SEEK_CUR or 1 to set it relative to the current position; os.SEEK_END or 2 to set it relative to the end of the file.

*Availability*: Unix, Windows.

**os.SEEK_SET**
**os.SEEK_CUR**
**os.SEEK_END**
Parameters to the lseek() function. Their values are 0, 1, and 2,
respectively.

Availability: Windows, Unix.

*New in version 2.5.*

**`os.open(file, flags[, mode])`**
Open the file `file` and set various flags according to `flags` and possibly its mode according to `mode`. The default `mode` is `0777` (octal), and the current umask value is first masked out. Return the file descriptor for the newly opened file.

For a description of the flag and mode values, see the C run-time documentation; flag constants (like `O_RDONLY` and `O_WRONLY`) are defined in this module too (see `open()` flag constants). In particular, on Windows adding `O_BINARY` is needed to open files in binary mode.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O. For normal usage, use the built-in function `open()`, which returns a “file object” with `read()` and `wprite()` methods (and many more). To wrap a file descriptor in a “file object”, use `fdopen()`.

**`os.openpty()`**
Open a new pseudo-terminal pair. Return a pair of file descriptors `(master, slave)` for the pty and the tty, respectively. For a (slightly) more portable approach, use the `pty` module.

Availability: some flavors of Unix.

**`os.pipe()`**
Create a pipe. Return a pair of file descriptors `(r, w)` usable for
reading and writing, respectively.

Availability: Unix, Windows.

```python
os.read(fd, n)
```
Read at most n bytes from file descriptor fd. Return a string containing the bytes read. If the end of the file referred to by fd has been reached, an empty string is returned.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by os.open() or pipe(). To read a “file object” returned by the built-in function open() or by popen() or fdopen(), or sys.stdin, use its read() or readline() methods.

```python
os.tcgetpgrp(fd)
```
Return the process group associated with the terminal given by fd (an open file descriptor as returned by os.open()).

Availability: Unix.

```python
os.tcsetpgrp(fd, pg)
```
Set the process group associated with the terminal given by fd (an open file descriptor as returned by os.open()) to pg.

Availability: Unix.

```python
os.ttyname(fd)
```
Return a string which specifies the terminal device associated with file descriptor fd. If fd is not associated with a terminal device, an exception is raised.

Availability: Unix.
**os.write(fd, str)**

Write the string *str* to file descriptor *fd*. Return the number of bytes actually written.

**Availability:** Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by *os.open()* or *pipe()*.

To write a “file object” returned by the built-in function *open()* or by *popen()* or *fdopen()* or *sys.stdout* or *sys.stderr*, use its *write()* method.

### 15.1.3.1. open() flag constants

The following constants are options for the *flags* parameter to the *open()* function. They can be combined using the bitwise OR operator |. Some of them are not available on all platforms. For descriptions of their availability and use, consult the *open(2)* manual page on Unix or the MSDN on Windows.

- os.O_RDONLY
- os.O_WRONLY
- os.O_RDWR
- os.O_APPEND
- os.O_CREAT
- os.O_EXCL
- os.O_TRUNC
- os.O_DSYNC
- os.O_RSYNC
- os.O_SYNC
- os.O_NDELAY
- os.O_NONBLOCK
- os.O_NOCTTY

These constants are available on Unix and Windows.
os. O_SHLOCK
os. O_EXLOCK

These constants are only available on Unix.

os. O_BINARY
os. O_NOINHERIT
os. O_SHORT_LIVED
os. O_TEMPORARY
os. O_RANDOM
os. O_SEQUENTIAL
os. O_TEXT

These constants are only available on Windows.

os. O_ASYNC
os. O_DIRECT
os. O_DIRECTORY
os. O_NOFOLLOW
os. O_NOATIME

These constants are GNU extensions and not present if they are not defined by the C library.
15.1.4. Files and Directories

`os.access(path, mode)`

Use the real uid/gid to test for access to `path`. Note that most operations will use the effective uid/gid, therefore this routine can be used in a suid/sgid environment to test if the invoking user has the specified access to `path`. `mode` should be `F_OK` to test the existence of `path`, or it can be the inclusive OR of one or more of `R_OK`, `W_OK`, and `X_OK` to test permissions. Return `True` if access is allowed, `False` if not. See the Unix man page `access(2)` for more information.

Availability: Unix, Windows.

**Note:** Using `access()` to check if a user is authorized to e.g. open a file before actually doing so using `open()` creates a security hole, because the user might exploit the short time interval between checking and opening the file to manipulate it.

**Note:** I/O operations may fail even when `access()` indicates that they would succeed, particularly for operations on network filesystems which may have permissions semantics beyond the usual POSIX permission-bit model.

`os.F_OK`

Value to pass as the `mode` parameter of `access()` to test the existence of `path`.

`os.R_OK`

Value to include in the `mode` parameter of `access()` to test the readability of `path`.

`os.W_OK`
Value to include in the mode parameter of `access()` to test the writability of `path`.

`os.X_OK`
Value to include in the mode parameter of `access()` to determine if `path` can be executed.

`os.chdir(path)`
Change the current working directory to `path`.

   Availability: Unix, Windows.

`os.fchdir(fd)`
Change the current working directory to the directory represented by the file descriptor `fd`. The descriptor must refer to an opened directory, not an open file.

   Availability: Unix.

   *New in version 2.3.*

`os.getcwd()`
Return a string representing the current working directory.

   Availability: Unix, Windows.

`os.getcwdu()`
Return a Unicode object representing the current working directory.

   Availability: Unix, Windows.

   *New in version 2.3.*

`os.chflags(path, flags)`
Set the flags of `path` to the numeric `flags`. `flags` may take a
combination (bitwise OR) of the following values (as defined in the `stat` module):

- UF_NODUMP
- UF_IMMUTABLE
- UF_APPEND
- UF_OPAQUE
- UF_NOUNLINK
- SF_ARCHIVED
- SF_IMMUTABLE
- SF_APPEND
- SF_NOUNLINK
- SF_SNAPSHOT

Availability: Unix.

*New in version 2.6.*

`os.chroot(path)`

Change the root directory of the current process to `path`. Availability: Unix.

*New in version 2.2.*

`os.chmod(path, mode)`

Change the mode of `path` to the numeric `mode`. `mode` may take one of the following values (as defined in the `stat` module) or bitwise ORed combinations of them:

- `stat.S_ISUID`
- `stat.S_ISGID`
- `stat.S_ENFMT`
- `stat.S_ISVTX`
- `stat.S_IWRITE`
• `stat.S_IWRITE`
• `stat.S_IEXEC`
• `stat.S_IRWXU`
• `stat.S_IRUSR`
• `stat.S_IWUSR`
• `stat.S_IXUSR`
• `stat.S_IRWXG`
• `stat.S_IRGRP`
• `stat.S_IWGRP`
• `stat.S_IXGRP`
• `stat.S_IRWXO`
• `stat.S_IROTH`
• `stat.S_IWOTH`
• `stat.S_IXOTH`

Availability: Unix, Windows.

**Note:** Although Windows supports `chmod()`, you can only set the file's read-only flag with it (via the `stat.S_IWRITE` and `stat.S_IREAD` constants or a corresponding integer value). All other bits are ignored.

```python
os.chown(path, uid, gid)
```
Change the owner and group id of `path` to the numeric `uid` and `gid`. To leave one of the ids unchanged, set it to `-1`.

Availability: Unix.

```python
os.lchflags(path, flags)
```
Set the flags of `path` to the numeric `flags`, like `chflags()`, but do not follow symbolic links.

Availability: Unix.
New in version 2.6.

**os.lchmod**(*path*, *mode*)
Change the mode of *path* to the numeric *mode*. If *path* is a symlink, this affects the symlink rather than the target. See the docs for `chmod()` for possible values of *mode*.

Availability: Unix.

New in version 2.6.

**os.lchown**(*path*, *uid*, *gid*)
Change the owner and group id of *path* to the numeric *uid* and *gid*. This function will not follow symbolic links.

Availability: Unix.

New in version 2.3.

**os.link**(*source*, *link_name*)
Create a hard link pointing to *source* named *link_name*.

Availability: Unix.

**os.listdir**(*path*)
Return a list containing the names of the entries in the directory given by *path*. The list is in arbitrary order. It does not include the special entries `.'` and `'..'` even if they are present in the directory.

Availability: Unix, Windows.

*Changed in version 2.3:* On Windows NT/2k/XP and Unix, if *path* is a Unicode object, the result will be a list of Unicode objects. Undecodable filenames will still be returned as string objects.
**os.lstat(path)**
Like `stat()`, but do not follow symbolic links. This is an alias for `stat()` on platforms that do not support symbolic links, such as Windows.

**os.mkfifo(path[, mode])**
Create a FIFO (a named pipe) named `path` with numeric mode `mode`. The default `mode` is `0666` (octal). The current umask value is first masked out from the mode.

Availability: Unix.

FIFOs are pipes that can be accessed like regular files. FIFOs exist until they are deleted (for example with `os.unlink()`). Generally, FIFOs are used as rendezvous between “client” and “server” type processes: the server opens the FIFO for reading, and the client opens it for writing. Note that `mkfifo()` doesn’t open the FIFO — it just creates the rendezvous point.

**os.mknod(filename[, mode=0600, device])**
Create a filesystem node (file, device special file or named pipe) named `filename`. `mode` specifies both the permissions to use and the type of node to be created, being combined (bitwise OR) with one of `stat.S_IFREG`, `stat.S_IFCHR`, `stat.S_IFBLK`, and `stat.S_IFIFO` (those constants are available in `stat`). For `stat.S_IFCHR` and `stat.S_IFBLK`, `device` defines the newly created device special file (probably using `os.makedev()`), otherwise it is ignored.

*New in version 2.3.*

**os.major(device)**
Extract the device major number from a raw device number
(usually the `st_dev` or `st_rdev` field from `stat`).

*New in version 2.3.*

```python
os.minor(device)
```

Extract the device minor number from a raw device number (usually the `st_dev` or `st_rdev` field from `stat`).

*New in version 2.3.*

```python
os.makedev(major, minor)
```

Compose a raw device number from the major and minor device numbers.

*New in version 2.3.*

```python
os.mkdir(path[, mode])
```

Create a directory named `path` with numeric mode `mode`. The default `mode` is `0777` (octal). On some systems, `mode` is ignored. Where it is used, the current umask value is first masked out. If the directory already exists, `OSError` is raised.

It is also possible to create temporary directories; see the `tempfile` module's `tempfile.mkdtemp()` function.

**Availability:** Unix, Windows.

```python
os.makedirs(path[, mode])
```

Recursive directory creation function. Like `mkdir()`, but makes all intermediate-level directories needed to contain the leaf directory. Throws an `error` exception if the leaf directory already exists or cannot be created. The default `mode` is `0777` (octal). On some systems, `mode` is ignored. Where it is used, the current umask value is first masked out.
**Note:** `makedirs()` will become confused if the path elements to create include `os.pardir`.

*New in version 1.5.2.*

*Changed in version 2.3:* This function now handles UNC paths correctly.

`os.pathconf(path, name)`

Return system configuration information relevant to a named file. `name` specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for `name` is also accepted.

If `name` is a string and is not known, `ValueError` is raised. If a specific value for `name` is not supported by the host system, even if it is included in `pathconf_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

**Availability:** Unix.

`os.pathconf_names` Dictionary mapping names accepted by `pathconf()` and `fpathconf()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. **Availability:** Unix.

`os.readlink(path)` Return a string representing the path to which the symbolic link
points. The result may be either an absolute or relative pathname; if it is relative, it may be converted to an absolute pathname using `os.path.join(os.path.dirname(path), result).

*Changed in version 2.6:* If the *path* is a Unicode object the result will also be a Unicode object.

**Availability:** Unix.

**os.remove(path)**
Remove (delete) the file *path*. If *path* is a directory, *OSError* is raised; see `rmdir()` below to remove a directory. This is identical to the `unlink()` function documented below. On Windows, attempting to remove a file that is in use causes an exception to be raised; on Unix, the directory entry is removed but the storage allocated to the file is not made available until the original file is no longer in use.

**Availability:** Unix, Windows.

**os.removedirs(path)**
Remove directories recursively. Works like `rmdir()` except that, if the leaf directory is successfully removed, `removedirs()` tries to successively remove every parent directory mentioned in *path* until an error is raised (which is ignored, because it generally means that a parent directory is not empty). For example, `os.removedirs('foo/bar/baz')` will first remove the directory 'foo/bar/baz', and then remove 'foo/bar' and 'foo' if they are empty. Raises *OSError* if the leaf directory could not be successfully removed.

*New in version 1.5.2.*

**os.rename(src, dst)**
Rename the file or directory `src` to `dst`. If `dst` is a directory, `OSError` will be raised. On Unix, if `dst` exists and is a file, it will be replaced silently if the user has permission. The operation may fail on some Unix flavors if `src` and `dst` are on different filesystems. If successful, the renaming will be an atomic operation (this is a POSIX requirement). On Windows, if `dst` already exists, `OSError` will be raised even if it is a file; there may be no way to implement an atomic rename when `dst` names an existing file.

**Availability:** Unix, Windows.

```python
os.renames(old, new)
```

Recursive directory or file renaming function. Works like `rename()`, except creation of any intermediate directories needed to make the new pathname good is attempted first. After the rename, directories corresponding to rightmost path segments of the old name will be pruned away using `removedirs()`.

*New in version 1.5.2.*

**Note:** This function can fail with the new directory structure made if you lack permissions needed to remove the leaf directory or file.

```python
os.rmdir(path)
```

Remove (delete) the directory `path`. Only works when the directory is empty, otherwise, `OSError` is raised. In order to remove whole directory trees, `shutil.rmtree()` can be used.

**Availability:** Unix, Windows.

```python
os.stat(path)
```

Perform a `stat()` system call on the given path. The return value
is an object whose attributes correspond to the members of the
\texttt{stat} structure, namely: \texttt{st\_mode} (protection bits), \texttt{st\_ino} (inode
number), \texttt{st\_dev} (device), \texttt{st\_nlink} (number of hard links),
\texttt{st\_uid} (user id of owner), \texttt{st\_gid} (group id of owner), \texttt{st\_size}
(size of file, in bytes), \texttt{st\_atime} (time of most recent access),
\texttt{st\_mtime} (time of most recent content modification), \texttt{st\_ctime}
(platform dependent; time of most recent metadata change on
Unix, or the time of creation on Windows):

\begin{verbatim}
>>> import os
>>> statinfo = os.stat('somefile.txt')
>>> statinfo
(33188, 422511L, 769L, 1, 1032, 100, 926L, 1105022698, 1105022732, 1105022732)
>>> statinfo.st\_size
926L
\end{verbatim}

\textit{Changed in version 2.3:} If \texttt{stat\_float\_times()} returns \texttt{True}, the
time values are floats, measuring seconds. Fractions of a second
may be reported if the system supports that. On Mac OS, the
times are always floats. See \texttt{stat\_float\_times()} for further
discussion.

On some Unix systems (such as Linux), the following attributes
may also be available: \texttt{st\_blocks} (number of blocks allocated for
file), \texttt{st\_blksize} (filesystem blocksize), \texttt{st\_rdev} (type of device if
an inode device). \texttt{st\_flags} (user defined flags for file).

On other Unix systems (such as FreeBSD), the following
attributes may be available (but may be only filled out if root tries
to use them): \texttt{st\_gen} (file generation number), \texttt{st\_birthtime} (time
of file creation).

On Mac OS systems, the following attributes may also be
available: \texttt{st\_rsize, st\_creator, st\_type}. 
On RISCOS systems, the following attributes are also available: st_ftype (file type), st_attrs (attributes), st_obtype (object type).

For backward compatibility, the return value of \texttt{stat()} is also accessible as a tuple of at least 10 integers giving the most important (and portable) members of the \texttt{stat} structure, in the order \texttt{st_mode}, \texttt{st_ino}, \texttt{st_dev}, \texttt{st_nlink}, \texttt{st_uid}, \texttt{st_gid}, \texttt{st_size}, \texttt{st_atime}, \texttt{st_mtime}, \texttt{st_ctime}. More items may be added at the end by some implementations. The standard module \texttt{stat} defines functions and constants that are useful for extracting information from a \texttt{stat} structure. (On Windows, some items are filled with dummy values.)

\textbf{Note:} The exact meaning and resolution of the \texttt{st_atime}, \texttt{st_mtime}, and \texttt{st_ctime} members depends on the operating system and the file system. For example, on Windows systems using the FAT or FAT32 file systems, \texttt{st_mtime} has 2-second resolution, and \texttt{st_atime} has only 1-day resolution. See your operating system documentation for details.

Availability: Unix, Windows.

\textit{Changed in version 2.2:} Added access to values as attributes of the returned object.

\textit{Changed in version 2.5:} Added \texttt{st_gen} and \texttt{st_birthtime}.

\texttt{os.stat_float_times([newvalue])}

Determine whether \texttt{stat_result} represents time stamps as float objects. If \texttt{newvalue} is \texttt{True}, future calls to \texttt{stat()} return floats, if it is \texttt{False}, future calls return ints. If \texttt{newvalue} is omitted, return the current setting.
For compatibility with older Python versions, accessing `stat_result` as a tuple always returns integers.

*Changed in version 2.5:* Python now returns float values by default. Applications which do not work correctly with floating point time stamps can use this function to restore the old behaviour.

The resolution of the timestamps (that is the smallest possible fraction) depends on the system. Some systems only support second resolution; on these systems, the fraction will always be zero.

It is recommended that this setting is only changed at program startup time in the `__main__` module; libraries should never change this setting. If an application uses a library that works incorrectly if floating point time stamps are processed, this application should turn the feature off until the library has been corrected.

`os.statvfs(path)`

Perform a `statvfs()` system call on the given path. The return value is an object whose attributes describe the filesystem on the given path, and correspond to the members of the `statvfs` structure, namely: `f_bsize`, `f_frsize`, `f_blocks`, `f_bfree`, `f_bavail`, `f_files`, `f_ffree`, `f_favail`, `f_flag`, `f_namemax`.

For backward compatibility, the return value is also accessible as a tuple whose values correspond to the attributes, in the order given above. The standard module `statvfs` defines constants that are useful for extracting information from a `statvfs` structure when accessing it as a sequence; this remains useful when writing code that needs to work with versions of Python that don’t support accessing the fields as attributes.
Availability: Unix.

Changed in version 2.2: Added access to values as attributes of the returned object.

```python
os.symlink(source, link_name)
```
Create a symbolic link pointing to `source` named `link_name`.

Availability: Unix.

```python
os.tempnam([dir[, prefix]])
```
Return a unique path name that is reasonable for creating a temporary file. This will be an absolute path that names a potential directory entry in the directory `dir` or a common location for temporary files if `dir` is omitted or `None`. If given and not `None`, `prefix` is used to provide a short prefix to the filename. Applications are responsible for properly creating and managing files created using paths returned by `tempnam()`; no automatic cleanup is provided. On Unix, the environment variable `TMPDIR` overrides `dir`, while on Windows `TMP` is used. The specific behavior of this function depends on the C library implementation; some aspects are underspecified in system documentation.

**Warning:** Use of `tempnam()` is vulnerable to symlink attacks; consider using `tmpfile()` (section *File Object Creation*) instead.

Availability: Unix, Windows.

```python
os.tmpnam()
```
Return a unique path name that is reasonable for creating a temporary file. This will be an absolute path that names a potential directory entry in a common location for temporary files. Applications are responsible for properly creating and managing
files created using paths returned by `tmpnam()`; no automatic cleanup is provided.

**Warning:** Use of `tmpnam()` is vulnerable to symlink attacks; consider using `tmpfile()` (section *File Object Creation*) instead.

Availability: Unix, Windows. This function probably shouldn’t be used on Windows, though: Microsoft’s implementation of `tmpnam()` always creates a name in the root directory of the current drive, and that’s generally a poor location for a temp file (depending on privileges, you may not even be able to open a file using this name).

**os.** `TMP_MAX`

The maximum number of unique names that `tmpnam()` will generate before reusing names.

**os.** `unlink(path)`

Remove (delete) the file `path`. This is the same function as `remove();`; the `unlink()` name is its traditional Unix name.

Availability: Unix, Windows.

**os.** `utime(path, times)`

Set the access and modified times of the file specified by `path`. If `times` is `None`, then the file’s access and modified times are set to the current time. (The effect is similar to running the Unix program `touch` on the path.) Otherwise, `times` must be a 2-tuple of numbers, of the form `(atime, mtime)` which is used to set the access and modified times, respectively. Whether a directory can be given for `path` depends on whether the operating system implements directories as files (for example, Windows does not). Note that the exact times you set here may not be returned by a subsequent `stat()` call, depending on the resolution with which
your operating system records access and modification times; see \texttt{stat()}.

\textit{Changed in version 2.0:} Added support for \texttt{None} for \texttt{times}.

\texttt{Availability: Unix, Windows.}

\texttt{os.walk(top[, topdown=True[, onerror=None[, followlinks=False]]])}

Generate the file names in a directory tree by walking the tree either top-down or bottom-up. For each directory in the tree rooted at directory \texttt{top} (including \texttt{top} itself), it yields a 3-tuple \texttt{(dirpath, dirnames, filenames)}.

\textit{dirpath} is a string, the path to the directory. \textit{dirnames} is a list of the names of the subdirectories in \textit{dirpath} (excluding "." and "."). \textit{filenames} is a list of the names of the non-directory files in \textit{dirpath}. Note that the names in the lists contain no path components. To get a full path (which begins with \texttt{top}) to a file or directory in \texttt{dirpath}, do \texttt{os.path.join(dirpath, name)}.

If optional argument \texttt{topdown} is \texttt{True} or not specified, the triple for a directory is generated before the triples for any of its subdirectories (directories are generated top-down). If \texttt{topdown} is \texttt{False}, the triple for a directory is generated after the triples for all of its subdirectories (directories are generated bottom-up).

When \texttt{topdown} is \texttt{True}, the caller can modify the \texttt{dirnames} list in-place (perhaps using \texttt{del} or slice assignment), and \texttt{walk()} will only recurse into the subdirectories whose names remain in \texttt{dirnames}; this can be used to prune the search, impose a specific order of visiting, or even to inform \texttt{walk()} about directories the caller creates or renames before it resumes \texttt{walk()} again. Modifying \texttt{dirnames} when \texttt{topdown} is \texttt{False} is ineffective, because in bottom-up mode the directories in
dirnames are generated before dirpath itself is generated.

By default errors from the listdir() call are ignored. If optional argument onerror is specified, it should be a function; it will be called with one argument, an OSError instance. It can report the error to continue with the walk, or raise the exception to abort the walk. Note that the filename is available as the filename attribute of the exception object.

By default, walk() will not walk down into symbolic links that resolve to directories. Set followlinks to True to visit directories pointed to by symlinks, on systems that support them.

New in version 2.6: The followlinks parameter.

**Note:** Be aware that setting followlinks to True can lead to infinite recursion if a link points to a parent directory of itself. walk() does not keep track of the directories it visited already.

**Note:** If you pass a relative pathname, don’t change the current working directory between resumptions of walk(). walk() never changes the current directory, and assumes that its caller doesn’t either.

This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn’t look under any CVS subdirectory:

```python
import os
from os.path import join, getsize
for root, dirs, files in os.walk('python/Lib/email'):
    print root, "consumes",
    print sum(getsize(join(root, name)) for name in files),
    print "bytes in", len(files), "non-directory files"
if 'CVS' in dirs:
    dirs.remove('CVS')  # don't visit CVS directories
```
In the next example, walking the tree bottom-up is essential: `rmdir()` doesn't allow deleting a directory before the directory is empty:

```python
import os
for root, dirs, files in os.walk(top, topdown=False):
    for name in files:
        os.remove(os.path.join(root, name))
    for name in dirs:
        os.rmdir(os.path.join(root, name))
```

`New in version 2.3.`
15.1.5. Process Management

These functions may be used to create and manage processes.

The various `exec*()` functions take a list of arguments for the new program loaded into the process. In each case, the first of these arguments is passed to the new program as its own name rather than as an argument a user may have typed on a command line. For the C programmer, this is the `argv[0]` passed to a program's `main()`. For example, `os.execv('/bin/echo', [ 'foo', 'bar' ])` will only print `bar` on standard output; `foo` will seem to be ignored.

`os.abort()`

Generate a `SIGABRT` signal to the current process. On Unix, the default behavior is to produce a core dump; on Windows, the process immediately returns an exit code of 3. Be aware that programs which use `signal.signal()` to register a handler for `SIGABRT` will behave differently.

Availability: Unix, Windows.

`os.exec1(path, arg0, arg1, ...)`
`os.execle(path, arg0, arg1, ..., env)`
`os.execlp(file, arg0, arg1, ...)`
`os.exec1pe(file, arg0, arg1, ..., env)`
`os.execv(path, args)`
`os.execve(path, args, env)`
`os.execvp(file, args)`
`os.execvpe(file, args, env)`

These functions all execute a new program, replacing the current process; they do not return. On Unix, the new executable is loaded into the current process, and will have the same process
id as the caller. Errors will be reported as **OSError** exceptions.

The current process is replaced immediately. Open file objects and descriptors are not flushed, so if there may be data buffered on these open files, you should flush them using `sys.stdout.flush()` or `os.fsync()` before calling an `exec*()` function.

The “l” and “v” variants of the `exec*()` functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `exec1*()` functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process should start with the name of the command being run, but this is not enforced.

The variants which include a “p” near the end (`exec1p()`, `exec1pe()`, `execvp()`, and `execvpe()`) will use the **PATH** environment variable to locate the program file. When the environment is being replaced (using one of the `exec*e()` variants, discussed in the next paragraph), the new environment is used as the source of the **PATH** variable. The other variants, `exec1()`, `execl()`, `execv()`, and `execve()`, will not use the **PATH** variable to locate the executable; `path` must contain an appropriate absolute or relative path.

For `execl()`, `execlpe()`, `execve()`, and `execvpe()` (note that these all end in “e”), the `env` parameter must be a mapping which is used to define the environment variables for the new process (these are used instead of the current process’ environment); the functions `exec1()`, `exec1p()`, `execv()`, and `execvp()` all cause the
new process to inherit the environment of the current process.

Availability: Unix, Windows.

`os._exit(n)`
Exit to the system with status n, without calling cleanup handlers, flushing stdio buffers, etc.

Availability: Unix, Windows.

**Note:** The standard way to exit is `sys.exit(n)`. `_exit()` should normally only be used in the child process after a `fork()`.

The following exit codes are defined and can be used with `_exit()`, although they are not required. These are typically used for system programs written in Python, such as a mail server’s external command delivery program.

**Note:** Some of these may not be available on all Unix platforms, since there is some variation. These constants are defined where they are defined by the underlying platform.

`os.EX_OK`
Exit code that means no error occurred.

Availability: Unix.

*New in version 2.3.*

`os.EX_USAGE`
Exit code that means the command was used incorrectly, such as when the wrong number of arguments are given.

Availability: Unix.
New in version 2.3.

**os. EX_DATAERR**
Exit code that means the input data was incorrect.

Availability: Unix.

New in version 2.3.

**os. EX_NOINPUT**
Exit code that means an input file did not exist or was not readable.

Availability: Unix.

New in version 2.3.

**os. EX_NOUSER**
Exit code that means a specified user did not exist.

Availability: Unix.

New in version 2.3.

**os. EX_NOHOST**
Exit code that means a specified host did not exist.

Availability: Unix.

New in version 2.3.

**os. EX_UNAVAILABLE**
Exit code that means that a required service is unavailable.

Availability: Unix.

New in version 2.3.
os.EX_SOFTWARE
   Exit code that means an internal software error was detected.

   Availability: Unix.

   New in version 2.3.

os.EX_OSERR
   Exit code that means an operating system error was detected, such as the inability to fork or create a pipe.

   Availability: Unix.

   New in version 2.3.

os.EX_OSFILE
   Exit code that means some system file did not exist, could not be opened, or had some other kind of error.

   Availability: Unix.

   New in version 2.3.

os.EX_CANTCREAT
   Exit code that means a user specified output file could not be created.

   Availability: Unix.

   New in version 2.3.

os.EX_IOERR
   Exit code that means that an error occurred while doing I/O on some file.

   Availability: Unix.

   New in version 2.3.
os. **EX_TEMPFAIL**
Exit code that means a temporary failure occurred. This indicates something that may not really be an error, such as a network connection that couldn’t be made during a retryable operation.

Availability: Unix.

*New in version 2.3.*

os. **EX_PROTOCOL**
Exit code that means that a protocol exchange was illegal, invalid, or not understood.

Availability: Unix.

*New in version 2.3.*

os. **EX_NOPERM**
Exit code that means that there were insufficient permissions to perform the operation (but not intended for file system problems).

Availability: Unix.

*New in version 2.3.*

os. **EX_CONFIG**
Exit code that means that some kind of configuration error occurred.

Availability: Unix.

*New in version 2.3.*

os. **EX_NOTFOUND**
Exit code that means something like “an entry was not found”.

Availability: Unix.
New in version 2.3.

**os.fork()**
Fork a child process. Return 0 in the child and the child’s process id in the parent. If an error occurs OSError is raised.

Note that some platforms including FreeBSD <= 6.3, Cygwin and OS/2 EMX have known issues when using fork() from a thread.

Availability: Unix.

**os.forkpty()**
Fork a child process, using a new pseudo-terminal as the child’s controlling terminal. Return a pair of (pid, fd), where pid is 0 in the child, the new child’s process id in the parent, and fd is the file descriptor of the master end of the pseudo-terminal. For a more portable approach, use the pty module. If an error occurs OSError is raised.

Availability: some flavors of Unix.

**os.kill(pid, sig)**
Send signal sig to the process pid. Constants for the specific signals available on the host platform are defined in the signal module.

Windows: The signal.CTRL_C_EVENT and signal.CTRL_BREAK_EVENT signals are special signals which can only be sent to console processes which share a common console window, e.g., some subprocesses. Any other value for sig will cause the process to be unconditionally killed by the TerminateProcess API, and the exit code will be set to sig. The Windows version of kill() additionally takes process handles to be killed.
New in version 2.7: Windows support

\texttt{os.killpg(pgid, sig)}

Send the signal \textit{sig} to the process group \textit{pgid}.

Availability: Unix.

\textit{New in version 2.3.}

\texttt{os.nice(increment)}

Add \textit{increment} to the process's "niceness". Return the new niceness.

Availability: Unix.

\texttt{os.plock(op)}

Lock program segments into memory. The value of \textit{op} (defined in \texttt{<sys/lock.h>}) determines which segments are locked.

Availability: Unix.

\texttt{os.popen(...)}
\texttt{os.popen2(...)}
\texttt{os.popen3(...)}
\texttt{os.popen4(...)}

Run child processes, returning opened pipes for communications. These functions are described in section \textit{File Object Creation}.

\texttt{os.spawnl(mode, path, ...)}
\texttt{os.spawnle(mode, path, ..., env)}
\texttt{os.spawnlp(mode, file, ...)}
\texttt{os.spawnlpe(mode, file, ..., env)}
\texttt{os.spawnv(mode, path, args)}
\texttt{os.spawnve(mode, path, args, env)}
\texttt{os.spawnvp(mode, file, args)}
os. `spawnvpe(mode, file, args, env)`

Execute the program *path* in a new process.

(Note that the `subprocess` module provides more powerful facilities for spawning new processes and retrieving their results; using that module is preferable to using these functions. Check especially the *Replacing Older Functions with the subprocess Module* section.)

If `mode` is `P_NOWAIT`, this function returns the process id of the new process; if `mode` is `P_WAIT`, returns the process's exit code if it exits normally, or `-signal`, where `signal` is the signal that killed the process. On Windows, the process id will actually be the process handle, so can be used with the `waitpid()` function.

The “l” and “v” variants of the `spawn*()` functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `spawnl*()` functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process must start with the name of the command being run.

The variants which include a second “p” near the end (`spawnlp()`, `spawnlpe()`, `spawnvp()`, and `spawnvpe()`) will use the `PATH` environment variable to locate the program *file*. When the environment is being replaced (using one of the `spawn*e()` variants, discussed in the next paragraph), the new environment is used as the source of the `PATH` variable. The other variants, `spawnl()`, `spawnle()`, `spawnv()`, and `spawnve()`, will not use the `PATH` variable to locate the executable; *path* must contain an appropriate absolute or relative path.
For `spawnle()`, `spawnlpe()`, `spawnve()`, and `spawnvpe()` (note that these all end in “e”), the `env` parameter must be a mapping which is used to define the environment variables for the new process (they are used instead of the current process’ environment); the functions `spawnl()`, `spawnlp()`, `spawnv()`, and `spawnvp()` all cause the new process to inherit the environment of the current process. Note that keys and values in the `env` dictionary must be strings; invalid keys or values will cause the function to fail, with a return value of 127.

As an example, the following calls to `spawnlp()` and `spawnvpe()` are equivalent:

```python
import os
os.spawnlp(os.P_WAIT, 'cp', 'cp', 'index.html', '/dev/null')

L = ['cp', 'index.html', '/dev/null']
os.spawnvpe(os.P_WAIT, 'cp', L, os.environ)
```

Availability: Unix, Windows. `spawnlp()`, `spawnlpe()`, `spawnvp()` and `spawnvpe()` are not available on Windows.

*New in version 1.6.*

`os.P_NOWAIT`

`os.P_NOWAITO`

Possible values for the `mode` parameter to the `spawn*()` family of functions. If either of these values is given, the `spawn*()` functions will return as soon as the new process has been created, with the process id as the return value.

Availability: Unix, Windows.

*New in version 1.6.*

`os.P_WAIT`
Possible value for the mode parameter to the spawn*() family of functions. If this is given as mode, the spawn*() functions will not return until the new process has run to completion and will return the exit code of the process the run is successful, or -signal if a signal kills the process.

Availability: Unix, Windows.

*New in version 1.6.*

```plaintext
os.P_DETACH
os.P_OVERLAY
```

Possible values for the mode parameter to the spawn*() family of functions. These are less portable than those listed above. P_DETACH is similar to P_NOWAIT, but the new process is detached from the console of the calling process. If P_OVERLAY is used, the current process will be replaced; the spawn*() function will not return.

Availability: Windows.

*New in version 1.6.*

```plaintext
os.startfile(path[, operation])
```

Start a file with its associated application.

When operation is not specified or 'open', this acts like double-clicking the file in Windows Explorer, or giving the file name as an argument to the start command from the interactive command shell: the file is opened with whatever application (if any) its extension is associated.

When another operation is given, it must be a “command verb” that specifies what should be done with the file. Common verbs documented by Microsoft are 'print' and 'edit' (to be used on
files) as well as 'explore' and 'find' (to be used on directories).

`startfile()` returns as soon as the associated application is launched. There is no option to wait for the application to close, and no way to retrieve the application's exit status. The path parameter is relative to the current directory. If you want to use an absolute path, make sure the first character is not a slash ('/'); the underlying Win32 `ShellExecute()` function doesn’t work if it is. Use the `os.path.normpath()` function to ensure that the path is properly encoded for Win32.

Availability: Windows.

New in version 2.0.

New in version 2.5: The operation parameter.

`os.system(command)`
Execute the command (a string) in a subshell. This is implemented by calling the Standard C function `system()`, and has the same limitations. Changes to `sys.stdin`, etc. are not reflected in the environment of the executed command.

On Unix, the return value is the exit status of the process encoded in the format specified for `wait()`. Note that POSIX does not specify the meaning of the return value of the C `system()` function, so the return value of the Python function is system-dependent.

On Windows, the return value is that returned by the system shell after running `command`, given by the Windows environment variable `COMSPEC`: on `command.com` systems (Windows 95, 98 and ME) this is always 0; on `cmd.exe` systems (Windows NT, 2000 and XP) this is the exit status of the command run; on systems using a non-native shell, consult your shell
The subprocess module provides more powerful facilities for spawning new processes and retrieving their results; using that module is preferable to using this function. Use the subprocess module. Check especially the Replacing Older Functions with the subprocess Module section.

Availability: Unix, Windows.

os.times()
Return a 5-tuple of floating point numbers indicating accumulated (processor or other) times, in seconds. The items are: user time, system time, children's user time, children's system time, and elapsed real time since a fixed point in the past, in that order. See the Unix manual page times(2) or the corresponding Windows Platform API documentation. On Windows, only the first two items are filled, the others are zero.

Availability: Unix, Windows

os.wait()
Wait for completion of a child process, and return a tuple containing its pid and exit status indication: a 16-bit number, whose low byte is the signal number that killed the process, and whose high byte is the exit status (if the signal number is zero); the high bit of the low byte is set if a core file was produced.

Availability: Unix.

os.waitpid(pid, options)
The details of this function differ on Unix and Windows.

On Unix: Wait for completion of a child process given by process id pid, and return a tuple containing its process id and exit status
indication (encoded as for \texttt{wait()}). The semantics of the call are affected by the value of the integer \texttt{options}, which should be \texttt{0} for normal operation.

If \texttt{pid} is greater than \texttt{0}, \texttt{waitpid()} requests status information for that specific process. If \texttt{pid} is \texttt{0}, the request is for the status of any child in the process group of the current process. If \texttt{pid} is \texttt{-1}, the request pertains to any child of the current process. If \texttt{pid} is less than \texttt{-1}, status is requested for any process in the process group \texttt{-pid} (the absolute value of \texttt{pid}).

An \texttt{OSError} is raised with the value of \texttt{errno} when the syscall returns \texttt{-1}.

On Windows: Wait for completion of a process given by process handle \texttt{pid}, and return a tuple containing \texttt{pid}, and its exit status shifted left by 8 bits (shifting makes cross-platform use of the function easier). A \texttt{pid} less than or equal to \texttt{0} has no special meaning on Windows, and raises an exception. The value of integer \texttt{options} has no effect. \texttt{pid} can refer to any process whose id is known, not necessarily a child process. The \texttt{spawn()} functions called with \texttt{P\_NOWAIT} return suitable process handles.

\begin{verbatim}
\texttt{os.wait3([options])}
\end{verbatim}

Similar to \texttt{waitpid()}, except no process id argument is given and a 3-element tuple containing the child’s process id, exit status indication, and resource usage information is returned. Refer to \texttt{resource.getrusage()} for details on resource usage information. The option argument is the same as that provided to \texttt{waitpid()} and \texttt{wait4()}.

Availability: Unix.
New in version 2.5.

**os.wait4(pid, options)**

Similar to `waitpid()`, except a 3-element tuple, containing the child's process id, exit status indication, and resource usage information is returned. Refer to `resource.getrusage()` for details on resource usage information. The arguments to `wait4()` are the same as those provided to `waitpid()`.

Availability: Unix.

New in version 2.5.

**os.WNOHANG**

The option for `waitpid()` to return immediately if no child process status is available immediately. The function returns `(0, 0)` in this case.

Availability: Unix.

**os.WCONTINUED**

This option causes child processes to be reported if they have been continued from a job control stop since their status was last reported.

Availability: Some Unix systems.

New in version 2.3.

**os.WUNTRACED**

This option causes child processes to be reported if they have been stopped but their current state has not been reported since they were stopped.

Availability: Unix.
New in version 2.3.

The following functions take a process status code as returned by \texttt{system()}, \texttt{wait()}, or \texttt{waitpid()} as a parameter. They may be used to determine the disposition of a process.

\begin{verbatim}
\texttt{os.WCOREDUMP(status)}

Return \texttt{True} if a core dump was generated for the process, otherwise return \texttt{False}.

Availability: Unix.
\end{verbatim}

\textit{New in version 2.3.}

\begin{verbatim}
\texttt{os.WIFCONTINUED(status)}

Return \texttt{True} if the process has been continued from a job control stop, otherwise return \texttt{False}.

Availability: Unix.
\end{verbatim}

\textit{New in version 2.3.}

\begin{verbatim}
\texttt{os.WIFSTOPPED(status)}

Return \texttt{True} if the process has been stopped, otherwise return \texttt{False}.

Availability: Unix.
\end{verbatim}

\begin{verbatim}
\texttt{os.WIFSIGNALED(status)}

Return \texttt{True} if the process exited due to a signal, otherwise return \texttt{False}.

Availability: Unix.
\end{verbatim}

\begin{verbatim}
\texttt{os.WIFEXITED(status)}
\end{verbatim}
Return True if the process exited using the exit(2) system call, otherwise return False.

Availability: Unix.

os.

WEXITSTATUS(status)
If WIFEXITED(status) is true, return the integer parameter to the exit(2) system call. Otherwise, the return value is meaningless.

Availability: Unix.

os.

WSTOPSIG(status)
Return the signal which caused the process to stop.

Availability: Unix.

os.

WTERMSIG(status)
Return the signal which caused the process to exit.

Availability: Unix.
15.1.6. Miscellaneous System Information

**os.confstr**(name)
Return string-valued system configuration values. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given as the keys of the `confstr_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If the configuration value specified by *name* isn’t defined, `None` is returned.

If *name* is a string and is not known, `ValueError` is raised. If a specific value for *name* is not supported by the host system, even if it is included in `confstr_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

Availability: Unix

**os.confstr_names**
Dictionary mapping names accepted by `confstr()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

**os.getloadavg()**
Return the number of processes in the system run queue averaged over the last 1, 5, and 15 minutes or raises `OSError` if
the load average was unobtainable.

Availability: Unix.

New in version 2.3.

**os.sysconf(name)**
Return integer-valued system configuration values. If the configuration value specified by name isn't defined, -1 is returned. The comments regarding the name parameter for confstr() apply here as well; the dictionary that provides information on the known names is given by **sysconf_names**.

Availability: Unix.

**os.sysconf_names**
Dictionary mapping names accepted by sysconf() to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

The following data values are used to support path manipulation operations. These are defined for all platforms.

Higher-level operations on pathnames are defined in the **os.path** module.

**os.getcwd**
The constant string used by the operating system to refer to the current directory. This is '..' for Windows and POSIX. Also available via **os.path**.

**os.pardir**
The constant string used by the operating system to refer to the
parent directory. This is '..' for Windows and POSIX. Also available via `os.path`.

`os.sep`
The character used by the operating system to separate pathname components. This is '/\' for POSIX and '\\' for Windows. Note that knowing this is not sufficient to be able to parse or concatenate pathnames — use `os.path.split()` and `os.path.join()` — but it is occasionally useful. Also available via `os.path`.

`os.altsep`
An alternative character used by the operating system to separate pathname components, or `None` if only one separator character exists. This is set to '/\' on Windows systems where `sep` is a backslash. Also available via `os.path`.

`os.extsep`
The character which separates the base filename from the extension; for example, the '.' in `os.py`. Also available via `os.path`.

*New in version 2.2.*

`os.pathsep`
The character conventionally used by the operating system to separate search path components (as in `PATH`), such as ':' for POSIX or ';' for Windows. Also available via `os.path`.

`os.defpath`
The default search path used by `exec*p*()` and `spawn*p*()` if the environment doesn’t have a 'PATH' key. Also available via `os.path`.
**os. linesep**
The string used to separate (or, rather, terminate) lines on the current platform. This may be a single character, such as '\n' for POSIX, or multiple characters, for example, '\r\n' for Windows. Do not use os.linesep as a line terminator when writing files opened in text mode (the default); use a single '\n' instead, on all platforms.

**os. devnull**
The file path of the null device. For example: '/dev/null' for POSIX, 'nul' for Windows. Also available via os.path.

*New in version 2.4.*
15.1.7. Miscellaneous Functions

`os.urandom(n)`

Return a string of $n$ random bytes suitable for cryptographic use.

This function returns random bytes from an OS-specific randomness source. The returned data should be unpredictable enough for cryptographic applications, though its exact quality depends on the OS implementation. On a UNIX-like system this will query `/dev/urandom`, and on Windows it will use `CryptGenRandom`. If a randomness source is not found, `NotImplementedError` will be raised.

*New in version 2.4.*
15.2. io — Core tools for working with streams

The io module provides the Python interfaces to stream handling. Under Python 2.x, this is proposed as an alternative to the built-in \texttt{file} object, but in Python 3.x it is the default interface to access files and streams.

\textbf{Note:} Since this module has been designed primarily for Python 3.x, you have to be aware that all uses of “bytes” in this document refer to the \texttt{str} type (of which \texttt{bytes} is an alias), and all uses of “text” refer to the \texttt{unicode} type. Furthermore, those two types are not interchangeable in the \texttt{io} APIs.

At the top of the I/O hierarchy is the abstract base class \texttt{IOBase}. It defines the basic interface to a stream. Note, however, that there is no separation between reading and writing to streams; implementations are allowed to throw an \texttt{IOError} if they do not support a given operation.

Extending \texttt{IOBase} is \texttt{RawIOBase} which deals simply with the reading and writing of raw bytes to a stream. \texttt{FileIO} subclasses \texttt{RawIOBase} to provide an interface to files in the machine's file system.

\texttt{BufferedIOBase} deals with buffering on a raw byte stream (\texttt{RawIOBase}). Its subclasses, \texttt{BufferedWriter}, \texttt{BufferedReader}, and \texttt{BufferedReader} buffer streams that are readable, writable, and both readable and writable. \texttt{BufferedReader} provides a buffered interface to random access streams. \texttt{BytesIO} is a simple stream of in-memory bytes.
Another `IOBase` subclass, `TextIOBase`, deals with streams whose bytes represent text, and handles encoding and decoding from and to `unicode` strings. `TextIOWrapper`, which extends it, is a buffered text interface to a buffered raw stream (`BufferedIOBase`). Finally, `StringIO` is an in-memory stream for unicode text.

Argument names are not part of the specification, and only the arguments of `open()` are intended to be used as keyword arguments.
15.2.1. Module Interface

10. **DEFAULT_BUFFER_SIZE**
   An int containing the default buffer size used by the module's buffered I/O classes. `open()` uses the file's blksize (as obtained by `os.stat()`) if possible.

10. **open(file, mode='r', buffering=-1, encoding=None, errors=None, newline=None, closefd=True)**
    Open file and return a corresponding stream. If the file cannot be opened, an IOError is raised.

    `file` is either a string giving the name (and the path if the file isn’t in the current working directory) of the file to be opened or an integer file descriptor of the file to be wrapped. (If a file descriptor is given, for example, from `os.fdopen()`, it is closed when the returned I/O object is closed, unless `closefd` is set to False.)

    `mode` is an optional string that specifies the mode in which the file is opened. It defaults to 'r' which means open for reading in text mode. Other common values are 'w' for writing (truncating the file if it already exists), and 'a' for appending (which on some Unix systems, means that all writes append to the end of the file regardless of the current seek position). In text mode, if `encoding` is not specified the encoding used is platform dependent. (For reading and writing raw bytes use binary mode and leave `encoding` unspecified.) The available modes are:

<table>
<thead>
<tr>
<th>Character</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>open for reading (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>open for writing, truncating the file first</td>
</tr>
<tr>
<td>'a'</td>
<td>open for writing, appending to the end of the file if it exists</td>
</tr>
<tr>
<td>Mode</td>
<td>Description</td>
</tr>
<tr>
<td>------</td>
<td>-------------</td>
</tr>
<tr>
<td><code>'b'</code></td>
<td>binary mode</td>
</tr>
<tr>
<td><code>'t'</code></td>
<td>text mode (default)</td>
</tr>
<tr>
<td><code>'+'</code></td>
<td>open a disk file for updating (reading and writing)</td>
</tr>
<tr>
<td><code>'U'</code></td>
<td>universal newline mode (for backwards compatibility; should not be used in new code)</td>
</tr>
</tbody>
</table>

The default mode is `'rt'` (open for reading text). For binary random access, the mode `'w+b'` opens and truncates the file to 0 bytes, while `'r+b'` opens the file without truncation.

Python distinguishes between files opened in binary and text modes, even when the underlying operating system doesn’t. Files opened in binary mode (including `'b'` in the `mode` argument) return contents as `bytes` objects without any decoding. In text mode (the default, or when `'t'` is included in the `mode` argument), the contents of the file are returned as `unicode` strings, the bytes having been first decoded using a platform-dependent encoding or using the specified `encoding` if given.

`buffering` is an optional integer used to set the buffering policy. Pass 0 to switch buffering off (only allowed in binary mode), 1 to select line buffering (only usable in text mode), and an integer > 1 to indicate the size of a fixed-size chunk buffer. When no `buffering` argument is given, the default buffering policy works as follows:

- Binary files are buffered in fixed-size chunks; the size of the buffer is chosen using a heuristic trying to determine the underlying device’s “block size” and falling back on `DEFAULT_BUFFER_SIZE`. On many systems, the buffer will typically be 4096 or 8192 bytes long.
- “Interactive” text files (files for which `isatty()` returns True) use line buffering. Other text files use the policy described above for binary files.
**encoding** is the name of the encoding used to decode or encode the file. This should only be used in text mode. The default encoding is platform dependent (whatever `locale.getpreferredencoding()` returns), but any encoding supported by Python can be used. See the `codecs` module for the list of supported encodings.

**errors** is an optional string that specifies how encoding and decoding errors are to be handled—this cannot be used in binary mode. Pass *strict* to raise a `ValueError` exception if there is an encoding error (the default of `None` has the same effect), or pass *ignore* to ignore errors. (Note that ignoring encoding errors can lead to data loss.) *replace* causes a replacement marker (such as `'?') to be inserted where there is malformed data. When writing, *xmlcharrefreplace* (replace with the appropriate XML character reference) or *backslashreplace* (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with `codecs.register_error()` is also valid.

**newline** controls how universal newlines works (it only applies to text mode). It can be `None`, '', '\n', '\r', and '\r\n'. It works as follows:

- On input, if **newline** is `None`, universal newlines mode is enabled. Lines in the input can end in '\n', '\r', or '\r\n', and these are translated into '\n' before being returned to the caller. If it is '', universal newline mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.
- On output, if **newline** is `None`, any '\n' characters written are
translated to the system default line separator, os.linesep. If newline is '', no translation takes place. If newline is any of the other legal values, any \n characters written are translated to the given string.

If closefd is False and a file descriptor rather than a filename was given, the underlying file descriptor will be kept open when the file is closed. If a filename is given closefd has no effect and must be True (the default).

The type of file object returned by the open() function depends on the mode. When open() is used to open a file in a text mode ('w', 'r', 'wt', 'rt', etc.), it returns a subclass of TextIOBase (specifically TextIOWrapper). When used to open a file in a binary mode with buffering, the returned class is a subclass of BufferedIOBase. The exact class varies: in read binary mode, it returns a BufferedReader; in write binary and append binary modes, it returns a BufferedWriter, and in read/write mode, it returns a BufferedRandom. When buffering is disabled, the raw stream, a subclass of RawIOBase, FileIO, is returned.

It is also possible to use an unicode or bytes string as a file for both reading and writing. For unicode strings StringIO can be used like a file opened in text mode, and for bytes a BytesIO can be used like a file opened in a binary mode.

exception io.BlockingIOError
Error raised when blocking would occur on a non-blocking stream. It inherits IOError.

In addition to those of IOError, BlockingIOError has one attribute:

characters_written
An integer containing the number of characters written to the stream before it blocked.

*exception* io. **UnsupportedOperation**

An exception inheriting `IOError` and `ValueError` that is raised when an unsupported operation is called on a stream.
15.2.2. I/O Base Classes

class io.IOBase

The abstract base class for all I/O classes, acting on streams of bytes. There is no public constructor.

This class provides empty abstract implementations for many methods that derived classes can override selectively; the default implementations represent a file that cannot be read, written or seeked.

Even though IOBase does not declare read(), readinto(), or write() because their signatures will vary, implementations and clients should consider those methods part of the interface. Also, implementations may raise a IOError when operations they do not support are called.

The basic type used for binary data read from or written to a file is bytes (also known as str). bytearrays are accepted too, and in some cases (such as readinto) required. Text I/O classes work with unicode data.

Note that calling any method (even inquiries) on a closed stream is undefined. Implementations may raise IOError in this case.

IOBase (and its subclasses) support the iterator protocol, meaning that an IOBase object can be iterated over yielding the lines in a stream. Lines are defined slightly differently depending on whether the stream is a binary stream (yielding bytes), or a text stream (yielding unicode strings). See readline() below.

IOBase is also a context manager and therefore supports the with statement. In this example, file is closed after the with
statement’s suite is finished—even if an exception occurs:

```python
with io.open('spam.txt', 'w') as file:
    file.write(u'Spam and eggs!')
```

**IOBase** provides these data attributes and methods:

- **close()**
  Flush and close this stream. This method has no effect if the file is already closed. Once the file is closed, any operation on the file (e.g. reading or writing) will raise a *ValueError*.

  As a convenience, it is allowed to call this method more than once; only the first call, however, will have an effect.

- **closed**
  True if the stream is closed.

- **fileno()**
  Return the underlying file descriptor (an integer) of the stream if it exists. An *IOError* is raised if the IO object does not use a file descriptor.

- **flush()**
  Flush the write buffers of the stream if applicable. This does nothing for read-only and non-blocking streams.

- **isatty()**
  Return *True* if the stream is interactive (i.e., connected to a terminal/tty device).

- **readable()**
  Return *True* if the stream can be read from. If False, *read()* will raise *IOError*.

- **readline(limit=-1)**
Read and return one line from the stream. If limit is specified, at most limit bytes will be read.

The line terminator is always b'\n' for binary files; for text files, the newlines argument to open() can be used to select the line terminator(s) recognized.

readlines(hint=-1)
Read and return a list of lines from the stream. hint can be specified to control the number of lines read: no more lines will be read if the total size (in bytes/characters) of all lines so far exceeds hint.

seek(offset, whence=SEEK_SET)
Change the stream position to the given byte offset. offset is interpreted relative to the position indicated by whence. Values for whence are:

- SEEK_SET or 0 – start of the stream (the default); offset should be zero or positive
- SEEK_CUR or 1 – current stream position; offset may be negative
- SEEK_END or 2 – end of the stream; offset is usually negative

Return the new absolute position.

New in version 2.7: The SEEK_* constants

seekable()
Return True if the stream supports random access. If False, seek(), tell() and truncate() will raise IOError.

tell()
Return the current stream position.
**truncate(size=None)**
Resize the stream to the given size in bytes (or the current position if size is not specified). The current stream position isn’t changed. This resizing can extend or reduce the current file size. In case of extension, the contents of the new file area depend on the platform (on most systems, additional bytes are zero-filled, on Windows they’re undetermined). The new file size is returned.

**writable()**
Return True if the stream supports writing. If False, write() and truncate() will raise IOError.

**writelines(lines)**
Write a list of lines to the stream. Line separators are not added, so it is usual for each of the lines provided to have a line separator at the end.

**class io.RawIOBase**
Base class for raw binary I/O. It inherits IOMode. There is no public constructor.

Raw binary I/O typically provides low-level access to an underlying OS device or API, and does not try to encapsulate it in high-level primitives (this is left to Buffered I/O and Text I/O, described later in this page).

In addition to the attributes and methods from IOMode, RawIOBase provides the following methods:

**read(n=-1)**
Read up to n bytes from the object and return them. As a convenience, if n is unspecified or -1, readall() is called. Otherwise, only one system call is ever made. Fewer than n bytes may be returned if the operating system call returns
fewer than $n$ bytes.

If 0 bytes are returned, and $n$ was not 0, this indicates end of file. If the object is in non-blocking mode and no bytes are available, $\text{None}$ is returned.

**readall()**

Read and return all the bytes from the stream until EOF, using multiple calls to the stream if necessary.

**readinto($b$)**

Read up to $\text{len}(b)$ bytes into bytearray $b$ and return the number of bytes read.

**write($b$)**

Write the given bytes or bytearray object, $b$, to the underlying raw stream and return the number of bytes written. This can be less than $\text{len}(b)$, depending on specifics of the underlying raw stream, and especially if it is in non-blocking mode. $\text{None}$ is returned if the raw stream is set not to block and no single byte could be readily written to it.

**class io.\texttt{BufferedIOBase}**

Base class for binary streams that support some kind of buffering. It inherits \texttt{IOMBase}. There is no public constructor.

The main difference with \texttt{RawIOMBase} is that methods \texttt{read()}, \texttt{readinto()} and \texttt{write()} will try (respectively) to read as much input as requested or to consume all given output, at the expense of making perhaps more than one system call.

In addition, those methods can raise \texttt{BlockingIOMError} if the underlying raw stream is in non-blocking mode and cannot take or give enough data; unlike their \texttt{RawIOMBase} counterparts, they will never return $\text{None}$.
Besides, the `read()` method does not have a default implementation that defers to `readinto()`.

A typical `BufferedIOBase` implementation should not inherit from a `RawIOBase` implementation, but wrap one, like `BufferedWriter` and `BufferedReader` do.

`BufferedIOBase` provides or overrides these members in addition to those from `IOBase`:

**raw**
- The underlying raw stream (a `RawIOBase` instance) that `BufferedIOBase` deals with. This is not part of the `BufferedIOBase` API and may not exist on some implementations.

**detach()**
- Separate the underlying raw stream from the buffer and return it.

  After the raw stream has been detached, the buffer is in an unusable state.

  Some buffers, like `BytesIO`, do not have the concept of a single raw stream to return from this method. They raise `UnsupportedOperation`.

  *New in version 2.7.*

**read(n=-1)**
- Read and return up to `n` bytes. If the argument is omitted, `None`, or negative, data is read and returned until EOF is reached. An empty bytes object is returned if the stream is already at EOF.
If the argument is positive, and the underlying raw stream is not interactive, multiple raw reads may be issued to satisfy the byte count (unless EOF is reached first). But for interactive raw streams, at most one raw read will be issued, and a short result does not imply that EOF is imminent.

A **BlockingIOError** is raised if the underlying raw stream is in non blocking-mode, and has no data available at the moment.

**read1**(n=-1)
Read and return up to n bytes, with at most one call to the underlying raw stream’s `read()` method. This can be useful if you are implementing your own buffering on top of a `BufferedIOBase` object.

**readinto**(b)
Read up to len(b) bytes into bytearray b and return the number of bytes read.

Like `read()`, multiple reads may be issued to the underlying raw stream, unless the latter is ‘interactive’.

A **BlockingIOError** is raised if the underlying raw stream is in non blocking-mode, and has no data available at the moment.

**write**(b)
Write the given bytes or bytearray object, b and return the number of bytes written (never less than `len(b)`, since if the write fails an `IOError` will be raised). Depending on the actual implementation, these bytes may be readily written to the underlying stream, or held in a buffer for performance and latency reasons.

When in non-blocking mode, a **BlockingIOError** is raised if the data needed to be written to the raw stream but it couldn’t
accept all the data without blocking.
15.2.3. Raw File I/O

```python
class io.FileIO(name, mode='r', closefd=True)
```

FileIO represents an OS-level file containing bytes data. It implements the RawIOBase interface (and therefore the IOBase interface, too).

The *name* can be one of two things:

- a string representing the path to the file which will be opened;
- an integer representing the number of an existing OS-level file descriptor to which the resulting FileIO object will give access.

The *mode* can be 'r', 'w' or 'a' for reading (default), writing, or appending. The file will be created if it doesn’t exist when opened for writing or appending; it will be truncated when opened for writing. Add a '+' to the mode to allow simultaneous reading and writing.

The `read()` (when called with a positive argument), `readinto()` and `write()` methods on this class will only make one system call.

In addition to the attributes and methods from IOBase and RawIOBase, FileIO provides the following data attributes and methods:

- **mode**
  
  The mode as given in the constructor.

- **name**

  The file name. This is the file descriptor of the file when no
name is given in the constructor.
15.2.4. Buffered Streams

In many situations, buffered I/O streams will provide higher performance (bandwidth and latency) than raw I/O streams. Their API is also more usable.

```python
class io.BytesIO([initial_bytes])
    A stream implementation using an in-memory bytes buffer. It inherits BufferedIOBase.
```

The argument `initial_bytes` is an optional initial `bytes`.

`BytesIO` provides or overrides these methods in addition to those from `BufferedIOBase` and `IOBase`:

- `getvalue()`
  Return `bytes` containing the entire contents of the buffer.

- `read1()`
  In `BytesIO`, this is the same as `read()`.

```python
class io.BufferedReader(raw, buffer_size=DEFAULT_BUFFER_SIZE)
    A buffer providing higher-level access to a readable, sequential `RawIOBase` object. It inherits `BufferedIOBase`. When reading data from this object, a larger amount of data may be requested from the underlying raw stream, and kept in an internal buffer. The buffered data can then be returned directly on subsequent reads.
```

The constructor creates a `BufferedReader` for the given readable `raw` stream and `buffer_size`. If `buffer_size` is omitted, `DEFAULT_BUFFER_SIZE` is used.
BufferedReader provides or overrides these methods in addition to those from BufferedReader and I0Base:

peek([n])
Return bytes from the stream without advancing the position. At most one single read on the raw stream is done to satisfy the call. The number of bytes returned may be less or more than requested.

read([n])
Read and return n bytes, or if n is not given or negative, until EOF or if the read call would block in non-blocking mode.

read1(n)
Read and return up to n bytes with only one call on the raw stream. If at least one byte is buffered, only buffered bytes are returned. Otherwise, one raw stream read call is made.

class io.BufferedWriter(raw,
buffer_size=DEFAULT_BUFFER_SIZE)
A buffer providing higher-level access to a writeable, sequential RawIOBase object. It inherits BufferedReader. When writing to this object, data is normally held into an internal buffer. The buffer will be written out to the underlying RawIOBase object under various conditions, including:

- when the buffer gets too small for all pending data;
- when flush() is called;
- when a seek() is requested (for BufferedRandom objects);
- when the BufferedWriter object is closed or destroyed.

The constructor creates a BufferedWriter for the given writeable raw stream. If the buffer_size is not given, it defaults to DEFAULT_BUFFER_SIZE.
A third argument, `max_buffer_size`, is supported, but unused and deprecated.

`BufferedWriter` provides or overrides these methods in addition to those from `BufferedIOBase` and `IOBase`:

`flush()`

Force bytes held in the buffer into the raw stream. A `BlockingIOError` should be raised if the raw stream blocks.

`write(b)`

Write the bytes or bytearray object, `b` and return the number of bytes written. When in non-blocking mode, a `BlockingIOError` is raised if the buffer needs to be written out but the raw stream blocks.

class `io.BufferedRWPair(reader, writer, buffer_size=DEFAULT_BUFFER_SIZE)`

A buffered I/O object giving a combined, higher-level access to two sequential `RawIOWBase` objects: one readable, the other writeable. It is useful for pairs of unidirectional communication channels (pipes, for instance). It inherits `BufferedIOBase`.

`reader` and `writer` are `RawIOWBase` objects that are readable and writeable respectively. If the `buffer_size` is omitted it defaults to `DEFAULT_BUFFER_SIZE`.

A fourth argument, `max_buffer_size`, is supported, but unused and deprecated.

`BufferedRWPair` implements all of `BufferedIOBase`'s methods except for `detach()`, which raises `UnsupportedOperation`.

class `io.BufferedRandom(raw,`
buffer_size=DEFAULT_BUFFER_SIZE

A buffered interface to random access streams. It inherits BufferedReader and BufferedWriter, and further supports seek() and tell() functionality.

The constructor creates a reader and writer for a seekable raw stream, given in the first argument. If the buffer_size is omitted it defaults to DEFAULT_BUFFER_SIZE.

A third argument, max_buffer_size, is supported, but unused and deprecated.

BufferedRandom is capable of anything BufferedReader or BufferedWriter can do.
15.2.5. Text I/O

*class* `io.TextIOBase`

Base class for text streams. This class provides an unicode character and line based interface to stream I/O. There is no `readinto()` method because Python’s `unicode` strings are immutable. It inherits `IOBase`. There is no public constructor.

`TextIOBase` provides or overrides these data attributes and methods in addition to those from `IOBase`:

**encoding**

The name of the encoding used to decode the stream’s bytes into strings, and to encode strings into bytes.

**errors**

The error setting of the decoder or encoder.

**newlines**

A string, a tuple of strings, or `None`, indicating the newlines translated so far. Depending on the implementation and the initial constructor flags, this may not be available.

**buffer**

The underlying binary buffer (a `BufferedIOBase` instance) that `TextIOBase` deals with. This is not part of the `TextIOBase` API and may not exist on some implementations.

**detach()**

Separate the underlying binary buffer from the `TextIOBase` and return it.

After the underlying buffer has been detached, the `TextIOBase` is in an unusable state.
Some TextIOBase implementations, like StringIO, may not have the concept of an underlying buffer and calling this method will raise UnsupportedOperation.

New in version 2.7.

**read(n)**

Read and return at most n characters from the stream as a single unicode. If n is negative or None, reads until EOF.

**readline()**

Read until newline or EOF and return a single unicode. If the stream is already at EOF, an empty string is returned.

**write(s)**

Write the unicode string s to the stream and return the number of characters written.

class io.TextIOWrapper(buffer, encoding=None, errors=None, newline=None, line_buffering=False)

A buffered text stream over a BufferedIOBase binary stream. It inherits TextIOBase.

encoding gives the name of the encoding that the stream will be decoded or encoded with. It defaults to locale.getpreferredencoding().

events is an optional string that specifies how encoding and decoding errors are to be handled. Pass 'strict' to raise a ValueError exception if there is an encoding error (the default of None has the same effect), or pass 'ignore' to ignore errors. (Note that ignoring encoding errors can lead to data loss.) 'replace' causes a replacement marker (such as '?') to be inserted where there is malformed data.
'xmlcharrefreplace' (replace with the appropriate XML character reference) or 'backslashreplace' (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with `codecs.register_error()` is also valid.

`newline` can be `None`, `'`, '\n', '\r', or '\r\n'. It controls the handling of line endings. If it is `None`, universal newlines is enabled. With this enabled, on input, the lines endings '\n', '\r', or '\r\n' are translated to '\n' before being returned to the caller. Conversely, on output, '\n' is translated to the system default line separator, `os.linesep`. If `newline` is any other of its legal values, that newline becomes the newline when the file is read and it is returned untranslated. On output, '\n' is converted to the `newline`.

If `line_buffering` is `True`, `flush()` is implied when a call to `write` contains a newline character.

`TextIOWrapper` provides one attribute in addition to those of `TextIOBase` and its parents:

`line_buffering`  
Whether line buffering is enabled.

class io.StringIO(initial_value=u'', newline=None)  
An in-memory stream for unicode text. It inherits `TextIOWrapper`.

The initial value of the buffer (an empty unicode string by default) can be set by providing `initial_value`. The `newline` argument works like that of `TextIOWrapper`. The default is to do no newline translation.

`StringIO` provides this method in addition to those from
**TextIOWrapper** and its parents:

**getvalue()**

Return a **unicode** containing the entire contents of the buffer at any time before the **StringIO** object's **close()** method is called.

Example usage:

```python
import io

output = io.StringIO()
output.write(u'First line.
')
output.write(u'Second line.
')

# Retrieve file contents -- this will be
# u'First line.
Second line.
' contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
```

**class io.IncrementalNewlineDecoder**

A helper codec that decodes newlines for universal newlines mode. It inherits **codecs.IncrementalDecoder**.
This module provides various time-related functions. For related functionality, see also the `datetime` and `calendar` modules.

Although this module is always available, not all functions are available on all platforms. Most of the functions defined in this module call platform C library functions with the same name. It may sometimes be helpful to consult the platform documentation, because the semantics of these functions varies among platforms.

An explanation of some terminology and conventions is in order.

- **The epoch** is the point where the time starts. On January 1st of that year, at 0 hours, the “time since the epoch” is zero. For Unix, the epoch is 1970. To find out what the epoch is, look at `gmtime(0)`.

- The functions in this module do not handle dates and times before the epoch or far in the future. The cut-off point in the future is determined by the C library; for Unix, it is typically in 2038.

- **Year 2000 (Y2K) issues**: Python depends on the platform’s C library, which generally doesn’t have year 2000 issues, since all dates and times are represented internally as seconds since the epoch. Functions accepting a `struct_time` (see below) generally require a 4-digit year. For backward compatibility, 2-digit years are supported if the module variable `accept2dyear` is a non-zero integer; this variable is initialized to 1 unless the environment variable `PYTHONY2K` is set to a non-empty string, in which case it is initialized to 0. Thus, you can set `PYTHONY2K` to a
non-empty string in the environment to require 4-digit years for all year input. When 2-digit years are accepted, they are converted according to the POSIX or X/Open standard: values 69-99 are mapped to 1969-1999, and values 0–68 are mapped to 2000–2068. Values 100–1899 are always illegal. Note that this is new as of Python 1.5.2(a2); earlier versions, up to Python 1.5.1 and 1.5.2a1, would add 1900 to year values below 1900.

- UTC is Coordinated Universal Time (formerly known as Greenwich Mean Time, or GMT). The acronym UTC is not a mistake but a compromise between English and French.

- DST is Daylight Saving Time, an adjustment of the timezone by (usually) one hour during part of the year. DST rules are magic (determined by local law) and can change from year to year. The C library has a table containing the local rules (often it is read from a system file for flexibility) and is the only source of True Wisdom in this respect.

- The precision of the various real-time functions may be less than suggested by the units in which their value or argument is expressed. E.g. on most Unix systems, the clock “ticks” only 50 or 100 times a second.

- On the other hand, the precision of time() and sleep() is better than their Unix equivalents: times are expressed as floating point numbers, time() returns the most accurate time available (using Unix gettimeofday() where available), and sleep() will accept a time with a nonzero fraction (Unix select() is used to implement this, where available).

- The time value as returned by gmtime(), localtime(), and strptime(), and accepted by asctime(), mktime() and strftime(), may be considered as a sequence of 9 integers.
The return values of `gmtime()`, `localtime()`, and `strptime()` also offer attribute names for individual fields.

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td><code>tm_year</code></td>
<td>(for example, 1993)</td>
</tr>
<tr>
<td>1</td>
<td><code>tm_mon</code></td>
<td>range [1, 12]</td>
</tr>
<tr>
<td>2</td>
<td><code>tm_mday</code></td>

<td><code>tm_yday</code></td>
<td>range [1, 366]</td>
</tr>
<tr>
<td>8</td>
<td><code>tm_isdst</code></td>
<td>0, 1 or -1; see below</td>
</tr>
</tbody>
</table>

Note that unlike the C structure, the month value is a range of [1, 12], not [0, 11]. A year value will be handled as described under “Year 2000 (Y2K) issues” above. A -1 argument as the daylight savings flag, passed to `mktime()` will usually result in the correct daylight savings state to be filled in.

When a tuple with an incorrect length is passed to a function expecting a `struct_time`, or having elements of the wrong type, a `TypeError` is raised.
Changed in version 2.2: The time value sequence was changed from a tuple to a `struct_time`, with the addition of attribute names for the fields.

- Use the following functions to convert between time representations:

<table>
<thead>
<tr>
<th>From</th>
<th>To</th>
<th>Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>seconds since the epoch</td>
<td><code>struct_time</code> in UTC</td>
<td><code>gmtime()</code></td>
</tr>
<tr>
<td>seconds since the epoch</td>
<td><code>struct_time</code> in local time</td>
<td><code>localtime()</code></td>
</tr>
<tr>
<td><code>struct_time</code> in UTC</td>
<td>seconds since the epoch</td>
<td><code>calendar.timegm()</code></td>
</tr>
<tr>
<td><code>struct_time</code> in local time</td>
<td>seconds since the epoch</td>
<td><code>mktime()</code></td>
</tr>
</tbody>
</table>

The module defines the following functions and data items:

`time.accept2dyear`

Boolean value indicating whether two-digit year values will be accepted. This is true by default, but will be set to false if the environment variable `PYTHON2K` has been set to a non-empty string. It may also be modified at run time.

`time.altzone`

The offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local DST timezone is east of UTC (as in Western Europe, including the UK). Only use this if `daylight` is nonzero.
time.asctime([t])

Convert a tuple or `struct_time` representing a time as returned by `gmtime()` or `localtime()` to a 24-character string of the following form: 'Sun Jun 20 23:21:05 1993'. If `t` is not provided, the current time as returned by `localtime()` is used. Locale information is not used by `asctime()`.

**Note:** Unlike the C function of the same name, there is no trailing newline.

*Changed in version 2.1:* Allowed `t` to be omitted.

time.clock()

On Unix, return the current processor time as a floating point number expressed in seconds. The precision, and in fact the very definition of the meaning of “processor time”, depends on that of the C function of the same name, but in any case, this is the function to use for benchmarking Python or timing algorithms.

On Windows, this function returns wall-clock seconds elapsed since the first call to this function, as a floating point number, based on the Win32 function `QueryPerformanceCounter()`. The resolution is typically better than one microsecond.

time.ctime([secs])

Convert a time expressed in seconds since the epoch to a string representing local time. If `secs` is not provided or `None`, the current time as returned by `time()` is used. `ctime(secs)` is equivalent to `asctime(localtime(secs))`. Locale information is not used by `ctime()`.

*Changed in version 2.1:* Allowed `secs` to be omitted.
*Changed in version 2.4:* If `secs` is `None`, the current time is used.

**time.daylight**
Nonzero if a DST timezone is defined.

**time.gmtime([secs])**
Convert a time expressed in seconds since the epoch to a `struct_time` in UTC in which the dst flag is always zero. If `secs` is not provided or `None`, the current time as returned by `time()` is used. Fractions of a second are ignored. See above for a description of the `struct_time` object. See `calendar.timegm()` for the inverse of this function.

*Changed in version 2.1:* Allowed `secs` to be omitted.

*Changed in version 2.4:* If `secs` is `None`, the current time is used.

**time.localtime([secs])**
Like `gmtime()` but converts to local time. If `secs` is not provided or `None`, the current time as returned by `time()` is used. The dst flag is set to 1 when DST applies to the given time.

*Changed in version 2.1:* Allowed `secs` to be omitted.

*Changed in version 2.4:* If `secs` is `None`, the current time is used.

**time.mktime(t)**
This is the inverse function of ` localtime()`. Its argument is the `struct_time` or full 9-tuple (since the dst flag is needed; use -1 as the dst flag if it is unknown) which expresses the time in local time, not UTC. It returns a floating point number, for compatibility with `time()`. If the input value cannot be represented as a valid time, either `OverflowError` or `ValueError` will be raised (which depends on whether the invalid value is caught by Python or the
underlying C libraries). The earliest date for which it can generate a time is platform-dependent.

**time.sleep(secs)**
Suspend execution for the given number of seconds. The argument may be a floating point number to indicate a more precise sleep time. The actual suspension time may be less than that requested because any caught signal will terminate the sleep() following execution of that signal’s catching routine. Also, the suspension time may be longer than requested by an arbitrary amount because of the scheduling of other activity in the system.

**time.strftime(format[, t])**
Convert a tuple or struct_time representing a time as returned by gmtime() or localtime() to a string as specified by the format argument. If t is not provided, the current time as returned by localtime() is used. format must be a string. ValueError is raised if any field in t is outside of the allowed range.

*Changed in version 2.1:* Allowed t to be omitted.

*Changed in version 2.4:* ValueError raised if a field in t is out of range.

*Changed in version 2.5:* 0 is now a legal argument for any position in the time tuple; if it is normally illegal the value is forced to a correct one.

The following directives can be embedded in the format string. They are shown without the optional field width and precision specification, and are replaced by the indicated characters in the strftime() result:

<table>
<thead>
<tr>
<th>Directive</th>

<tr>
<td>%Z</td>
<td>Time zone name (no characters if no time zone exists).</td>
</tr>
<tr>
<td>%%</td>
<td>A literal '%' character.</td>
</tr>
</tbody>
</table>

Notes:

1. When used with the `strptime()` function, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.
2. The range really is 0 to 61; this accounts for leap seconds and the (very rare) double leap seconds.
3. When used with the `strptime()` function, `%u` and `%w` are only used in calculations when the day of the week and the year are specified.

Here is an example, a format for dates compatible with that specified in the RFC 2822 Internet email standard. [1]

```python
>>> from time import gmtime, strftime
gmtime())
>>> strftime("%a, %d %b %Y %H:%M:%S +0000", gmtime())
'Thu, 28 Jun 2001 14:17:15 +0000'
```

Additional directives may be supported on certain platforms, but only the ones listed here have a meaning standardized by ANSI C.

On some platforms, an optional field width and precision specification can immediately follow the initial '%' of a directive in the following order; this is also not portable. The field width is normally 2 except for %j where it is 3.

```python
time.strptime(string[, format])
```

Parse a string representing a time according to a format. The return value is a `struct_time` as returned by `gmtime()` or
The `format` parameter uses the same directives as those used by `strftime()`; it defaults to "%a %b %d %H:%M:%S %Y" which matches the formatting returned by `ctime()`. If `string` cannot be parsed according to `format`, or if it has excess data after parsing, `ValueError` is raised. The default values used to fill in any missing data when more accurate values cannot be inferred are (1900, 1, 1, 0, 0, 0, 0, 1, -1).

For example:

```python
>>> import time
>>> time.strptime("30 Nov 00", "%d %b %y")  # doctest: +NORMALIZE_WHITESPACE
(time.struct_time(tm_year=2000, tm_mon=11, tm_mday=30, tm_hour=0,
     tm_min=0, tm_sec=0, tm_wday=3, tm_yday=335, tm_isdst=-1)
```

Support for the `%z` directive is based on the values contained in `tzname` and whether `daylight` is true. Because of this, it is platform-specific except for recognizing UTC and GMT which are always known (and are considered to be non-daylight savings timezones).

Only the directives specified in the documentation are supported. Because `strftime()` is implemented per platform it can sometimes offer more directives than those listed. But `strptime()` is independent of any platform and thus does not necessarily support all directives available that are not documented as supported.

`time.struct_time`

The type of the time value sequence returned by `gmtime()`, `localtime()`, and `strptime()`.

*New in version 2.2.*
time.time()

Return the time as a floating point number expressed in seconds since the epoch, in UTC. Note that even though the time is always returned as a floating point number, not all systems provide time with a better precision than 1 second. While this function normally returns non-decreasing values, it can return a lower value than a previous call if the system clock has been set back between the two calls.

time.timezone

The offset of the local (non-DST) timezone, in seconds west of UTC (negative in most of Western Europe, positive in the US, zero in the UK).

time.tzname

A tuple of two strings: the first is the name of the local non-DST timezone, the second is the name of the local DST timezone. If no DST timezone is defined, the second string should not be used.

time.tzset()

Resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done.

New in version 2.3.

Availability: Unix.

Note: Although in many cases, changing the TZ environment variable may affect the output of functions like localtime() without calling tzset(), this behavior should not be relied on. The TZ environment variable should contain no whitespace.

The standard format of the TZ environment variable is
(whitespace added for clarity):

```
std offset [dst [offset [,start[/time], end[/time]]]]
```

Where the components are:

```
std and dst

Three or more alphanumerics giving the timezone abbreviations. These will be propagated into time.tzname
```

```
offset

The offset has the form: ± hh[:mm[:ss]]. This indicates the value added the local time to arrive at UTC. If preceded by a ‘-‘, the timezone is east of the Prime Meridian; otherwise, it is west. If no offset follows dst, summer time is assumed to be one hour ahead of standard time.
```

```
start[/time], end[/time]

Indicates when to change to and back from DST. The format of the start and end dates are one of the following:
```

```
Jn

The Julian day \(n\) \((1 \leq n \leq 365)\). Leap days are not counted, so in all years February 28 is day 59 and March 1 is day 60.
```

```
n

The zero-based Julian day \((0 \leq n \leq 365)\). Leap days are counted, and it is possible to refer to February 29.
```

```
Mm.n.d

The \(d^{th}\) day \((0 \leq d \leq 6)\) or week \(n\) of month \(m\) of the year \((1 \leq n \leq 5, 1 \leq m \leq 12,\) where week 5 means “the last \(d\) day in month \(m\)” which may occur in either the fourth or the fifth week). Week 1 is the first week in which the \(d^{th}\) day occurs. Day zero is Sunday.
```
time has the same format as offset except that no leading sign ('-' or '+') is allowed. The default, if time is not given, is 02:00:00.

```python
>>> os.environ['TZ'] = 'EST+05EDT,M4.1.0,M10.5.0'
>>> time.tzset()
>>> time.strftime('%X %x %Z')
'02:07:36 05/08/03 EDT'
>>> os.environ['TZ'] = 'AEST-10AEDT-11,M10.5.0,M3.5.0'
>>> time.tzset()
>>> time.strftime('%X %x %Z')
'16:08:12 05/08/03 AEST'
```

On many Unix systems (including *BSD, Linux, Solaris, and Darwin), it is more convenient to use the system's zoneinfo (tzfile(5)) database to specify the timezone rules. To do this, set the TZ environment variable to the path of the required timezone datafile, relative to the root of the systems 'zoneinfo' timezone database, usually located at /usr/share/zoneinfo. For example, 'US/Eastern', 'Australia/Melbourne', 'Egypt' or 'Europe/Amsterdam'.

```python
>>> os.environ['TZ'] = 'US/Eastern'
>>> time.tzset()
>>> time.tzname
('EST', 'EDT')
>>> os.environ['TZ'] = 'Egypt'
>>> time.tzset()
>>> time.tzname
('EET', 'EEST')
```

See also:

Module datetime
More object-oriented interface to dates and times.

Module locale
Internationalization services. The locale settings can affect the return values for some of the functions in the time module.
Module **calendar**

General calendar-related functions. `timegm()` is the inverse of `gmtime()` from this module.

---

**Footnotes**

The use of `%Z` is now deprecated, but the `%z` escape that expands to the preferred hour/minute offset is not supported by all ANSI C libraries. Also, a strict reading of the original 1982 [RFC 822](https://tools.ietf.org/html/rfc822) standard calls for a two-digit year (%y rather than %Y), but practice moved to 4-digit years long before the year 2000. The 4-digit year has been mandated by [RFC 2822](https://tools.ietf.org/html/rfc2822), which obsoletes [RFC 822](https://tools.ietf.org/html/rfc822).

---

[1] **RFC 822**
15.4. argparse – Parser for command line options, arguments and sub-commands

New in version 2.7.

The argparse module makes it easy to write user friendly command line interfaces. The program defines what arguments it requires, and argparse will figure out how to parse those out of sys.argv. The argparse module also automatically generates help and usage messages and issues errors when users give the program invalid arguments.
15.4.1. Example

The following code is a Python program that takes a list of integers and produces either the sum or the max:

```python
import argparse

parser = argparse.ArgumentParser(description='Process some integers.

parser.add_argument('integers', metavar='N', type=int, nargs='+', help='an integer for the accumulator')
parser.add_argument('--sum', dest='accumulate', action='store_const', const=sum, default=max, help='sum the integers (default: find the max)

args = parser.parse_args()
print args.accumulate(args.integers)
```

Assuming the Python code above is saved into a file called `prog.py`, it can be run at the command line and provides useful help messages:

```
$ prog.py -h
usage: prog.py [-h] [--sum] N [N ...]

Process some integers.

positional arguments:
  N                  an integer for the accumulator

optional arguments:
  -h, --help  show this help message and exit
  --sum       sum the integers (default: find the max)
```

When run with the appropriate arguments, it prints either the sum or the max of the command-line integers:

```
$ prog.py 1 2 3 4
4
```
If invalid arguments are passed in, it will issue an error:

```
$ prog.py a b c
usage: prog.py [-h] [--sum] N [N ...]
prog.py: error: argument N: invalid int value: 'a'
```

The following sections walk you through this example.

### 15.4.1.1. Creating a parser

The first step in using the `argparse` is creating an `ArgumentParser` object:

```
>>> parser = argparse.ArgumentParser(description='Process some integers.')
```

The `ArgumentParser` object will hold all the information necessary to parse the command line into python data types.

### 15.4.1.2. Adding arguments

Filling an `ArgumentParser` with information about program arguments is done by making calls to the `add_argument()` method. Generally, these calls tell the `ArgumentParser` how to take the strings on the command line and turn them into objects. This information is stored and used when `parse_args()` is called. For example:

```
>>> parser.add_argument('integers', metavar='N', type=int, nargs='+',
                      help='an integer for the accumulator')
>>> parser.add_argument('--sum', dest='accumulate',
                      action='store_const', const=sum, default=max,
                      help='sum the integers (default: find the max)')
```
Later, calling `parse_args()` will return an object with two attributes, `integers` and `accumulate`. The `integers` attribute will be a list of one or more ints, and the `accumulate` attribute will be either the `sum()` function, if `--sum` was specified at the command line, or the `max()` function if it was not.

### 15.4.1.3. Parsing arguments

`ArgumentParser` parses args through the `parse_args()` method. This will inspect the command-line, convert each arg to the appropriate type and then invoke the appropriate action. In most cases, this means a simple namespace object will be built up from attributes parsed out of the command-line:

```python
>>> parser.parse_args(['--sum', '7', '-1', '42'])
Namespace(accumulate=<built-in function sum>, integers=[7, -1, 42])
```

In a script, `parse_args()` will typically be called with no arguments, and the `ArgumentParser` will automatically determine the command-line args from `sys.argv`.
15.4.2. ArgumentParser objects

class argparse.ArgumentParser([description], [epilog], [prog], [usage], [add_help], [argument_default], [parents], [prefix_chars], [conflict_handler], [formatter_class])

Create a new ArgumentParser object. Each parameter has its own more detailed description below, but in short they are:

- **description** - Text to display before the argument help.
- **epilog** - Text to display after the argument help.
- **add_help** - Add a -h/--help option to the parser. (default: True)
- **argument_default** - Set the global default value for arguments. (default: None)
- **parents** - A list of ArgumentParser objects whose arguments should also be included.
- **prefix_chars** - The set of characters that prefix optional arguments. (default: ‘-‘)
- **fromfile_prefix_chars** - The set of characters that prefix files from which additional arguments should be read. (default: None)
- **formatter_class** - A class for customizing the help output.
- **conflict_handler** - Usually unnecessary, defines strategy for resolving conflicting optionals.
- **prog** - The name of the program (default: sys.argv[0])
- **usage** - The string describing the program usage (default: generated)

The following sections describe how each of these are used.

15.4.2.1. description
Most calls to the `ArgumentParser` constructor will use the `description=` keyword argument. This argument gives a brief description of what the program does and how it works. In help messages, the description is displayed between the command-line usage string and the help messages for the various arguments:

```python
>>> parser = argparse.ArgumentParser(description='A foo that bars')
>>> parser.print_help()
usage: argparse.py [-h]
A foo that bars
optional arguments:
    -h, --help    show this help message and exit
```

By default, the description will be line-wrapped so that it fits within the given space. To change this behavior, see the `formatter_class` argument.

### 15.4.2.2. epilog

Some programs like to display additional description of the program after the description of the arguments. Such text can be specified using the `epilog=` argument to `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(
...     description='A foo that bars',
...     epilog='And that's how you'd foo a bar')
>>> parser.print_help()
usage: argparse.py [-h]
A foo that bars
optional arguments:
    -h, --help    show this help message and exit
And that's how you'd foo a bar
```
As with the `description` argument, the `epilog` text is by default line-wrapped, but this behavior can be adjusted with the `formatter_class` argument to `ArgumentParser`.

### 15.4.2.3. `add_help`  

By default, `ArgumentParser` objects add a `-h/--help` option which simply displays the parser’s help message. For example, consider a file named `myprogram.py` containing the following code:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument('--foo', help='foo help')
args = parser.parse_args()
```

If `-h` or `--help` is supplied is at the command-line, the `ArgumentParser` help will be printed:

```
$ python myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
```

Occasionally, it may be useful to disable the addition of this help option. This can be achieved by passing `False` as the `add_help` argument to `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', add_help=False)
>>> parser.add_argument('--foo', help='foo help')
>>> parser.print_help()
usage: PROG [-h]

optional arguments:
  --foo FOO     foo help
```
15.4.2.4. prefix_chars

Most command-line options will use `-` as the prefix, e.g. `-f/--foo`. Parsers that need to support additional prefix characters, e.g. for options like `+f` or `/foo`, may specify them using the `prefix_chars=` argument to the `ArgumentParser` constructor:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', prefix_chars='-+)
>>> parser.add_argument('+f')
>>> parser.add_argument('++bar')
>>> parser.parse_args('+f X ++bar Y'.split())
Namespace(bar='Y', f='X')
```

The `prefix_chars=` argument defaults to `-`. Supplying a set of characters that does not include `-` will cause `-f/--foo` options to be disallowed.

15.4.2.5. fromfile_prefix_chars

Sometimes, for example when dealing with a particularly long argument lists, it may make sense to keep the list of arguments in a file rather than typing it out at the command line. If the `fromfile_prefix_chars=` argument is given to the `ArgumentParser` constructor, then arguments that start with any of the specified characters will be treated as files, and will be replaced by the arguments they contain. For example:

```python
>>> with open('args.txt', 'w') as fp:
...     fp.write('-f
bar')
>>> parser = argparse.ArgumentParser(fromfile_prefix_chars='@')
>>> parser.add_argument('-f')
>>> parser.parse_args(['-f', 'foo', '@args.txt'])
Namespace(f='bar')
```

Arguments read from a file must by default be one per line (but see
also `convert_arg_line_to_args()` and are treated as if they were in the same place as the original file referencing argument on the command line. So in the example above, the expression `['-f', 'foo', '@args.txt']` is considered equivalent to the expression `['-f', 'foo', '-f', 'bar']`.

The `fromfile_prefix_chars=` argument defaults to `None`, meaning that arguments will never be treated as file references.

### 15.4.2.6. argument_default

Generally, argument defaults are specified either by passing a default to `add_argument()` or by calling the `set_defaults()` methods with a specific set of name-value pairs. Sometimes however, it may be useful to specify a single parser-wide default for arguments. This can be accomplished by passing the `argument_default=` keyword argument to `ArgumentParser`. For example, to globally suppress attribute creation on `parse_args()` calls, we supply `argument_default=argparse.SUPPRESS`:

```python
>>> parser = argparse.ArgumentParser(argument_default=argparse.SUPPRESS)
>>> parser.add_argument('--foo')
>>> parser.add_argument('bar', nargs='?')
>>> parser.parse_args(['--foo', '1', 'BAR'])
Namespace(bar='BAR', foo='1')
>>> parser.parse_args([])
Namespace()
```

### 15.4.2.7. parents

Sometimes, several parsers share a common set of arguments. Rather than repeating the definitions of these arguments, a single parser with all the shared arguments and passed to `parents=` argument to `ArgumentParser` can be used. The `parents=` argument
takes a list of `ArgumentParser` objects, collects all the positional and optional actions from them, and adds these actions to the `ArgumentParser` object being constructed:

```python
>>> parent_parser = argparse.ArgumentParser(add_help=False)
>>> parent_parser.add_argument('--parent', type=int)

>>> foo_parser = argparse.ArgumentParser(parents=[parent_parser])
>>> foo_parser.add_argument('foo')
>>> foo_parser.parse_args(['--parent', '2', 'XXX'])
Namespace(foo='XXX', parent=2)

>>> bar_parser = argparse.ArgumentParser(parents=[parent_parser])
>>> bar_parser.add_argument('--bar')
>>> bar_parser.parse_args(['--bar', 'YYY'])
Namespace(bar='YYY', parent=None)
```

Note that most parent parsers will specify `add_help=False`. Otherwise, the `ArgumentParser` will see two `-h/--help` options (one in the parent and one in the child) and raise an error.

### 15.4.2.8. formatter_class

`ArgumentParser` objects allow the help formatting to be customized by specifying an alternate formatting class. Currently, there are three such classes: `argparse.RawDescriptionHelpFormatter`, `argparse.RawTextHelpFormatter` and `argparse.ArgumentDefaultsHelpFormatter`. The first two allow more control over how textual descriptions are displayed, while the last automatically adds information about argument default values.

By default, `ArgumentParser` objects line-wrap the `description` and `epilog` texts in command-line help messages:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     description='''this description
```

this description was indented weird but that is okay

optional arguments:
- `h`, `--help`  show this help message and exit

likewise for this epilog whose whitespace will be cleaned up and whose words will be wrapped across a couple lines

Passing `argparse.RawDescriptionHelpFormatter` as
`formatter_class=` indicates that `description` and `epilog` are already correctly formatted and should not be line-wrapped:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.RawDescriptionHelpFormatter,
...     description=textwrap.dedent('''
...         Please do not mess up this text!
...         --------------------------------
...         I have indented it
...         exactly the way
...         I want it
...         '''
...     ))
>>> parser.print_help()
usage: PROG [-h]

Please do not mess up this text!
--------------------------------
I have indented it
exactly the way
I want it

optional arguments:
- `h`, `--help`  show this help message and exit
```
RawTextHelpFormatter maintains whitespace for all sorts of help text including argument descriptions.

The other formatter class available, ArgumentDefaultsHelpFormatter, will add information about the default value of each of the arguments:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.ArgumentDefaultsHelpFormatter)
>>> parser.add_argument('--foo', type=int, default=42, help='FOO!')
>>> parser.add_argument('bar', nargs='*', default=[1, 2, 3], help='BAR!')
>>> parser.print_help()
```

```
usage: PROG [-h] [--foo FOO] [bar [bar ...]]

positional arguments:
    bar                     BAR! (default: [1, 2, 3])

optional arguments:
    -h, --help              show this help message and exit
    --foo FOO               FOO! (default: 42)
```

15.4.2.9. conflict_handler

ArgumentParser objects do not allow two actions with the same option string. By default, ArgumentParser objects raises an exception if an attempt is made to create an argument with an option string that is already in use:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-f', '--foo', help='old foo help')
>>> parser.add_argument('--foo', help='new foo help')
Traceback (most recent call last):
  ...
ArgumentError: argument --foo: conflicting option string(s): --
```

Sometimes (e.g. when using parents) it may be useful to simply override any older arguments with the same option string. To get this
behavior, the value 'resolve' can be supplied to the `conflict_handler` argument of `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', conflict_handler='resolve')
>>> parser.add_argument('-f', '--foo', help='old foo help')
>>> parser.add_argument('--foo', help='new foo help')
>>> parser.print_help()

usage: PROG [-h] [-f FOO] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  -f FOO        old foo help
  --foo FOO     new foo help
```

Note that `ArgumentParser` objects only remove an action if all of its option strings are overridden. So, in the example above, the old `-f/-
-foo` action is retained as the `-f` action, because only the `-foo` option string was overridden.

## 15.4.2.10. prog

By default, `ArgumentParser` objects use `sys.argv[0]` to determine how to display the name of the program in help messages. This default is almost always desirable because it will make the help messages match how the program was invoked on the command line. For example, consider a file named `myprogram.py` with the following code:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument('--foo', help='foo help')
args = parser.parse_args()
```

The help for this program will display `myprogram.py` as the program name (regardless of where the program was invoked from):

```
$ python myprogram.py --help
```
usage: myprogram.py [-h] [-f FOO]

optional arguments:
    -h, --help  show this help message and exit
    -f FOO      foo help
$ cd ..
$ python subdir\myprogram.py --help
usage: myprogram.py [-h] [-f FOO]

optional arguments:
    -h, --help  show this help message and exit
    -f FOO      foo help

To change this default behavior, another value can be supplied using the prog= argument to ArgumentParser:

```python
>>> parser = argparse.ArgumentParser(prog='myprogram')
>>> parser.print_help()
usage: myprogram [-h]

optional arguments:
    -h, --help  show this help message and exit
```

Note that the program name, whether determined from sys.argv[0] or from the prog= argument, is available to help messages using the %prog format specifier.

```python
>>> parser = argparse.ArgumentParser(prog='myprogram')
>>> parser.add_argument('--foo', help='foo of the %prog program')
>>> parser.print_help()
usage: myprogram [-h] [-f FOO]

optional arguments:
    -h, --help  show this help message and exit
    -f FOO      foo of the myprogram program
```

15.4.2.11. usage

By default, ArgumentParser calculates the usage message from the arguments it contains:
The default message can be overridden with the `usage=` keyword argument:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', usage='%(prog)s [options]
>>> parser.add_argument('--foo', nargs='?', help='foo help')
>>> parser.add_argument('bar', nargs='+', help='bar help')
>>> parser.print_help()
usage: PROG [options]
positional arguments:
  bar        bar help
optional arguments:
  -h, --help  show this help message and exit
  --foo [FOO]  foo help
```

The `%prog` format specifier is available to fill in the program name in your usage messages.
15.4.3. The add_argument() method

```
ArgumentParser.add_argument(name_or_flags..., [action][, nargs][, const][, default][, type][, choices][, required][, help][, metavar][, dest])
```

Define how a single command line argument should be parsed. Each parameter has its own more detailed description below, but in short they are:

- **name or flags** - Either a name or a list of option strings, e.g. `foo` or `-f, --foo`
- **action** - The basic type of action to be taken when this argument is encountered at the command-line.
- **nargs** - The number of command-line arguments that should be consumed.
- **const** - A constant value required by some action and nargs selections.
- **default** - The value produced if the argument is absent from the command-line.
- **type** - The type to which the command-line arg should be converted.
- **choices** - A container of the allowable values for the argument.
- **required** - Whether or not the command-line option may be omitted (optionals only).
- **help** - A brief description of what the argument does.
- **metavar** - A name for the argument in usage messages.
- **dest** - The name of the attribute to be added to the object returned by `parse_args()`.

The following sections describe how each of these are used.
15.4.3.1. name or flags

The `add_argument()` method must know whether an optional argument, like `-f` or `--foo`, or a positional argument, like a list of filenames, is expected. The first arguments passed to `add_argument()` must therefore be either a series of flags, or a simple argument name. For example, an optional argument could be created like:

```python
>>> parser.add_argument('-f', '--foo')
```

while a positional argument could be created like:

```python
>>> parser.add_argument('bar')
```

When `parse_args()` is called, optional arguments will be identified by the `-` prefix, and the remaining arguments will be assumed to be positional:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-f', '--foo')
>>> parser.add_argument('bar')
>>> parser.parse_args(['BAR'])
Namespace(bar='BAR', foo=None)
```

```python
>>> parser.parse_args(['BAR', '--foo', 'FOO'])
Namespace(bar='BAR', foo='FOO')
```

```python
>>> parser.parse_args(['--foo', 'FOO'])
usage: PROG [-h] [-f FOO] bar
PROG: error: too few arguments
```

15.4.3.2. action

`ArgumentParser` objects associate command-line args with actions. These actions can do just about anything with the command-line args associated with them, though most actions simply add an attribute to the object returned by `parse_args()`. The `action` keyword
argument specifies how the command-line args should be handled. The supported actions are:

- **'store'** - This just stores the argument's value. This is the default action. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo')
  >>> parser.parse_args('--foo 1'.split())
  Namespace(foo='1')
  ```

- **'store_const'** - This stores the value specified by the const keyword argument. (Note that the const keyword argument defaults to the rather unhelpful `None`.) The 'store_const' action is most commonly used with optional arguments that specify some sort of flag. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', action='store_const', const=42)
  >>> parser.parse_args('--foo'.split())
  Namespace(foo=42)
  ```

- **'store_true' and 'store_false'** - These store the values `True` and `False` respectively. These are special cases of 'store_const'. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', action='store_true')
  >>> parser.add_argument('--bar', action='store_false')
  >>> parser.parse_args('--foo --bar'.split())
  Namespace(bar=False, foo=True)
  ```

- **'append'** - This stores a list, and appends each argument value to the list. This is useful to allow an option to be specified multiple times. Example usage:
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action='append')
>>> parser.parse_args('--foo 1 --foo 2'.split())
Namespace(foo=['1', '2'])

*append_const* - This stores a list, and appends the value specified by the *const* keyword argument to the list. (Note that the *const* keyword argument defaults to *None*.) The *append_const* action is typically useful when multiple arguments need to store constants to the same list. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--str', dest='types', action='append_const', const=str)
>>> parser.add_argument('--int', dest='types', action='append_const', const=int)
>>> parser.parse_args('--str --int'.split())
Namespace(types=[<type 'str'>, <type 'int'>])
```

*version* - This expects a *version* keyword argument in the *add_argument()* call, and prints version information and exits when invoked.

```python
>>> import argparse
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--version', action='version', version='%(prog)s 2.0')
>>> parser.parse_args(['--version'])
PROG 2.0
```

You can also specify an arbitrary action by passing an object that implements the Action API. The easiest way to do this is to extend *argparse.Action*, supplying an appropriate *__call__* method. The *__call__* method should accept four parameters:

- *parser* - The ArgumentParser object which contains this action.
- *namespace* - The namespace object that will be returned by *parse_args()*.
- *parsed arguments* - The parsed arguments passed to the function.
- *optional keyword arguments* - The optional keyword arguments passed to the function.

Most actions add an attribute to this object.
values - The associated command-line args, with any type-conversions applied. (Type-conversions are specified with the type keyword argument to add_argument).

option_string - The option string that was used to invoke this action. The option_string argument is optional, and will be absent if the action is associated with a positional argument.

An example of a custom action:

```python
>>> class FooAction(argparse.Action):
...     def __call__(self, parser, namespace, values, option_string=None):
...         print '%r %r %r' % (namespace, values, option_string)
...         setattr(namespace, self.dest, values)
... >>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action=FooAction)
>>> parser.add_argument('bar', action=FooAction)
>>> args = parser.parse_args('1 --foo 2'.split())
Namespace(bar=None, foo=None)
Namespace(bar='1', foo=None) '2' '--foo'
>>> args
Namespace(bar='1', foo='2')
```

15.4.3.3. nargs

ArgumentParser objects usually associate a single command-line argument with a single action to be taken. The nargs keyword argument associates a different number of command-line arguments with a single action.. The supported values are:

- N (an integer). N args from the command-line will be gathered together into a list. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs=2)
>>> parser.add_argument('bar', nargs=1)
>>> parser.parse_args('c --foo a b'.split())
Namespace(bar=['c'], foo=['a', 'b'])
```
Note that ``nargs=1`` produces a list of one item. This is the default, in which the item is produced by itself.

- `'?'`. One arg will be consumed from the command-line if possible, and produced as a single item. If no command-line arg is present, the value from default will be produced. Note that for optional arguments, there is an additional case - the option string is present but not followed by a command-line arg. In this case the value from const will be produced. Some examples to illustrate this:

```python
generator = argparse.ArgumentParser()
generator.add_argument('--foo', nargs='?', const='c', default='d')
generator.add_argument('bar', nargs='?', default='d')
generator.parse_args('XX --foo YY'.split())
Namespace(bar='XX', foo='YY')
generator.parse_args('XX --foo'.split())
Namespace(bar='XX', foo='c')
generator.parse_args(''.split())
Namespace(bar='d', foo='d')
```

One of the more common uses of `nargs='?'` is to allow optional input and output files:

```python
generator = argparse.ArgumentParser()
generator.add_argument('infile', nargs='?', type=argparse.FileType('r'), default=sys.stdin)
generator.add_argument('outfile', nargs='?', type=argparse.FileType('w'), default=sys.stdout)
generator.parse_args(['input.txt', 'output.txt'])
Namespace(infile=<open file 'input.txt', mode 'r' at 0x...>, outfile=<open file 'output.txt', mode 'w' at 0x...>)
generator.parse_args([])
Namespace(infile=<open file '<stdin>', mode 'r' at 0x...>, outfile=<open file '<stdout>', mode 'w' at 0x...>)
```

- '*'. All command-line args present are gathered into a list. Note that it generally doesn’t make much sense to have more than one positional argument with `nargs='*'`, but multiple optional arguments with `nargs='*'` is possible. For example:

```python
generator = argparse.ArgumentParser()
generator.add_argument('infile', nargs='?', default=sys.stdin)
generator.add_argument('outfile', nargs='?', default=sys.stdout)
generator.parse_args(['input.txt', 'output.txt'])
Namespace(infile=<open file 'input.txt', mode 'r' at 0x...>, outfile=<open file 'output.txt', mode 'w' at 0x...>)
generator.parse_args([])
Namespace(infile=<open file '<stdin>', mode 'r' at 0x...>, outfile=<open file '<stdout>', mode 'w' at 0x...>)
```
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs='*')
>>> parser.add_argument('--bar', nargs='*')
>>> parser.add_argument('baz', nargs='*')
>>> parser.parse_args('a b --foo x y --bar 1 2'.split())
Namespace(bar=['1', '2'], baz=['a', 'b'], foo=['x', 'y'])

- `'+'`. Just like `'*'`, all command-line args present are gathered into a list. Additionally, an error message will be generated if there wasn’t at least one command-line arg present. For example:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', nargs='+')
>>> parser.parse_args('a b'.split())
Namespace(foo=['a', 'b'])
```

```python
>>> parser.parse_args('').split())
usage: PROG [-h] foo [foo ...]
PROG: error: too few arguments
```

If the `nargs` keyword argument is not provided, the number of args consumed is determined by the `action`. Generally this means a single command-line arg will be consumed and a single item (not a list) will be produced.

15.4.3.4. const

The `const` argument of `add_argument()` is used to hold constant values that are not read from the command line but are required for the various ArgumentParser actions. The two most common uses of it are:

- When `add_argument()` is called with `action='store_const'` or `action='append_const'`. These actions add the `const` value to one of the attributes of the object returned by `parse_args()`. See the `action` description for examples.
- When `add_argument()` is called with option strings (like `-f` or `--`
foo) and nargs='?'. This creates an optional argument that can be followed by zero or one command-line args. When parsing the command-line, if the option string is encountered with no command-line arg following it, the value of `const` will be assumed instead. See the `nargs` description for examples.

The `const` keyword argument defaults to `None`.

### 15.4.3.5. default

All optional arguments and some positional arguments may be omitted at the command-line. The `default` keyword argument of `add_argument()`, whose value defaults to `None`, specifies what value should be used if the command-line arg is not present. For optional arguments, the `default` value is used when the option string was not present at the command line:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default=42)
>>> parser.parse_args('--foo 2'.split())
Namespace(foo='2')
>>> parser.parse_args('').split())
Namespace(foo=42)
```

For positional arguments with `nargs ='?` or ' * ', the `default` value is used when no command-line arg was present:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', nargs='?', default=42)
>>> parser.parse_args('a'.split())
Namespace(foo='a')
>>> parser.parse_args('').split())
Namespace(foo=42)
```

Providing `default=argparse.SUPPRESS` causes no attribute to be added if the command-line argument was not present.
15.4.3.6. type

By default, ArgumentParser objects read command-line args in as simple strings. However, quite often the command-line string should instead be interpreted as another type, like a float, int or file. The type keyword argument of add_argument() allows any necessary type-checking and type-conversions to be performed. Many common built-in types can be used directly as the value of the type argument:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.add_argument('bar', type=file)
>>> parser.parse_args('2 temp.txt'.split())
Namespace(bar=<open file 'temp.txt', mode 'r' at 0x...>, foo=2)
```

To ease the use of various types of files, the argparse module provides the factory FileType which takes the mode= and bufsize= arguments of the file object. For example, FileType('w') can be used to create a writable file:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('bar', type=argparse.FileType('w'))
>>> parser.parse_args(['out.txt'])
Namespace(bar=<open file 'out.txt', mode 'w' at 0x...>)
```

type= can take any callable that takes a single string argument and returns the type-converted value:

```python
>>> def perfect_square(string):
...     value = int(string)
```
... sqrt = math.sqrt(value)
... if sqrt != int(sqrt):
...     msg = "%r is not a perfect square" % string
...     raise argparse.ArgumentTypeError(msg)
... return value
...
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', type=perfect_square)
>>> parser.parse_args('9'.split())
Namespace(foo=9)
>>> parser.parse_args('7'.split())
usage: PROG [-h]
foo
PROG: error: argument foo: '7' is not a perfect square

The **choices** keyword argument may be more convenient for type checkers that simply check against a range of values:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', type=int, choices=xrange(5, 10))
>>> parser.parse_args('7'.split())
Namespace(foo=7)
>>> parser.parse_args('11'.split())
usage: PROG [-h] {5,6,7,8,9}
PROG: error: argument foo: invalid choice: 11 (choose from 5, 6
```

See the **choices** section for more details.

### 15.4.3.7. choices

Some command-line args should be selected from a restricted set of values. These can be handled by passing a container object as the **choices** keyword argument to `add_argument()`. When the command-line is parsed, arg values will be checked, and an error message will be displayed if the arg was not one of the acceptable values:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', choices='abc')
>>> parser.parse_args('c'.split())
Namespace(foo='c')
>>> parser.parse_args('X'.split())
```
usage: PROG [-h] {a,b,c}
PROG: error: argument foo: invalid choice: 'X' (choose from 'a'

Note that inclusion in the choices container is checked after any type
conversions have been performed, so the type of the objects in the
choices container should match the type specified:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', type=complex, choices=[1, 1j])
>>> parser.parse_args('1j'.split())
Namespace(foo=1j)
>>> parser.parse_args('-- -4'.split())
usage: PROG [-h] {1,1j}
PROG: error: argument foo: invalid choice: (-4+0j) (choose from
```

Any object that supports the in operator can be passed as the
choices value, so dict objects, set objects, custom containers, etc.
are all supported.

### 15.4.3.8. required

In general, the argparse module assumes that flags like -f and --
bar indicate optional arguments, which can always be omitted at the
command-line. To make an option required, True can be specified for
the required= keyword argument to add_argument():

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', required=True)
>>> parser.parse_args(['--foo', 'BAR'])
Namespace(foo='BAR')
>>> parser.parse_args([])
usage: argparse.py [-h] [--foo FOO]
argparse.py: error: option --foo is required
```

As the example shows, if an option is marked as required,
parse_args() will report an error if that option is not present at the
command line.

**Note:** Required options are generally considered bad form because users expect *options* to be *optional*, and thus they should be avoided when possible.

### 15.4.3.9. help

The `help` value is a string containing a brief description of the argument. When a user requests help (usually by using `-h` or `--help` at the command-line), these `help` descriptions will be displayed with each argument:

```python
g>>> parser = argparse.ArgumentParser(prog='frobble')
g>>> parser.add_argument('--foo', action='store_true', ...
...     help='foo the bars before frobling')
g>>> parser.add_argument('bar', nargs='+', ...
...     help='one of the bars to be frobbled')
g>>> parser.parse_args('-h'.split())
usage: frobble [-h] [--foo] bar [bar ...]

positional arguments:
  bar       one of the bars to be frobbled

optional arguments:
  -h, --help  show this help message and exit
  --foo      foo the bars before frobling
```

The `help` strings can include various format specifiers to avoid repetition of things like the program name or the argument default. The available specifiers include the program name, `%(prog)s` and most keyword arguments to `add_argument()`, e.g. `%(default)s`, `%(type)s`, etc.:

```python
g>>> parser = argparse.ArgumentParser(prog='frobble')
g>>> parser.add_argument('bar', nargs='?', type=int, default=42, ...
...     help='the bar to %(prog)s (default: %(default)s)')
g>>> parser.print_help()
```
usage: frobble [-h] [bar]

positional arguments:
  bar    the bar to frobble (default: 42)

optional arguments:
  -h, --help  show this help message and exit

15.4.3.10. metavar

When ArgumentParser generates help messages, it need some way to refer to each expected argument. By default, ArgumentParser objects use the dest value as the “name” of each object. By default, for positional argument actions, the dest value is used directly, and for optional argument actions, the dest value is uppercased. So, a single positional argument with dest='bar' will that argument will be referred to as bar. A single optional argument --foo that should be followed by a single command-line arg will be referred to as foo. An example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> parser.add_argument('bar')
>>> parser.parse_args('X --foo Y'.split())
Namespace(bar='X', foo='Y')
>>> parser.print_help()
usage:     [-h] [--foo FOO] bar

positional arguments:
  bar

optional arguments:
  -h, --help  show this help message and exit
              --foo FOO
```

An alternative name can be specified with metavar:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', metavar='YYY')
```
Note that `metavar` only changes the *displayed* name - the name of the attribute on the `parse_args()` object is still determined by the `dest` value.

Different values of `nargs` may cause the metavar to be used multiple times. Providing a tuple to `metavar` specifies a different display for each of the arguments:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x', nargs=2)
>>> parser.add_argument('--foo', nargs=2, metavar=('bar', 'baz'))
>>> parser.print_help()
usage: PROG [-h] [-x X X] [--foo bar baz]
optional arguments:
  -h, --help  show this help message and exit
  -x X X
  --foo bar baz
```

### 15.4.3.11. `dest`

Most `ArgumentParser` actions add some value as an attribute of the object returned by `parse_args()`. The name of this attribute is determined by the `dest` keyword argument of `add_argument()`. For positional argument actions, `dest` is normally supplied as the first
argument to `add_argument()`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('bar')
>>> parser.parse_args('XXX'.split())
Namespace(bar='XXX')
```

For optional argument actions, the value of `dest` is normally inferred from the option strings. `ArgumentParser` generates the value of `dest` by taking the first long option string and stripping away the initial `'--'` string. If no long option strings were supplied, `dest` will be derived from the first short option string by stripping the initial `'-'` character. Any internal `'-'` characters will be converted to `'_ '` characters to make sure the string is a valid attribute name. The examples below illustrate this behavior:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('-f', '--foo-bar', '--foo')
>>> parser.add_argument('-x', '-y')
>>> parser.parse_args('-f 1 -x 2'.split())
Namespace(foo_bar='1', x='2')
>>> parser.parse_args('--foo 1 -y 2'.split())
Namespace(foo_bar='1', x='2')
```

dest allows a custom attribute name to be provided:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', dest='bar')
>>> parser.parse_args('--foo XXX'.split())
Namespace(bar='XXX')
```
15.4.4. The parse_args() method

ArgumentParser.parse_args([args][, namespace])

Convert argument strings to objects and assign them as attributes of the namespace. Return the populated namespace.

Previous calls to add_argument() determine exactly what objects are created and how they are assigned. See the documentation for add_argument() for details.

By default, the arg strings are taken from sys.argv, and a new empty Namespace object is created for the attributes.

15.4.4.1. Option value syntax

The parse_args() method supports several ways of specifying the value of an option (if it takes one). In the simplest case, the option and its value are passed as two separate arguments:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument(  
'\-x',
>>> parser.add_argument('--foo')
>>> parser.parse_args('-x	X'.split())
Namespace(foo=None, x='X')
>>> parser.parse_args('--foo	FOO'.split())
Namespace(foo='FOO', x=None)
```

For long options (options with names longer than a single character), the option and value can also be passed as a single command line argument, using = to separate them:

```python
>>> parser.parse_args('--foo=FOO'.split())
Namespace(foo='FOO', x=None)
```

For short options (options only one character long), the option and its
value can be concatenated:

```python
>>> parser.parse_args('-xx'.split())
Namespace(foo= None, x='X')
```

Several short options can be joined together, using only a single `-` prefix, as long as only the last option (or none of them) requires a value:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x', action='store_true')
>>> parser.add_argument('-y', action='store_true')
>>> parser.add_argument('-z')
>>> parser.parse_args('-xyzZ'.split())
Namespace(x=True, y=True, z='Z')
```

### 15.4.4.2. Invalid arguments

While parsing the command-line, `parse_args` checks for a variety of errors, including ambiguous options, invalid types, invalid options, wrong number of positional arguments, etc. When it encounters such an error, it exits and prints the error along with a usage message:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', type=int)
>>> parser.add_argument('bar', nargs='?')

>>> # invalid type
>>> parser.parse_args([ '--foo', 'spam'])
usage: PROG [-h] [--foo FOO] [bar]
PROG: error: argument --foo: invalid int value: 'spam'

>>> # invalid option
>>> parser.parse_args([ '--bar'])
usage: PROG [-h] [--foo FOO] [bar]
PROG: error: no such option: --bar

>>> # wrong number of arguments
>>> parser.parse_args([ 'spam', 'badger'])
usage: PROG [-h] [--foo FOO] [bar]
PROG: error: extra arguments found: badger
```
15.4.4.3. Arguments containing "-"

The `parse_args` method attempts to give errors whenever the user has clearly made a mistake, but some situations are inherently ambiguous. For example, the command-line arg `-1` could either be an attempt to specify an option or an attempt to provide a positional argument. The `parse_args` method is cautious here: positional arguments may only begin with `-` if they look like negative numbers and there are no options in the parser that look like negative numbers:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x')
>>> parser.add_argument('foo', nargs='?')

>>> # no negative number options, so -1 is a positional argument
>>> parser.parse_args(['-x', '-1'])
Namespace(foo=None, x='-1')

>>> # no negative number options, so -1 and -5 are positional arguments
>>> parser.parse_args(['-x', '-1', '-5'])
Namespace(foo='-5', x='-1')

>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-1', dest='one')
>>> parser.add_argument('foo', nargs='?')

>>> # negative number options present, so -1 is an option
>>> parser.parse_args(['-1', 'X'])
Namespace(foo=None, one='X')

>>> # negative number options present, so -2 is an option
>>> parser.parse_args(['-2'])
usage: PROG [-h] [-1 ONE] [foo]
PROG: error: no such option: -2

>>> # negative number options present, so both -1s are options
>>> parser.parse_args(['-1', '-1'])
usage: PROG [-h] [-1 ONE] [foo]
PROG: error: argument -1: expected one argument
```
If you have positional arguments that must begin with `'-` and don’t look like negative numbers, you can insert the pseudo-argument `--` which tells `parse_args` that everything after that is a positional argument:

```python
>>> parser.parse_args(['--', '-f'])
Namespace(foo='-f', one=None)
```

### 15.4.4.4. Argument abbreviations

The `parse_args()` method allows long options to be abbreviated if the abbreviation is unambiguous:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-bacon')
>>> parser.add_argument('-badger')
>>> parser.parse_args('-bac MMM'.split())
Namespace(bacon='MMM', badger=None)
>>> parser.parse_args('-bad WOOD'.split())
Namespace(bacon=None, badger='WOOD')
```

An error is produced for arguments that could produce more than one options.

### 15.4.4.5. Beyond `sys.argv`

Sometimes it may be useful to have an `ArgumentParser` parse args other than those of `sys.argv`. This can be accomplished by passing a list of strings to `parse_args`. This is useful for testing at the interactive prompt:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument(
```
15.4.4.6. Custom namespaces

It may also be useful to have an `ArgumentParser` assign attributes to an already existing object, rather than the newly-created `Namespace` object that is normally used. This can be achieved by specifying the `namespace=` keyword argument:

```python
>>> class C(object):
...     pass
...
>>> c = C()
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> parser.parse_args(args=['--foo', 'BAR'], namespace=c)
>>> c.foo
'BAR'
```
15.4.5. Other utilities

15.4.5.1. Sub-commands

ArgumentParser.add_subparsers()

Many programs split up their functionality into a number of sub-commands, for example, the `svn` program can invoke sub-commands like `svn checkout`, `svn update`, and `svn commit`. Splitting up functionality this way can be a particularly good idea when a program performs several different functions which require different kinds of command-line arguments. ArgumentParser supports the creation of such sub-commands with the `add_subparsers()` method. The `add_subparsers()` method is normally called with no arguments and returns an special action object. This object has a single method, `add_parser`, which takes a command name and any ArgumentParser constructor arguments, and returns an ArgumentParser object that can be modified as usual.

Some example usage:

```python
>>> # create the top-level parser
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', action='store_true', help='foo help')
>>> subparsers = parser.add_subparsers(help='sub-command help')

>>> # create the parser for the "a" command
>>> parser_a = subparsers.add_parser('a', help='a help')
>>> parser_a.add_argument('bar', type=int, help='bar help')

>>> # create the parser for the "b" command
>>> parser_b = subparsers.add_parser('b', help='b help')
>>> parser_b.add_argument('--baz', choices='XYZ', help='baz help')

>>> # parse some arg lists
>>> parser.parse_args(['a', '12'])
```
Namespace(bar=12, foo=False)

>>> parser.parse_args(['--foo', 'b', '--baz', 'Z'])
Namespace(baz='Z', foo=True)

Note that the object returned by `parse_args()` will only contain attributes for the main parser and the subparser that was selected by the command line (and not any other subparsers). So in the example above, when the "a" command is specified, only the `foo` and `bar` attributes are present, and when the "b" command is specified, only the `foo` and `baz` attributes are present.

Similarly, when a help message is requested from a subparser, only the help for that particular parser will be printed. The help message will not include parent parser or sibling parser messages. (A help message for each subparser command, however, can be given by supplying the `help=` argument to `add_parser` as above.)

```python
>>> parser.parse_args(['--help'])
usage: PROG [-h] [-f] {a,b} ...

positional arguments:
    {a,b}  sub-command help
    a      a help
    b      b help

optional arguments:
    -h, --help  show this help message and exit
    --foo foo help
```

```python
>>> parser.parse_args(['a', '--help'])
usage: PROG a [-h] bar

positional arguments:
    bar     bar help

optional arguments:
    -h, --help  show this help message and exit
```
The `add_subparsers()` method also supports `title` and `description` keyword arguments. When either is present, the subparser’s commands will appear in their own group in the help output. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers(title='subcommands',
...                                    description='valid subcommands',
...                                    help='additional help')
>>> subparsers.add_parser('foo')
>>> subparsers.add_parser('bar')
```

One particularly effective way of handling sub-commands is to combine the use of the `add_subparsers()` method with calls to `set_defaults()` so that each subparser knows which Python function it should execute. For example:

```python
>>> # sub-command functions
>>> def foo(args):
...     print args.x * args.y
...
>>> def bar(args):
...     print '(%s)' % args.z
...```
This way, you can let `parse_args()` do the job of calling the appropriate function after argument parsing is complete. Associating functions with actions like this is typically the easiest way to handle the different actions for each of your subparsers. However, if it is necessary to check the name of the subparser that was invoked, the `dest` keyword argument to the `add_subparsers()` call will work:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers(dest='subparser_name')
>>> subparser1 = subparsers.add_parser('1')
>>> subparser1.add_argument('-x')
>>> subparser2 = subparsers.add_parser('2')
>>> subparser2.add_argument('y')
>>> parser.parse_args(['2', 'frobble'])
Namespace(subparser_name='2', y='frobble')
```
15.4.5.2. FileType objects

```
class argparse.FileType(mode='r', bufsize=None)
```

The `FileType` factory creates objects that can be passed to the type argument of `ArgumentParser.add_argument()`. Arguments that have `FileType` objects as their type will open command-line args as files with the requested modes and buffer sizes:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--output', type=argparse.FileType('wb', 0))
>>> parser.parse_args(['--output', 'out'])
Namespace(output=<open file 'out', mode 'wb' at 0x...>)
```

FileType objects understand the pseudo-argument `-` and automatically convert this into `sys.stdin` for readable `FileType` objects and `sys.stdout` for writable `FileType` objects:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('infile', type=argparse.FileType('r'))
>>> parser.parse_args(['-'])
Namespace(infile=<open file '<stdin>', mode 'r' at 0x...>)
```

15.4.5.3. Argument groups

```
ArgumentParser.add_argument_group([title][, description])
```

By default, `ArgumentParser` groups command-line arguments into “positional arguments” and “optional arguments” when displaying help messages. When there is a better conceptual grouping of arguments than this default one, appropriate groups can be created using the `add_argument_group()` method:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', add_help=False)
>>> group = parser.add_argument_group('group')
>>> group.add_argument('--foo', help='foo help')
```
The `add_argument_group()` method returns an argument group object which has an `add_argument()` method just like a regular ArgumentParser. When an argument is added to the group, the parser treats it just like a normal argument, but displays the argument in a separate group for help messages. The `add_argument_group()` method accepts `title` and `description` arguments which can be used to customize this display:

```python
>>> group.add_argument('bar', help='bar help')
>>> parser.print_help()
usage: PROG [--foo FOO] bar

group:
    bar    bar help
    --foo FOO  foo help
```

```python
>>> parser = argparse.ArgumentParser(prog='PROG', add_help=False)
>>> group1 = parser.add_argument_group('group1', 'group1 description')
>>> group1.add_argument('foo', help='foo help')
>>> group2 = parser.add_argument_group('group2', 'group2 description')
>>> group2.add_argument('--bar', help='bar help')
>>> parser.print_help()
usage: PROG [--bar BAR] foo

  group1:
       group1 description

       foo    foo help

  group2:
       group2 description

       --bar BAR  bar help
```

Note that any arguments not your user defined groups will end up back in the usual “positional arguments” and “optional arguments” sections.

### 15.4.5.4. Mutual exclusion
argparse.add_mutually_exclusive_group([required=False])

Create a mutually exclusive group. argparse will make sure that only one of the arguments in the mutually exclusive group was present on the command line:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> group = parser.add_mutually_exclusive_group()
>>> group.add_argument('--foo', action='store_true')
>>> group.add_argument('--bar', action='store_false')
>>> parser.parse_args(['--foo'])
Namespace(bar=True, foo=True)
>>> parser.parse_args(['--bar'])
Namespace(bar=False, foo=False)
>>> parser.parse_args(['--foo', '--bar'])
usage: PROG [-h] [-f | -b]
PROG: error: argument --bar: not allowed with argument --foo
```

The add_mutually_exclusive_group() method also accepts a required argument, to indicate that at least one of the mutually exclusive arguments is required:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> group = parser.add_mutually_exclusive_group(required=True)
>>> group.add_argument('--foo', action='store_true')
>>> group.add_argument('--bar', action='store_false')
>>> parser.parse_args([])
usage: PROG [-h] (-f | -b)
PROG: error: one of the arguments --foo --bar is required
```

Note that currently mutually exclusive argument groups do not support the title and description arguments of add_argument_group().

### 15.4.5.5. Parser defaults

ArgumentParser.set_defaults(**kwargs)

Most of the time, the attributes of the object returned by
parse_args() will be fully determined by inspecting the command-line args and the argument actions. ArgumentParser.set_defaults() allows some additional attributes that are determined without any inspection of the command-line to be added:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.set_defaults(bar=42, baz='badger')
>>> parser.parse_args(['736'])
Namespace(bar=42, baz='badger', foo=736)
```

Note that parser-level defaults always override argument-level defaults:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default='bar')
>>> parser.set_defaults(foo='spam')
>>> parser.parse_args([])
Namespace(foo='spam')
```

Parser-level defaults can be particularly useful when working with multiple parsers. See the add_subparsers() method for an example of this type.

ArgumentParser.get_default(dest)
Get the default value for a namespace attribute, as set by either add_argument() or by set_defaults():

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default='badger')
>>> parser.get_default('foo')
'badger'
```

15.4.5.6. Printing help

In most typical applications, parse_args() will take care of formatting
and printing any usage or error messages. However, several formatting methods are available:

**ArgumentParser.print_usage([file]):**

Print a brief description of how the `ArgumentParser` should be invoked on the command line. If `file` is not present, `sys.stderr` is assumed.

**ArgumentParser.print_help([file]):**

Print a help message, including the program usage and information about the arguments registered with the `ArgumentParser`. If `file` is not present, `sys.stderr` is assumed.

There are also variants of these methods that simply return a string instead of printing it:

**ArgumentParser.format_usage():**

Return a string containing a brief description of how the `ArgumentParser` should be invoked on the command line.

**ArgumentParser.format_help():**

Return a string containing a help message, including the program usage and information about the arguments registered with the `ArgumentParser`.

### 15.4.5.7. Partial parsing

**ArgumentParser.parse_known_args([args][, namespace]):**

Sometimes a script may only parse a few of the command line arguments, passing the remaining arguments on to another script or program. In these cases, the `parse_known_args()` method can be useful. It works much like `parse_args()` except that it does not produce an error when extra arguments are present. Instead, it returns a two item tuple containing the populated namespace and
the list of remaining argument strings.

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action='store_true')
>>> parser.add_argument('bar')
>>> parser.parse_known_args(['--foo', '--badger', 'BAR', 'spam']
(Namespace(bar='BAR', foo=True), ['--badger', 'spam'])
```

## 15.4.5.8. Customizing file parsing

`ArgumentParser.convert_arg_line_to_args(arg_line)`

Arguments that are read from a file (see the `fromfile_prefix_chars` keyword argument to the `ArgumentParser` constructor) are read one argument per line. `convert_arg_line_to_args()` can be overridden for fancier reading.

This method takes a single argument `arg_line` which is a string read from the argument file. It returns a list of arguments parsed from this string. The method is called once per line read from the argument file, in order.

A useful override of this method is one that treats each space-separated word as an argument:

```python
def convert_arg_line_to_args(self, arg_line):
    for arg in arg_line.split():
        if not arg.strip():
            continue
        yield arg
```
15.4.6. Upgrading optparse code

Originally, the argparse module had attempted to maintain compatibility with optparse. However, optparse was difficult to extend transparently, particularly with the changes required to support the new `nargs=` specifiers and better usage messages. When most everything in optparse had either been copy-pasted over or monkey-patched, it no longer seemed practical to try to maintain the backwards compatibility.

A partial upgrade path from optparse to argparse:

- Replace all `add_option()` calls with `ArgumentParser.add_argument()` calls.
- Replace `options, args = parser.parse_args()` with `args = parser.parse_args()` and add additional `ArgumentParser.add_argument()` calls for the positional arguments.
- Replace callback actions and the `callback_*` keyword arguments with `type` or `action` arguments.
- Replace string names for `type` keyword arguments with the corresponding type objects (e.g. `int`, `float`, `complex`, etc).
- Replace strings with implicit arguments such as `%default` or `%prog` with the standard python syntax to use dictionaries to format strings, that is, `%(default)s` and `%(prog)s`.
- Replace the OptionParser constructor `version` argument with a call to `parser.add_argument('--version', action='version', version='<the version>')`
15.5. optparse — Parser for command line options

Deprecated since version 2.7: The optparse module is deprecated and will not be developed further; development will continue with the argparse module.

New in version 2.3.

optparse is a more convenient, flexible, and powerful library for parsing command-line options than the old getopt module. optparse uses a more declarative style of command-line parsing: you create an instance of OptionParser, populate it with options, and parse the command line. optparse allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here's an example of using optparse in a simple script:

```python
from optparse import OptionParser

parser = OptionParser()
parser.add_option("-f", "--file", dest="filename",
        help="write report to FILE", metavar="FILE")
parser.add_option("-q", "--quiet",
        action="store_false", dest="verbose", default=True,
        help="don't print status messages to stdout")

(options, args) = parser.parse_args()
```

With these few lines of code, users of your script can now do the "usual thing" on the command-line, for example:

```bash
<yourscript> --file=outfile -q
```
As it parses the command line, `optparse` sets attributes of the `options` object returned by `parse_args()` based on user-supplied command-line values. When `parse_args()` returns from parsing this command line, `options.filename` will be "outfile" and `options.verbose` will be `False`. `optparse` supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q -f outfile
<yourscript> -q outfile
```

Additionally, users can run one of

```
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script’s options:

```
usage: <yourscript> [options]

options:
  -h, --help                      show this help message and exit
  -f FILE, --file=FILE            write report to FILE
  -q, --quiet                     don't print status messages to stdout
```

where the value of `yourscript` is determined at runtime (normally from `sys.argv[0]`).
15.5.1. Background

**optparse** was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

15.5.1.1. Terminology

**argument**

A string entered on the command-line, and passed by the shell to **exec1()** or **execv()**. In Python, arguments are elements of **sys.argv[1:]** (**sys.argv[0]** is the name of the program being executed). Unix shells also use the term “word”.

It is occasionally desirable to substitute an argument list other than **sys.argv[1:]**, so you should read “argument” as “an element of **sys.argv[1:]**”, or of some other list provided as a substitute for **sys.argv[1:]**.

**option**

An argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen (“-“) followed by a single letter, e.g. "-x" or "-F". Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. "-x -F" is equivalent to "-xF". The GNU project introduced "--" followed by a series of hyphen-separated words, e.g. "--file" or "--dry-run". These are the only two option syntaxes provided by **optparse**.
Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. "-pf" (this is not the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. "-file" (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. "+f", "+rgb"
- a slash followed by a letter, or a few letters, or a word, e.g. "/f", "/file"

These option syntaxes are not supported by optparse, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you’re exclusively targeting VMS, MS-DOS, and/or Windows.

**option argument**

an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With optparse, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-ffoo
--file=foo
```

Typically, a given option either takes an argument or it doesn’t. Lots of people want an “optional option arguments” feature, meaning that some options will take an argument if they see it, and won’t if they don’t. This is somewhat controversial, because it makes parsing ambiguous: if "-a" takes an optional argument
and "-b" is another option entirely, how do we interpret "-ab"? Because of this ambiguity, **optparse** does not support this feature.

**positional argument**

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

**required option**

an option that must be supplied on the command-line; note that the phrase “required option” is self-contradictory in English. **optparse** doesn’t prevent you from implementing required options, but doesn’t give you much help at it either.

For example, consider this hypothetical command-line:

```
prog -v --report /tmp/report.txt foo bar
```

"-v" and "--report" are both options. Assuming that --report takes one argument, "/tmp/report.txt" is an option argument. "foo" and "bar" are positional arguments.

### 15.5.1.2. What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn’t clear, options are usually **optional**. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main exceptions are **find**, **tar**, and **dd**—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think
about it. If it’s required, then it’s not optional! If there is a piece of information that your program absolutely requires in order to run successfully, that’s what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn’t make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

### 15.5.1.3. What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in order to run successfully, it doesn’t much matter *how* you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are
absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.
While `optparse` is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any `optparse`-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```python
from optparse import OptionParser
...
parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```python
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as `"-f"` or `"--file"`, and several option attributes that tell `optparse` what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```python
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to `add_option()` are effectively labels for the option defined by that call. For brevity, we will frequently refer to *encountering an option* on the command line; in reality, `optparse`
encounters *option strings* and looks up options from them.

Once all of your options are defined, instruct `optparse` to parse your program’s command line:

```python
(options, args) = parser.parse_args()
```

(If you like, you can pass a custom argument list to `parse_args()`, but that’s rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- `options`, an object containing values for all of your options—e.g. if "--file" takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option
- `args`, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: `action`, `type`, `dest` (destination), and `help`. Of these, `action` is the most fundamental.

**15.5.2.1. Understanding option actions**

Actions tell `optparse` what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into `optparse`; adding new actions is an advanced topic covered in section *Extending optparse*. Most actions tell `optparse` to store a value in some variable—for example, take a string from the command line and store it in an attribute of `options`.

If you don’t specify an option action, `optparse` defaults to `store`. 
The most common option action is `store`, which tells `optparse` to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```python
parser.add_option("-f", "--file",
    action="store", type="string", dest="filename"
)
```

Now let's make up a fake command line and ask `optparse` to parse it:

```python
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When `optparse` sees the option string `-f`, it consumes the next argument, "foo.txt", and stores it in `options.filename`. So, after this call to `parse_args()`, `options.filename` is "foo.txt".

Some other option types supported by `optparse` are `int` and `float`. Here's an option that expects an integer argument:

```python
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly acceptable. Also, there's no explicit action, since the default is `store`.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since `-n42` (one argument) is equivalent to `-n 42` (two arguments), the code
(options, args) = parser.parse_args(["-n42"])
print options.num

will print "42".

If you don’t specify a type, optparse assumes string. Combined with the fact that the default action is store, that means our first example can be a lot shorter:

parser.add_option("-f", "--file", dest="filename")

If you don’t supply a destination, optparse figures out a sensible default from the option strings: if the first long option string is "--foo-bar", then the default destination is foo_bar. If there are no long option strings, optparse looks at the first short option string: the default destination for "-f" is f.

optparse also includes built-in long and complex types. Adding types is covered in section Extending optparse.

15.5.2.3. Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. optparse supports them with two separate actions, store_true and store_false. For example, you might have a verbose flag that is turned on with "-v" and off with "-q":

parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")

Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)
When `optparse` encounters `-v` on the command line, it sets `options.verbose` to `True`; when it encounters `-q`, `options.verbose` is set to `False`.

### 15.5.2.4. Other actions

Some other actions supported by `optparse` are:

- **"store_const"**
  - store a constant value
- **"append"**
  - append this option's argument to a list
- **"count"**
  - increment a counter by one
- **"callback"**
  - call a specified function

These are covered in section *Reference Guide*, Reference Guide and section *Option Callbacks*.

### 15.5.2.5. Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What happens if those options are never seen? Since we didn’t supply any defaults, they are all set to `None`. This is usually fine, but sometimes you want more control. `optparse` lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want `optparse` to set `verbose` to `True` unless `-q` is seen, then we can do this:

```
parser.add_option("-v", action="store_true", dest="verbose", de
```
Since default values apply to the destination rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose", default=True)
```

Consider this:

```python
parser.add_option("-v", action="store_true", dest="verbose", default=False)
parser.add_option("-q", action="store_false", dest="verbose", default=True)
```

Again, the default value for verbose will be True: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the `set_defaults()` method of OptionParser, which you can call at any time before calling `parse_args()`:

```python
parser.set_defaults(verbose=True)
p = parser.add_option(...) (options, args) = parser.parse_args()
```

As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

### 15.5.2.6. Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a
short usage message for your whole program. Here's an OptionParser populated with user-friendly (documented) options:

```python
usage = "usage: %prog [options] arg1 arg2"
pARSER = OptionParser(usage=usage)
pARSER.add_option("-v", "--verbose",
action="store_true", dest="verbose", default=
help="make lots of noise [default]")
pARSER.add_option("-q", "--quiet",
action="store_false", dest="verbose",
help="be vewwy quiet (I'm hunting wabbits)"
PARSER.add_option("-f", "--filename",
metavar="FILE", help="write output to FILE"
PARSER.add_option("-m", "--mode",
default="intermediate",
help="interaction mode: novice, intermediate,
or expert [default: %default]")
```

If `optparse` encounters either "-h" or "--help" on the command-line, or if you just call `PARSER.print_help()`, it prints the following to standard output:

```text
usage: <yourscript> [options] arg1 arg2

options:
    -h, --help          show this help message and exit
    -v, --verbose       make lots of noise [default]
    -q, --quiet         be vewwy quiet (I'm hunting wabbits)
    -f FILE, --filename=FILE
                        write output to FILE
    -m MODE, --mode=MODE interaction mode: novice, intermediate,
    expert [default: intermediate]
```

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There's a lot going on here to help `optparse` generate the best possible help message:
• the script defines its own usage message:

```
usage = "usage: %prog [options] arg1 arg2"
```

`optparse` expands "%prog" in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

If you don’t supply a usage string, `optparse` uses a bland but sensible default: "usage: %prog [options]", which is fine if your script doesn’t take any positional arguments.

• every option defines a help string, and doesn’t worry about line-wrapping— `optparse` takes care of wrapping lines and making the help output look good.

• options that take a value indicate this fact in their automatically-generated help message, e.g. for the “mode” option:

```
-m MODE, --mode=MODE
```

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to `-m|--mode`. By default, `optparse` converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that’s not what you want—for example, the `--filename` option explicitly sets `metavar="FILE"`, resulting in this automatically-generated option description:

```
-f FILE, --filename=FILE
```

This is important for more than just saving space, though: the manually written help text uses the meta-variable “FILE” to clue the user in that there’s a connection between the semi-formal syntax “-f FILE” and the informal semantic description “write
output to FILE”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

**New in version 2.4:** Options that have a default value can include `%default` in the help string—`optparse` will replace it with `str()` of the option's default value. If an option has no default value (or the default value is `None`), `%default` expands to `none`.

When dealing with many options, it is convenient to group these options for better help output. An `OptionParser` can contain several option groups, each of which can contain several options.

Continuing with the parser defined above, adding an `OptionGroup` to a parser is easy:

```python
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your own risk
                    "It is believed that some of them bite.")
group.add_option("-g", action="store_true", help="Group option.
parser.add_option_group(group)
```

This would result in the following help output:

```
usage:  [options] arg1 arg2

options:
  -h, --help        show this help message and exit
  -v, --verbose    make lots of noise [default]
  -q, --quiet      be vewwy quiet (I'm hunting wabbits)
  -fFILE, --file=FILE write output to FILE
  -mMODE, --mode=MODE  interaction mode: one of 'novice', 'inte
                      [default], 'expert'

Dangerous Options:
Caution: use of these options is at your own risk. It is bel
some of them bite.
  -g               Group option.
```
15.5.2.7. Printing a version string

Similar to the brief usage string, `optparse` can also print a version string for your program. You have to supply the string as the `version` argument to OptionParser:

```python
parser = OptionParser(usage="%prog [-f] [-q]", version="%prog 1.0")

"%prog" is expanded just like it is in `usage`. Apart from that, `version` can contain anything you like. When you supply it, `optparse` automatically adds a "--version" option to your parser. If it encounters this option on the command line, it expands your `version` string (by replacing "%prog"), prints it to stdout, and exits.

For example, if your script is called `/usr/bin/foo`:

```
$ /usr/bin/foo --version
foo 1.0
```

The following two methods can be used to print and get the `version` string:

`OptionParser.print_version(file=None)`

Print the version message for the current program (`self.version`) to `file` (default stdout). As with `print_usage()`, any occurrence of "%prog" in `self.version` is replaced with the name of the current program. Does nothing if `self.version` is empty or undefined.

`OptionParser.get_version()`

Same as `print_version()` but returns the version string instead of printing it.

15.5.2.8. How `optparse` handles errors
There are two broad classes of errors that optparse has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to `OptionParser.add_option()`, e.g. invalid option strings, unknown option attributes, missing option attributes, etc. These are dealt with in the usual way: raise an exception (either `optparse.OptionError` or `TypeError`) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. optparse can automatically detect some user errors, such as bad option arguments (passing `-n 4x` where `-n` takes an integer argument), missing arguments (`"-n"` at the end of the command line, where `-n` takes an argument of any type). Also, you can call `OptionParser.error()` to signal an application-defined error condition:

```python
(options, args) = parser.parse_args()
[...
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
```

In either case, optparse handles the error the same way: it prints the program’s usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes "4x" to an option that takes an integer:

```
$ /usr/bin/foo -n 4x
usage: foo [options]
foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:
$ /usr/bin/foo -n
usage: foo [options]
foo: error: -n option requires an argument

optparse-generated error messages take care always to mention the
option involved in the error; be sure to do the same when calling
OptionParser.error() from your application code.

If optparse's default error-handling behaviour does not suit your
needs, you'll need to subclass OptionParser and override its exit()
and/or error() methods.

15.5.2.9. Putting it all together

Here's what optparse-based scripts usually look like:

```python
from optparse import OptionParser
[...]
def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                       help="read data from FILENAME")
    parser.add_option("-v", "--verbose",
                       action="store_true", dest="verbose")
    parser.add_option("-q", "--quiet",
                       action="store_false", dest="verbose")
    [...]
    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print "reading %s..." % options.filename
    [...]
    if __name__ == "__main__":
        main()
```
The first step in using `optparse` is to create an OptionParser instance.

```python
class optparse.OptionParser(...)
```

The OptionParser constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

`usage` (default: `"%prog [options]"`)  
The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

`option_list` (default: `[]`)  
A list of Option objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by OptionParser subclasses), but before any version or help options. Deprecated; use `add_option()` after creating the parser instead.

`option_class` (default: `optparse.Option`)  
Class to use when adding options to the parser in `add_option()`.
**version** (default: `None`)

A version string to print when the user supplies a version option. If you supply a true value for `version`, `optparse` automatically adds a version option with the single option string `"--version"`. The substring `"%prog"` is expanded the same as for `usage`.

**conflict_handler** (default: "error")

Specifies what to do when options with conflicting option strings are added to the parser; see section *Conflicts between options*.

**description** (default: `None`)

A paragraph of text giving a brief overview of your program. `optparse` reformats this paragraph to fit the current terminal width and prints it when the user requests help (after `usage`, but before the list of options).

**formatter** (default: a new `IndentedHelpFormatter`)

An instance of `optparse.HelpFormatter` that will be used for printing help text. `optparse` provides two concrete classes for this purpose: `IndentedHelpFormatter` and `TitledHelpFormatter`.

**add_help_option** (default: `True`)

If true, `optparse` will add a help option (with option strings `"-h"` and `"--help"`) to the parser.

**prog**

The string to use when expanding `"%prog"` in `usage` and `version` instead of `os.path.basename(sys.argv[0])`.

**epilog** (default: `None`)

A paragraph of help text to print after the option help.
15.5.3.2. Populating the parser

There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section Tutorial. `add_option()` can be called in one of two ways:

- pass it an Option instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the Option constructor), and it will create the Option instance for you.

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [
    make_option("-f", "--filename",
                action="store", type="string", dest="filename"),
    make_option("-q", "--quiet",
                action="store_false", dest="verbose"),
]
parser = OptionParser(option_list=option_list)
```

`make_option()` is a factory function for creating Option instances; currently it is an alias for the Option constructor. A future version of `optparse` may split Option into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate Option directly.)

15.5.3.3. Defining options

Each Option instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.
The canonical way to create an Option instance is with the `add_option()` method of `OptionParser`.

OptionParser.remove_option(`opt_str[, ...], attr=value[, ...]`)

To define an option with only a short option string:

```python
parser.add_option("-f", attr=value, ...)  
```

And to define an option with only a long option string:

```python
parser.add_option("--foo", attr=value, ...)  
```

The keyword arguments define attributes of the new Option object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an `OptionError` exception explaining your mistake.

An option's `action` determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

- "store"
  - store this option's argument (default)
- "store_const"
  - store a constant value
- "store_true"
  - store a true value
- "store_false"
  - store a false value
- "append"
append this option’s argument to a list

"append_const"
append a constant value to a list

"count"
increment a counter by one

"callback"
call a specified function

"help"
print a usage message including all options and the documentation for them

(If you don’t supply an action, the default is "store". For this action, you may also supply type and dest option attributes; see Standard option actions.)

As you can see, most actions involve storing or updating a value somewhere. optparse always creates a special object for this, conventionally called options (it happens to be an instance of optparse.Values). Option arguments (and various other values) are stored as attributes of this object, according to the dest (destination) option attribute.

For example, when you call

    parser.parse_args()

one of the first things optparse does is create the options object:

    options = Values()

If one of the options in this parser is defined with

    parser.add_option("-f", "--file", action="store", type="string"
and the command-line being parsed includes any of the following:

- ffoo
- f foo
--file=foo
--file foo

then optparse, on seeing this option, will do the equivalent of

```python
options.filename = "foo"
```

The `type` and `dest` option attributes are almost as important as `action`, but `action` is the only one that makes sense for all options.

### 15.5.3.4. Option attributes

The following option attributes may be passed as keyword arguments to `OptionParser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, optparse raises `OptionError`.

**Option. action**

(default: "store")

Determines optparse's behaviour when this option is seen on the command line; the available options are documented [here](#).

**Option. type**

(default: "string")

The argument type expected by this option (e.g., "string" or "int"); the available option types are documented [here](#).

**Option. dest**

(default: derived from option strings)
If the option’s action implies writing or modifying a value somewhere, this tells optparse where to write it: `dest` names an attribute of the `options` object that optparse builds as it parses the command line.

**Option. default**

The value to use for this option’s destination if the option is not seen on the command line. See also `OptionParser.set_defaults()`.

**Option. nargs**

(default: 1)

How many arguments of type `type` should be consumed when this option is seen. If > 1, optparse will store a tuple of values to `dest`.

**Option. const**

For actions that store a constant value, the constant value to store.

**Option. choices**

For options of type "choice", the list of strings the user may choose from.

**Option. callback**

For options with action "callback", the callable to call when this option is seen. See section `Option Callbacks` for detail on the arguments passed to the callable.

**Option. callback_args**

**Option. callback_kwargs**

Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.
Option. **help**

Help text to print for this option when listing all available options after the user supplies a help option (such as `--help`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `optparse.SUPPRESS_HELP`.

Option. **metavar**

(default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section *Tutorial* for an example.

### 15.5.3.5. Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`'s behaviour; a few have required attributes, which you must specify for any option using that action.

- **"store"** [relevant: `type`, `dest`, `nargs`, `choices`]

  The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs > 1`, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a tuple. See the *Standard option types* section.

  If `choices` is supplied (a list or tuple of strings), the type defaults to "choice".

  If `type` is not supplied, it defaults to "string".

  If `dest` is not supplied, `optparse` derives a destination from the first long option string (e.g., `"--foo-bar"` implies `foo_bar`). If
there are no long option strings, `optparse` derives a destination from the first short option string (e.g., `"-f"` implies `f`).

Example:

```
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

`optparse` will set

```
options.f = "foo.txt"
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- "store_const" [required: `const`; relevant: `dest`]

The value `const` is stored in `dest`.

Example:

```
parser.add_option("-q", "--quiet",
    action="store_const", const=0, dest="verb"
parser.add_option("-v", "--verbose",
    action="store_const", const=1, dest="verb"
parser.add_option("--noisy",
    action="store_const", const=2, dest="verb"
```

If "--noisy" is seen, `optparse` will set

```
options.verbos e = 2
```

- "store_true" [relevant: `dest`]

A special case of "store_const" that stores a true value to dest.

- "store_false" [relevant: dest]

Like "store_true", but stores a false value.

Example:

```python
cparser.add_option("--clobber", action="store_true", dest="clobber")
cparser.add_option("--no-clobber", action="store_false", dest="clobber")
```

- "append" [relevant: type, dest, nargs, choices]

The option must be followed by an argument, which is appended to the list in dest. If no default value for dest is supplied, an empty list is automatically created when optparse first encounters this option on the command-line. If nargs > 1, multiple arguments are consumed, and a tuple of length nargs is appended to dest.

The defaults for type and dest are the same as for the "store" action.

Example:

```python
cparser.add_option("-t", "--tracks", action="append", type="
```

If "-t3" is seen on the command-line, optparse does the equivalent of:

```python
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, "--tracks=4" is seen, it does:
options.tracks.append(int("4"))

- **"append_const"** [required: `const`; relevant: `dest`]
  
  Like **"store_const"**, but the value `const` is appended to `dest`; as with **"append"**, `dest` defaults to `None`, and an empty list is automatically created the first time the option is encountered.

- **"count"** [relevant: `dest`]
  
  Increment the integer stored at `dest`. If no default value is supplied, `dest` is set to zero before being incremented the first time.

  Example:

  ```python
  parser.add_option("-v", action="count", dest="verbosity")
  ```

  The first time **"-v"** is seen on the command line, `optparse` does the equivalent of:

  ```python
  options.verbosity = 0
  options.verbosity += 1
  ```

  Every subsequent occurrence of **"-v"** results in

  ```python
  options.verbosity += 1
  ```

- **"callback"** [required: `callback`; relevant: `type`, `nargs`, `callback_args`, `callback_kwargs`]
  
  Call the function specified by `callback`, which is called as

  ```python
  func(option, opt_str, value, parser, *args, **kwargs)
  ```

  See section **Option Callbacks** for more detail.
"help"

Prints a complete help message for all the options in the current option parser. The help message is constructed from the `usage` string passed to `OptionParser`'s constructor and the `help` string passed to every option.

If no `help` string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value `optparse.SUPPRESS_HELP`.

`optparse` automatically adds a `help` option to all `OptionParser`s, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

# usually, a help option is added automatically, but that can be suppressed using the add_help_option argument
parser = OptionParser(add_help_option=False)

parser.add_option("-h", "--help", action="help")
parser.add_option("-v", action="store_true", dest="verbose",
               help="Be moderately verbose")
parser.add_option("--file", dest="filename",
               help="Input file to read data from")
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If `optparse` sees either "-h" or "--help" on the command line, it will print something like the following help message to stdout (assuming `sys.argv[0]` is "foo.py"):

```
usage: foo.py [options]

options:
    -h, --help              Show this help message and exit
    -v                      Be moderately verbose
```
After printing the help message, `optparse` terminates your process with `sys.exit(0)`.

- "version"

Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the `print_version()` method of OptionParser. Generally only relevant if the `version` argument is supplied to the OptionParser constructor. As with help options, you will rarely create version options, since `optparse` automatically adds them when needed.

### 15.5.3.6. Standard option types

`optparse` has six built-in option types: "string", "int", "long", "choice", "float" and "complex". If you need to add new option types, see section *Extending optparse*.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type "int" or "long") are parsed as follows:

- if the number starts with `0x`, it is parsed as a hexadecimal number
- if the number starts with `0`, it is parsed as an octal number
- if the number starts with `0b`, it is parsed as a binary number
- otherwise, the number is parsed as a decimal number

The conversion is done by calling either `int()` or `long()` with the appropriate base (2, 8, 10, or 16). If this fails, so will `optparse`,
although with a more useful error message.

"float" and "complex" option arguments are converted directly with float() and complex(), with similar error-handling.

"choice" options are a subtype of "string" options. The choices` option attribute (a sequence of strings) defines the set of allowed option arguments. optparse.check_choice() compares user-supplied option arguments against this master list and raises OptionValueError if an invalid string is given.

### 15.5.3.7. Parsing arguments

The whole point of creating and populating an OptionParser is to call its parse_args() method:

```python
(options, args) = parser.parse_args(args=None, values=None)
```

where the input parameters are

**args**

the list of arguments to process (default: sys.argv[1:])

**values**

object to store option arguments in (default: a new instance of optparse.Values)

and the return values are

**options**

the same object that was passed in as values, or the optparse.Values instance created by optparse

**args**

the leftover positional arguments after all options have been processed
The most common usage is to supply neither keyword argument. If you supply `values`, it will be modified with repeated `setattr()` calls (roughly one for every option argument stored to an option destination) and returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the OptionParser’s `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

### 15.5.3.8. Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what’s there. `OptionParser` provides several methods to help you out:

- `OptionParser.disable_interspersed_args()`  
  Set parsing to stop on the first non-option. For example, if "-a" and "-b" are both simple options that take no arguments, `optparse` normally accepts this syntax:

  ```
  prog -a arg1 -b arg2
  ```

  and treats it as equivalent to

  ```
  prog -a -b arg1 arg2
  ```

  To disable this feature, call `disable_interspersed_args()`. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

  Use this if you have a command processor which runs another command which has options of its own and you want to make
sure these options don't get confused. For example, each command might have a different set of options.

OptionParser.enable_interspersed_args()
Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. This is the default behavior.

OptionParser.get_option(opt_str)
Returns the Option instance with the option string opt_str, or None if no options have that option string.

OptionParser.has_option(opt_str)
Return true if the OptionParser has an option with option string opt_str (e.g., "-q" or "--verbose").

OptionParser.remove_option(opt_str)
If the OptionParser has an option corresponding to opt_str, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If opt_str does not occur in any option belonging to this OptionParser, raises ValueError.

15.5.3.9. Conflicts between options
If you're not careful, it's easy to define options with conflicting option strings:

parser.add_option("-n", "--dry-run", ...)
[...]
parser.add_option("-n", "--noisy", ...)

(This is particularly true if you've defined your own OptionParser subclass with some standard options.)
Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```python
parser = OptionParser(..., conflict_handler=handler)
```
or with a separate call:

```python
parser.set_conflict_handler(handler)
```

The available conflict handlers are:

- "error" (default)
  - assume option conflicts are a programming error and raise `OptionConflictError`
- "resolve"
  - resolve option conflicts intelligently (see below)

As an example, let's define an `OptionParser` that resolves conflicts intelligently and add conflicting options to it:

```python
parser = OptionParser(conflict_handler="resolve")
png = OptionParser("-n", "--dry-run", ..., help="do no harm")
png = OptionParser("-n", "--noisy", ..., help="be noisy")
```

At this point, `optparse` detects that a previously-added option is already using the "-n" option string. Since `conflict_handler` is "resolve", it resolves the situation by removing "-n" from the earlier option's list of option strings. Now "--dry-run" is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```plaintext
options:
  --dry-run        do no harm
[...]
```
-n, --noisy   be noisy

It’s possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, optparse removes that option completely, so it doesn’t show up in help text or anywhere else. Carrying on with our existing OptionParser:

```python
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original -n/--dry-run option is no longer accessible, so optparse removes it, leaving this help text:

```
options:
  [...]
  -n, --noisy   be noisy
  --dry-run     new dry-run option
```

### 15.5.3.10. Cleanup

OptionParser instances have several cyclic references. This should not be a problem for Python’s garbage collector, but you may wish to break the cyclic references explicitly by calling `destroy()` on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.

### 15.5.3.11. Other methods

OptionParser supports several other public methods:

```python
OptionParser.set_usage(usage)
```

Set the usage string according to the rules described above for the `usage` constructor keyword argument. Passing `None` sets the default usage string; use `optparse.SUPPRESS_USAGE` to suppress a
usage message.

OptionParser. **print_usage**(file=None)
Print the usage message for the current program (self.usage) to file (default stdout). Any occurrence of the string "%prog" in self.usage is replaced with the name of the current program. Does nothing if self.usage is empty or not defined.

OptionParser. **get_usage()**
Same as print_usage() but returns the usage string instead of printing it.

OptionParser. **set_defaults**(dest=value, ...)
Set default values for several option destinations at once. Using set_defaults() is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```python
parser.add_option("--advanced", action="store_const",
    dest="mode", const="advanced",
    default="novice")  # overridden below
parser.add_option("--novice", action="store_const",
    dest="mode", const="novice",
    default="advanced")  # overrides above set
```

To avoid this confusion, use set_defaults():

```python
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const",
    dest="mode", const="advanced")
parser.add_option("--novice", action="store_const",
    dest="mode", const="novice")
```
15.5.4. Option Callbacks

When \texttt{optparse}'s built-in actions and types aren't quite enough for your needs, you have two choices: extend \texttt{optparse} or define a callback option. Extending \texttt{optparse} is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the "\texttt{callback}" action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

15.5.4.1. Defining a callback option

As always, the easiest way to define a callback option is by using the \texttt{OptionParser.add_option()} method. Apart from \texttt{action}, the only option attribute you must specify is \texttt{callback}, the function to call:

\begin{verbatim}
parser.add_option("-c", action="callback", callback=my_callback)
\end{verbatim}

\texttt{callback} is a function (or other callable object), so you must have already defined \texttt{my\_callback()} when you create this callback option. In this simple case, \texttt{optparse} doesn't even know if \texttt{-c} takes any arguments, which usually means that the option takes no arguments—the mere presence of \texttt{-c} on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this section.

\texttt{optparse} always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via
**callback_args** and **callback_kwargs**. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

**type**

has its usual meaning: as with the "store" or "append" actions, it instructs **optparse** to consume one argument and convert it to **type**. Rather than storing the converted value(s) anywhere, though, **optparse** passes it to your callback function.

**nargs**

also has its usual meaning: if it is supplied and > 1, **optparse** will consume **nargs** arguments, each of which must be convertible to **type**. It then passes a tuple of converted values to your callback.

**callback_args**

a tuple of extra positional arguments to pass to the callback

**callback_kwargs**

a dictionary of extra keyword arguments to pass to the callback

### 15.5.4.2. How callbacks are called

All callbacks are called as follows:

```python
func(option, opt_str, value, parser, *args, **kwargs)
```

where

**option**

is the Option instance that's calling the callback
opt_str

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, opt_str will be the full, canonical option string—e.g. if the user puts "--foo" on the command-line as an abbreviation for "--foobar", then opt_str will be "--foobar".)

value

is the argument to this option seen on the command-line. optparse will only expect an argument if type is set; the type of value will be the type implied by the option's type. If type for this option is None (no argument expected), then value will be None. If nargs > 1, value will be a tuple of values of the appropriate type.

parser

is the OptionParser instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

parser.largs

the current list of leftover arguments, ie. arguments that have been consumed but are neither options nor option arguments. Feel free to modify parser.largs, e.g. by adding more arguments to it. (This list will become args, the second return value of parse_args().)

parser.rargs

the current list of remaining arguments, ie. with opt_str and value (if applicable) removed, and only the arguments following them still there. Feel free to modify parser.rargs, e.g. by consuming more arguments.

parser.values

the object where option values are by default stored (an instance of optparse.OptionValues). This lets callbacks use
the same mechanism as the rest of **optparse** for storing option values; you don’t need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

**args**
is a tuple of arbitrary positional arguments supplied via the **callback_args** option attribute.

**kwargs**
is a dictionary of arbitrary keyword arguments supplied via **callback_kwargs**.

### 15.5.4.3. Raising errors in a callback

The callback function should raise **OptionValueError** if there are any problems with the option or its argument(s). **optparse** catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what he did wrong.

### 15.5.4.4. Callback example 1: trivial callback

Here’s an example of a callback option that takes no arguments, and simply records that the option was seen:

```python
def record_foo_seen(option, opt_str, value, parser):
    parser.values.saw_foo = True

parser.add_option("--foo", action="callback", callback=record_foo_seen)
```

Of course, you could do that with the **"store_true"** action.

### 15.5.4.5. Callback example 2: check option order
Here's a slightly more interesting example: record the fact that "-a" is seen, but blow up if it comes after "-b" in the command-line.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1

parser.add_option("-a", action="callback", callback=check_order)
parser.add_option("-b", action="store_true", dest="b")
```

15.5.4.6. Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if "-b" has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b" % opt_str)
    setattr(parser.values, option.dest, 1)

parser.add_option("-a", action="callback", callback=check_order)
parser.add_option("-b", action="store_true", dest="b")
parser.add_option("-c", action="callback", callback=check_order)
```

15.5.4.7. Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you’re not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when moon is full" % opt_str)
    setattr(parser.values, option.dest, 1)

parser.add_option("--foo",
    action="callback", callback=check_moon, dest="foo")

(The definition of is_moon_full() is left as an exercise for the reader.)

15.5.4.8. Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a "store" or "append" option: if you define type, then the option takes one argument that must be convertible to that type; if you further define nargs, then the option takes nargs arguments.

Here's an example that just emulates the standard "store" action:

def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)

parser.add_option("--foo",
    action="callback", callback=store_value, type="int", nargs=3, dest="foo")

Note that optparse takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don’t need a callback for this example.)

15.5.4.9. Callback example 6: variable arguments
Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as *optparse* doesn’t provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that *optparse* normally handles for you. In particular, callbacks should implement the conventional rules for bare "--" and "-" arguments:

- either "--" or "-" can be option arguments
- bare "--" (if not the argument to some option): halt command-line processing and discard the "--"
- bare "-" (if not the argument to some option): halt command-line processing but keep the "-" (append it to `parser.largs`)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact implementation you choose will be based on which trade-offs you're willing to make for your application (which is why *optparse* doesn’t support this sort of thing directly).

Nevertheless, here’s a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    value = []

    def floatable(str):
        try:
            float(str)
            return True
        except ValueError:
            return False

    for arg in parser.rargs:
        # stop on --foo like options
        if arg[:2] == "--" and len(arg) > 2:
            break
```
# stop on -a, but not on -3 or -3.0
if arg[:1] == "-" and len(arg) > 1 and not floatable(arg):
    break
value.append(arg)

del parser.rargs[:len(value)]
setattr(parser.values, option.dest, value)

[...]  
parser.add_option("-c", "--callback", dest="vararg_attr",
    action="callback", callback=vararg_callback)
15.5.5. Extending optparse

Since the two major controlling factors in how optparse interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

15.5.5.1. Adding new types

To add new types, you need to define your own subclass of optparse's Option class. This class has a couple of attributes that define optparse's types: TYPES and TYPE_CHECKER.

Option. TYPES

A tuple of type names; in your subclass, simply define a new tuple TYPES that builds on the standard one.

Option. TYPE_CHECKER

A dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```python
def check_mytype(option, opt, value)
```

where option is an Option instance, opt is an option string (e.g., "-f"), and value is the string from the command line that must be checked and converted to your desired type. check_mytype() should return an object of the hypothetical type mytype. The value returned by a type-checking function will wind up in the OptionValues instance returned by OptionParser.parse_args(), or be passed to a callback as the value parameter.

Your type-checking function should raise OptionValueError if it encounters any problems. OptionValueError takes a single string
argument, which is passed as-is to OptionParser's error() method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a "complex" option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because optparse 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the TYPE_CHECKER class attribute of your Option subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError(
            "option %s: invalid complex value: %r" % (opt, value))
```

Finally, the Option subclass:

```python
class MyOption(Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```

(If we didn’t make a copy() of Option.TYPE_CHECKER, we would end up modifying the TYPE_CHECKER attribute of optparse’s Option class. This being Python, nothing stops you from doing that except good manners and common sense.)
That’s it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to instruct your OptionParser to use `MyOption` instead of `Option`:

```python
parser = OptionParser(option_class=MyOption)
parsed.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to `OptionParser`; if you don’t use `add_option()` in the above way, you don’t need to tell `OptionParser` which option class to use:

```python
option_list = [MyOption("-c", action="store", type="complex", dest="c")]
parsed = OptionParser(option_list=option_list)
```

### 15.5.5.2. Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

**“store” actions**
- actions that result in `optparse` storing a value to an attribute of the current `OptionValues` instance; these options require a `dest` attribute to be supplied to the Option constructor.

**“typed” actions**
- actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the Option constructor.

These are overlapping sets: some default “store” actions are "store", "store_const", "append", and "count", while the default “typed” actions are "store", "append", and "callback".

When you add an action, you need to categorize it by listing it in at
least one of the following class attributes of Option (all are lists of strings):

Option. **ACTIONS**
   
   All actions must be listed in ACTIONS.

Option. **STORE_ACTIONS**
   
   “store” actions are additionally listed here.

Option. **TYPED_ACTIONS**
   
   “typed” actions are additionally listed here.

Option. **ALWAYS_TYPED_ACTIONS**
   
   Actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that `optparse` assigns the default type, "string", to options with no explicit type whose action is listed in **ALWAYS_TYPED_ACTIONS**.

In order to actually implement your new action, you must override Option's `take_action()` method and add a case that recognizes your action.

For example, let's add an "extend" action. This is similar to the standard "append" action, but instead of taking a single value from the command-line and appending it to an existing list, "extend" will take multiple values in a single comma-delimited string, and extend an existing list with them. That is, if "--names" is an "extend" option of type "string", the command line

```
--names=foo,bar --names blah --names abc,xyz
```

would result in a list

```
["foo", "bar", "blah", "abc", "xyz"]
```
Again we define a subclass of Option:

```python
class MyOption(Option):

    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTIONS = OptionSTORE_ACTIONS + ("extend",)
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend",)
    ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS + ("extend",)

    def take_action(self, action, dest, opt, value, values, parser):
        if action == "extend":
            lvalue = value.split("",")
            values.ensure_value(dest, []).extend(lvalue)
        else:
            Option.take_action(
                self, action, dest, opt, value, values, parser)
```

Features of note:

- "extend" both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`.

- to ensure that `optparse` assigns the default type of "string" to "extend" actions, we put the "extend" action in `ALWAYS_TYPED_ACTIONS` as well.

- `MyOption.take_action()` implements just this one new action, and passes control back to `Option.take_action()` for the standard `optparse` actions.

- `values` is an instance of the `optparse_parser.Values` class, which provides the very useful `ensure_value()` method. `ensure_value()` is essentially `getattr()` with a safety valve; it is called as

```python
values.ensure_value(attr, value)
```
If the attr attribute of values doesn’t exist or is None, then ensure_value() first sets it to value, and then returns ‘value. This is very handy for actions like "extend", "append", and "count", all of which accumulate data in a variable and expect that variable to be of a certain type (a list for the first two, an integer for the latter). Using ensure_value() means that scripts using your action don’t have to worry about setting a default value for the option destinations in question; they can just leave the default as None and ensure_value() will take care of getting it right when it's needed.
15.6. getopt — C-style parser for command line options

**Note:** The `getopt` module is a parser for command line options whose API is designed to be familiar to users of the C `getopt()` function. Users who are unfamiliar with the C `getopt()` function or who would like to write less code and get better help and error messages should consider using the `argparse` module instead.

This module helps scripts to parse the command line arguments in `sys.argv`. It supports the same conventions as the Unix `getopt()` function (including the special meanings of arguments of the form '-' and '--'). Long options similar to those supported by GNU software may be used as well via an optional third argument.

A more convenient, flexible, and powerful alternative is the `optparse` module.

This module provides two functions and an exception:

```python
getopt.getopt(args, options[, long_options])
```

Parses command line options and parameter list. `args` is the argument list to be parsed, without the leading reference to the running program. Typically, this means `sys.argv[1:]`. `options` is the string of option letters that the script wants to recognize, with options that require an argument followed by a colon (':'; i.e., the same format that Unix `getopt()` uses).

**Note:** Unlike GNU `getopt()`, after a non-option argument, all further arguments are considered also non-options. This is similar to the way non-GNU Unix systems work.
long_options, if specified, must be a list of strings with the names of the long options which should be supported. The leading '---' characters should not be included in the option name. Long options which require an argument should be followed by an equal sign ('='). Optional arguments are not supported. To accept only long options, options should be an empty string. Long options on the command line can be recognized so long as they provide a prefix of the option name that matches exactly one of the accepted options. For example, if long_options is ['foo', 'frob'], the option --fo will match as --foo, but --f will not match uniquely, so GetoptError will be raised.

The return value consists of two elements: the first is a list of (option, value) pairs; the second is the list of program arguments left after the option list was stripped (this is a trailing slice of args). Each option-and-value pair returned has the option as its first element, prefixed with a hyphen for short options (e.g., '-x') or two hyphens for long options (e.g., '--long-option'), and the option argument as its second element, or an empty string if the option has no argument. The options occur in the list in the same order in which they were found, thus allowing multiple occurrences. Long and short options may be mixed.

getopt. gnu_getopt(args, options[, long_options])
This function works like getopt(), except that GNU style scanning mode is used by default. This means that option and non-option arguments may be intermixed. The getopt() function stops processing options as soon as a non-option argument is encountered.

If the first character of the option string is '+', or if the environment variable POSIXLY_CORRECT is set, then option processing stops as soon as a non-option argument is
encountered.

New in version 2.3.

**exception** `getopt.GetoptError`

This is raised when an unrecognized option is found in the argument list or when an option requiring an argument is given none. The argument to the exception is a string indicating the cause of the error. For long options, an argument given to an option which does not require one will also cause this exception to be raised. The attributes `msg` and `opt` give the error message and related option; if there is no specific option to which the exception relates, `opt` is an empty string.

*Changed in version 1.6:* Introduced `GetoptError` as a synonym for `error`.

**exception** `getopt.error`

Alias for `GetoptError`; for backward compatibility.

An example using only Unix style options:

```python
>>> import getopt
>>> args = '-a -b -cfoo -d bar a1 a2'.split()
>>> args
['-a', '-b', '-cfoo', '-d', 'bar', 'a1', 'a2']
>>> optlist, args = getopt.getopt(args, 'abc:d:')[0]
>>> optlist
[('-a', ''), ('-b', ''), ('-c', 'foo'), ('-d', 'bar')]
>>> args
['a1', 'a2']
```

Using long option names is equally easy:

```python
>>> s = '--condition=foo --testing --output-file abc.def -x a1
>>> args = s.split()
>>> args
['--condition=foo', '--testing', '--output-file', 'abc.def', '-x', 'a1']
```
In a script, typical usage is something like this:

```python
import getopt, sys

def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], "ho:v", ["help", "output="])
    except getopt.GetoptError, err:
        # print help information and exit:
        print str(err) # will print something like "option -a n
        usage()
        sys.exit(2)
    output = None
    verbose = False
    for o, a in opts:
        if o == "-v":
            verbose = True
        elif o in ("-h", "--help"):
            usage()
            sys.exit()
        elif o in ("-o", "--output"):
            output = a
        else:
            assert False, "unhandled option"
    # ...

if __name__ == "__main__":
    main()
```

Note that an equivalent command line interface could be produced with less code and more informative help and error messages by using the `argparse` module:

```python
import argparse
```
See also:

Module argparse

Alternative command line option and argument parsing library.
15.7. logging — Logging facility for Python

New in version 2.3.

This module defines functions and classes which implement a flexible error logging system for applications.

Logging is performed by calling methods on instances of the Logger class (hereafter called loggers). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named “scan” is the parent of loggers “scan.text”, “scan.html” and “scan.pdf”. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

Logged messages also have levels of importance associated with them. The default levels provided are DEBUG, INFO, WARNING, ERROR and CRITICAL. As a convenience, you indicate the importance of a logged message by calling an appropriate method of Logger. The methods are debug(), info(), warning(), error() and critical(), which mirror the default levels. You are not constrained to use these levels: you can specify your own and use a more general Logger method, log(), which takes an explicit level argument.
15.7.1. Logging tutorial

The key benefit of having the logging API provided by a standard library module is that all Python modules can participate in logging, so your application log can include messages from third-party modules.

It is, of course, possible to log messages with different verbosity levels or to different destinations. Support for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, or OS-specific logging mechanisms are all supported by the standard module. You can also create your own log destination class if you have special requirements not met by any of the built-in classes.

15.7.1.1. Simple examples

Most applications are probably going to want to log to a file, so let's start with that case. Using the `basicConfig()` function, we can set up the default handler so that debug messages are written to a file (in the example, we assume that you have the appropriate permissions to create a file called `example.log` in the current directory):

```python
import logging
LOG_FILENAME = 'example.log'
logging.basicConfig(filename=LOG_FILENAME, level=logging.DEBUG)
logging.debug('This message should go to the log file')
```

And now if we open the file and look at what we have, we should find the log message:

```
DEBUG:root:This message should go to the log file
```
If you run the script repeatedly, the additional log messages are appended to the file. To create a new file each time, you can pass a `filemode` argument to `basicConfig()` with a value of `'w'`. Rather than managing the file size yourself, though, it is simpler to use a `RotatingFileHandler`:

```python
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```

The result should be 6 separate files, each with part of the log history for the application:

```
logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5
```
The most current file is always `logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing backup files is renamed to increment the suffix (.1 becomes .2, etc.) and the .6 file is erased.

Obviously this example sets the log length much much too small as an extreme example. You would want to set `maxBytes` to an appropriate value.

Another useful feature of the logging API is the ability to produce different messages at different log levels. This allows you to instrument your code with debug messages, for example, but turning the log level down so that those debug messages are not written for your production system. The default levels are `NOTSET`, `DEBUG`, `INFO`, `WARNING`, `ERROR` and `CRITICAL`.

The logger, handler, and log message call each specify a level. The log message is only emitted if the handler and logger are configured to emit messages of that level or lower. For example, if a message is `CRITICAL`, and the logger is set to `ERROR`, the message is emitted. If a message is a `WARNING`, and the logger is set to produce only `ERRORS`, the message is not emitted:

```python
import logging
import sys

LEVELS = {'debug': logging.DEBUG,
          'info': logging.INFO,
          'warning': logging.WARNING,
          'error': logging.ERROR,
          'critical': logging.CRITICAL}

if len(sys.argv) > 1:
    level_name = sys.argv[1]
    level = LEVELS.get(level_name, logging.NOTSET)
    logging.basicConfig(level=level)

logging.debug('This is a debug message')
```
Run the script with an argument like 'debug' or 'warning' to see which messages show up at different levels:

```bash
$ python logging_level_example.py debug
DEBUG:root:This is a debug message
INFO:root:This is an info message
WARNING:root:This is a warning message
ERROR:root:This is an error message
CRITICAL:root:This is a critical error message

$ python logging_level_example.py info
INFO:root:This is an info message
WARNING:root:This is a warning message
ERROR:root:This is an error message
CRITICAL:root:This is a critical error message
```

You will notice that these log messages all have root embedded in them. The logging module supports a hierarchy of loggers with different names. An easy way to tell where a specific log message comes from is to use a separate logger object for each of your modules. Each new logger “inherits” the configuration of its parent, and log messages sent to a logger include the name of that logger. Optionally, each logger can be configured differently, so that messages from different modules are handled in different ways. Let’s look at a simple example of how to log from different modules so it is easy to trace the source of the message:

```python
import logging

logging.basicConfig(level=logging.WARNING)

logger1 = logging.getLogger('package1.module1')
logger2 = logging.getLogger('package2.module2')

logger1.warning('This message comes from one module')
logger2.warning('And this message comes from another module')
```
And the output:

```
$ python logging_modules_example.py
WARNING:package1.module1:This message comes from one module
WARNING:package2.module2:And this message comes from another module
```

There are many more options for configuring logging, including different log message formatting options, having messages delivered to multiple destinations, and changing the configuration of a long-running application on the fly using a socket interface. All of these options are covered in depth in the library module documentation.

## 15.7.1.2. Loggers

The logging library takes a modular approach and offers the several categories of components: loggers, handlers, filters, and formatters. Loggers expose the interface that application code directly uses. Handlers send the log records to the appropriate destination. Filters provide a finer grained facility for determining which log records to send on to a handler. Formatters specify the layout of the resultant log record.

**Logger** objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

- **Logger.setLevel()** specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity
level and critical is the highest built-in severity. For example, if the severity level is info, the logger will handle only info, warning, error, and critical messages and will ignore debug messages.

- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. This tutorial does not address filters.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to **kwargs, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.
- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call this method only from an exception handler.
- `Logger.log()` takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with
the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of foo, loggers with names of foo.bar, foo.bar.baz, and foo.bam are all descendants of foo. Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed.

15.7.1.3. Handlers

**Handler** objects are responsible for dispatching the appropriate log messages (based on the log messages’ severity) to the handler’s specified destination. Logger objects can add zero or more handler objects to themselves with an **addHandler()** method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types; this tutorial uses only **StreamHandler** and **FileHandler** in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The **Handler.setLevel()** method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two **setLevel()**
methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- `setFormatter()` selects a Formatter object for this handler to use.
- `addFilter()` and `removeFilter()` respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of `Handler`. Instead, the `Handler` class is a base class that defines the interface that all handlers should have and establishes some default behavior that child classes can use (or override).

### 15.7.1.4. Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base `logging.Handler` class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes two optional arguments: a message format string and a date format string. If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end.

The message format string uses `%(<dictionary key>)s` styled string substitution; the possible keys are documented in `Formatter Objects`.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:
15.7.1.5. Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the `fileConfig()` function.
3. Creating a dictionary of configuration information and passing it to the `dictConfig()` function.

The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```python
import logging

# create logger
logger = logging.getLogger("simple_example")
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter("%(asctime)s - %(name)s - %(levelname)s - %(message)s")

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# "application" code
logger.debug("debug message")
logger.info("info message")
logger.warn("warn message")
logger.error("error message")
logger.critical("critical message")
```
Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message
```

The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with the only difference being the names of the objects:

```python
import logging
import logging.config

logging.config.fileConfig("logging.conf")

# create logger
logger = logging.getLogger("simpleExample")

# "application" code
logger.debug("debug message")
logger.info("info message")
logger.warn("warn message")
logger.error("error message")
logger.critical("critical message")
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter
```
The output is nearly identical to that of the non-config-file-based example:

$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn message
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical message

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either handlers.WatchedFileHandler (relative to the logging module) or mypackage.mymodule.MyHandler (for a class defined in package
`mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

*Changed in version 2.7.*

In Python 2.7, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense for your application.

Here’s an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```yaml
version: 1
formatters:
simple:
    format: format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
handlers:
    console:
        class: logging.StreamHandler
        level: DEBUG
        formatter: simple
        stream: ext://sys.stdout
loggers:
simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
    level: DEBUG
    handlers: [console]
```
For more information about logging using a dictionary, see `Configuration functions`.

### 15.7.1.6. Configuring Logging for a Library

When developing a library which uses logging, some consideration needs to be given to its configuration. If the using application does not use logging, and library code makes logging calls, then a one-off message “No handlers could be found for logger X.Y.Z” is printed to the console. This message is intended to catch mistakes in logging configuration, but will confuse an application developer who is not aware of logging by the library.

In addition to documenting how a library uses logging, a good way to configure library logging so that it does not cause a spurious message is to add a handler which does nothing. This avoids the message being printed, since a handler will be found: it just doesn’t produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler can be simply defined as follows:

```python
import logging
class NullHandler(logging.Handler):
    def emit(self, record):
        pass
```

An instance of this handler should be added to the top-level logger of the logging namespace used by the library. If all logging by a library `foo` is done using loggers with names matching “foo.x.y”, then the code:
import logging

h = NullHandler()
logging.getLogger("foo").addHandler(h)

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be “orgname.foo” rather than just “foo”.

*New in version 2.7.*

The **NullHandler** class was not present in previous versions, but is now included, so that it need not be defined in library code.
15.7.2. Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CRITICAL</td>
<td>50</td>
</tr>
<tr>
<td>ERROR</td>
<td>40</td>
</tr>
<tr>
<td>WARNING</td>
<td>30</td>
</tr>
<tr>
<td>INFO</td>
<td>20</td>
</tr>
<tr>
<td>DEBUG</td>
<td>10</td>
</tr>
<tr>
<td>NOTSET</td>
<td>0</td>
</tr>
</tbody>
</table>

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger's level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the `LogRecord` class. When a logger decides to actually log an event, a `LogRecord` instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of `handlers`, which are instances of subclasses of the `Handler` class. Handlers are responsible for ensuring that a logged message (in the form of a `LogRecord`) ends up in a particular location.
(or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed LogRecord instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the addHandler() method of Logger). In addition to any handlers directly associated with a logger, all handlers associated with all ancestors of the logger are called to dispatch the message (unless the propagate flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the emit() method is used to send the message to its destination. Most user-defined subclasses of Handler will need to override this emit().
15.7.3. Useful Handlers

In addition to the base Handler class, many useful subclasses are provided:

1. **StreamHandler** instances send error messages to streams (file-like objects).
2. **FileHandler** instances send error messages to disk files.
3. **BaseRotatingHandler** is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use **RotatingFileHandler** or **TimedRotatingFileHandler**.
4. **RotatingFileHandler** instances send error messages to disk files, with support for maximum log file sizes and log file rotation.
5. **TimedRotatingFileHandler** instances send error messages to disk files, rotating the log file at certain timed intervals.
6. **SocketHandler** instances send error messages to TCP/IP sockets.
7. **DatagramHandler** instances send error messages to UDP sockets.
8. **SMTPHandler** instances send error messages to a designated email address.
9. **SysLogHandler** instances send error messages to a Unix syslog daemon, possibly on a remote machine.
10. **NTEventLogHandler** instances send error messages to a Windows NT/2000/XP event log.
11. **MemoryHandler** instances send error messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. **HTTPHandler** instances send error messages to an HTTP server using either **GET** or **POST** semantics.
13. **WatchedFileHandler** instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does
not support the underlying mechanism used.

14. **NullHandler** instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the “No handlers could be found for logger XXX” message which can be displayed if the library user has not configured logging. See *Configuring Logging for a Library* for more information.

*New in version 2.7.*

The **NullHandler** class was not present in previous versions.

The **NullHandler**, **StreamHandler** and **FileHandler** classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the **Formatter** class. They are initialized with a format string suitable for use with the `%` operator and a dictionary.

For formatting multiple messages in a batch, instances of **BufferingFormatter** can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of **Filter** can be added to both **Logger** and **Handler** instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic **Filter** functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger
and its children are allowed through the filter, and all others dropped.
15.7.4. Module-Level Functions

In addition to the classes described above, there are a number of module-level functions.

logging.getLogger([name])

Return a logger with the specified name or, if no name is specified, return a logger which is the root logger of the hierarchy. If specified, the name is typically a dot-separated hierarchical name like “a”, “a.b” or “a.b.c.d”. Choice of these names is entirely up to the developer who is using logging.

All calls to this function with a given name return the same logger instance. This means that logger instances never need to be passed between different parts of an application.

logging.getLoggerClass()

Return either the standard Logger class, or the last class passed to setLoggerClass(). This function may be called from within a new class definition, to ensure that installing a customised Logger class will not undo customisations already applied by other code. For example:

class MyLogger(logging.getLoggerClass()):
    # ... override behaviour here

logging.debug(msg[, *args[, **kwargs]])

Logs a message with level DEBUG on the root logger. The msg is the message format string, and the args are the arguments which are merged into msg using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)
There are two keyword arguments in `kwargs` which are inspected: `exc_info` which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by `sys.exc_info()`) is provided, it is used; otherwise, `sys.exc_info()` is called to get the exception information.

The other optional keyword argument is `extra` which can be used to pass a dictionary which is used to populate the `__dict__` of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:

```python
FORMAT = "%(asctime)-15s %(clientip)s %(user)-8s %(message)s"
logging.basicConfig(format=FORMAT)
d = {'clientip': '192.168.0.1', 'user': 'fbloggs'}
logging.warning("Protocol problem: %s", "connection reset",

would print something like

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs  Protocol problem: connection reset
```

The keys in the dictionary passed in `extra` should not clash with the keys used by the logging system. (See the `Formatter` documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the `Formatter` has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case, you always need to pass the `extra` dictionary with these keys.
While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized **Formatters** would be used with particular **Handlers**.

*Changed in version 2.5: extra was added.*

```python
logging.info(msg[, args[, kwargs]])
```
Logs a message with level **INFO** on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.warning(msg[, args[, kwargs]])
```
Logs a message with level **WARNING** on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.error(msg[, args[, kwargs]])
```
Logs a message with level **ERROR** on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.critical(msg[, args[, kwargs]])
```
Logs a message with level **CRITICAL** on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.exception(msg[, args])
```
Logs a message with level **ERROR** on the root logger. The arguments are interpreted as for `debug()`. Exception info is added to the logging message. This function should only be called from an exception handler.
logging.\texttt{log}(\textit{level}, \textit{msg}[\texttt{,*args}[\texttt{,**kwargs}]])

Logs a message with level \textit{level} on the root logger. The other arguments are interpreted as for \texttt{debug}().

logging.\texttt{disable}(\textit{lvl})

Provides an overriding level \textit{lvl} for all loggers which takes precedence over the logger’s own level. When the need arises to temporarily throttle logging output down across the whole application, this function can be useful. Its effect is to disable all logging calls of severity \textit{lvl} and below, so that if you call it with a value of \texttt{INFO}, then all \texttt{INFO} and \texttt{DEBUG} events would be discarded, whereas those of severity \texttt{WARNING} and above would be processed according to the logger’s effective level.

logging.\texttt{addLevelName}(\textit{lvl}, \textit{levelName})

Associates level \textit{lvl} with text \textit{levelName} in an internal dictionary, which is used to map numeric levels to a textual representation, for example when a \texttt{Formatter} formats a message. This function can also be used to define your own levels. The only constraints are that all levels used must be registered using this function, levels should be positive integers and they should increase in increasing order of severity.

logging.\texttt{getLevelName}(\textit{lvl})

Returns the textual representation of logging level \textit{lvl}. If the level is one of the predefined levels \texttt{CRITICAL}, \texttt{ERROR}, \texttt{WARNING}, \texttt{INFO} or \texttt{DEBUG} then you get the corresponding string. If you have associated levels with names using \texttt{addLevelName()} then the name you have associated with \textit{lvl} is returned. If a numeric value corresponding to one of the defined levels is passed in, the corresponding string representation is returned. Otherwise, the string “Level \texttt{\texttt{%s}}” \texttt{\texttt{%} lvl} is returned.

logging.\texttt{makeLogRecord}(\textit{attrdict})
Creates and returns a new `LogRecord` instance whose attributes are defined by `attrdict`. This function is useful for taking a pickled `LogRecord` attribute dictionary, sent over a socket, and reconstituting it as a `LogRecord` instance at the receiving end.

**logging.basicConfig(**kwargs)**

Does basic configuration for the logging system by creating a `StreamHandler` with a default `Formatter` and adding it to the root logger. The functions `debug()`, `info()`, `warning()`, `error()` and `critical()` will call `basicConfig()` automatically if no handlers are defined for the root logger.

This function does nothing if the root logger already has handlers configured for it.

*Changed in version 2.4:* Formerly, `basicConfig()` did not take any keyword arguments.

The following keyword arguments are supported.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>filename</code></td>
<td>Specifies that a FileHandler be created, using the specified filename, rather than a StreamHandler.</td>
</tr>
<tr>
<td><code>filemode</code></td>
<td>Specifies the mode to open the file, if filename is specified (if filemode is unspecified, it defaults to ‘a’).</td>
</tr>
<tr>
<td><code>format</code></td>
<td>Use the specified format string for the handler.</td>
</tr>
<tr>
<td><code>datefmt</code></td>
<td>Use the specified date/time format.</td>
</tr>
<tr>
<td><code>level</code></td>
<td>Set the root logger level to the specified level.</td>
</tr>
<tr>
<td><code>stream</code></td>
<td>Use the specified stream to initialize the StreamHandler. Note that this argument is incompatible with ‘filename’ - if both are present, ‘stream’ is ignored.</td>
</tr>
</tbody>
</table>
logging.shutdown()

Informs the logging system to perform an orderly shutdown by flushing and closing all handlers. This should be called at application exit and no further use of the logging system should be made after this call.

logging.setLoggerClass(klass)

Tells the logging system to use the class klass when instantiating a logger. The class should define __init__() such that only a name argument is required, and the __init__() should call Logger.__init__(). This function is typically called before any loggers are instantiated by applications which need to use custom logger behavior.

See also:

PEP 282 - A Logging System

The proposal which described this feature for inclusion in the Python standard library.

Original Python logging package

This is the original source for the logging package. The version of the package available from this site is suitable for use with Python 1.5.2, 2.1.x and 2.2.x, which do not include the logging package in the standard library.
15.7.5. Logger Objects

Loggers have the following attributes and methods. Note that Loggers are never instantiated directly, but always through the module-level function `logging.getLogger(name)`.

**Logger. **`propagate`

If this evaluates to false, logging messages are not passed by this logger or by its child loggers to the handlers of higher level (ancestor) loggers. The constructor sets this attribute to 1.

**Logger. **`setLevel(lvl)`

Sets the threshold for this logger to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a logger is created, the level is set to `NOTSET` (which causes all messages to be processed when the logger is the root logger, or delegation to the parent when the logger is a non-root logger). Note that the root logger is created with level `WARNING`.

The term “delegation to the parent” means that if a logger has a level of `NOTSET`, its chain of ancestor loggers is traversed until either an ancestor with a level other than `NOTSET` is found, or the root is reached.

If an ancestor is found with a level other than `NOTSET`, then that ancestor’s level is treated as the effective level of the logger where the ancestor search began, and is used to determine how a logging event is handled.

If the root is reached, and it has a level of `NOTSET`, then all messages will be processed. Otherwise, the root’s level will be used as the effective level.

**Logger. **`isEnabledFor(lvl)`
Indicates if a message of severity lvl would be processed by this logger. This method checks first the module-level level set by `logging.disable(lvl)` and then the logger's effective level as determined by `getEffectiveLevel()`.

**Logger.** `getEffectiveLevel()`

Indicates the effective level for this logger. If a value other than `NOTSET` has been set using `setLevel()`, it is returned. Otherwise, the hierarchy is traversed towards the root until a value other than `NOTSET` is found, and that value is returned.

**Logger.** `getChild(suffix)`

Returns a logger which is a descendant to this logger, as determined by the suffix. Thus, `logging.getLogger('abc').getChild('def.ghi')` would return the same logger as would be returned by `logging.getLogger('abc.def.ghi')`. This is a convenience method, useful when the parent logger is named using e.g. `__name__` rather than a literal string.

*New in version 2.7.*

**Logger.** `debug(msg[, *args[, **kwargs]])`

Logs a message with level `DEBUG` on this logger. The `msg` is the message format string, and the `args` are the arguments which are merged into `msg` using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)

There are two keyword arguments in `kwars` which are inspected: `exc_info` which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by `sys.exc_info()`) is
provided, it is used; otherwise, \texttt{sys.exc_info()} is called to get the exception information.

The other optional keyword argument is \textit{extra} which can be used to pass a dictionary which is used to populate the \texttt{__dict__} of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:

```python
FORMAT = "%(asctime)-15s %(clientip)s %(user)-8s %(message)s"
logging.basicConfig(format=FORMAT)
d = { 'clientip' : '192.168.0.1', 'user' : 'fbloggs' }
logger = logging.getLogger("tcpserver")
logger.warning("Protocol problem: %s", "connection reset", extra=d)
```

would print something like

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol problem: connection reset
```

The keys in the dictionary passed in \textit{extra} should not clash with the keys used by the logging system. (See the \texttt{Formatter} documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the \texttt{Formatter} has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case, you always need to pass the \textit{extra} dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where
