will cause the source distribution and the Windows installer to be uploaded to PyPI. Note that these will be uploaded even if they are built using an earlier invocation of `setup.py`, but that only distributions named on the command line for the invocation including the **upload** command are uploaded.

The **upload** command uses the username, password, and repository URL from the `$HOME/.pypirc` file (see section *The .pypirc file* for more on this file). If a **register** command was previously called in the same command, and if the password was entered in the prompt, **upload** will reuse the entered password. This is useful if you do not want to store a clear text password in the `$HOME/.pypirc` file.

You can specify another PyPI server with the **--repository=*url*** option:

```python
python setup.py sdist bdist_wininst upload -r http://example.com/pypi
```

See section *The .pypirc file* for more on defining several servers.
You can use the --sign option to tell `upload` to sign each uploaded file using GPG (GNU Privacy Guard). The `gpg` program must be available for execution on the system `PATH`. You can also specify which key to use for signing using the `--identity=*name*` option.

Other `upload` options include `--repository=` or `--repository=` where `url` is the url of the server and `section` the name of the section in `$HOME/.pypirc`, and `--show-response` (which displays the full response text from the PyPI server for help in debugging upload problems).
7.1. PyPI package display

The `long_description` field plays a special role at PyPI. It is used by
the server to display a home page for the registered package.

If you use the reStructuredText syntax for this field, PyPI will parse it
and display an HTML output for the package home page.

The `long_description` field can be attached to a text file located in
the package:

```python
from distutils.core import setup
setup(name='Distutils',
      long_description=open('README.txt'))
```

In that case, `README.txt` is a regular reStructuredText text file located
in the root of the package besides `setup.py`.

To prevent registering broken reStructuredText content, you can use
the `rst2html` program that is provided by the `docutils` package and
check the `long_description` from the command line:

```bash
$ python setup.py --long-description | rst2html.py > output.html
```

docutils will display a warning if there’s something wrong with your
syntax.
This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

See also:

Distutils Cookbook
Collection of recipes showing how to achieve more control over distutils.
8.1. Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, `foo.py` in this example:

```
<root>/
    setup.py
    foo.py
```

(In all diagrams in this section, `<root>` will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```python
from distutils.core import setup
setup(name='foo',
    version='1.0',
    py_modules=['foo'],
)
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules `foo` and `bar`, your setup might look like this:

```
<root>/
    setup.py
```
and the setup script might be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      py_modules=['foo', 'bar'],
)
```

You can put module source files into another directory, but if you have enough modules to do that, it’s probably easier to specify modules by package rather than listing them individually.
8.2. Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an __init__.py file).

The setup script from the last example could also be written as

```python
from distutils.core import setup
setup(name='foobar',
     version='1.0',
     packages=[''],
)
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
    setup.py
    src/
        foo.py
        bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```python
from distutils.core import setup
setup(name='foobar',
     version='1.0',
     package_dir={'': 'src'},
     packages=[''],
)
```
More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the foo and bar modules belong in package foobar, one way to layout your source tree is

```
<root/>
    setup.py
    foobar/
        __init__.py
        foo.py
        bar.py
```

This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```
from distutils.core import setup
setup(name='foobar',  
      version='1.0',  
      packages=['foobar'],
      )
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the src directory holds modules in the foobar package:

```
<root/>
    setup.py
    src/
        __init__.py
        foo.py
        bar.py
```

an appropriate setup script would be

```
from distutils.core import setup
setup(name='foobar',  
      version='1.0',  
      package_dir={'foobar': 'src'},  
      packages=['foobar'],
      )
```
Or, you might put modules from your main package right in the distribution root:

```python
<root>/
 setup.py
 __init__.py
 foo.py
 bar.py
```

in which case your setup script would be

```python
from distutils.core import setup
setup(name='foobar',
     version='1.0',
     package_dir={'foobar': ''},
     packages=['foobar'],
)
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does not scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```python
<root>/
 setup.py
 foobar/
     __init__.py
     foo.py
     bar.py
     subfoo/
         __init__.py
         blah.py
```

then the corresponding setup script would be

```python
from distutils.core import setup
```
setup(name='foobar',
     version='1.0',
     packages=['foobar', 'foobar.subfoo'],
)

(Again, the empty string in package_dir stands for the current directory.)
8.3. Single extension module

Extension modules are specified using the \textit{ext\_modules} option. \texttt{package\_dir} has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

\begin{verbatim}
<root>/
  setup.py
  foo.c
\end{verbatim}

If the \texttt{foo} extension belongs in the root package, the setup script for this could be

\begin{verbatim}
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
  version='1.0',
  ext_modules=[Extension('foo', ['foo.c'])],
)
\end{verbatim}

If the extension actually belongs in a package, say \texttt{foopkg}, then

With exactly the same source tree layout, this extension can be put in the \texttt{foopkg} package simply by changing the name of the extension:

\begin{verbatim}
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
  version='1.0',
  ext_modules=[Extension('foopkg.foo', ['foo.c'])],
)
\end{verbatim}
9. Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within setup.py scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to .py files as a convenience.

Most distutils command implementations are subclasses of the Command class from distutils.cmd. New commands may directly inherit from Command, while replacements often derive from Command indirectly, directly subclassing the command they are replacing. Commands are required to derive from Command.
9.1. Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your setup.py script, and cause the distutils.core.setup() function use them:

```python
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

    # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
      ...
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing setup.py scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration option, command_packages (command-line option --command-packages), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils
options, this can be specified on the command line or in a configuration file. This option can only be set in the [global] section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the distutils.command package. When setup.py is run with the option --command-packages distcmds,buildcmds, however, the packages distutils.command, distcmds, and buildcmds will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command bdist_openpkg could be implemented by the class distcmds.bdist_openpkg.bdist_openpkg or buildcmds.bdist_openpkg.bdist_openpkg.
9.2. Adding new distribution types

Commands that create distributions (files in the dist/ directory) need to add (command, filename) pairs to self.distribution.dist_files so that upload can upload it to PyPI. The filename in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.
10. Command Reference
10.1. Installing modules: the \texttt{install}\newline command family

The install command ensures that the build commands have been run and then runs the subcommands \texttt{install\_lib}, \texttt{install\_data} and \texttt{install\_scripts}.

10.1.1. \texttt{install\_data}

This command installs all data files provided with the distribution.

10.1.2. \texttt{install\_scripts}

This command installs all (Python) scripts in the distribution.
11. API Reference
The `distutils.core` module is the only module that needs to be installed to use the Distutils. It provides the `setup()` (which is called from the setup script). Indirectly provides the `distutils.dist.Distribution` and `distutils.cmd.Command` class.

`distutils.core.setup(arguments)`

The basic do-everything function that does most everything you could ever ask for from a Distutils method. See XXXXX

The setup function takes a large number of arguments. These are laid out in the following table.

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>The name of the package</td>
<td>a string</td>
</tr>
<tr>
<td>version</td>
<td>The version number of the package</td>
<td>See <code>distutils.version</code></td>
</tr>
<tr>
<td>description</td>
<td>A single line describing the package</td>
<td>a string</td>
</tr>
<tr>
<td>long_description</td>
<td>Longer description of the package</td>
<td>a string</td>
</tr>
<tr>
<td>author</td>
<td>The name of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>author_email</td>
<td>The email address of the package author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer</strong></td>
<td>the package author</td>
<td></td>
</tr>
<tr>
<td>---------------</td>
<td>-------------------</td>
<td></td>
</tr>
</tbody>
</table>

**maintainer_email**

The name of the current maintainer, if different from the author

<table>
<thead>
<tr>
<th><strong>url</strong></th>
<th>A URL for the package (homepage)</th>
</tr>
</thead>
</table>

**download_url**

A URL to download the package

<table>
<thead>
<tr>
<th><strong>packages</strong></th>
<th>A list of Python packages that distutils will manipulate</th>
</tr>
</thead>
</table>

**py_modules**

A list of Python modules that distutils will manipulate

<table>
<thead>
<tr>
<th><strong>scripts</strong></th>
<th>A list of standalone script files to be built and installed</th>
</tr>
</thead>
</table>

<table>
<thead>
<tr>
<th><strong>py_modules</strong></th>
<th>A list of Python</th>
</tr>
</thead>
</table>
| **ext_modules** | extensions to be built | A list of instances of `distutils.core.Extension`
| **classifiers** | A list of categories for the package | The list of available categorizations: [http://pypi.python.org/pypi?:action=list_classifiers](http://pypi.python.org/pypi?:action=list_classifiers)
| **distclass** | the `Distribution` class to use | A subclass of `distutils.core.Distribution`
| **script_name** | The name of the setup.py script - defaults to `sys.argv[0]` | a string
| **script_args** | Arguments to supply to the setup script | a list of strings
| **options** | default options for the setup script | a string
| **license** | The license for the package | a string
| **keywords** | Descriptive meta-data, see [PEP 314](http://www.python.org/doc/pep-0314/) | [PEP 314](http://www.python.org/doc/pep-0314/)
| **platforms** | | |
| **cmdclass** | A mapping of command names to `Command` subclasses | a dictionary
| **data_files** | A list of data files to install | a list |
**package_dir**

A mapping of package to directory names

---

distutils.core.run_setup(script_name[, script_args=None, stop_after='run'])

Run a setup script in a somewhat controlled environment, and return the distutils.dist.Distribution instance that drives things. This is useful if you need to find out the distribution metadata (passed as keyword args from script to setup()), or the contents of the config files or command-line.

**script_name** is a file that will be run with execfile() sys.argv[0] will be replaced with script for the duration of the call. **script_args** is a list of strings; if supplied, sys.argv[1:] will be replaced by script_args for the duration of the call.

**stop_after** tells setup() when to stop processing; possible values:

<table>
<thead>
<tr>
<th>value</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>init</td>
<td>Stop after the Distribution instance has been created and populated with the keyword arguments to setup()</td>
</tr>
<tr>
<td>config</td>
<td>Stop after config files have been parsed (and their data stored in the Distribution instance)</td>
</tr>
<tr>
<td>commandline</td>
<td>Stop after the command-line (sys.argv[1:] or script_args) have been parsed (and the data stored in the Distribution instance.)</td>
</tr>
<tr>
<td>run</td>
<td>Stop after all commands have been run (the same as if setup() had been called in the usual way). This is the default value.</td>
</tr>
</tbody>
</table>

In addition, the distutils.core module exposed a number of classes that live elsewhere.
• **Extension** from `distutils.extension`
• **Command** from `distutils.cmd`
• **Distribution** from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.

**class** `distutils.core.Extension`

The `Extension` class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor:

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>the full name of the extension, including any packages — ie. <em>not</em> a filename or pathname, but Python dotted name</td>
<td>string</td>
</tr>
<tr>
<td>sources</td>
<td>list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the <code>build_ext</code> command as source for a Python extension.</td>
<td>string</td>
</tr>
<tr>
<td>include_dirs</td>
<td>list of directories to search for C/C++ header files (in Unix)</td>
<td>string</td>
</tr>
<tr>
<td><strong>define_macros</strong></td>
<td>Form for portability) list of macros to define; each macro is defined using a 2-tuple <code>(name, value)</code>, where <code>value</code> is either the string to define it to or <code>None</code> to define it without a particular value (equivalent of <code>#define FOO</code> in source or <code>-DFOO</code> on Unix C compiler command line)</td>
<td>(string, string) tuple or <code>(name, None)</code></td>
</tr>
<tr>
<td>-------------------</td>
<td>---------------------------------------------------------------------------------</td>
<td>---------------------------------------------</td>
</tr>
<tr>
<td><strong>undef_macros</strong></td>
<td>List of macros to undefine explicitly</td>
<td>string</td>
</tr>
<tr>
<td><strong>library_dirs</strong></td>
<td>List of directories to search for C/C++ libraries at link time</td>
<td>string</td>
</tr>
<tr>
<td><strong>libraries</strong></td>
<td>List of library names (not filenames or paths) to link against</td>
<td>string</td>
</tr>
<tr>
<td><strong>runtime_library_dirs</strong></td>
<td>List of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)</td>
<td>string</td>
</tr>
<tr>
<td><strong>extra_objects</strong></td>
<td>List of extra files to link with (e.g. object files not implied by <code>sources</code>, static library that must be explicitly specified, binary resource files, etc.)</td>
<td>string</td>
</tr>
<tr>
<td>any extra platform- and compiler-specific information to use</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Variable</strong></td>
<td><strong>Description</strong></td>
<td><strong>Type</strong></td>
</tr>
<tr>
<td>-------------------</td>
<td>---------------------------------------------------------------------------------</td>
<td>----------</td>
</tr>
<tr>
<td><code>extra_compile_args</code></td>
<td>when compiling the source files in <code>sources</code>. For platforms and compilers where a command line makes sense, this is typically a list of command-line arguments, but for other platforms it could be anything.</td>
<td><code>string</code></td>
</tr>
<tr>
<td><code>extra_link_args</code></td>
<td>any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for <code>extra_compile_args</code>.</td>
<td><code>string</code></td>
</tr>
<tr>
<td><code>export_symbols</code></td>
<td>list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: <code>init</code> + <code>extension_name</code>.</td>
<td><code>string</code></td>
</tr>
<tr>
<td><code>depends</code></td>
<td>list of files that the extension depends on.</td>
<td><code>string</code></td>
</tr>
<tr>
<td><code>language</code></td>
<td>extension language (i.e. <code>'c'</code>, <code>'c++'</code>, <code>'objc'</code>). Will be detected from the source extensions if not provided.</td>
<td><code>string</code></td>
</tr>
</tbody>
</table>
class distutils.core.Distribution

A Distribution describes how to build, install and package up a Python software package.

See the setup() function for a list of keyword arguments accepted by the Distribution constructor. setup() creates a Distribution instance.

class distutils.core.Command

A Command class (or rather, an instance of one of its subclasses) implement a single distutils command.
11.2. distutils.ccompiler — CCompiler base class

This module provides the abstract base class for the \texttt{CCompiler} classes. A \texttt{CCompiler} instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

\texttt{distutils.ccompiler.\texttt{gen\_lib\_options}(\texttt{compiler}, \texttt{library\_dirs}, \texttt{runtime\_library\_dirs, libraries})}

Generate linker options for searching library directories and linking with specific libraries. \texttt{libraries} and \texttt{library\_dirs} are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

\texttt{distutils.ccompiler.\texttt{gen\_preprocess\_options}(\texttt{macros}, \texttt{include\_dirs})}

Generate C pre-processor options (\texttt{-D}, \texttt{-U}, \texttt{-I}) as used by at least two types of compilers: the typical Unix compiler and Visual C++. \texttt{macros} is the usual thing, a list of 1- or 2-tuples, where \texttt{(name,)} means undefine (\texttt{-U}) macro \texttt{name}, and \texttt{(name, value)} means define (\texttt{-D}) macro \texttt{name} to \texttt{value}. \texttt{include\_dirs} is just a list of directory names to be added to the header file search path (\texttt{-I}). Returns a list of command-line options suitable for either Unix compilers or Visual C++.

\texttt{distutils.ccompiler.\texttt{get\_default\_compiler}(\texttt{osname}, \texttt{platform})}
Determine the default compiler to use for the given platform.

`osname` should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and `platform` the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

```python
distutils.ccompiler.new_compiler(plat=None, compiler=None, verbose=0, dry_run=0, force=0)
```

Factory function to generate an instance of some CCompiler subclass for the supplied platform/compiler combination. `plat` defaults to `os.name` (e.g. `posix`, `nt`), and `compiler` defaults to the default compiler for that platform. Currently only `posix` and `nt` are supported, and the default compilers are “traditional Unix interface” (`UnixCCompiler` class) and Visual C++ (`MSVCCompiler` class). Note that it’s perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for `compiler`, `plat` is ignored.

```python
distutils.ccompiler.show_compilers()
```

Print list of available compilers (used by the `--help-compiler` options to `build`, `build_ext`, `build_clib`).

```python
class distutils.ccompiler.CCompiler([verbose=0, dry_run=0, force=0])
```

The abstract base class `CCompiler` defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each
instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are verbose (show verbose output), dry_run (don’t actually execute the steps) and force (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don’t want to instantiate CCompiler or one of its subclasses directly – use the distutils.CCompiler.new_compiler() factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

**add_include_dir(dir)**
Add dir to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to add_include_dir().

**set_include_dirs(dirs)**
Set the list of directories that will be searched to dirs (a list of strings). Overrides any preceding calls to add_include_dir(); subsequent calls to add_include_dir() add to the list passed to set_include_dirs(). This does not affect any list of standard include directories that the compiler may search by default.

**add_library(libname)**
Add \textit{libname} to the list of libraries that will be included in all links driven by this compiler object. Note that \textit{libname} should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to \texttt{add_library()} and/or \texttt{set_libraries()}. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

\texttt{set_libraries(libnames)}

Set the list of libraries to be included in all links driven by this compiler object to \texttt{libnames} (a list of strings). This does not affect any standard system libraries that the linker may include by default.

\texttt{add_library_dir(dir)}

Add \texttt{dir} to the list of directories that will be searched for libraries specified to \texttt{add_library()} and \texttt{set_libraries()}. The linker will be instructed to search for libraries in the order they are supplied to \texttt{add_library_dir()} and/or \texttt{set_library_dirs()}.

\texttt{set_library_dirs(dirs)}

Set the list of library search directories to \texttt{dirs} (a list of strings). This does not affect any standard library search path that the linker may search by default.

\texttt{add_runtime_library_dir(dir)}

Add \texttt{dir} to the list of directories that will be searched for shared libraries at runtime.

\texttt{set_runtime_library_dirs(dirs)}
Set the list of directories to search for shared libraries at runtime to `dirs` (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

**define_macro**(name[, value=None])
Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter `value` should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used (XXX true? does ANSI say anything about this?)

**undefine_macro**(name)
Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by `define_macro()` and undefined by `undefine_macro()` the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to `compile()`), then that takes precedence.

**add_link_object**(object)
Add `object` to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler object.

**set_link_objects**(objects)
Set the list of object files (or analogues) to be included in every link to `objects`. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of
compiler options, providing some functionality similar to GNU autoconf.

detect_language(sources)
  Detect the language of a given file, or list of files. Uses the instance attributes language_map (a dictionary), and language_order (a list) to do the job.

find_library_file(dirs, lib[, debug=0])
  Search the specified list of directories for a static or shared library file lib and return the full path to that file. If debug is true, look for a debugging version (if that makes sense on the current platform). Return None if lib wasn’t found in any of the specified directories.

has_function(funcname[, includes=None, include_dirs=None, libraries=None, library_dirs=None])
  Return a boolean indicating whether funcname is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

library_dir_option(dir)
  Return the compiler option to add dir to the list of directories searched for libraries.

library_option(lib)
  Return the compiler option to add dir to the list of libraries linked into the shared library or executable.

runtime_library_dir_option(dir)
  Return the compiler option to add dir to the list of directories searched for runtime libraries.

set_executables(**args)
Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the ‘executables’ class attribute), but most will have:

<table>
<thead>
<tr>
<th>attribute</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>compiler</td>
<td>the C/C++ compiler</td>
</tr>
<tr>
<td>linker_so</td>
<td>linker used to create shared objects and libraries</td>
</tr>
<tr>
<td>linker_exe</td>
<td>linker used to create binary executables</td>
</tr>
<tr>
<td>archiver</td>
<td>static library creator</td>
</tr>
</tbody>
</table>

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See `distutils.util.split_quoted()`.)

The following methods invoke stages in the build process.

```python
compile(sources[], output_dir=None, macros=None, include_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, depends=None)
```

Compile one or more source files. Generates object files (e.g. transforms a `.c` file to a `.o` file.)

`sources` must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. `MSVCCompiler` can handle resource files in `sources`). Return a list of object filenames, one per source filename in `sources`. Depending on the implementation, not all source files will necessarily be
compiled, but all corresponding object filenames will be returned.

If `output_dir` is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if `output_dir` is `build`, then it would compile to `build/foo/bar.o`.

`macros`, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

`include_dirs`, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

`debug` is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

`extra_preargs` and `extra_postargs` are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn’t cut the mustard.

`depends`, if given, is a list of filenames that all targets depend on. If a source file is older than any file in depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.
Raises :obj:`CompileError` on failure.

.. code-block:: python

    create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])

    Link a bunch of stuff together to create a static library file. The
    "bunch of stuff" consists of the list of object files supplied as
    :obj:`objects`, the extra object files supplied to :meth:`add_link_object`
    and/or :meth:`set_link_objects`, the libraries supplied to
    :meth:`add_library` and/or :meth:`set_libraries`, and the libraries
    supplied as :obj:`libraries` (if any).

    :param objects: List of object files.
    :param output_libname: Library name.
    :param output_dir: Directory where the library file will be put.
    :param debug: Debugging information will be included in the library (note that on most platforms, it is the compile step where this matters: the debug flag is included here just for consistency).
    :param target_lang: Target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

    Raises :obj:`LibError` on failure.

.. code-block:: python

    link(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])

    Link a bunch of stuff together to create an executable or
    shared library file.
The “bunch of stuff” consists of the list of object files supplied as objects. `output_filename` should be a filename. If `output_dir` is supplied, `output_filename` is relative to it (i.e. `output_filename` can provide directory components if needed).

*libraries* is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. *foo* becomes *libfoo.a* on Unix and *foo.lib* on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

*library_dirs*, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to `add_library_dir()` and/or `set_library_dirs()`. *runtime_library_dirs* is a list of directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at runtime. (This may only be relevant on Unix.)

*export_symbols* is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

*debug* is as for `compile()` and `create_static_lib()`, with the slight distinction that it actually matters on most platforms (as opposed to `create_static_lib()`, which includes a `debug` flag mostly for form’s sake).

*extra_preargs* and *extra_postargs* are as for `compile()` (except of course that they supply command-line arguments for the particular linker being used).

*target_lang* is the target language for which the given objects
are being compiled. This allows specific linkage time treatment of certain languages.

Raises \texttt{LinkError} on failure.

\texttt{link\_executable}(\texttt{objects, output\_progname}, \texttt{output\_dir=None, libraries=None, library\_dirs=None, runtime\_library\_dirs=None, debug=0, extra\_preargs=None, extra\_postargs=None, target\_lang=None})

Link an executable. \texttt{output\_progname} is the name of the file executable, while \texttt{objects} are a list of object filenames to link in. Other arguments are as for the \texttt{link()} method.

\texttt{link\_shared\_lib}(\texttt{objects, output\_libname}, \texttt{output\_dir=None, libraries=None, library\_dirs=None, runtime\_library\_dirs=None, export\_symbols=None, debug=0, extra\_preargs=None, extra\_postargs=None, build\_temp=None, target\_lang=None})

Link a shared library. \texttt{output\_libname} is the name of the output library, while \texttt{objects} is a list of object filenames to link in. Other arguments are as for the \texttt{link()} method.

\texttt{link\_shared\_object}(\texttt{objects, output\_filename}, \texttt{output\_dir=None, libraries=None, library\_dirs=None, runtime\_library\_dirs=None, export\_symbols=None, debug=0, extra\_preargs=None, extra\_postargs=None, build\_temp=None, target\_lang=None})

Link a shared object. \texttt{output\_filename} is the name of the shared object that will be created, while \texttt{objects} is a list of object filenames to link in. Other arguments are as for the \texttt{link()} method.

\texttt{preprocess}(\texttt{source, output\_file=None, macros=None, include\_dirs=None, extra\_preargs=None, extra\_postargs=None})
Preprocess a single C/C++ source file, named in `source`. Output will be written to file named `output_file`, or `stdout` if `output_file` not supplied. `macros` is a list of macro definitions as for `compile()`, which will augment the macros set with `define_macro()` and `undefine_macro()`. `include_dirs` is a list of directory names that will be added to the default list, in the same way as `add_include_dir()`.

Raises `PreprocessError` on failure.

The following utility methods are defined by the `CCompiler` class, for use by the various concrete subclasses.

```python
executable_filename(basename[, strip_dir=0, output_dir=''])
```

Returns the filename of the executable for the given `basename`. Typically for non-Windows platforms this is the same as the basename, while Windows will get a `.exe` added.

```python
library_filename(libname[, lib_type='static', strip_dir=0, output_dir=''])
```

Returns the filename for the given library name on the current platform. On Unix a library with `lib_type` of `static` will typically be of the form `liblibname.a`, while a `lib_type` of `dynamic` will be of the form `liblibname.so`.

```python
object_filenames(source_filenames[, strip_dir=0, output_dir=''])
```

Returns the name of the object files for the given source files. `source_filenames` should be a list of filenames.

```python
shared_object_filename(basename[, strip_dir=0, output_dir=''])
```

Returns the name of a shared object file for the given file
name *basename*.

**execute**(*func, args[, msg=None, level=1]*)

Invokes `distutils.util.execute()` This method invokes a Python function *func* with the given arguments *args*, after logging and taking into account the *dry_run* flag. XXX see also.

**spawn**(*cmd*)

Invokes `distutils.util.spawn()` This invokes an external process to run the given command. XXX see also.

**mkpath**(*name[, mode=511]*)

Invokes `distutils.dir_util.mkpath()` This creates a directory and any missing ancestor directories. XXX see also.

**move_file**(*src, dst*)

Invokes `distutils.file_util.move_file()` Renames *src* to *dst*. XXX see also.

**announce**(*msg[, level=1]*)

Write a message using `distutils.log.debug()` XXX see also.

**warn**(*msg*)

Write a warning message *msg* to standard error.

**debug_print**(*msg*)

If the *debug* flag is set on this *CCompiler* instance, print *msg* to standard output, otherwise do nothing.
This module provides the *UnixCCompiler* class, a subclass of *CCompiler* that handles the typical Unix-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-l?lib`
- library search directories specified with `-Ldir`
- compile handled by `cc` (or similar) executable with `-c` option: compiles `.c` to `.o`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc` `-shared`
11.4. distutils.msvccompiler — Microsoft Compiler

This module provides `MSVCCompiler`, an implementation of the abstract `CCompiler` class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

`MSVCCompiler` will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables `DISTUTILS_USE_SDK` and `MSSdk` must be both set. `MSSdk` indicates that the current environment has been setup by the SDK's `SetEnv.Cmd` script, or that the environment variables had been registered when the SDK was installed; `DISTUTILS_USE_SDK` indicates that the distutils user has made an explicit choice to override the compiler selection by `MSVCCompiler`. 
This module provides `BorlandCCCompiler`, an subclass of the abstract `CCompiler` class for the Borland C++ compiler.
This module provides the `CygwinCCompiler` class, a subclass of `UnixCCompiler` that handles the Cygwin port of the GNU C compiler to Windows. It also contains the `Mingw32CCompiler` class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).
This module provides the EMXCCompiler class, a subclass of UnixCCompiler that handles the EMX port of the GNU C compiler to OS/2.
11.8. distutils.archive_util — Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

distutils.archive_util.make_archive(base_name, format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])

Create an archive file (eg. zip or tar). base_name is the name of the file to create, minus any format-specific extension; format is the archive format: one of zip, tar, ztar, or gztar. root_dir is a directory that will be the root directory of the archive; ie. we typically chdir into root_dir before creating the archive. base_dir is the directory where we start archiving from; ie. base_dir will be the common prefix of all files and directories in the archive. root_dir and base_dir both default to the current directory. Returns the name of the archive file.

distutils.archive_util.make_tarball(base_name, base_dir[, compress='gzip', verbose=0, dry_run=0])

‘Create an (optional compressed) archive as a tar file from all files in and under base_dir. compress must be 'gzip' (the default), 'compress', 'bzip2', or None. Both tar and the compression utility named by compress must be on the default program search path, so this is probably Unix-specific. The output tar file will be named base_dir.tar, possibly plus the appropriate compression extension (.gz, .bz2 or .Z). Return the output filename.

distutils.archive_util.make_zipfile(base_name, base_dir[, compress, verbose=0, dry_run=0])
Create a zip file from all files in and under `base_dir`. The output zip file will be named `base_dir + .zip`. Uses either the `zipfile` Python module (if available) or the InfoZIP `zip` utility (if installed and found on the default search path). If neither tool is available, raises `DistutilsExecError`. Returns the name of the output zip file.
11.9. distutils.dep_util — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

```
distutils.dep_util.newer(source, target)
```

Return true if `source` exists and is more recently modified than `target`, or if `source` exists and `target` doesn't. Return false if both exist and `target` is the same age or newer than `source`. Raise `DistutilsFileError` if `source` does not exist.

```
distutils.dep_util.newer_pairwise(sources, targets)
```

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists `(sources, targets)` where source is newer than target, according to the semantics of `newer()`

```
distutils.dep_util.newer_group(sources, target[, missing='error'])
```

Return true if `target` is out-of-date with respect to any file listed in `sources` In other words, if `target` exists and is newer than every file in `sources`, return false; otherwise return true. `missing` controls what we do when a source file is missing; the default (`'error'`) is to blow up with an `OSError` from inside `os.stat()`; if it is `'ignore'`, we silently drop any missing source files; if it is `'newer'`, any missing source files make us assume that `target` is out-of-date (this is handy in “dry-run” mode: it’ll make you pretend to carry out commands that wouldn’t work because inputs are missing, but that doesn’t matter because you’re not actually going to run the commands).
11.10. distutils.dir_util — Directory tree operations

This module provides functions for operating on directories and trees of directories.

```python
import distutils.dir_util

distutils.dir_util.mkpath(name[, mode=0777, verbose=0,
dry_run=0])
```

Create a directory and any missing ancestor directories. If the directory already exists (or if `name` is the empty string, which means the current directory, which of course exists), then do nothing. Raise `DistutilsFileError` if unable to create some directory along the way (e.g. some sub-path exists, but is a file rather than a directory). If `verbose` is true, print a one-line summary of each mkdir to stdout. Return the list of directories actually created.

```python
import distutils.dir_util

distutils.dir_util.create_tree(base_dir, files[, mode=0777,
verbose=0, dry_run=0])
```

Create all the empty directories under `base_dir` needed to put `files` there. `base_dir` is just the a name of a directory which doesn’t necessarily exist yet; `files` is a list of filenames to be interpreted relative to `base_dir`. `base_dir` + the directory portion of every file in `files` will be created if it doesn’t already exist. `mode`, `verbose` and `dry_run` flags are as for `mkpath()`.

```python
import distutils.dir_util

distutils.dir_util.copy_tree(src, dst[, preserve_mode=1,
preserve_times=1, preserve_symlinks=0, update=0, verbose=0,
dry_run=0])
```

Copy an entire directory tree `src` to a new location `dst`. Both `src` and `dst` must be directory names. If `src` is not a directory, raise
**DistutilsFileError.** If *dst* does not exist, it is created with \texttt{mkpath()}. The end result of the copy is that every file in *src* is copied to *dst*, and directories under *src* are recursively copied to *dst*. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by *update* or *dry_run*: it is simply the list of all files under *src*, with the names changed to be under *dst*.

*preserve_mode* and *preserve_times* are the same as for \texttt{copy_file()} in \texttt{distutils.file_util}; note that they only apply to regular files, not to directories. If *preserve_symlinks* is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. *update* and *verbose* are the same as for \texttt{copy_file()}. 

\begin{verbatim}
\textbf{distutils.dir_util.remove_tree(directory[, verbose=0, dry_run=0])}
\end{verbatim}

Recursively remove *directory* and all files and directories underneath it. Any errors are ignored (apart from being reported to \texttt{sys.stdout} if *verbose* is true).

** Some of this could be replaced with the shutil module? **
This module contains some utility functions for operating on individual files.

```python
distutils.file_util.copy_file(src, dst[, preserve_mode=1,
preserve_times=1, update=0, link=None, verbose=0, dry_run=0])
```

Copy file `src` to `dst`. If `dst` is a directory, then `src` is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If `preserve_mode` is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If `preserve_times` is true (the default), the last-modified and last-access times are copied as well. If `update` is true, `src` will only be copied if `dst` does not exist, or if `dst` does exist but is older than `src`.

`link` allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to `'hard'` or `'sym'`; if it is `None` (the default), files are copied. Don’t set `link` on systems that don’t support it: `copy_file()` doesn’t check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple `(dest_name, copied): dest_name is the actual name of the output file, and copied is true if the file was copied (or would have been copied, if `dry_run` true).

```python
distutils.file_util.move_file(src, dst[, verbose, dry_run])
```

Move file `src` to `dst`. If `dst` is a directory, the file will be moved into it with the same name; otherwise, `src` is just renamed to `dst`. 
Returns the new full name of the file.

**Warning:** Handles cross-device moves on Unix using `copy_file()`. What about other systems?

distutils.file_util.write_file(filename, contents)

Create a file called *filename* and write *contents* (a sequence of strings without line terminators) to it.
This module contains other assorted bits and pieces that don’t fit into any other utility module.

**distutils.util.get_platform()**

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by ‘os.uname()’), although the exact information included depends on the OS; eg. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn’t particularly important.

Examples of returned values:

- linux-i586
- linux-alpha
- solaris-2.6-sun4u
- irix-5.3
- irix64-6.2

For non-POSIX platforms, currently just returns `sys.platform`.

For Mac OS X systems the OS version reflects the minimal version on which binaries will run (that is, the value of `MACOSX_DEPLOYMENT_TARGET` during the build of Python), not the OS version of the current system.

For universal binary builds on Mac OS X the architecture value reflects the univeral binary status instead of the architecture of
the current processor. For 32-bit universal binaries the architecture is fat, for 64-bit universal binaries the architecture is fat64, and for 4-way universal binaries the architecture is universal. Starting from Python 2.7 and Python 3.2 the architecture fat3 is used for a 3-way universal build (ppc, i386, x86_64) and intel is used for a universal build with the i386 and x86_64 architectures.

Examples of returned values on Mac OS X:

- macosx-10.3-ppc
- macosx-10.3-fat
- macosx-10.5-universal
- macosx-10.6-intel

distutils.util.convert_path(pathname)

Return ‘pathname’ as a name that will work on the native filesystem, i.e. split it on ‘/’ and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises ValueError on non-Unix-ish systems if pathname either starts or ends with a slash.

distutils.util.change_root(new_root, pathname)

Return pathname with new_root prepended. If pathname is relative, this is equivalent to os.path.join(new_root, pathname). Otherwise, it requires making pathname relative and then joining the two, which is tricky on DOS/Windows.

distutils.util.check_environ()

Ensure that ‘os.environ’ has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:
- **HOME** - user's home directory (Unix only)
- **PLAT** - description of the current platform, including hardware and OS (see `get_platform()`)  

```
distutils.util.subst_vars(s, local_vars)
```

Perform shell/Perl-style variable substitution on `s`. Every occurrence of `$` followed by a name is considered a variable, and variable is substituted by the value found in the `local_vars` dictionary, or in `os.environ` if it’s not in `local_vars`. `os.environ` is first checked/augmented to guarantee that it contains certain values: see `check_environ()`. Raise `ValueError` for any variables not found in either `local_vars` or `os.environ`.

Note that this is not a fully-fledged string interpolation function. A valid `$variable` can consist only of upper and lower case letters, numbers and an underscore. No `{ }` or `( )` style quoting is available.

```
distutils.util.grok_environment_error(exc[, prefix='error: '])
```

Generate a useful error message from an `EnvironmentError` (`IOError` or `OSError`) exception object. Handles Python 1.5.1 and later styles, and does what it can to deal with exception objects that don’t have a filename (which happens when the error is due to a two-file operation, such as `rename()` or `link()`). Returns the error message as a string prefixed with `prefix`.

```
distutils.util.split_quoted(s)
```

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the
escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

```
import distutils.util

distutils.util.execute(func, args[, msg=None, verbose=0, dry_run=0])
```

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the `dry_run` flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

```
import distutils.util

distutils.util.strtobool(val)
```

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises `ValueError` if `val` is anything else.

```
import distutils.util

distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])
```

Byte-compile a collection of Python source files to either `.pyc` or `.pyo` files in the same directory. `py_files` is a list of files to compile; any files that don’t end in `.py` are silently skipped. `optimize` must be one of the following:

- 0 - don’t optimize (generate `.pyc`)
- 1 - normal optimization (like `python -O`)
- 2 - extra optimization (like `python -OO`)

If `force` is true, all files are recompiled regardless of timestamps.

The source filename encoded in each bytecode file defaults to the filenames listed in `py_files`; you can modify these with `prefix` and `basedir`. `prefix` is a string that will be stripped off of each
source filename, and `base_dir` is a directory name that will be prepended (after `prefix` is stripped). You can supply either or both (or neither) of `prefix` and `base_dir`, as you wish.

If `dry_run` is true, doesn’t actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard `py_compile` module, or indirectly by writing a temporary script and executing it. Normally, you should let `byte_compile()` figure out to use direct compilation or not (see the source for details). The `direct` flag is used by the script generated in indirect mode; unless you know what you’re doing, leave it set to `None`.

```
distutils.util.rfc822_escape(header)
```

Return a version of `header` escaped for inclusion in an RFC 822 header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.
This module provides the `Distribution` class, which represents the module distribution being built/installed/distributed.
This module provides the Extension class, used to describe C/C++ extension modules in setup scripts.
This module provides the DEBUG flag.
Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user's fault (e.g. bad command-line arguments).

This module is safe to use in `from ... import *` mode; it only exports symbols whose names start with `Distutils` and end with `Error`. 
11.17. distutils.fancy_getopt — Wrapper around the standard getopt module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

** Should be replaced with `optik` (which is also now known as `optparse` in Python 2.3 and later). **

distutils.fancy_getopt.**fancy_getopt**(options, negative_opt, object, args)

Wrapper function. `options` is a list of `(long_option, short_option, help_string)` 3-tuples as described in the constructor for `FancyGetopt`. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). `args` is the argument list. Will use `sys.argv[1:]` if you pass `None` as `args`.

distutils.fancy_getopt.**wrap_text**(text, width)

Wraps `text` to less than `width` wide.

class distutils.fancy_getopt.**FancyGetopt**([option_table=None])
The option_table is a list of 3-tuples: (long_option, short_option, help_string)

If an option takes an argument, its long_option should have '=' appended; short_option should just be a single character, no ':' in any case. short_option should be None if a long_option doesn’t have a corresponding short_option. All option tuples must have long options.

The FancyGetopt class provides the following methods:

FancyGetopt.getopt([args=None, object=None])
Parse command-line options in args. Store as attributes on object.

If args is None or not supplied, uses sys.argv[1:]. If object is None or not supplied, creates a new OptionDummy instance, stores option values there, and returns a tuple (args, object). If object is supplied, it is modified in place and getopt() just returns args; in both cases, the returned args is a modified copy of the passed-in args list, which is left untouched.

FancyGetopt.get_option_order()
Returns the list of (option, value) tuples processed by the previous run of getopt() Raises RuntimeError if getopt() hasn’t been called yet.

FancyGetopt.generate_help([header=None])
Generate help text (a list of strings, one per suggested line of output) from the option table for this FancyGetopt object.

If supplied, prints the supplied header at the top of the help.
11.18. distutils.filelist — The FileList class

This module provides the FileList class, used for poking about the filesystem and building lists of files.
11.19. distutils.log — Simple PEP 282-style logging
This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a subprocess. Also provides `find_executable()` to search the path for a given executable name.
11.21. distutils.sysconfig — System configuration information

The `distutils.sysconfig` module provides access to Python’s low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the Makefile and configuration header that are installed with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the `distutils` package.

`distutils.sysconfig.PREFIX`

The result of `os.path.normpath(sys.prefix)`.

`distutils.sysconfig.EXEC_PREFIX`

The result of `os.path.normpath(sys.exec_prefix)`.

`distutils.sysconfig.get_config_var(name)`

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

`distutils.sysconfig.get_config_vars(...)`

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, `None` will be
included for that variable.

\texttt{distutils.sysconfig.get\_config\_h\_filename()}

Return the full path name of the configuration header. For Unix, this will be the header generated by the \texttt{configure} script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

\texttt{distutils.sysconfig.get\_makefile\_filename()}

Return the full path name of the \texttt{Makefile} used to build Python. For Unix, this will be a file generated by the \texttt{configure} script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

\texttt{distutils.sysconfig.get\_python\_inc([[\texttt{plat\_specific}], \texttt{prefix}]])}

Return the directory for either the general or platform-dependent C include files. If \texttt{plat\_specific} is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If \texttt{prefix} is given, it is used as either the prefix instead of \texttt{PREFIX}, or as the exec-prefix instead of \texttt{EXEC\_PREFIX} if \texttt{plat\_specific} is true.

\texttt{distutils.sysconfig.get\_python\_lib([[\texttt{plat\_specific}], \texttt{standard\_lib}], \texttt{prefix}])}

Return the directory for either the general or platform-dependent library installation. If \texttt{plat\_specific} is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If \texttt{prefix} is given, it is used as either the prefix instead of \texttt{PREFIX}, or as the exec-prefix instead of \texttt{EXEC\_PREFIX} if \texttt{plat\_specific} is true. If \texttt{standard\_lib} is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.
The following function is only intended for use within the `distutils` package.

`distutils.sysconfig.customize_compiler(compiler)`

Do any platform-specific customization of a `distutils.ccompiler.CCompiler` instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python’s `Makefile`. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

`distutils.sysconfig.set_python_build()`

Inform the `distutils.sysconfig` module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.
This module provides the **TextFile** class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

```python
class distutils.text_file.TextFile([filename=None, file=None, **options])
```

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as # is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

**TextFile** instances are create with either `filename`, `file`, or both. `RuntimeError` is raised if both are `None`. `filename` should be a string, and `file` a file object (or something that provides `readline()` and `close()` methods). It is recommended that you supply at least `filename`, so that **TextFile** can include it in warning messages. If `file` is not supplied, **TextFile** creates its own using the `open()` built-in function.

The options are all boolean, and affect the values returned by
**readline()**

<table>
<thead>
<tr>
<th>option name</th>
<th>description</th>
<th>default</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>strip_comments</code></td>
<td>strip from ' #' to end-of-line, as well as any whitespace leading up to the ' #:' —unless it is escaped by a backslash</td>
<td>true</td>
</tr>
<tr>
<td><code>lstrip_ws</code></td>
<td>strip leading whitespace from each line before returning it</td>
<td>false</td>
</tr>
<tr>
<td><code>rstrip_ws</code></td>
<td>strip trailing whitespace (including line terminator!) from each line before returning it.</td>
<td>true</td>
</tr>
<tr>
<td><code>skip_blanks</code></td>
<td>skip lines that are empty <em>after</em> stripping comments and whitespace. (If both lstrip_ws and rstrip_ws are false, then some lines may consist of solely whitespace: these will <em>not</em> be skipped, even if skip_blanks is true.)</td>
<td>true</td>
</tr>
<tr>
<td><code>join_lines</code></td>
<td>if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.</td>
<td>false</td>
</tr>
<tr>
<td><code>collapse_join</code></td>
<td>strip leading whitespace from lines that are joined to their predecessor; only matters if (join_lines and not lstrip_ws)</td>
<td>false</td>
</tr>
</tbody>
</table>

Note that since `rstrip_ws` can strip the trailing newline, the semantics of `readline()` must differ from those of the built-in file object's `readline()` method! In particular, `readline()` returns
None for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if \textit{rstrip\_ws} is true but \textit{skip\_blanks} is not.

\textbf{open(\textit{filename})}

Open a new file \textit{filename}. This overrides any \textit{file} or \textit{filename} constructor arguments.

\textbf{close()}

Close the current file and forget everything we know about it (including the filename and the current line number).

\textbf{warn(\textit{msg}, line=\textit{None})}

Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as \texttt{\"lines 3-5\"}. If \textit{line} is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

\textbf{readline()}

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with \texttt{unreadline()}). If the \texttt{join\_lines} option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling \texttt{warn()} after \texttt{readline()} emits a warning about the physical line(s) just read. Returns \texttt{None} on end-of-file, since the empty string can occur if \textit{rstrip\_ws} is true but \textit{strip\_blanks} is not.

\textbf{readlines()}

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

\textbf{unreadline(\textit{line})}
Push `line` (a string) onto an internal buffer that will be checked by future `readline()` calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread” with `unreadline()` are not subsequently re-cleansed (whitespace stripped, or whatever) when read with `readline()`. If multiple calls are made to `unreadline()` before a call to `readline()`, the lines will be returned most in most recent first order.
11.23. distutils.version — Version number classes
This module supplies the abstract base class Command.

class distutils.cmd.Command(dist)

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called options. The options are declared in initialize_options() and defined (given their final values) in finalize_options(), both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence finalize_options(). The body of the subroutine, where it does all its work based on the values of its options, is the run() method, which must also be implemented by every command class.

The class constructor takes a single argument dist, a Distribution instance.
11.25. distutils.command — Individual
Distutils commands
11.26. distutils.command.bdist — Build a binary installer
Abstract base class for packagers
11.28. distutils.command.bdist_dumb — Build a “dumb” installer
class distutils.command.bdist_msi.bdist_msi(Command)
    Builds a Windows Installer (.msi) binary package.

    In most cases, the bdist_msi installer is a better choice than the bdist_wininst installer, because it provides better support for Win64 platforms, allows administrators to perform non-interactive installations, and allows installation through group policies.
11.30. distutils.command.bdist_rpm — Build a binary distribution as a Redhat RPM and SRPM
11.31. distutils.command.bdist_wininst —
Build a Windows installer
11.32. distutils.command.sdist — Build a source distribution
11.33. distutils.command.build — Build all files of a package
11.34. distutils.command.build_clib — Build any C libraries in a package
11.35. distutils.command.build_ext — Build any extensions in a package
11.36. distutils.command.build_py — Build the .py/.pyc files of a package
11.37. distutils.command.build_scripts —
Build the scripts of a package
11.38. distutils.command.clean — Clean a package build area
11.39. distutils.command.config — Perform package configuration
11.40. distutils.command.install — Install a package
11.41. distutils.command.install_data —
Install data files from a package
11.42. distutils.command.install_headers — Install C/C++ header files from a package
11.43. `distutils.command.install_lib` — Install library files from a package
11.44. distutils.command.install_scripts —
Install script files from a package
The `register` command registers the package with the Python Package Index. This is described in more detail in PEP 301.
11.46. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the distutils.command package. There is a sample template in that directory called command_template. Copy this file to a new module with the same name as the new command you’re implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command peel_banana (so that users can run setup.py peel_banana), you’d copy command_template to distutils/command/peel_banana.py, then edit it so that it’s implementing the class peel_banana, a subclass of distutils.cmd.Command.

Subclasses of Command must define the following methods.

**Command.initialize_options()**

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, initialize_options() implementations are just a bunch of self.foo = None assignments.

**Command.finalize_options()**

Set final values for all the options that this command supports. This is always called as late as possible, i.e. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to to code option dependencies: if foo depends on bar, then it is safe to set foo from bar as long as foo still has the same value it was assigned
in `initialize_options()`.

Command `.run()`

A command's raison d'être: carry out the action it exists to perform, controlled by the options initialized in `initialize_options()`, customized by other commands, the setup script, the command-line, and config files, and finalized in `finalize_options()`. All terminal output and filesystem interaction should be done by `run()`.

`subCommands` formalizes the notion of a “family” of commands, eg. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines `subCommands` as a class attribute; it’s a list of 2-tuples `(command_name, predicate)`, with `command_name` a string and `predicate` an unbound method, a string or None. `predicate` is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (Eg. we `install_headers` is only applicable if we have any C header files to install.) If `predicate` is None, that command is always applicable.

`subCommands` is usually defined at the *end* of a class, because predicates can be unbound methods, so they must already have been defined. The canonical example is the `install` command.
1. Introduction

Python's documentation has long been considered to be good for a free programming language. There are a number of reasons for this, the most important being the early commitment of Python's creator, Guido van Rossum, to providing documentation on the language and its libraries, and the continuing involvement of the user community in providing assistance for creating and maintaining documentation.

The involvement of the community takes many forms, from authoring to bug reports to just plain complaining when the documentation could be more complete or easier to use.

This document is aimed at authors and potential authors of documentation for Python. More specifically, it is for people contributing to the standard documentation and developing additional documents using the same tools as the standard documents. This guide will be less useful for authors using the Python documentation tools for topics other than Python, and less useful still for authors not using the tools at all.

If your interest is in contributing to the Python documentation, but you don’t have the time or inclination to learn reStructuredText and the markup structures documented here, there's a welcoming place for you among the Python contributors as well. Any time you feel that you can clarify existing documentation or provide documentation that’s missing, the existing documentation team will gladly work with you to integrate your text, dealing with the markup for you. Please don’t let the material in this document stand between the documentation and your desire to help out!
2. Style Guide

The Python documentation should follow the Apple Publications Style Guide wherever possible. This particular style guide was selected mostly because it seems reasonable and is easy to get online.

Topics which are not covered in Apple’s style guide will be discussed in this document.

All reST files use an indentation of 3 spaces. The maximum line length is 80 characters for normal text, but tables, deeply indented code samples and long links may extend beyond that.

Make generous use of blank lines where applicable; they help grouping things together.

A sentence-ending period may be followed by one or two spaces; while reST ignores the second space, it is customarily put in by some users, for example to aid Emacs’ auto-fill mode.

Footnotes are generally discouraged, though they may be used when they are the best way to present specific information. When a footnote reference is added at the end of the sentence, it should follow the sentence-ending punctuation. The reST markup should appear something like this:

```
This sentence has a footnote reference. [#]_ This is the next sentence.
```

Footnotes should be gathered at the end of a file, or if the file is very long, at the end of a section. The docutils will automatically create backlinks to the footnote reference.

Footnotes may appear in the middle of sentences where appropriate.
Many special names are used in the Python documentation, including the names of operating systems, programming languages, standards bodies, and the like. Most of these entities are not assigned any special markup, but the preferred spellings are given here to aid authors in maintaining the consistency of presentation in the Python documentation.

Other terms and words deserve special mention as well; these conventions should be used to ensure consistency throughout the documentation:

**CPU**
For “central processing unit.” Many style guides say this should be spelled out on the first use (and if you must use it, do so!). For the Python documentation, this abbreviation should be avoided since there’s no reasonable way to predict which occurrence will be the first seen by the reader. It is better to use the word “processor” instead.

**POSIX**
The name assigned to a particular group of standards. This is always uppercase.

**Python**
The name of our favorite programming language is always capitalized.

**Unicode**
The name of a character set and matching encoding. This is always written capitalized.

**Unix**
The name of the operating system developed at AT&T Bell Labs in the early 1970s.
3. reStructuredText Primer

This section is a brief introduction to reStructuredText (reST) concepts and syntax, intended to provide authors with enough information to author documents productively. Since reST was designed to be a simple, unobtrusive markup language, this will not take too long.

See also: The authoritative reStructuredText User Documentation.
3.1. Paragraphs

The paragraph is the most basic block in a reST document. Paragraphs are simply chunks of text separated by one or more blank lines. As in Python, indentation is significant in reST, so all lines of the same paragraph must be left-aligned to the same level of indentation.
3.2. Inline markup

The standard reST inline markup is quite simple: use

- one asterisk: *text* for emphasis (italics),
- two asterisks: **text** for strong emphasis (boldface), and
- backquotes: ``text`` for code samples.

If asterisks or backquotes appear in running text and could be confused with inline markup delimiters, they have to be escaped with a backslash.

Be aware of some restrictions of this markup:

- it may not be nested,
- content may not start or end with whitespace: * `text`* is wrong,
- it must be separated from surrounding text by non-word characters. Use a backslash escaped space to work around that: this is\ *one*\ word.

These restrictions may be lifted in future versions of the docutils.

reST also allows for custom “interpreted text roles”’, which signify that the enclosed text should be interpreted in a specific way. Sphinx uses this to provide semantic markup and cross-referencing of identifiers, as described in the appropriate section. The general syntax is :rolename:`content`.
3.3. Lists and Quotes

List markup is natural: just place an asterisk at the start of a paragraph and indent properly. The same goes for numbered lists; they can also be autonumbered using a # sign:

* This is a bulleted list.
  * It has two items, the second item uses two lines.

1. This is a numbered list.
2. It has two items too.

#. This is a numbered list.
#. It has two items too.

Nested lists are possible, but be aware that they must be separated from the parent list items by blank lines:

* this is
  * a list
    * with a nested list
      * and some subitems
    * and here the parent list continues

Definition lists are created as follows:

term (up to a line of text)
  Definition of the term, which must be indented
    and can even consist of multiple paragraphs
next term
  Description.

Paragraphs are quoted by just indenting them more than the surrounding paragraphs.
3.4. Source Code

Literal code blocks are introduced by ending a paragraph with the special marker `::`. The literal block must be indented:

This is a normal text paragraph. The next paragraph is a code sample:

```
It is not processed in any way, except that the indentation is removed.
It can span multiple lines.
```

This is a normal text paragraph again.

The handling of the `::` marker is smart:

- If it occurs as a paragraph of its own, that paragraph is completely left out of the document.
- If it is preceded by whitespace, the marker is removed.
- If it is preceded by non-whitespace, the marker is replaced by a single colon.

That way, the second sentence in the above example’s first paragraph would be rendered as “The next paragraph is a code sample.”.
3.5. Hyperlinks

3.5.1. External links

Use `Link text <http://target>` for inline web links. If the link text should be the web address, you don’t need special markup at all, the parser finds links and mail addresses in ordinary text.

3.5.2. Internal links

Internal linking is done via a special reST role, see the section on specific markup, Cross-linking markup.
3.6. Sections

Section headers are created by underlining (and optionally overlining) the section title with a punctuation character, at least as long as the text:

```
=================
This is a heading
=================
```

Normally, there are no heading levels assigned to certain characters as the structure is determined from the succession of headings. However, for the Python documentation, we use this convention:

- `#` with overline, for parts
- `*` with overline, for chapters
- `=` for sections
- `-` for subsections
- `^` for subsubsections
- `"` for paragraphs
3.7. Explicit Markup

“Explicit markup” is used in reST for most constructs that need special handling, such as footnotes, specially-highlighted paragraphs, comments, and generic directives.

An explicit markup block begins with a line starting with `..` followed by whitespace and is terminated by the next paragraph at the same level of indentation. (There needs to be a blank line between explicit markup and normal paragraphs. This may all sound a bit complicated, but it is intuitive enough when you write it.)
3.8. Directives

A directive is a generic block of explicit markup. Besides roles, it is one of the extension mechanisms of reST, and Sphinx makes heavy use of it.

Basically, a directive consists of a name, arguments, options and content. (Keep this terminology in mind, it is used in the next chapter describing custom directives.) Looking at this example,

```
.. function:: foo(x)
    foo(y, z)
    :bar: no

    Return a line of text input from the user.
```

`function` is the directive name. It is given two arguments here, the remainder of the first line and the second line, as well as one option `bar` (as you can see, options are given in the lines immediately following the arguments and indicated by the colons).

The directive content follows after a blank line and is indented relative to the directive start.
3.9. Footnotes

For footnotes, use [#]_ to mark the footnote location, and add the footnote body at the bottom of the document after a “Footnotes” rubric heading, like so:

Lorem ipsum [#]_ dolor sit amet ... [#]_

.. rubric:: Footnotes

.. [#] Text of the first footnote.
.. [#] Text of the second footnote.

You can also explicitly number the footnotes for better context.
3.10. Comments

Every explicit markup block which isn’t a valid markup construct (like the footnotes above) is regarded as a comment.
3.11. Source encoding

Since the easiest way to include special characters like em dashes or copyright signs in reST is to directly write them as Unicode characters, one has to specify an encoding:

All Python documentation source files must be in UTF-8 encoding, and the HTML documents written from them will be in that encoding as well.
3.12. Gotchas

There are some problems one commonly runs into while authoring reST documents:

- **Separation of inline markup**: As said above, inline markup spans must be separated from the surrounding text by non-word characters, you have to use an escaped space to get around that.
4. Additional Markup Constructs

Sphinx adds a lot of new directives and interpreted text roles to standard reST markup. This section contains the reference material for these facilities. Documentation for “standard” reST constructs is not included here, though they are used in the Python documentation.

**Note:** This is just an overview of Sphinx’ extended markup capabilities; full coverage can be found in its own documentation.
4.1. Meta-information markup

[sectionauthor]

Identifies the author of the current section. The argument should include the author’s name such that it can be used for presentation (though it isn’t) and email address. The domain name portion of the address should be lower case. Example:

```
.. sectionauthor:: Guido van Rossum <guido@python.org>
```

Currently, this markup isn’t reflected in the output in any way, but it helps keep track of contributions.
4.2. Module-specific markup

The markup described in this section is used to provide information about a module being documented. Each module should be documented in its own file. Normally this markup appears after the title heading of that file; a typical file might start like this:

```
:mod:`parrot` -- Dead parrot access
===================================
.. module:: parrot
   :platform: Unix, Windows
   :synopsis: Analyze and reanimate dead parrots.
.. moduleauthor:: Eric Cleese <eric@python.invalid>
.. moduleauthor:: John Idle <john@python.invalid>
```

As you can see, the module-specific markup consists of two directives, the `module` directive and the `moduleauthor` directive.

`module`

This directive marks the beginning of the description of a module (or package submodule, in which case the name should be fully qualified, including the package name).

The `platform` option, if present, is a comma-separated list of the platforms on which the module is available (if it is available on all platforms, the option should be omitted). The keys are short identifiers; examples that are in use include “IRIX”, “Mac”, “Windows”, and “Unix”. It is important to use a key which has already been used when applicable.

The `synopsis` option should consist of one sentence describing the module’s purpose – it is currently only used in the Global Module Index.

The `deprecated` option can be given (with no value) to mark a
module as deprecated; it will be designated as such in various locations then.

moduleauthor

The `moduleauthor` directive, which can appear multiple times, names the authors of the module code, just like `sectionauthor` names the author(s) of a piece of documentation. It too does not result in any output currently.

**Note:** It is important to make the section title of a module-describing file meaningful since that value will be inserted in the table-of-contents trees in overview files.
4.3. Information units

There are a number of directives used to describe specific features provided by modules. Each directive requires one or more signatures to provide basic information about what is being described, and the content should be the description. The basic version makes entries in the general index; if no index entry is desired, you can give the directive option flag :noindex:. The following example shows all of the features of this directive type:

```
.. function:: spam(eggs)
    ham(eggs)
    :noindex:

    Spam or ham the foo.
```

The signatures of object methods or data attributes should always include the type name (.. method:: FileInput.input(...)), even if it is obvious from the context which type they belong to; this is to enable consistent cross-references. If you describe methods belonging to an abstract protocol, such as “context managers”, include a (pseudo-)type name too to make the index entries more informative.

The directives are:

**cfunction**

Describes a C function. The signature should be given as in C, e.g.:

```
.. cfunction:: PyObject* PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)
```

This is also used to describe function-like preprocessor macros. The names of the arguments should be given so they may be
used in the description.

Note that you don’t have to backslash-escape asterisks in the signature, as it is not parsed by the reST inliner.

cmember
Describes a C struct member. Example signature:

```plaintext
.. cmember:: PyObject* PyTypeObject.tp_bases
```

The text of the description should include the range of values allowed, how the value should be interpreted, and whether the value can be changed. References to structure members in text should use the **member** role.

cmacro
Describes a “simple” C macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include `PyObject_HEAD` and `Py_BEGIN_ALLOW_THREADS`.

class
Describes a C type. The signature should just be the type name.

cvar
Describes a global C variable. The signature should include the type, such as:

```plaintext
.. cvar:: PyObject* PyObject
```

data
Describes global data in a module, including both variables and values used as “defined constants.” Class and object attributes are not documented using this environment.
exception
Describes an exception class. The signature can, but need not include parentheses with constructor arguments.

function
Describes a module-level function. The signature should include the parameters, enclosing optional parameters in brackets. Default values can be given if it enhances clarity. For example:

```
.. function:: Timer.repeat([repeat=3[, number=1000000]])
```

Object methods are not documented using this directive. Bound object methods placed in the module namespace as part of the public interface of the module are documented using this, as they are equivalent to normal functions for most purposes.

The description should include information about the parameters required and how they are used (especially whether mutable objects passed as parameters are modified), side effects, and possible exceptions. A small example may be provided.

class
Describes a class. The signature can include parentheses with parameters which will be shown as the constructor arguments.

attribute
Describes an object data attribute. The description should include information about the type of the data to be expected and whether it may be changed directly.

method
Describes an object method. The parameters should not include the self parameter. The description should include similar information to that described for function.

opcode
Describes a Python *bytecode* instruction.

**cmdoption**

Describes a command line option or switch. Option argument names should be enclosed in angle brackets. Example:

```plaintext
.. cmdoption:: -m <module>
   
   Run a module as a script.
```

**envvar**

Describes an environment variable that Python uses or defines.

There is also a generic version of these directives:

**describe**

This directive produces the same formatting as the specific ones explained above but does not create index entries or cross-referencing targets. It is used, for example, to describe the directives in this document. Example:

```plaintext
.. describe:: opcode

   Describes a Python bytecode instruction.
```
4.4. Showing code examples

Examples of Python source code or interactive sessions are represented using standard reST literal blocks. They are started by a :: at the end of the preceding paragraph and delimited by indentation.

Representing an interactive session requires including the prompts and output along with the Python code. No special markup is required for interactive sessions. After the last line of input or output presented, there should not be an “unused” primary prompt; this is an example of what not to do:

```python
>>> 1 + 1
2
>>> 
```

Syntax highlighting is handled in a smart way:

- There is a “highlighting language” for each source file. Per default, this is 'python' as the majority of files will have to highlight Python snippets.

- Within Python highlighting mode, interactive sessions are recognized automatically and highlighted appropriately.

- The highlighting language can be changed using the highlightlang directive, used as follows:

```python
.. highlightlang:: c
```

This language is used until the next highlightlang directive is encountered.

- The values normally used for the highlighting language are:
- python (the default)
- c
- rest
- none (no highlighting)

- If highlighting with the current language fails, the block is not highlighted in any way.

Longer displays of verbatim text may be included by storing the example text in an external file containing only plain text. The file may be included using the `literalinclude` directive. [1] For example, to include the Python source file `example.py`, use:

```
.. literalinclude:: example.py
```

The file name is relative to the current file’s path. Documentation-specific include files should be placed in the `Doc/includes` subdirectory.
4.5. Inline markup

As said before, Sphinx uses interpreted text roles to insert semantic markup in documents.

Names of local variables, such as function/method arguments, are an exception, they should be marked simply with *var*.

For all other roles, you have to write :rolename:`content`.

There are some additional facilities that make cross-referencing roles more versatile:

- You may supply an explicit title and reference target, like in reST direct hyperlinks: :role:`title `<target>` will refer to target, but the link text will be title.

- If you prefix the content with !, no reference/hyperlink will be created.

- For the Python object roles, if you prefix the content with ~, the link text will only be the last component of the target. For example, :meth:`~Queue.Queue.get` will refer to `Queue.Queue.get` but only display `get` as the link text.

In HTML output, the link's title attribute (that is e.g. shown as a tool-tip on mouse-hover) will always be the full target name.

The following roles refer to objects in modules and are possibly hyperlinked if a matching identifier is found:

mod

The name of a module; a dotted name may be used. This should also be used for package names.
**func**

The name of a Python function; dotted names may be used. The role text should not include trailing parentheses to enhance readability. The parentheses are stripped when searching for identifiers.

**data**

The name of a module-level variable or constant.

**const**

The name of a “defined” constant. This may be a C-language `#define` or a Python variable that is not intended to be changed.

**class**

A class name; a dotted name may be used.

**meth**

The name of a method of an object. The role text should include the type name and the method name. A dotted name may be used.

**attr**

The name of a data attribute of an object.

**exc**

The name of an exception. A dotted name may be used.

The name enclosed in this markup can include a module name and/or a class name. For example, `:`func:`filter` could refer to a function named `filter` in the current module, or the built-in function of that name. In contrast, `:`func:`foo.filter` clearly refers to the `filter` function in the `foo` module.

Normally, names in these roles are searched first without any further qualification, then with the current module name prepended, then with the current module and class name (if any) prepended. If you
prefix the name with a dot, this order is reversed. For example, in the documentation of the `codecs` module, `:func:`open` always refers to the built-in function, while `:func:`.open` refers to `codecs.open()`.

A similar heuristic is used to determine whether the name is an attribute of the currently documented class.

The following roles create cross-references to C-language constructs if they are defined in the API documentation:

**cdata**
- The name of a C-language variable.

**cfunc**
- The name of a C-language function. Should include trailing parentheses.

**cmacro**
- The name of a “simple” C macro, as defined above.

**ctype**
- The name of a C-language type.

The following role does possibly create a cross-reference, but does not refer to objects:

**token**
- The name of a grammar token (used in the reference manual to create links between production displays).

The following role creates a cross-reference to the term in the glossary:

**term**
- Reference to a term in the glossary. The glossary is created using the `glossary` directive containing a definition list with terms
and definitions. It does not have to be in the same file as the term markup, in fact, by default the Python docs have one global glossary in the `glossary.rst` file.

If you use a term that's not explained in a glossary, you'll get a warning during build.

The following roles don't do anything special except formatting the text in a different style:

**command**

The name of an OS-level command, such as `rm`.

**dfn**

Mark the defining instance of a term in the text. (No index entries are generated.)

**envvar**

An environment variable. Index entries are generated.

**file**

The name of a file or directory. Within the contents, you can use curly braces to indicate a “variable” part, for example:

```plaintext
... is installed in :file:`/usr/lib/python2.{x}/site-package`
```

In the built documentation, the `x` will be displayed differently to indicate that it is to be replaced by the Python minor version.

**guilabel**

Labels presented as part of an interactive user interface should be marked using `guilabel`. This includes labels from text-based interfaces such as those created using `curses` or other text-based libraries. Any label used in the interface should be marked with
this role, including button labels, window titles, field names, menu and menu selection names, and even values in selection lists.

kbd
Mark a sequence of keystrokes. What form the key sequence takes may depend on platform- or application-specific conventions. When there are no relevant conventions, the names of modifier keys should be spelled out, to improve accessibility for new users and non-native speakers. For example, an xemacs key sequence may be marked like :kbd:`C-x C-f`, but without reference to a specific application or platform, the same sequence should be marked as :kbd:`Control-x Control-f`.

keyword
The name of a keyword in Python.

mailheader
The name of an RFC 822-style mail header. This markup does not imply that the header is being used in an email message, but can be used to refer to any header of the same “style.” This is also used for headers defined by the various MIME specifications. The header name should be entered in the same way it would normally be found in practice, with the camel-casing conventions being preferred where there is more than one common usage. For example: :mailheader:`Content-Type`.

makevar
The name of a make variable.

manpage
A reference to a Unix manual page including the section, e.g. :manpage:`ls(1)`.

menuselection
Menu selections should be marked using the menuselection role.
This is used to mark a complete sequence of menu selections, including selecting submenus and choosing a specific operation, or any subsequence of such a sequence. The names of individual selections should be separated by ```--->```

For example, to mark the selection “Start > Programs”, use this markup:

```
:menuselection:`Start --> Programs`
```

When including a selection that includes some trailing indicator, such as the ellipsis some operating systems use to indicate that the command opens a dialog, the indicator should be omitted from the selection name.

mimetype
The name of a MIME type, or a component of a MIME type (the major or minor portion, taken alone).

newsgroup
The name of a Usenet newsgroup.

option
A command-line option to an executable program. The leading hyphen(s) must be included.

program
The name of an executable program. This may differ from the file name for the executable for some platforms. In particular, the `.exe` (or other) extension should be omitted for Windows programs.

regexp
A regular expression. Quotes should not be included.

samp
A piece of literal text, such as code. Within the contents, you can use curly braces to indicate a “variable” part, as in :file:.

If you don’t need the “variable part” indication, use the standard `code` instead.

**var**

A Python or C variable or parameter name.

The following roles generate external links:

**pep**

A reference to a Python Enhancement Proposal. This generates appropriate index entries. The text “PEP number” is generated; in the HTML output, this text is a hyperlink to an online copy of the specified PEP.

**rfc**

A reference to an Internet Request for Comments. This generates appropriate index entries. The text “RFC number” is generated; in the HTML output, this text is a hyperlink to an online copy of the specified RFC.

Note that there are no special roles for including hyperlinks as you can use the standard reST markup for that purpose.
4.6. Cross-linking markup

To support cross-referencing to arbitrary sections in the documentation, the standard reST labels are “abused” a bit: Every label must precede a section title; and every label name must be unique throughout the entire documentation source.

You can then reference to these sections using the :ref:`label-name` role.

Example:

```
.. _my-reference-label:

Section to cross-reference
--------------------------
This is the text of the section.
It refers to the section itself, see :ref:`my-reference-label`.
```

The :ref: invocation is replaced with the section title.
4.7. Paragraph-level markup

These directives create short paragraphs and can be used inside information units as well as normal text:

**note**

An especially important bit of information about an API that a user should be aware of when using whatever bit of API the note pertains to. The content of the directive should be written in complete sentences and include all appropriate punctuation.

Example:

```
.. note::
    This function is not suitable for sending spam e-mails.
```

**warning**

An important bit of information about an API that a user should be aware of when using whatever bit of API the warning pertains to. The content of the directive should be written in complete sentences and include all appropriate punctuation. In the interest of not scaring users away from pages filled with warnings, this directive should only be chosen over note for information regarding the possibility of crashes, data loss, or security implications.

**versionadded**

This directive documents the version of Python which added the described feature to the library or C API. When this applies to an entire module, it should be placed at the top of the module section before any prose.

The first argument must be given and is the version in question; you can add a second argument consisting of a *brief* explanation
of the change.

Example:

```
.. versionadded:: 2.5
    The *spam* parameter.
```

Note that there must be no blank line between the directive head and the explanation; this is to make these blocks visually continuous in the markup.

**versionchanged**

Similar to `versionadded`, but describes when and what changed in the named feature in some way (new parameters, changed side effects, etc.).

**impl-detail**

This directive is used to mark CPython-specific information. Use either with a block content or a single sentence as an argument, i.e. either

```
.. impl-detail::

    This describes some implementation detail.

    More explanation.
```

or

```
.. impl-detail:: This shortly mentions an implementation detail:
```

"CPython implementation detail:" is automatically prepended to the content.

**seealso**

Many sections include a list of references to module
documentation or external documents. These lists are created using the `seealso` directive.

The `seealso` directive is typically placed in a section just before any sub-sections. For the HTML output, it is shown boxed off from the main flow of the text.

The content of the `seealso` directive should be a reST definition list. Example:

```rest
.. seealso::

    Module :mod:`zipfile`
    Documentation of the :mod:`zipfile` standard module.

    `GNU tar manual, Basic Tar Format <http://link>`_
    Documentation for tar archive files, including GNU tar
```

rubric
This directive creates a paragraph heading that is not used to create a table of contents node. It is currently used for the “Footnotes” caption.

centered
This directive creates a centered boldfaced paragraph. Use it as follows:

```rest
.. centered::

    Paragraph contents.
```
4.8. Table-of-contents markup

Since reST does not have facilities to interconnect several documents, or split documents into multiple output files, Sphinx uses a custom directive to add relations between the single files the documentation is made of, as well as tables of contents. The \texttt{toctree} directive is the central element.

\texttt{toctree}

This directive inserts a “TOC tree” at the current location, using the individual TOCs (including “sub-TOC trees”) of the files given in the directive body. A numeric \texttt{maxdepth} option may be given to indicate the depth of the tree; by default, all levels are included.

Consider this example (taken from the library reference index):

\begin{Verbatim}
.. toctree::
:maxdepth: 2

intro
strings
datatypes
numeric
(many more files listed here)
\end{Verbatim}

This accomplishes two things:

- Tables of contents from all those files are inserted, with a maximum depth of two, that means one nested heading. \texttt{toctree} directives in those files are also taken into account.
- Sphinx knows that the relative order of the files \texttt{intro}, \texttt{strings} and so forth, and it knows that they are children of the shown file, the library index. From this information it generates “next chapter”, “previous chapter” and “parent chapter” links.
In the end, all files included in the build process must occur in one `toctree` directive; Sphinx will emit a warning if it finds a file that is not included, because that means that this file will not be reachable through standard navigation.

The special file `contents.rst` at the root of the source directory is the “root” of the TOC tree hierarchy; from it the “Contents” page is generated.
4.9. Index-generating markup

Sphinx automatically creates index entries from all information units (like functions, classes or attributes) like discussed before.

However, there is also an explicit directive available, to make the index more comprehensive and enable index entries in documents where information is not mainly contained in information units, such as the language reference.

The directive is `index` and contains one or more index entries. Each entry consists of a type and a value, separated by a colon.

For example:

```
.. index::
  single: execution; context
  module: __main__
  module: sys
  triple: module; search; path
```

This directive contains five entries, which will be converted to entries in the generated index which link to the exact location of the index statement (or, in case of offline media, the corresponding page number).

The possible entry types are:

- **single**: Creates a single index entry. Can be made a subentry by separating the subentry text with a semicolon (this notation is also used below to describe what entries are created).

- **pair**: `pair: loop; statement` is a shortcut that creates two index entries, namely `loop; statement` and `statement; loop`. 
triple

Likewise, triple: module; search; path is a shortcut that creates three index entries, which are module; search path, search; path, module and path; module search.

module, keyword, operator, object, exception, statement, builtin

These all create two index entries. For example, module: hashlib creates the entries module; hashlib and hashlib; module.

For index directives containing only “single” entries, there is a shorthand notation:

```
.. index:: BNF, grammar, syntax, notation
```

This creates four index entries.
4.10. Grammar production displays

Special markup is available for displaying the productions of a formal grammar. The markup is simple and does not attempt to model all aspects of BNF (or any derived forms), but provides enough to allow context-free grammars to be displayed in a way that causes uses of a symbol to be rendered as hyperlinks to the definition of the symbol. There is this directive:

**productionlist**

This directive is used to enclose a group of productions. Each production is given on a single line and consists of a name, separated by a colon from the following definition. If the definition spans multiple lines, each continuation line must begin with a colon placed at the same column as in the first line.

Blank lines are not allowed within **productionlist** directive arguments.

The definition can contain token names which are marked as interpreted text (e.g. `unaryneg ::= "-\ `integer`") – this generates cross-references to the productions of these tokens.

Note that no further reST parsing is done in the production, so that you don’t have to escape `*` or `|` characters.

The following is an example taken from the Python Reference Manual:

```
.. productionlist::
   try_stmt: try1_stmt | try2_stmt
   try1_stmt: "try" ":" `suite`
                 : ("except" [`expression` ["," `target`]] ":" `suit
                     : ["else" ":" `suite`]
                     : ["finally" ":" `suite`]
   try2_stmt: "try" ":" `suite`
```
: "finally" ":" `suite`
4.11. Substitutions

The documentation system provides three substitutions that are defined by default. They are set in the build configuration file `conf.py`.

**|release|**
Replaced by the Python release the documentation refers to. This is the full version string including alpha/beta/release candidate tags, e.g. 2.5.2b3.

**|version|**
Replaced by the Python version the documentation refers to. This consists only of the major and minor version parts, e.g. 2.5, even for version 2.5.1.

**|today|**
Replaced by either today's date, or the date set in the build configuration file. Normally has the format April 14, 2007.

Footnotes

[1] There is a standard .. include directive, but it raises errors if the file is not found. This one only emits a warning.
5. Differences to the LaTeX markup

Though the markup language is different, most of the concepts and markup types of the old LaTeX docs have been kept – environments as reST directives, inline commands as reST roles and so forth.

However, there are some differences in the way these work, partly due to the differences in the markup languages, partly due to improvements in Sphinx. This section lists these differences, in order to give those familiar with the old format a quick overview of what they might run into.
5.1. Inline markup

These changes have been made to inline markup:

- **Cross-reference roles**

  Most of the following semantic roles existed previously as inline commands, but didn’t do anything except formatting the content as code. Now, they cross-reference to known targets (some names have also been shortened):

  mod (previously `refmodule` or `module`)
  func (previously `function`)
  data (new)
  const
  class
  meth (previously `method`)
  attr (previously `member`)
  exc (previously `exception`)
  cdata
  cfunc (previously `cfunction`)
  cmacro (previously `csimplemacro`)
  ctype

  Also different is the handling of `func` and `meth`: while previously parentheses were added to the callable name (like `\func{str()}`), they are now appended by the build system – appending them in the source will result in double parentheses. This also means that `:func:`str(object) does not work as expected – use ``str(object)` instead!

- **Inline commands implemented as directives**

  These were inline commands in LaTeX, but are now directives in
reST:

deprecated
versionadded
versionchanged

These are used like so:

```rest
.. deprecated::
   :version: 2.5
   Reason of deprecation.
```

Also, no period is appended to the text for versionadded and versionchanged.

note
warning

These are used like so:

```rest
.. note::
   Content of note.
```

- **Otherwise changed commands**

  The `samp` command previously formatted code and added quotation marks around it. The `samp` role, however, features a new highlighting system just like `file` does:

  ```rest
  :samp:`open({filename}, {mode})`
  results in
  open(filename, mode)
  ```

- **Dropped commands**

  These were commands in LaTeX, but are not available as roles:

  `bfcode`
character (use `c`)  
citetitle (use `Title <URL>`)  
code (use ``code``)  
email (just write the address in body text)  
filenq  
filevar (use the {...} highlighting feature of file)  
programopt, longprogramopt (use option)  
ulink (use `Title <URL>`)  
url (just write the URL in body text)  
var (use *var*)  
infinity, plusminus (use the Unicode character)  
shortversion, version (use the `|version|` and `|release|` substitutions)  
emph, strong (use the reST markup)

- **Backslash escaping**

  In reST, a backslash must be escaped in normal text, and in the content of roles. However, in code literals and literal blocks, it must not be escaped. Example: ```file:`C:\Temp\my.tmp` VS. `open("C:\Temp\my.tmp")``. 
5.2. Information units

Information units (...desc environments) have been made reST directives. These changes to information units should be noted:

- **New names**

  “desc” has been removed from every name. Additionally, these directives have new names:

  - `cfunction` (previously `cfuncdesc`)
  - `cmacro` (previously `csimplemacrodesc`)
  - `exception` (previously `excdesc`)
  - `function` (previously `funcdesc`)
  - `attribute` (previously `memberdesc`)

  The `classdesc*` and `excclassdesc` environments have been dropped, the `class` and `exception` directives support classes documented with and without constructor arguments.

- **Multiple objects**

  The equivalent of the `...line` commands is:

  ```
  .. function:: do_foo(bar)
     do_bar(baz)

  Description of the functions.
  ```

  IOW, just give one signatures per line, at the same indentation level.

- **Arguments**

  There is no `optional` command. Just give function signatures like they should appear in the output:
Note: markup in the signature is not supported.

- **Indexing**

The ...*descni* environments have been dropped. To mark an information unit as unsuitable for index entry generation, use the *noindex* option like so:

```plaintext
.. function:: foo_*
   :noindex:

   Description.
```

- **New information units**

There are new generic information units: One is called “describe” and can be used to document things that are not covered by the other units:

```plaintext
.. describe:: a == b

   The equals operator.
```

The others are:

```plaintext
.. cmdoption:: -O

   Describes a command-line option.

.. envvar:: PYTHONINSPECT

   Describes an environment variable.
```
5.3. Structure

The LaTeX docs were split in several toplevel manuals. Now, all files are part of the same documentation tree, as indicated by the `toctree` directives in the sources (though individual output formats may choose to split them up into parts again). Every `toctree` directive embeds other files as subdocuments of the current file (this structure is not necessarily mirrored in the filesystem layout). The toplevel file is `contents.rst`.

However, most of the old directory structure has been kept, with the directories renamed as follows:

- `api` --> `c-api`
- `dist` --> `distutils`, with the single TeX file split up
- `doc` --> `documenting`
- `ext` --> `extending`
- `inst` --> `installing`
- `lib` --> `library`
- `mac` --> merged into `library`, with `mac/using.tex` moved to `using/mac.rst`
- `ref` --> `reference`
- `tut` --> `tutorial`, with the single TeX file split up
6. Building the documentation

You need to have Python 2.4 or higher installed; the toolset used to build the docs is written in Python. It is called Sphinx, it is not included in this tree, but maintained separately. Also needed are the docutils, supplying the base markup that Sphinx uses, Jinja, a templating engine, and optionally Pygments, a code highlighter.
6.1. Using make

Luckily, a Makefile has been prepared so that on Unix, provided you have installed Python and Subversion, you can just run

```
make html
```

to check out the necessary toolset in the `tools/` subdirectory and build the HTML output files. To view the generated HTML, point your favorite browser at the top-level index `build/html/index.html` after running “make”.

Available make targets are:

- “html”, which builds standalone HTML files for offline viewing.

- “htmlhelp”, which builds HTML files and a HTML Help project file usable to convert them into a single Compiled HTML (.chm) file – these are popular under Microsoft Windows, but very handy on every platform.

  To create the CHM file, you need to run the Microsoft HTML Help Workshop over the generated project (.hhp) file.

- “latex”, which builds LaTeX source files as input to “pdflatex” to produce PDF documents.

- “text”, which builds a plain text file for each source file.

- “linkcheck”, which checks all external references to see whether they are broken, redirected or malformed, and outputs this information to stdout as well as a plain-text (.txt) file.
• “changes”, which builds an overview over all versionadded/versionchanged/deprecated items in the current version. This is meant as a help for the writer of the “What’s New” document.

• “coverage”, which builds a coverage overview for standard library modules and C API.

• “pydoc-topics”, which builds a Python module containing a dictionary with plain text documentation for the labels defined in tools/sphinxext/pyspecific.py – pydoc needs these to show topic and keyword help.

A “make update” updates the Subversion checkouts in tools/.
6.2. Without make

You'll need to install the Sphinx package, either by checking it out via

```
svn co http://svn.python.org/projects/external/Sphinx-0.6.5/sphinx
```

or by installing it from PyPI.

Then, you need to install Docutils, either by checking it out via

```
svn co http://svn.python.org/projects/external/docutils-0.6/docutils
```

or by installing it from http://docutils.sf.net/.

You also need Jinja2, either by checking it out via

```
svn co http://svn.python.org/projects/external/Jinja-2.3.1/jinja2
```

or by installing it from PyPI.

You can optionally also install Pygments, either as a checkout via

```
svn co http://svn.python.org/projects/external/Pygments-1.3.1/pygments
```

or from PyPI at http://pypi.python.org/pypi/Pygments.

Then, make an output directory, e.g. under `build/`, and run

```
python tools/sphinx-build.py -b<builder> . build/<outputdirectory>
```

where `<builder>` is one of html, text, latex, or htmlhelp (for explanations see the make targets above).
Abstract

It's usually difficult to get your management to accept open source software, and Python is no exception to this rule. This document discusses reasons to use Python, strategies for winning acceptance, facts and arguments you can use, and cases where you shouldn’t try to use Python.
Reasons to Use Python

There are several reasons to incorporate a scripting language into your development process, and this section will discuss them, and why Python has some properties that make it a particularly good choice.

Programmability

Programs are often organized in a modular fashion. Lower-level operations are grouped together, and called by higher-level functions, which may in turn be used as basic operations by still further upper levels.

For example, the lowest level might define a very low-level set of functions for accessing a hash table. The next level might use hash tables to store the headers of a mail message, mapping a header name like **Date** to a value such as **Tue, 13 May 1997 20:00:54 -0400**. A yet higher level may operate on message objects, without knowing or caring that message headers are stored in a hash table, and so forth.

Often, the lowest levels do very simple things; they implement a data structure such as a binary tree or hash table, or they perform some simple computation, such as converting a date string to a number. The higher levels then contain logic connecting these primitive operations. Using the approach, the primitives can be seen as basic building blocks which are then glued together to produce the complete product.

Why is this design approach relevant to Python? Because Python is well suited to functioning as such a glue language. A common approach is to write a Python module that implements the lower level
operations; for the sake of speed, the implementation might be in C, Java, or even Fortran. Once the primitives are available to Python programs, the logic underlying higher level operations is written in the form of Python code. The high-level logic is then more understandable, and easier to modify.

John Ousterhout wrote a paper that explains this idea at greater length, entitled “Scripting: Higher Level Programming for the 21st Century”. I recommend that you read this paper; see the references for the URL. Ousterhout is the inventor of the Tcl language, and therefore argues that Tcl should be used for this purpose; he only briefly refers to other languages such as Python, Perl, and Lisp/Scheme, but in reality, Ousterhout's argument applies to scripting languages in general, since you could equally write extensions for any of the languages mentioned above.

Prototyping

In *The Mythical Man-Month*, Fredrick Brooks suggests the following rule when planning software projects: “Plan to throw one away; you will anyway.” Brooks is saying that the first attempt at a software design often turns out to be wrong; unless the problem is very simple or you're an extremely good designer, you'll find that new requirements and features become apparent once development has actually started. If these new requirements can’t be cleanly incorporated into the program’s structure, you're presented with two unpleasant choices: hammer the new features into the program somehow, or scrap everything and write a new version of the program, taking the new features into account from the beginning.

Python provides you with a good environment for quickly developing an initial prototype. That lets you get the overall program structure and logic right, and you can fine-tune small details in the fast development cycle that Python provides. Once you're satisfied with the GUI interface or program output, you can translate the Python
code into C++, Fortran, Java, or some other compiled language.

Prototyping means you have to be careful not to use too many Python features that are hard to implement in your other language. Using `eval()`, or regular expressions, or the `pickle` module, means that you’re going to need C or Java libraries for formula evaluation, regular expressions, and serialization, for example. But it’s not hard to avoid such tricky code, and in the end the translation usually isn’t very difficult. The resulting code can be rapidly debugged, because any serious logical errors will have been removed from the prototype, leaving only more minor slip-ups in the translation to track down.

This strategy builds on the earlier discussion of programmability. Using Python as glue to connect lower-level components has obvious relevance for constructing prototype systems. In this way Python can help you with development, even if end users never come in contact with Python code at all. If the performance of the Python version is adequate and corporate politics allow it, you may not need to do a translation into C or Java, but it can still be faster to develop a prototype and then translate it, instead of attempting to produce the final version immediately.

One example of this development strategy is Microsoft Merchant Server. Version 1.0 was written in pure Python, by a company that subsequently was purchased by Microsoft. Version 2.0 began to translate the code into C++, shipping with some C++code and some Python code. Version 3.0 didn’t contain any Python at all; all the code had been translated into C++. Even though the product doesn’t contain a Python interpreter, the Python language has still served a useful purpose by speeding up development.

This is a very common use for Python. Past conference papers have also described this approach for developing high-level numerical algorithms; see David M. Beazley and Peter S. Lomdahl's paper
“Feeding a Large-scale Physics Application to Python” in the references for a good example. If an algorithm’s basic operations are things like “Take the inverse of this 4000x4000 matrix”, and are implemented in some lower-level language, then Python has almost no additional performance cost; the extra time required for Python to evaluate an expression like `m.invert()` is dwarfed by the cost of the actual computation. It’s particularly good for applications where seemingly endless tweaking is required to get things right. GUI interfaces and Web sites are prime examples.

The Python code is also shorter and faster to write (once you’re familiar with Python), so it’s easier to throw it away if you decide your approach was wrong; if you’d spent two weeks working on it instead of just two hours, you might waste time trying to patch up what you’ve got out of a natural reluctance to admit that those two weeks were wasted. Truthfully, those two weeks haven’t been wasted, since you’ve learnt something about the problem and the technology you’re using to solve it, but it’s human nature to view this as a failure of some sort.

Simplicity and Ease of Understanding

Python is definitely not a toy language that’s only usable for small tasks. The language features are general and powerful enough to enable it to be used for many different purposes. It’s useful at the small end, for 10- or 20-line scripts, but it also scales up to larger systems that contain thousands of lines of code.

However, this expressiveness doesn’t come at the cost of an obscure or tricky syntax. While Python has some dark corners that can lead to obscure code, there are relatively few such corners, and proper design can isolate their use to only a few classes or modules. It’s certainly possible to write confusing code by using too many features with too little concern for clarity, but most Python code can
look a lot like a slightly-formalized version of human-understandable pseudocode.

In *The New Hacker’s Dictionary*, Eric S. Raymond gives the following definition for “compact”:

Compact *adj.* Of a design, describes the valuable property that it can all be apprehended at once in one’s head. This generally means the thing created from the design can be used with greater facility and fewer errors than an equivalent tool that is not compact. Compactness does not imply triviality or lack of power; for example, C is compact and FORTRAN is not, but C is more powerful than FORTRAN. Designs become non-compact through accreting features and cruft that don’t merge cleanly into the overall design scheme (thus, some fans of Classic C maintain that ANSI C is no longer compact).

In this sense of the word, Python is quite compact, because the language has just a few ideas, which are used in lots of places. Take namespaces, for example. Import a module with `import math`, and you create a new namespace called `math`. Classes are also namespaces that share many of the properties of modules, and have a few of their own; for example, you can create instances of a class. Instances? They’re yet another namespace. Namespaces are currently implemented as Python dictionaries, so they have the same methods as the standard dictionary data type: `.keys()` returns all the keys, and so forth.

This simplicity arises from Python’s development history. The language syntax derives from different sources; ABC, a relatively obscure teaching language, is one primary influence, and Modula-3 is another. (For more information about ABC and Modula-3, consult their respective Web sites at [http://www.cwi.nl/~steven/abc/](http://www.cwi.nl/~steven/abc/) and
Other features have come from C, Icon, Algol-68, and even Perl. Python hasn’t really innovated very much, but instead has tried to keep the language small and easy to learn, building on ideas that have been tried in other languages and found useful.

Simplicity is a virtue that should not be underestimated. It lets you learn the language more quickly, and then rapidly write code – code that often works the first time you run it.

### Java Integration

If you’re working with Java, Jython ([http://www.jython.org/](http://www.jython.org/)) is definitely worth your attention. Jython is a re-implementation of Python in Java that compiles Python code into Java bytecodes. The resulting environment has very tight, almost seamless, integration with Java. It’s trivial to access Java classes from Python, and you can write Python classes that subclass Java classes. Jython can be used for prototyping Java applications in much the same way CPython is used, and it can also be used for test suites for Java code, or embedded in a Java application to add scripting capabilities.
Let’s say that you’ve decided upon Python as the best choice for your application. How can you convince your management, or your fellow developers, to use Python? This section lists some common arguments against using Python, and provides some possible rebuttals.

**Python is freely available software that doesn’t cost anything. How good can it be?**

Very good, indeed. These days Linux and Apache, two other pieces of open source software, are becoming more respected as alternatives to commercial software, but Python hasn’t had all the publicity.

Python has been around for several years, with many users and developers. Accordingly, the interpreter has been used by many people, and has gotten most of the bugs shaken out of it. While bugs are still discovered at intervals, they’re usually either quite obscure (they’d have to be, for no one to have run into them before) or they involve interfaces to external libraries. The internals of the language itself are quite stable.

Having the source code should be viewed as making the software available for peer review; people can examine the code, suggest (and implement) improvements, and track down bugs. To find out more about the idea of open source code, along with arguments and case studies supporting it, go to [http://www.opensource.org](http://www.opensource.org).

**Who’s going to support it?**

Python has a sizable community of developers, and the number is still growing. The Internet community surrounding the language is an
active one, and is worth being considered another one of Python’s advantages. Most questions posted to the comp.lang.python newsgroup are quickly answered by someone.

Should you need to dig into the source code, you’ll find it’s clear and well-organized, so it’s not very difficult to write extensions and track down bugs yourself. If you’d prefer to pay for support, there are companies and individuals who offer commercial support for Python.

Who uses Python for serious work?

Lots of people; one interesting thing about Python is the surprising diversity of applications that it’s been used for. People are using Python to:

- Run Web sites
- Write GUI interfaces
- Control number-crunching code on supercomputers
- Make a commercial application scriptable by embedding the Python interpreter inside it
- Process large XML data sets
- Build test suites for C or Java code

Whatever your application domain is, there’s probably someone who’s used Python for something similar. Yet, despite being useable for such high-end applications, Python’s still simple enough to use for little jobs.

See http://wiki.python.org/moin/OrganizationsUsingPython for a list of some of the organizations that use Python.

What are the restrictions on Python’s use?

They’re practically nonexistent. Consult the Misc/COPYRIGHT file in the source distribution, or the section History and License for the full language, but it boils down to three conditions:
• You have to leave the copyright notice on the software; if you don’t include the source code in a product, you have to put the copyright notice in the supporting documentation.
• Don’t claim that the institutions that have developed Python endorse your product in any way.
• If something goes wrong, you can’t sue for damages. Practically all software licenses contain this condition.

Notice that you don’t have to provide source code for anything that contains Python or is built with it. Also, the Python interpreter and accompanying documentation can be modified and redistributed in any way you like, and you don’t have to pay anyone any licensing fees at all.

**Why should we use an obscure language like Python instead of well-known language X?**

I hope this HOWTO, and the documents listed in the final section, will help convince you that Python isn’t obscure, and has a healthily growing user base. One word of advice: always present Python’s positive advantages, instead of concentrating on language X’s failings. People want to know why a solution is good, rather than why all the other solutions are bad. So instead of attacking a competing solution on various grounds, simply show how Python’s virtues can help.

The Python Success Stories are a collection of stories from successful users of Python, with the emphasis on business and corporate users.

http://home.pacbell.net/ouster/scripting.html

John Ousterhout’s white paper on scripting is a good argument for the utility of scripting languages, though naturally enough, he emphasizes Tcl, the language he developed. Most of the arguments would apply to any scripting language.

http://www.python.org/workshops/1997-10/proceedings/beazley.html

The authors, David M. Beazley and Peter S. Lomdahl, describe their use of Python at Los Alamos National Laboratory. It’s another good example of how Python can help get real work done. This quotation from the paper has been echoed by many people:

Originally developed as a large monolithic application for massively parallel processing systems, we have used Python to transform our application into a flexible, highly modular, and extremely powerful system for performing simulation, data analysis, and visualization. In addition, we describe how Python has solved a number of important problems related to the development, debugging, deployment, and maintenance of scientific software.

This interview with Andy Feit, discussing Infoseek’s use of Python, can be used to show that choosing Python didn’t introduce any difficulties into a company’s development process,
and provided some substantial benefits.

http://www.python.org/workshops/1997-10/proceedings/stein.ps

For the 6th Python conference, Greg Stein presented a paper that traced Python’s adoption and usage at a startup called eShop, and later at Microsoft.

http://www.opensource.org

Management may be doubtful of the reliability and usefulness of software that wasn’t written commercially. This site presents arguments that show how open source software can have considerable advantages over closed-source software.

http://www.faqs.org/docs/Linux-mini/Advocacy.html

The Linux Advocacy mini-HOWTO was the inspiration for this document, and is also well worth reading for general suggestions on winning acceptance for a new technology, such as Linux or Python. In general, you won’t make much progress by simply attacking existing systems and complaining about their inadequacies; this often ends up looking like unfocused whining. It’s much better to point out some of the many areas where Python is an improvement over other systems.
Porting Extension Modules to 3.0

author: Benjamin Peterson

Abstract

Although changing the C-API was not one of Python 3.0's objectives, the many Python level changes made leaving 2.x's API intact impossible. In fact, some changes such as `int()` and `long()` unification are more obvious on the C level. This document endeavors to document incompatibilities and how they can be worked around.
Conditional compilation

The easiest way to compile only some code for 3.0 is to check if `PY_MAJOR_VERSION` is greater than or equal to 3.

```c
#if PY_MAJOR_VERSION >= 3
#define IS_PY3K
#endif
```

API functions that are not present can be aliased to their equivalents within conditional blocks.
Changes to Object APIs

Python 3.0 merged together some types with similar functions while cleanly separating others.

str/unicode Unification

Python 3.0’s `str()` (PyString_* functions in C) type is equivalent to 2.x’s `unicode()` (PyUnicode_*). The old 8-bit string type has become `bytes()`. Python 2.6 and later provide a compatibility header, `bytesobject.h`, mapping `PyBytes` names to `PyString` ones. For best compatibility with 3.0, `PyUnicode` should be used for textual data and `PyBytes` for binary data. It’s also important to remember that `PyBytes` and `PyUnicode` in 3.0 are not interchangeable like `PyString` and `PyString` are in 2.x. The following example shows best practices with regards to `PyUnicode`, `PyString`, and `PyBytes`.

```c
#include "stdlib.h"
#include "Python.h"
#include "bytesobject.h"

/* text example */
static PyObject *
say_hello(PyObject *self, PyObject *args) {
    PyObject *name, *result;

    if (!PyArg_ParseTuple(args, "U:say_hello", &name))
        return NULL;

    result = PyUnicode_FromFormat("Hello, %S!", name);
    return result;
}

/* just a forward */
static char * do_encode(PyObject *);

/* bytes example */
```
In Python 3.0, there is only one integer type. It is called `int()` on the Python level, but actually corresponds to 2.x’s `long()` type. In the C-API, `PyInt_*` functions are replaced by their `PyLong_*` neighbors. The best course of action here is using the `PyInt_*` functions aliased to `PyLong_*` found in `intobject.h`. The abstract `PyNumber_*` APIs can also be used in some cases.

```c
#include "Python.h"
#include "intobject.h"

static PyObject *
add_ints(PyObject *self, PyObject *args) {
    int one, two;
    PyObject *result;

    if (!PyArg_ParseTuple(args, "ii:add_ints", &one, &two))
        return NULL;

    return PyInt_FromLong(one + two);
}
```
Module initialization and state

Python 3.0 has a revamped extension module initialization system. (See [PEP 3121](https://www.python.org/dev/peps/pep-03121/).) Instead of storing module state in globals, they should be stored in an interpreter specific structure. Creating modules that act correctly in both 2.x and 3.0 is tricky. The following simple example demonstrates how.

```c
#include "Python.h"

struct module_state {
    PyObject *error;
};

#if PY_MAJOR_VERSION >= 3
#define GETSTATE(m) ((struct module_state*)PyModule_GetState(m))
#else
#define GETSTATE(m) (&_state)
#endif
static struct module_state _state;

static PyObject *
error_out(PyObject *m) {
    struct module_state *st = GETSTATE(m);
    PyErr_SetString(st->error, "something bad happened");
    return NULL;
}

static PyMethodDef myextension_methods[] = {
    {"error_out", (PyCFunction)error_out, METH_NOARGS, NULL},
    {NULL, NULL}
};

#if PY_MAJOR_VERSION >= 3
static int myextension_traverse(PyObject *m, visitproc visit, void *arg)
    Py_VISIT(GETSTATE(m)->error);
    return 0;
#endif

static int myextension_clear(PyObject *m) {
    Py_CLEAR(GETSTATE(m)->error);
}
```
return 0;
}

static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    "myextension",
    NULL,
    sizeof(struct module_state),
    myextension_methods,
    NULL,
    myextension_traverse,
    myextension_clear,
    NULL
};

#define INITERROR return NULL

PyObject *
PyInit_myextension(void)

#else
#define INITERROR return

void
initmyextension(void)
#endif

{ #if PY_MAJOR_VERSION >= 3
    PyObject *module = PyModule_Create(&moduledef);
#else
    PyObject *module = Py_InitModule("myextension",
    myextension_methods);
#endif
    void
initmyextension(void)
#endif

{ #if PY_MAJOR_VERSION >= 3
    PyObject *module = PyModule_Create(&moduledef);
#else
    PyObject *module = Py_InitModule("myextension", myextension
#endif

if (module == NULL)  
    INITERROR;
    struct module_state *st = GETSTATE(module);

    st->error = PyErr_NewException("myextension.Error", NULL, N
    if (st->error == NULL) {
        Py_XDECREF(module);
        INITERROR;
    }

#if PY_MAJOR_VERSION >= 3
    return module;
#else
    return NULL;
#endif
Other options

If you are writing a new extension module, you might consider Cython. It translates a Python-like language to C. The extension modules it creates are compatible with Python 3.x and 2.x.
Abstract

This document describes how to write text-mode programs with Python 2.x, using the `curses` extension module to control the display.
What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by X11 programs such as xterm and rxvt. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of X displays, one might ask “why bother”? It's true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One is on small-footprint or embedded Unixes that don’t carry an X server. Another is for tools like OS installers and kernel configurators that may have to run before X is available.

The curses library hides all the details of different terminals, and provides the programmer with an abstraction of a display, containing multiple non-overlapping windows. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will automagically figure out what control codes need to be sent to the terminal to produce the right output.

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you're using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older
versions of curses carried by some proprietary Unixes may not support everything, though.

No one has made a Windows port of the curses module. On a Windows platform, try the Console module written by Fredrik Lundh. The Console module provides cursor-addressable text output, plus full support for mouse and keyboard input, and is available from http://effbot.org/zone/console-index.htm.

The Python curses module

Thy Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler, by merging different C functions such as addstr(), mvaddstr(), mvwaddstr(), into a single addstr() method. You'll see this covered in more detail later.

This HOWTO is simply an introduction to writing text-mode programs with curses and Python. It doesn't attempt to be a complete guide to the curses API; for that, see the Python library guide's section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.
Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr`, after the name of the corresponding C variable.

```python
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```python
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```python
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you’ll have to enable keypad mode.

```python
stdscr.keypad(1)
```

Terminating a curses application is much easier than starting one.
You'll need to call

```c
    curses.nocbreak(); stdscr.keypad(0); curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

```c
    curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer be echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the module `curses.wrapper`. It supplies a `wrapper()` function that takes a callable. It does the initializations described above, and also initializes colors if color support is present. It then runs your provided callable and finally deinitializes appropriately. The callable is called inside a try-catch clause which catches exceptions, performs curses deinitialization, and then passes the exception upwards. Thus, your terminal won’t be left in a funny state on exception.
Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports various methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```plaintext
begin_x = 20 ; begin_y = 7
height = 5 ; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

A word about the coordinate system used in curses: coordinates are always passed in the order y,x, and the top-left corner of a window is coordinate (0,0). This breaks a common convention for handling coordinates, where the x coordinate usually comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

When you call a method to display or erase text, the effect doesn’t immediately show up on the display. This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen is very important. This lets curses accumulate changes to the screen, and display them in the most efficient manner. For example, if your program displays some characters in a window, and then clears the window, there's no need to send the original characters
because they’d never be visible.

Accordingly, curses requires that you explicitly tell it to redraw windows, using the \texttt{refresh()} method of window objects. In practice, this doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by simply calling \texttt{stdscr.refresh()} or the \texttt{refresh()} method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of it displayed at a time. Creating a pad simply requires the pad’s height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```python
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; this is
# explained in the next section
for y in range(0, 100):
    for x in range(0, 100):
        try:
            pad.addch(y, x, ord('a') + (x*x+y*y) % 26 )
        except curses.error:
            pass

# Displays a section of the pad in the middle of the screen
pad.refresh( 0,0, 5,5, 20,75)
```

The \texttt{refresh()} call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to go, which will prevent annoying screen flicker at refresh time. Use the \texttt{noutrefresh()} method of each window to
update the data structure representing the desired state of the screen; then change the physical screen to match the desired state in one go with the function `doupdate()`. The normal `refresh()` method calls `doupdate()` as its last act.
Displaying Text

From a C programmer’s point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, `addstr()` displays a string at the current cursor location in the `stdscr` window, while `mvaddstr()` moves to a given y,x coordinate first before displaying the string. `waddstr()` is just like `addstr()`, but allows specifying a window to use, instead of using `stdscr` by default. `mvwaddstr()` follows similarly.

Fortunately the Python interface hides all these details; `stdscr` is a window object like any other, and methods like `addstr()` accept multiple argument forms. Usually there are four different forms.

<table>
<thead>
<tr>
<th>Form</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>str</code> or <code>ch</code></td>
<td>Display the string <code>str</code> or character <code>ch</code> at the current position</td>
</tr>
<tr>
<td><code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Display the string <code>str</code> or character <code>ch</code>, using attribute <code>attr</code> at the current position</td>
</tr>
<tr>
<td><code>y</code>, <code>x</code>, <code>str</code> or <code>ch</code></td>
<td>Move to position <code>y</code>,<code>x</code> within the window, and display <code>str</code> or <code>ch</code></td>
</tr>
<tr>
<td><code>y</code>, <code>x</code>, <code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Move to position <code>y</code>,<code>x</code> within the window, and display <code>str</code> or <code>ch</code>, using attribute <code>attr</code></td>
</tr>
</tbody>
</table>

Attributes allow displaying text in highlighted forms, such as in boldface, underline, reverse code, or in color. They’ll be explained in more detail in the next subsection.

The `addstr()` function takes a Python string as the value to be displayed, while the `addch()` functions take a character, which can be either a Python string of length 1 or an integer. If it’s a string, you’re
limited to displaying characters between 0 and 255. SVr4 curses provides constants for extension characters; these constants are integers greater than 255. For example, \texttt{ACS_PLMINUS} is a +/- symbol, and \texttt{ACS_ULCORNER} is the upper left corner of a box (handy for drawing borders).

Windows remember where the cursor was left after the last operation, so if you leave out the \texttt{y,x} coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the \texttt{move(y,x)} method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won't be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn't need a blinking cursor at all, you can call \texttt{curs_set(0)} to make it invisible. Equivalently, and for compatibility with older curses versions, there's a \texttt{leaveok(bool)} function. When \texttt{bool} is true, the curses library will attempt to suppress the flashing cursor, and you won't need to worry about leaving it in odd locations.

\section*{Attributes and Color}

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video; a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is a integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn't guarantee that all the possible combinations are available, or that they're all visually distinct. That depends on the ability of the terminal being used, so it's safest to stick to the most commonly available attributes, listed here.
<table>
<thead>
<tr>
<th>Attribute</th>

<tr>
<td>A_REVERSE</td>
<td>Reverse-video text</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>The best highlighting mode available</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underlined text</td>
</tr>
</tbody>
</table>

So, to display a reverse-video status line on the top line of the screen, you could code:

```python
stdscr.addstr(0, 0, "Current mode: Typing mode",
curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it, The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper.wrapper()` function does this automatically). Once that's done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling ‘color’, instead of the Canadian/British spelling ‘colour’. If you’re used to the British spelling, you’ll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR’ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work
on all terminals.

An example, which displays a line of text using color pair 1:

```python
stdscr.addstr( "Pretty text", curses.color_pair(1) )
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The curses module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

The `init_pair(n, f, b)` function changes the definition of color pair `n`, to foreground color `f` and background color `b`. Color pair 0 is hard-wired to white on black, and cannot be changed.

Let’s put all this together. To change color 1 to red text on a white background, you would call:

```python
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```python
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1) )
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn’t support this, so I’m unable to try it out, and can’t provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `TRUE` if the
capability is there. If you’re lucky enough to have such a talented terminal, consult your system’s man pages for more information.
The curses library itself offers only very simple input mechanisms. Python’s support adds a text-input widget that makes up some of the lack.

The most common way to get input to a window is to use its `getch()` method. `getch()` pauses and waits for the user to hit a key, displaying it if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.

It’s possible to change this behavior with the method `nodelay()`. After `nodelay(1), getch()` for the window becomes non-blocking and returns `curses.ERR` (a value of -1) when no input is ready. There’s also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch();` if no input becomes available within a specified delay (measured in tenths of a second), curses raises an exception.

The `getch()` method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE, curses.KEY_HOME,` or `curses.KEY_LEFT`. Usually the main loop of your program will look something like this:

```python
while 1:
    c = stdscr.getch()
    if c == ord('p'): PrintDocument()
    elif c == ord('q'): break  # Exit the while()
    elif c == curses.KEY_HOME: x = y = 0
```

The `curses.ascii` module supplies ASCII class membership
functions that take either integer or 1-character-string arguments; these may be useful in writing more readable tests for your command interpreters. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```python
import curses

curses.echo()  # Enable echoing of characters

# Get a 15-character string, with the cursor on the top line
s = stdscr.getstr(0,0, 15)
```

The Python `curses.textpad` module supplies something better. With it, you can turn a window into a text box that supports an Emacs-like set of keybindings. Various methods of `TextBox` class support editing with input validation and gathering the edit results either with or without trailing spaces. See the library documentation on `curses.textpad` for the details.
This HOWTO didn't cover some advanced topics, such as screen-scraping or capturing mouse events from an xterm instance. But the Python library page for the curses modules is now pretty complete. You should browse it next.

If you're in doubt about the detailed behavior of any of the ncurses entry points, consult the manual pages for your curses implementation, whether it's ncurses or a proprietary Unix vendor's. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and ACS_* characters available to you.

Because the curses API is so large, some functions aren’t supported in the Python interface, not because they're difficult to implement, but because no one has needed them yet. Feel free to add them and then submit a patch. Also, we don’t yet have support for the menu library associated with ncurses; feel free to add that.

If you write an interesting little program, feel free to contribute it as another demo. We can always use more of them!

Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Examines a custom descriptor and several built-in python descriptors including functions, properties, static methods, and class methods. Shows how each works by giving a pure Python equivalent and a sample application.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works and an appreciation for the elegance of its design.
Definition and Introduction

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol. Those methods are \_\_get\_\_(), \_\_set\_\_(), and \_\_delete\_\_(). If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, \texttt{a.x} has a lookup chain starting with \texttt{a.__dict__['x']}, then \texttt{type(a).__dict__['x']}, and continuing through the base classes of \texttt{type(a)} excluding metaclasses. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined. Note that descriptors are only invoked for new style objects or classes (a class is new style if it inherits from \texttt{object} or \texttt{type}).

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and \texttt{super()}. They are used used throughout Python itself to implement the new style classes introduced in version 2.2. Descriptors simplify the underlying C-code and offer a flexible set of new tools for everyday Python programs.
Descriptor Protocol

```python
descr.__get__(self, obj, type=None) --> value

descr.__set__(self, obj, value) --> None

descr.__delete__(self, obj) --> None
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines both `__get__()` and `__set__()`, it is considered a data descriptor. Descriptors that only define `__get__()` are called non-data descriptors (they are typically used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both `__get__()` and `__set__()` with the `__set__()` raising an `AttributeError` when called. Defining the `__set__()` method with an exception raising placeholder is enough to make it a data descriptor.
Invoking Descriptors

A descriptor can be called directly by its method name. For example, 
\[ d.__get__(obj) \].

Alternatively, it is more common for a descriptor to be invoked automatically upon attribute access. For example, \[ obj.d \] looks up \[ d \] in the dictionary of \[ obj \]. If \[ d \] defines the method \[ __get__() \], then \[ d.__get__(obj) \] is invoked according to the precedence rules listed below.

The details of invocation depend on whether \[ obj \] is an object or a class. Either way, descriptors only work for new style objects and classes. A class is new style if it is a subclass of \[ object \].

For objects, the machinery is in \[ object.__getattribute__() \] which transforms \[ b.x \] into \[ type(b).__dict__['x'].__get__(b, type(b)) \].

The implementation works through a precedence chain that gives data descriptors priority over instance variables, instance variables priority over non-data descriptors, and assigns lowest priority to \[ __getattr__() \] if provided. The full C implementation can be found in \[ PyObject_GenericGetAttr() \] in \[ Objects/object.c \].

For classes, the machinery is in \[ type.__getattribute__() \] which transforms \[ B.x \] into \[ B.__dict__['x'].__get__(None, B) \]. In pure Python, it looks like:

```python
def __getattribute__(self, key):
    "Emulate type_getattro() in Objects/typeobject.c"
    v = object.__getattribute__(self, key)
    if hasattr(v, '__get__'):
        return v.__get__(None, self)
    return v
```
The important points to remember are:

- descriptors are invoked by the \_\_getattribute\_\_(\_) method
- overriding \_\_getattribute\_\_() prevents automatic descriptor calls
- \_\_getattribute\_\_() is only available with new style classes and objects
- object.__getattribute__() and type.__getattribute__() make different calls to \_\_get\_\_().
- data descriptors always override instance dictionaries.
- non-data descriptors may be overridden by instance dictionaries.

The object returned by super() also has a custom \_\_getattribute\_\_() method for invoking descriptors. The call super(B, obj).m() searches obj.__class__.__mro__ for the base class A immediately following B and then returns A.__dict__['m'].\_\_get\_\_(obj, A). If not a descriptor, m is returned unchanged. If not in the dictionary, m reverts to a search using object.__getattribute__().

Note, in Python 2.2, super(B, obj).m() would only invoke \_\_get\_\_() if m was a data descriptor. In Python 2.3, non-data descriptors also get invoked unless an old-style class is involved. The implementation details are in super_getattro() in Objects/typeobject.c and a pure Python equivalent can be found in Guido's Tutorial.

The details above show that the mechanism for descriptors is embedded in the \_\_getattribute\_\_() methods for object, type, and super(). Classes inherit this machinery when they derive from object or if they have a meta-class providing similar functionality. Likewise, classes can turn-off descriptor invocation by overriding \_\_getattribute\_\_().
Descriptor Example

The following code creates a class whose objects are data descriptors which print a message for each get or set. Overriding \_\_getattribute\_\_() is alternate approach that could do this for every attribute. However, this descriptor is useful for monitoring just a few chosen attributes:

class RevealAccess(object):
    """A data descriptor that sets and returns values normally and prints a message logging their access.
    """
    def __init__(self, initval=None, name='var'):
        self.val = initval
        self.name = name

    def __get__(self, obj, objtype):
        print 'Retrieving', self.name
        return self.val

    def __set__(self, obj, val):
        print 'Updating', self.name
        self.val = val

>>> class MyClass(object):
    x = RevealAccess(10, 'var "x"')
    y = 5

>>> m = MyClass()
>>> m.x
Retrieving var "x"
10
>>> m.x = 20
Updating var "x"
>>> m.x
Retrieving var "x"
20
>>> m.y
5
The protocol is simple and offers exciting possibilities. Several use cases are so common that they have been packaged into individual function calls. Properties, bound and unbound methods, static methods, and class methods are all based on the descriptor protocol.
Properties

Calling `property()` is a succinct way of building a data descriptor that triggers function calls upon access to an attribute. Its signature is:

```python
property(fget=None, fset=None, fdel=None, doc=None) -> property
```

The documentation shows a typical use to define a managed attribute `x`:

```python
class C(object):
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property.")
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```python
class Property(object):
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None, doc=None)
        self.fget = fget
        self.fset = fset
        self.fdel = fdel
        self.__doc__ = doc

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
        if self.fget is None:
            raise AttributeError, "unreadable attribute"
        return self.fget(obj)

    def __set__(self, obj, value):
        if self.fset is None:
            raise AttributeError, "can't set attribute"
        self.fset(obj, value)
```
def __delete__(self, obj):
    if self.fdel is None:
        raise AttributeError, "can't delete attribute"
    self.fdel(obj)

The \texttt{property()}\ builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through \texttt{Cell('b10').value}. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the \texttt{value} attribute in a property data descriptor:

class Cell(object):
    .
    .
    .
    def getvalue(self, obj):
        "Recalculate cell before returning value"
        self.recalc()
        return obj._value
    value = property(getvalue)
Python’s object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Class dictionaries store methods as functions. In a class definition, methods are written using `def` and `lambda`, the usual tools for creating functions. The only difference from regular functions is that the first argument is reserved for the object instance. By Python convention, the instance reference is called `self` but may be called `this` or any other variable name.

To support method calls, functions include the `__get__()` method for binding methods during attribute access. This means that all functions are non-data descriptors which return bound or unbound methods depending whether they are invoked from an object or a class. In pure python, it works like this:

```python
class Function(object):  
    
    def __get__(self, obj, objtype=None):
        "Simulate func_descr_get() in Objects/funcobject.c"
        return types.MethodType(self, obj, objtype)
```

Running the interpreter shows how the function descriptor works in practice:

```python
>>> class D(object):
    def f(self, x):
        return x

>>> d = D()
>>> D.__dict__['f']  # Stored internally as a function
<function f at 0x00C45070>
>>> D.f              # Get from a class becomes an unbound method
<unbound method D.f>
```
The output suggests that bound and unbound methods are two different types. While they could have been implemented that way, the actual C implementation of `PyMethod_Type` in `Objects/classobject.c` is a single object with two different representations depending on whether the `im_self` field is set or is `NULL` (the C equivalent of `None`).

Likewise, the effects of calling a method object depend on the `im_self` field. If set (meaning bound), the original function (stored in the `im_func` field) is called as expected with the first argument set to the instance. If unbound, all of the arguments are passed unchanged to the original function. The actual C implementation of `instancemethod_call()` is only slightly more complex in that it includes some type checking.
Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a \texttt{__get__()} method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms a \texttt{obj.f(*args)} call into \texttt{f(obj, *args)}. Calling \texttt{klass.f(*args)} becomes \texttt{f(*args)}.

This chart summarizes the binding and its two most useful variants:

<table>
<thead>
<tr>
<th>Transformation</th>
<th>Called from an Object</th>
<th>Called from a Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>function</td>
<td>\texttt{f(obj, *args)}</td>
<td>\texttt{f(*args)}</td>
</tr>
<tr>
<td>staticmethod</td>
<td>\texttt{f(*args)}</td>
<td>\texttt{f(*args)}</td>
</tr>
<tr>
<td>classmethod</td>
<td>\texttt{f(type(obj), *args)}</td>
<td>\texttt{f(klass, *args)}</td>
</tr>
</tbody>
</table>

Static methods return the underlying function without changes. Calling either \texttt{c.f} or \texttt{C.f} is the equivalent of a direct lookup into \texttt{object.__getattribute__(c, "f")} or \texttt{object.__getattribute__(C, "f").} As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the \texttt{self} variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful functions which are conceptually related but do not depend on the data. For instance, \texttt{erf(x)} is handy conversion routine that comes
up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: 

s.erf(1.5) --> .9332 Or Sample.erf(1.5) --> .9332.

Since staticmethods return the underlying function with no changes, the example calls are unexciting:

```py
>>> class E(object):
    def f(x):
        print x
    f = staticmethod(f)

>>> print E.f(3)
3
>>> print E().f(3)
3
```

Using the non-data descriptor protocol, a pure Python version of `staticmethod()` would look like this:

```py
class StaticMethod(object):
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, objtype=None):
        return self.f
```

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:

```py
>>> class E(object):
    def f(klass, x):
        return klass.__name__, x
    f = classmethod(f)

>>> print E.f(3)
('E', 3)
>>> print E().f(3)
```
This behavior is useful whenever the function only needs to have a class reference and does not care about any underlying data. One use for classmethods is to create alternate class constructors. In Python 2.3, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```python
class Dict:
    ...
    def fromkeys(klass, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c"
        d = klass()
        for key in iterable:
            d[key] = value
        return d
fromkeys = classmethod(fromkeys)
```

Now a new dictionary of unique keys can be constructed like this:

```python
>>> Dict.fromkeys('abracadabra')
{'a': None, 'r': None, 'b': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:

```python
class ClassMethod(object):
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"
    def __init__(self, f):
        self.f = f
    def __get__(self, obj, klass=None):
        if klass is None:
            klass = type(obj)
        def newfunc(*args):
            return self.f(klass, *args)
        return newfunc
```
Idioms and Anti-Idioms in Python

This document is placed in the public domain.

Abstract

This document can be considered a companion to the tutorial. It shows how to use Python, and even more importantly, how not to use Python.
Language Constructs You Should Not Use

While Python has relatively few gotchas compared to other languages, it still has some constructs which are only useful in corner cases, or are plain dangerous.

**from module import ***

**Inside Function Definitions**

`from module import *` is *invalid* inside function definitions. While many versions of Python do not check for the invalidity, it does not make it more valid, no more than having a smart lawyer makes a man innocent. Do not use it like that ever. Even in versions where it was accepted, it made the function execution slower, because the compiler could not be certain which names are local and which are global. In Python 2.1 this construct causes warnings, and sometimes even errors.

**At Module Level**

While it is valid to use `from module import *` at module level it is usually a bad idea. For one, this loses an important property Python otherwise has — you can know where each toplevel name is defined by a simple “search” function in your favourite editor. You also open yourself to trouble in the future, if some module grows additional functions or classes.

One of the most awful question asked on the newsgroup is why this code:

```python
f = open("www")
f.read()
```
does not work. Of course, it works just fine (assuming you have a file called “www”.) But it does not work if somewhere in the module, the statement \texttt{from os import *} is present. The \texttt{os} module has a function called \texttt{open()} which returns an integer. While it is very useful, shadowing a builtin is one of its least useful properties.

Remember, you can never know for sure what names a module exports, so either take what you need — \texttt{from module import name1, name2}, or keep them in the module and access on a per-need basis — \texttt{import module; print module.name}.

### When It Is Just Fine

There are situations in which \texttt{from module import *} is just fine:

- The interactive prompt. For example, \texttt{from math import *} makes Python an amazing scientific calculator.
- When extending a module in C with a module in Python.
- When the module advertises itself as \texttt{from import * safe}.

### Unadorned \texttt{exec, execfile()} and friends

The word “unadorned” refers to the use without an explicit dictionary, in which case those constructs evaluate code in the \texttt{current} environment. This is dangerous for the same reasons \texttt{from import *} is dangerous — it might step over variables you are counting on and mess up things for the rest of your code. Simply do not do that.

**Bad examples:**

```python
>>> for name in sys.argv[1:]:
    exec "%s=1" % name
>>> def func(s, **kw):
    for var, val in kw.items():
        exec "s.%s=val" % var  # invalid!
```
from module import name1, name2

This is a “don’t” which is much weaker than the previous “don’t”s but is still something you should not do if you don’t have good reasons to do that. The reason it is usually bad idea is because you suddenly have an object which lives in two separate namespaces. When the binding in one namespace changes, the binding in the other will not, so there will be a discrepancy between them. This happens when, for example, one module is reloaded, or changes the definition of a function at runtime.

Bad example:

```python
# foo.py
a = 1

# bar.py
from foo import a
if something():
    a = 2  # danger: foo.a != a
```

Good example:
except:

Python has the `except:` clause, which catches all exceptions. Since every error in Python raises an exception, this makes many programming errors look like runtime problems, and hinders the debugging process.

The following code shows a great example:

```python
try:
    foo = opne("file")  # misspelled "open"
except:
    sys.exit("could not open file!")
```

The second line triggers a `NameError` which is caught by the `except` clause. The program will exit, and you will have no idea that this has nothing to do with the readability of "file".

The example above is better written

```python
try:
    foo = opne("file")  # will be changed to "open" as soon as we run it
except IOError:
    sys.exit("could not open file")
```

There are some situations in which the `except:` clause is useful: for example, in a framework when running callbacks, it is good not to let any callback disturb the framework.
Exceptions

Exceptions are a useful feature of Python. You should learn to raise them whenever something unexpected occurs, and catch them only where you can do something about them.

The following is a very popular anti-idiom

```python
def get_status(file):
    if not os.path.exists(file):
        print "file not found"
        sys.exit(1)
    return open(file).readline()
```

Consider the case the file gets deleted between the time the call to `os.path.exists()` is made and the time `open()` is called. That means the last line will throw an `IOError`. The same would happen if `file` exists but has no read permission. Since testing this on a normal machine on existing and non-existing files make it seem bugless, that means in testing the results will seem fine, and the code will get shipped. Then an unhandled `IOError` escapes to the user, who has to watch the ugly traceback.

Here is a better way to do it.

```python
def get_status(file):
    try:
        return open(file).readline()
    except (IOError, OSError):
        print "file not found"
        sys.exit(1)
```

In this version, *either* the file gets opened and the line is read (so it works even on flaky NFS or SMB connections), or the message is printed and the application aborted.
Still, `get_status()` makes too many assumptions — that it will only be used in a short running script, and not, say, in a long running server. Sure, the caller could do something like

```python
try:
    status = get_status(log)
except SystemExit:
    status = None
```

So, try to make as few `except` clauses in your code — those will usually be a catch-all in the `main()`, or inside calls which should always succeed.

So, the best version is probably

```python
def get_status(file):
    return open(file).readline()
```

The caller can deal with the exception if it wants (for example, if it tries several files in a loop), or just let the exception filter upwards to its caller.

The last version is not very good either — due to implementation details, the file would not be closed when an exception is raised until the handler finishes, and perhaps not at all in non-C implementations (e.g., Jython).

```python
def get_status(file):
    with open(file) as fp:
        return fp.readline()
```
Using the Batteries

Every so often, people seem to be writing stuff in the Python library again, usually poorly. While the occasional module has a poor interface, it is usually much better to use the rich standard library and data types that come with Python than inventing your own.

A useful module very few people know about is `os.path`. It always has the correct path arithmetic for your operating system, and will usually be much better than whatever you come up with yourself.

Compare:

```python
# ugh!
return dir+"/"+file
# better
return os.path.join(dir, file)
```

More useful functions in `os.path`: `basename()`, `dirname()` and `splitext()`.

There are also many useful built-in functions people seem not to be aware of for some reason: `min()` and `max()` can find the minimum/maximum of any sequence with comparable semantics, for example, yet many people write their own `max()/min()`. Another highly useful function is `reduce()`. A classical use of `reduce()` is something like

```python
import sys, operator
ums = map(float, sys.argv[1:])
print reduce(operator.add, nums)/len(nums)
```

This cute little script prints the average of all numbers given on the command line. The `reduce()` adds up all the numbers, and the rest is just some pre- and postprocessing.
On the same note, note that `float()`, `int()` and `long()` all accept arguments of type string, and so are suited to parsing — assuming you are ready to deal with the `ValueError` they raise.
Using Backslash to Continue Statements

Since Python treats a newline as a statement terminator, and since statements are often more than is comfortable to put in one line, many people do:

```python
if foo.bar()['first'][0] == baz.quux(1, 2)[5:9] and 
    calculate_number(10, 20) != forbulate(500, 360):
    pass
```

You should realize that this is dangerous: a stray space after the `\` would make this line wrong, and stray spaces are notoriously hard to see in editors. In this case, at least it would be a syntax error, but if the code was:

```python
value = foo.bar()['first'][0]*baz.quux(1, 2)[5:9] \ 
    + calculate_number(10, 20)*forbulate(500, 360)
```

then it would just be subtly wrong.

It is usually much better to use the implicit continuation inside parenthesis:

This version is bulletproof:

```python
value = (foo.bar()['first'][0]*baz.quux(1, 2)[5:9] 
    + calculate_number(10, 20)*forbulate(500, 360))
```
In this document, we'll take a tour of Python’s features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as *iterators* and *generators* and relevant library modules such as *itertools* and *functools*.
Introduction

This section explains the basic concept of functional programming; if you’re just interested in learning about Python language features, skip to the next section.

Programming languages support decomposing problems in several different ways:

- **Most programming languages are procedural**: programs are lists of instructions that tell the computer what to do with the program’s input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you’re most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.
- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don’t force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don’t have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize
one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren't visible in the function's return value. Functions that have no side effects at all are called purely functional. Avoiding side effects means not using data structures that get updated as a program runs; every function's output must only depend on its input.

Some languages are very strict about purity and don't even have assignment statements such as a=3 or c = a + b, but it's difficult to avoid all side effects. Printing to the screen or writing to a disk file are side effects, for example. For example, in Python a print statement or a time.sleep(1) both return no useful value; they're only called for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won't go to the extreme of avoiding all I/O or all assignments; instead, they'll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won't modify global variables or have other side effects.

Functional programming can be considered the opposite of object-
oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

**Formal provability**

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program’s source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program's variables that are always true. For each line of code, you then show that if invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is
executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program's output.

Functional programming's avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there's an error in it, and you wrongly believe you've proved the program correct.

## Modularity

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It's easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

## Ease of debugging and testing

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn't work, each function is an interface point where you can check that the data are correct. You
can look at the intermediate inputs and outputs to quickly isolate the function that's responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don’t depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

**Composability**

As you work on a functional-style program, you'll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you’ll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.
Iterators

I’ll start by looking at a Python language feature that’s an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `next()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `next()` must raise the `StopIteration` exception. Iterators don’t have to be finite, though; it’s perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object’s contents or elements, raising `TypeError` if the object doesn’t support iteration. Several of Python’s built-in data types support iteration, the most common being lists and dictionaries. An object is called an `iterable` object if you can get an iterator for it.

You can experiment with the iteration interface manually:

```python
>>> L = [1,2,3]
>>> it = iter(L)
>>> print it
<...iterator object at ...>
>>> it.next()
1
>>> it.next()
2
>>> it.next()
3
>>> it.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
StopIteration
```
Python expects iterable objects in several different contexts, the most important being the `for` statement. In the statement `for X in Y`, Y must be an iterator or some object for which `iter()` can create an iterator. These two statements are equivalent:

```python
for i in iter(obj):
    print i
for i in obj:
    print i
```

Iterators can be materialized as lists or tuples by using the `list()` or `tuple()` constructor functions:

```python
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an N-tuple:

```python
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> a,b,c = iterator
>>> a,b,c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator argument and will return the largest or smallest element. The "in" and "not in" operators also support iterators: `X in iterator` is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; `max()`, `min()`, and "not in" will never return, and if the element X never appears in the stream,
the "in" operator won’t return either.

Note that you can only go forward in an iterator; there’s no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the `next()` method. Functions may therefore consume all of the iterator’s output, and if you need to do something different with the same stream, you’ll have to create a new iterator.

Data Types That Support Iterators

We’ve already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling `iter()` on a dictionary returns an iterator that will loop over the dictionary’s keys:

```python
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5, 'Jun ...
   'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11, 'Dec'
>>> for key in m:
...   print key, m[key]
Mar 3
Feb 2
Aug 8
Sep 9
Apr 4
Jun 6
Jul 7
Jan 1
May 5
Nov 11
Dec 12
Oct 10
```

Note that the order is essentially random, because it’s based on the hash ordering of the objects in the dictionary.
Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over keys, values, or key/value pairs, you can explicitly call the `iterkeys()`, `itervalues()`, or `iteritems()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of (key, value) tuples:

```python
L = [('Italy', 'Rome'), ('France', 'Paris'), ('US', 'Washington DC')]
dict(iter(L))
{'Italy': 'Rome', 'US': 'Washington DC', 'France': 'Paris'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```python
for line in file:
    # do something for each line
...
```

Sets can take their contents from an iterable and let you iterate over the set’s elements:

```python
S = set((2, 3, 5, 7, 11, 13))
for i in S:
    print i
```
Generator expressions and list comprehensions

Two common operations on an iterator’s output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (http://www.haskell.org/). You can strip all the whitespace from a stream of strings with the following code:

```python
line_list = [' line 1\n', 'line 2 \n', ...]

# Generator expression -- returns iterator
stripped_iter = (line.strip() for line in line_list)

# List comprehension -- returns list
stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an "if" condition:

```python
stripped_list = [line.strip() for line in line_list
                if line != '"
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren’t useful if you’re working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.
Generator expressions are surrounded by parentheses ("()") and list comprehensions are surrounded by square brackets ("[]"). Generator expressions have the form:

```
(expression for expr in sequence1
    if condition1
    for expr2 in sequence2
    if condition2
    for expr3 in sequence3 ...
    if condition3
    for exprN in sequenceN
    if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, `not` in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:
for expr1 in sequence1:
    if not (condition1):
        continue  # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue  # Skip this element
...
for exprN in sequenceN:
    if not (conditionN):
        continue  # Skip this element

# Output the value of
# the expression.

This means that when there are multiple for...in clauses but no if clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```python
>>> seq1 = 'abc'
>>> seq2 = (1,2,3)
>>> [(x,y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```

To avoid introducing an ambiguity into Python's grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```python
# Syntax error
[ x,y for x in seq1 for y in seq2]
# Correct
[(x,y) for x in seq1 for y in seq2]
```
Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You’re doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a return statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
def generate_ints(N):
    for i in range(N):
        yield i
```

Any function containing a yield keyword is a generator function; this is detected by Python’s bytecode compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the yield expression, the generator outputs the value of i, similar to a return statement. The big difference between yield and a return statement is that on reaching a yield the generator’s state of execution is suspended and local variables are preserved. On the next call to the generator’s .next() method, the function will resume executing.
Here's a sample usage of the `generate_ints()` generator:

```python
>>> gen = generate_ints(3)
>>> gen
<generator object generate_ints at ...>
>>> gen.next()
0
>>> gen.next()
1
>>> gen.next()
2
>>> gen.next()
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a, b, c = generate_ints(3)`.

Inside a generator function, the `return` statement can only be used without a value, and signals the end of the procession of values; after executing a `return` the generator cannot return any further values. `return` with a value, such as `return 5`, is a syntax error inside a generator function. The end of the generator’s results can also be indicated by raising `StopIteration` manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `next()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python’s library, `test_generators.py`,
contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```python
# A recursive generator that generates Tree leaves in in-order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x

        yield t.label

        for x in inorder(t.right):
            yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight’s Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

**Passing values into a generator**

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator. **yield** became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```python
val = (yield i)
```
I recommend that you **always** put parentheses around a `yield` expression when you’re doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it’s easier to always add them instead of having to remember when they’re needed.

(PEP 342 explains the exact rules, which are that a `yield` expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there’s an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator’s code and the `yield` expression returns the specified value. If the regular `next()` method is called, the `yield` returns `None`.

Here’s a simple counter that increments by 1 and allows changing the value of the internal counter.

```python
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here’s an example of changing the counter:

```python
>>> it = counter(10)
>>> print it.next()
0
>>> print it.next()
1
>>> print it.send(8)
```
Because `yield` will often be returning `None`, you should always check for this case. Don’t just use its value in expressions unless you’re sure that the `send()` method will be the only method used to resume your generator function.

In addition to `send()`, there are two other new methods on generators:

- `throw(type, value=None, traceback=None)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator’s execution is paused.

- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python’s garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.
Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).
Let's look in more detail at built-in functions often used with iterators.

Two of Python’s built-in functions, `map()` and `filter()`, are somewhat obsolete; they duplicate the features of list comprehensions but return actual lists instead of iterators.

```python
>>> def upper(s): ...	return s.upper()

>>> map(upper, ['sentence', 'fragment'])
['SENTENCE', 'FRAGMENT']

>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']
```

As shown above, you can achieve the same effect with a list comprehension. The `itertools.imap()` function does the same thing but can handle infinite iterators; it'll be discussed later, in the section on the `itertools` module.

```python
>>> def is_even(x):
... return (x % 2) == 0

>>> filter(is_even, range(10))
```
This can also be written as a list comprehension:

```python
>>> [x for x in range(10) if is_even(x)]
[0, 2, 4, 6, 8]
```

`filter()` also has a counterpart in the `itertools` module, `itertools.ifilter()`, that returns an iterator and can therefore handle infinite sequences just as `itertools.imap()` can.

`reduce(func, iter, [initial_value])` doesn't have a counterpart in the `itertools` module because it cumulatively performs an operation on all the iterable's elements and therefore can't be applied to infinite iterables. `func` must be a function that takes two elements and returns a single value. `reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it's used as a starting point and `func(initial_value, A)` is the first calculation.

```python
>>> import operator
>>> reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> reduce(operator.concat, [])
Traceback (most recent call last):
  TypeError: reduce() of empty sequence with no initial value
>>> reduce(operator.mul, [1,2,3], 1)
6
>>> reduce(operator.mul, [], 1)
1
```

If you use `operator.add()` with `reduce()`, you'll add up all the
elements of the iterable. This case is so common that there's a special built-in called `sum()` to compute it:

```python
>>> reduce(operator.add, [1, 2, 3, 4], 0)
10
>>> sum([1, 2, 3, 4])
10
>>> sum([])
0
```

For many uses of `reduce()`, though, it can be clearer to just write the obvious `for` loop:

```python
# Instead of:
product = reduce(operator.mul, [1, 2, 3], 1)

# You can write:
product = 1
for i in [1, 2, 3]:
    product *= i
```

`enumerate(iter)` counts off the elements in the iterable, returning 2-tuples containing the count and each element.

```python
>>> for item in enumerate(['subject', 'verb', 'object']):
...     print item
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```python
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print 'Blank line at line #%i' % i
```

`sorted(iterable, [cmp=None], [key=None], [reverse=False])`
collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The `cmp`, `key`, and `reverse` arguments are passed through to the constructed list's `.sort()` method.

```python
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[2207, 6213, 6431, 7953, 769, 8442, 8928, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the Sorting mini-HOWTO in the Python wiki at http://wiki.python.org/moin/HowTo/Sorting.)

The `any(iter)` and `all(iter)` built-ins look at the truth values of an iterable's contents. `any()` returns True if any element in the iterable is a true value, and `all()` returns True if all of the elements are true values:

```python
>>> any([0,1,0])
True
>>> any([0,0,0])
False
>>> any([1,1,1])
True
>>> all([0,1,0])
False
>>> all([0,0,0])
False
>>> all([1,1,1])
True
```
Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```python
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` statement. `lambda` takes a number of parameters and an expression combining these parameters, and creates a small function that returns the value of the expression:

```python
lowercase = lambda x: x.lower()
print_assign = lambda name, value: name + '=' + str(value)
adder = lambda x, y: x+y
```

An alternative is to just use the `def` statement and define a function in the usual way:

```python
def lowercase(x):
    return x.lower()

def print_assign(name, value):
    return name + '=' + str(value)

def adder(x,y):
    return x + y
```

Which alternative is preferable? That's a style question; my usual
course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can’t have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you’ll end up with an overly complicated expression that’s hard to read. Quick, what’s the following code doing?

```python
total = reduce(lambda a, b: (0, a[1] + b[1]), items)[1]
```

You can figure it out, but it takes time to disentangle the expression to figure out what’s going on. Using a short nested `def` statements makes things a little bit better:

```python
def combine (a, b):
    return 0, a[1] + b[1]

total = reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```python
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```python
total = sum(b for a,b in items)
```

Many uses of `reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:
1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you’re free to disagree about whether this lambda-free style is better.
The itertools module

The `itertools` module contains a number of commonly-used iterators as well as functions for combining several iterators. This section will introduce the module’s contents by showing small examples.

The module’s functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator’s elements as function arguments.
- Functions for selecting portions of an iterator’s output.
- A function for grouping an iterator’s output.

Creating new iterators

`itertools.count(n)` returns an infinite stream of integers, increasing by 1 each time. You can optionally supply the starting number, which defaults to 0:

```python
itertools.count() =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```python
itertools.cycle([1, 2, 3, 4, 5]) =>
  1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```
**itertools.repeat(elem, [n])** returns the provided element $n$ times, or returns the element endlessly if $n$ is not provided.

```python
itertools.repeat('abc') => abc, abc, abc, abc, abc, abc, abc, abc, abc, abc, ...
itertools.repeat('abc', 5) => abc, abc, abc, abc, abc
```

**itertools.chain(iterA, iterB, ...)** takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```python
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) => a, b, c, 1, 2, 3
```

**itertools.izip(iterA, iterB, ...)** takes one element from each iterable and returns them in a tuple:

```python
itertools.izip(['a', 'b', 'c'], (1, 2, 3)) => ('a', 1), ('b', 2), ('c', 3)
```

It's similar to the built-in `zip()` function, but doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is lazy evaluation.)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```python
itertools.izip(['a', 'b'], (1, 2, 3)) => ('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can't
go on to use the iterators further because you risk skipping a
discarded element.

`itertools.islice(iter, [start], stop, [step])` returns a stream
that's a slice of the iterator. With a single `stop` argument, it will return
the first `stop` elements. If you supply a starting index, you'll get `stop-`
`start` elements, and if you supply a value for `step`, elements will be
skipped accordingly. Unlike Python’s string and list slicing, you can't
use negative values for `start`, `stop`, or `step`.

```
itertools.islice(range(10), 8) =>
  0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
  2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
  2, 4, 6
```

`itertools.tee(iter, [n])` replicates an iterator; it returns `n`
independent iterators that will all return the contents of the source
iterator. If you don’t supply a value for `n`, the default is 2. Replicating
iterators requires saving some of the contents of the source iterator,
so this can consume significant memory if the iterator is large and
one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
  iterA, iterB
where iterA ->
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and   iterB ->
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

**Calling functions on elements**

Two functions are used for calling other functions on the contents of
an iterable.
**itertools.imap(f, iterA, iterB, ...)** returns a stream containing
\[ f(iterA[0], iterB[0]), f(iterA[1], iterB[1]), f(iterA[2], iterB[2]), \ldots : \]

```
import itertools
import operator

itertools.imap(operator.add, [5, 6, 5], [1, 2, 3]) =>
  6, 8, 8
```

The `operator` module contains a set of functions corresponding to
Python's operators. Some examples are `operator.add(a, b)` (adds
two values), `operator.ne(a, b)` (same as `a!=b`), and
operator.attrgetter('id') (returns a callable that fetches the "id"
attribute).

**itertools.starmap(func, iter)** assumes that the iterable will return
a stream of tuples, and calls `f()` using these tuples as the
arguments:

```
import os

itertools.starmap(os.path.join, 
  [('/usr', 'bin', 'java'), ('/bin', 'python'), 
   ('/usr', 'bin', 'perl'), ('/usr', 'bin', 'ruby')]) =>
  /usr/bin/java, /bin/python, /usr/bin/perl, /usr/bin/ruby
```

---

**Selecting elements**

Another group of functions chooses a subset of an iterator's
elements based on a predicate.

**itertools.ifilter(predicate, iter)** returns all the elements for
which the predicate returns true:

```
def is_even(x):
    return (x % 2) == 0

itertools.ifilter(is_even, itertools.count()) =>
  0, 2, 4, 6, 8, 10, 12, 14, ...
```
**itertools.ifilterfalse**(predicate, iter) is the opposite, returning all elements for which the predicate returns false:

```python
itertools.ifilterfalse(is_even, itertools.count()) =>
1, 3, 5, 7, 9, 11, 13, 15, ...
```

**itertools.takewhile**(predicate, iter) returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```python
def less_than_10(x):
    return (x < 10)

itertools.takewhile(less_than_10, itertools.count()) =>
0, 1, 2, 3, 4, 5, 6, 7, 8, 9

itertools.takewhile(is_even, itertools.count()) =>
0
```

**itertools.dropwhile**(predicate, iter) discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```python
itertools.dropwhile(less_than_10, itertools.count()) =>
10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

**Grouping elements**

The last function I'll discuss, **itertools.groupby**(iter, key_func=None), is the most complicated. key_func(elem) is a function that can compute a key value for each element returned by the iterable. If you don’t supply a key function, the key is simply each element itself.
groupby() collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

\[
\text{city_list} = [(\text{'Decatur'}, \text{'AL'}), (\text{'Huntsville'}, \text{'AL'}), (\text{'Selma'},
\text{'Anchorage'}, \text{'AK'}), (\text{'Nome'}, \text{'AK'}),
(\text{'Flagstaff'}, \text{'AZ'}), (\text{'Phoenix'}, \text{'AZ'}), (\text{'Tucson'},
...]
\]

\[
def \text{get_state} ((\text{city}, \text{state})): \quad \text{return state}
\]

\[
\text{itertools.groupby(city_list, get_state)} =>
\quad (\text{'AL'}, \text{iterator-1}),
\quad (\text{'AK'}, \text{iterator-2}),
\quad (\text{'AZ'}, \text{iterator-3}), ...
\]

where
\[
\text{iterator-1} =>
\quad (\text{'Decatur'}, \text{'AL'}), (\text{'Huntsville'}, \text{'AL'}), (\text{'Selma'}, \text{'AL'})
\]
\[
\text{iterator-2} =>
\quad (\text{'Anchorage'}, \text{'AK'}), (\text{'Nome'}, \text{'AK'})
\]
\[
\text{iterator-3} =>
\quad (\text{'Flagstaff'}, \text{'AZ'}), (\text{'Phoenix'}, \text{'AZ'}), (\text{'Tucson'}, \text{'AZ'})
\]

\[
\text{groupby()} \text{ assumes that the underlying iterable’s contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.}
\]
The **functools** module in Python 2.5 contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the **functools.partial()** function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function \( f(a, b, c) \); you may wish to create a new function \( g(b, c) \) that's equivalent to \( f(1, b, c) \); you're filling in a value for one of \( f() \)'s parameters. This is called "partial function application".

The constructor for **partial** takes the arguments \((function, \ arg1, \ arg2, \ ... \ \ kwarg1=value1, \ kwarg2=value2)\). The resulting object is callable, so you can just call it to invoke \( function \) with the filled-in arguments.

Here's a small but realistic example:

```python
import functools

def log (message, subsystem):
    "Write the contents of 'message' to the specified subsystem"
    print '%%s: %%s' % (subsystem, message)
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

**The operator module**

The **operator** module was mentioned earlier. It contains a set of
functions corresponding to Python's operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- **Math operations:** `add()`, `sub()`, `mul()`, `div()`, `floordiv()`, `abs()`, ...
- **Logical operations:** `not_()`, `truth()`.
- **Bitwise operations:** `and_()`, `or_()`, `invert()`.
- **Comparisons:** `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- **Object identity:** `is_()`, `is_not()`.

Consult the operator module's documentation for a complete list.

**The functional module**

Collin Winter's **functional module** provides a number of more advanced tools for functional programming. It also reimplements several Python built-ins, trying to make them more intuitive to those used to functional programming in other languages.

This section contains an introduction to some of the most important functions in **functional**; full documentation can be found at the project's website.

```
compose(outer, inner, unpack=False)
```

The `compose()` function implements function composition. In other words, it returns a wrapper around the `outer` and `inner` callables, such that the return value from `inner` is fed directly to `outer`. That is,

```python
>>> def add(a, b):
...     return a + b
... ```
```python
>>> def double(a):
...   return 2 * a
...
>>> compose(double, add)(5, 6)
22
```

is equivalent to

```python
>>> double(add(5, 6))
22
```

The `unpack` keyword is provided to work around the fact that Python functions are not always fully curried. By default, it is expected that the inner function will return a single object and that the outer function will take a single argument. Setting the `unpack` argument causes `compose` to expect a tuple from inner which will be expanded before being passed to outer. Put simply,

```
compose(f, g)(5, 6)
```

is equivalent to:

```
f(g(5, 6))
```

while

```
compose(f, g, unpack=True)(5, 6)
```

is equivalent to:

```
f(*g(5, 6))
```

Even though `compose()` only accepts two functions, it's trivial to build up a version that will compose any number of functions. We'll use `reduce()`, `compose()` and `partial()` (the last of which is provided by both functional and `functools`).
We can also use `map()`, `compose()` and `partial()` to craft a version of `"".join(...)` that converts its arguments to string:

```python
from functional import compose, partial
join = compose("".join, partial(map, str))
```

`flip(func)`

`flip()` wraps the callable in `func` and causes it to receive its non-keyword arguments in reverse order.

```python
>>> def triple(a, b, c):
...     return (a, b, c)
... >>> triple(5, 6, 7)
(5, 6, 7)
>>> >>> flipped_triple = flip(triple)
>>> flipped_triple(5, 6, 7)
(7, 6, 5)
```

`foldl(func, start, iterable)`

`foldl()` takes a binary function, a starting value (usually some kind of ‘zero’), and an iterable. The function is applied to the starting value and the first element of the list, then the result of that and the second element of the list, then the result of that and the third element of the list, and so on.

This means that a call such as:

```python
foldl(f, 0, [1, 2, 3])
```
is equivalent to:

\[
f(f(f(0, 1), 2), 3)
\]

`foldl()` is roughly equivalent to the following recursive function:

```python
def foldl(func, start, seq):
    if len(seq) == 0:
        return start
    return foldl(func, func(start, seq[0]), seq[1:])
```

Speaking of equivalence, the above `foldl` call can be expressed in terms of the built-in `reduce` like so:

```python
reduce(f, [1, 2, 3], 0)
```

We can use `foldl()`, `operator.concat()` and `partial()` to write a cleaner, more aesthetically-pleasing version of Python's `"".join(...)` idiom:

```python
from functional import foldl, partial from operator import concat
join = partial(foldl, concat, "")
```
Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the functional module written by Collin Winter; adds short section on the operator module; a few other edits.

**PEP 289**: “Generator Expressions”

**PEP 342**: “Coroutines via Enhanced Generators” describes the new generator features in Python 2.5.
Abstract

This document is an introductory tutorial to using regular expressions in Python with the `re` module. It provides a gentler introduction than the corresponding section in the Library Reference.
The `re` module was added in Python 1.5, and provides Perl-style regular expression patterns. Earlier versions of Python came with the `regex` module, which provided Emacs-style patterns. The `regex` module was removed completely in Python 2.5.

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine’s internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that can be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.
Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression test will match the string test exactly. (You can enable a case-insensitive mode that would let this RE match Test or TEST as well; more about this later.)

There are exceptions to this rule; some characters are special metacharacters, and don't match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

. ^ $ * + ? { [ ] \ | ( )

The first metacharacters we'll look at are [ and ]. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of
characters can be indicated by giving two characters and separating them by a '-'. For example, `[abc]` will match any of the characters a, b, or c; this is the same as `[a-c]`, which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be `[a-z]`.

Metacharacters are not active inside classes. For example, `[akm$]` will match any of the characters 'a', 'k', 'm', or '$'; '$' is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by complementing the set. This is indicated by including a '^' as the first character of the class; '^' outside a character class will simply match the '^' character. For example, `[^5]` will match any character except '5'.

Perhaps the most important metacharacter is the backslash, \\. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a [ or \, you can precede them with a backslash to remove their special meaning: `\[` or `\\`.

Some of the special sequences beginning with `'\'` represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace. The following predefined special sequences are available:

```
\d
```
Matches any decimal digit; this is equivalent to the class `[0-9]`.

```
\D
```
Matches any non-digit character; this is equivalent to the class
Matches any whitespace character; this is equivalent to the class \[ \t\n\r\f\v\].

\S
Matches any non-whitespace character; this is equivalent to the class \[^\t\n\r\f\v\].

\w
Matches any alphanumeric character; this is equivalent to the class \[a-zA-Z0-9_\].

\W
Matches any non-alphanumeric character; this is equivalent to the class \[^a-zA-Z0-9_\].

These sequences can be included inside a character class. For example, [\s,.] is a character class that will match any whitespace character, or \, or \.

The final metacharacter in this section is . It matches anything except a newline character, and there’s an alternate mode (re.DOTALL) where it will match even a newline. . is often used where you want to match “any character”.

### Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn’t already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn’t be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we’ll look at is *.
doesn’t match the literal character *; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, ca*t will match ct (0 a characters), cat (1 a), caaat (3 a characters), and so forth. The RE engine has various internal limitations stemming from the size of C’s int type that will prevent it from matching over 2 billion a characters; you probably don’t have enough memory to construct a string that large, so you shouldn’t run into that limit.

Repetitions such as * are greedy; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don’t match, the matching engine will then back up and try again with few repetitions.

A step-by-step example will make this more obvious. Let’s consider the expression a[bcd]*b. This matches the letter ‘a’, zero or more letters from the class [bcd], and finally ends with a ‘b’. Now imagine matching this RE against the string abcbd.

<table>
<thead>
<tr>
<th>Step</th>
<th>Matched</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
<td>The a in the RE matches.</td>
</tr>
<tr>
<td>2</td>
<td>abcbd</td>
<td>The engine matches [bcd]*, going as far as it can, which is to the end of the string.</td>
</tr>
<tr>
<td>3</td>
<td>Failure</td>
<td>The engine tries to match b, but the current position is at the end of the string, so it fails.</td>
</tr>
<tr>
<td>4</td>
<td>abcb</td>
<td>Back up, so that [bcd]* matches one less character.</td>
</tr>
<tr>
<td>5</td>
<td>Failure</td>
<td>Try b again, but the current position is at the last character, which is a ‘d’.</td>
</tr>
<tr>
<td>6</td>
<td>abc</td>
<td>Back up again, so that [bcd]* is only matching bc.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Try b again. This time the character at the</td>
</tr>
</tbody>
</table>
The end of the RE has now been reached, and it has matched `abcb`. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for `[bcd]`*, and if that subsequently fails, the engine will conclude that the string doesn’t match the RE at all.

Another repeating metacharacter is `+`, which matches one or more times. Pay careful attention to the difference between `*` and `+`; `*` matches zero or more times, so whatever’s being repeated may not be present at all, while `+` requires at least one occurrence. To use a similar example, `ca+t` will match `cat` (1 `a`), `caaat` (3 `a`'s), but won’t match `ct`.

There are two more repeating qualifiers. The question mark character, `?`, matches either once or zero times; you can think of it as marking something as being optional. For example, `home-?brew` matches either `homebrew` or `home-brew`.

The most complicated repeated qualifier is `{m,n}`, where `m` and `n` are decimal integers. This qualifier means there must be at least `m` repetitions, and at most `n`. For example, `a/{1,3}b` will match `a/b`, `a//b`, and `a///b`. It won’t match `ab`, which has no slashes, or `a/////b`, which has four.

You can omit either `m` or `n`; in that case, a reasonable value is assumed for the missing value. Omitting `m` is interpreted as a lower limit of 0, while omitting `n` results in an upper bound of infinity — actually, the upper bound is the 2-billion limit mentioned earlier, but that might as well be infinity.
Readers of a reductionist bent may notice that the three other qualifiers can all be expressed using this notation. \(\{0,\}\) is the same as *, \(\{1,\}\) is equivalent to +, and \(\{0,1\}\) is the same as ?. It’s better to use *, +, or ? when you can, simply because they’re shorter and easier to read.
Using Regular Expressions

Now that we've looked at some simple regular expressions, how do we actually use them in Python? The `re` module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```python
>>> import re
>>> p = re.compile('ab*')
>>> print p
<_sre.SRE_Pattern object at 80b4150>
```

`re.compile()` also accepts an optional `flags` argument, used to enable various special features and syntax variations. We'll go over the available settings later, but for now a single example will do:

```python
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don't need REs at all, so there's no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.

Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.
The Backslash Plague

As stated earlier, regular expressions use the backslash character (\) to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python’s usage of the same character for the same purpose in string literals.

Let’s say you want to write a RE that matches the string \section, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string \section. The resulting string that must be passed to \re.compile()\ must be \section. However, to express this as a Python string literal, both backslashes must be escaped again.

<table>
<thead>
<tr>
<th>Characters</th>
<th>Stage</th>
</tr>
</thead>
<tbody>
<tr>
<td>\section</td>
<td>Text string to be matched</td>
</tr>
<tr>
<td>\section</td>
<td>Escaped backslash for \re.compile()</td>
</tr>
<tr>
<td>&quot;\section&quot;</td>
<td>Escaped backslashes for a string literal</td>
</tr>
</tbody>
</table>

In short, to match a literal backslash, one has to write '\\' as the RE string, because the regular expression must be \, and each backslash must be expressed as \ inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.

The solution is to use Python’s raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with 'r', so r"\n" is a two-character string
containing \ and 'n', while "\n" is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

<table>
<thead>
<tr>
<th>Regular String</th>
<th>Raw string</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;ab*&quot;</td>
<td>r&quot;ab*&quot;</td>
</tr>
<tr>
<td>&quot;\\section&quot;</td>
<td>r&quot;\section&quot;</td>
</tr>
<tr>
<td>&quot;\w+\s+\l&quot;</td>
<td>r&quot;\w+\s+\l&quot;</td>
</tr>
</tbody>
</table>

## Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the re docs for a complete listing.

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>match()</td>
<td>Determine if the RE matches at the beginning of the string.</td>
</tr>
<tr>
<td>search()</td>
<td>Scan through a string, looking for any location where this RE matches.</td>
</tr>
<tr>
<td>findall()</td>
<td>Find all substrings where the RE matches, and returns them as a list.</td>
</tr>
<tr>
<td>finditer()</td>
<td>Find all substrings where the RE matches, and returns them as an iterator.</td>
</tr>
</tbody>
</table>

match() and search() return None if no match can be found. If they're successful, a MatchObject instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the re module. If you have Tkinter available, you may also want to look at Tools/scripts/redemo.py, a demonstration program included with the Python distribution. It allows you to enter REs and strings, and
displays whether the RE matches or fails. `redemo.py` can be quite useful when trying to debug a complicated RE. Phil Schwartz's *Kodos* is also an interactive tool for developing and testing RE patterns.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the *re* module, and compile a RE:

```
Python 2.2.2 (#1, Feb 10 2003, 12:57:01)
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
<_sre.SRE_Pattern object at 80c3c28>
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn't match at all, since `+` means 'one or more repetitions'. `match()` should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of `match()` to make this clear.

```
>>> p.match('')
>>> print p.match('')
None
```

Now, let's try it on a string that it should match, such as `tempo`. In this case, `match()` will return a *MatchObject*, so you should store the result in a variable for later use.

```
>>> m = p.match('tempo')
>>> print m
<_sre.SRE_Match object at 80c4f68>
```

Now you can query the *MatchObject* for information about the matching string. *MatchObject* instances also have several methods and attributes; the most important ones are:
<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>group()</td>
<td>Return the string matched by the RE</td>
</tr>
<tr>
<td>start()</td>
<td>Return the starting position of the match</td>
</tr>
<tr>
<td>end()</td>
<td>Return the ending position of the match</td>
</tr>
<tr>
<td>span()</td>
<td>Return a tuple containing the (start, end) positions of the match</td>
</tr>
</tbody>
</table>

Trying these methods will soon clarify their meaning:

```
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

`group()` returns the substring that was matched by the RE. `start()` and `end()` return the starting and ending index of the match. `span()` returns both start and end indexes in a single tuple. Since the `match()` method only checks if the RE matches at the start of a string, `start()` will always be zero. However, the `search()` method of patterns scans through the string, so the match may not start at zero in that case.

```
>>> print p.match('::: message')
None
>>> m = p.search('::: message') ; print m
<re.MatchObject instance at 80c9650>
>>> m.group()
'message'
>>> m.span()
(4, 11)
```

In actual programs, the most common style is to store the `MatchObject` in a variable, and then check if it was `None`. This usually looks like:

```python
p = re.compile( ... )
```
```python
m = p.match( 'string goes here' )
if m:
    print 'Match found: ', m.group()
else:
    print 'No match'
```

Two pattern methods return all of the matches for a pattern. `findall()` returns a list of matching strings:

```python
>>> p = re.compile( '\d+'
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords [''12'', '11', '10']
```

`findall()` has to create the entire list before it can be returned as the result. The `finditer()` method returns a sequence of `MatchObject` instances as an iterator. [1]

```python
>>> iterator = p.finditer('12 drummers drumming, 11 ... 10 ...'
>>> for match in iterator:
...     print match.span()
...
(0, 2)
(22, 24)
(29, 31)
```

**Module-Level Functions**

You don’t have to create a pattern object and call its methods; the `re` module also provides top-level functions called `match()`, `search()`, `findall()`, `sub()`, and so forth. These functions take the same arguments as the corresponding pattern method, with the RE string added as the first argument, and still return either `None` or a `MatchObject` instance.
Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE are faster.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? That choice depends on how frequently the RE will be used, and on your personal coding style. If the RE is being used at only one point in the code, then the module functions are probably more convenient. If a program contains a lot of regular expressions, or re-uses the same ones in several locations, then it might be worthwhile to collect all the definitions in one place, in a section of code that compiles all the REs ahead of time. To take an example from the standard library, here's an extract from `xmllib.py`:

```python
ref = re.compile( ... )
entityref = re.compile( ... )
charref = re.compile( ... )
starttagopen = re.compile( ... )
```

I generally prefer to work with the compiled object, even for one-time uses, but few people will be as much of a purist about this as I am.

### Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `i`. (If you’re familiar with Perl’s pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is
Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `i` and `m` flags, for example.

Here’s a table of the available flags, followed by a more detailed explanation of each one.

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>DOTALL, S</td>
<td>Make . match any character, including newlines</td>
</tr>
<tr>
<td>IGNORECASE, I</td>
<td>Do case-insensitive matches</td>
</tr>
<tr>
<td>LOCALE, L</td>
<td>Do a locale-aware match</td>
</tr>
<tr>
<td>MULTILINE, M</td>
<td>Multi-line matching, affecting ^ and $</td>
</tr>
<tr>
<td>VERBOSE, X</td>
<td>Enable verbose REs, which can be organized more cleanly and understandably.</td>
</tr>
<tr>
<td>UNICODE, U</td>
<td>Makes several escapes like \w, \b, \s and \d dependent on the Unicode character database.</td>
</tr>
</tbody>
</table>

**I**

**IGNORECASE**

Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too, and `Spam` will match `Spam`, `spam`, or `spAM`. This lowercasing doesn’t take the current locale into account; it will if you also set the `locale` flag.

**L**

**LOCALE**

Make `\w`, `\w`, `\b`, and `\B`, dependent on the current locale.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you’re processing French text, you’d want to be able to write `\w+` to match words, but `\w` only matches the character
class [A-Za-z]; it won’t match ‘é’ or ‘ç’. If your system is configured properly and a French locale is selected, certain C functions will tell the program that ‘é’ should also be considered a letter. Setting the \texttt{locale} flag when compiling a regular expression will cause the resulting compiled object to use these C functions for \w; this is slower, but also enables \w+ to match French words as you’d expect.

\section*{M \texttt{MULTILINE}}

(\^ and $ haven’t been explained yet; they’ll be introduced in section \textit{More Metacharacters}.)

Usually \^ matches only at the beginning of the string, and $ matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, \^ matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline. Similarly, the $ metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

\section*{S \texttt{DOTALL}}

Makes the \.' special character match any character at all, including a newline; without this flag, \.' will match anything except a newline.

\section*{U \texttt{UNICODE}}

Make \w, \W, \b, \B, \d, \D, \s and \S dependent on the Unicode character properties database.

\section*{X \texttt{VERBOSE}}
This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a '#' that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses `re.VERBOSE`; see how much easier it is to read?

```python
charref = re.compile(r'''
&[#]       # Start of a numeric entity reference
  (     # Octal form
    0[0-7]+   # Octal form
    | [0-9]+  # Decimal form
    | x[0-9a-fA-F]+ # Hexadecimal form
  );
''', re.VERBOSE)
```

Without the verbose setting, the RE would look like this:

```python
charref = re.compile("&#{0[0-7]+"
                   "|[0-9]+"
                   "|x[0-9a-fA-F]+};")
```

In the above example, Python’s automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`. 
More Pattern Power

So far we've only covered a part of the features of regular expressions. In this section, we'll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven't covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are zero-width assertions. They don't cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, \b is an assertion that the current position is located at a word boundary; the position isn't changed by the \b at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

Alternation, or the “or” operator. If A and B are regular expressions, A|B will match any string that matches either A or B. | has very low precedence in order to make it work reasonably when you're alternating multi-character strings. Row|Servo will match either Row or Servo, not Ro, a 'w' or an 'S', and ervo.

To match a literal ' | ', use \|, or enclose it inside a character class, as in [ | ].

^ Matches at the beginning of lines. Unless the MULTILINE flag has
been set, this will only match at the beginning of the string. In `MULTILINE` mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word `From` only at the beginning of a line, the RE to use is `^From`.

```python
>>> print re.search('^From', 'From Here to Eternity')
<re.MatchObject instance at 80c1520>
>>> print re.search('^From', 'Reciting From Memory')
None
```

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```python
>>> print re.search('}$', '{block}')
<re.MatchObject instance at 80adfa8>
>>> print re.search('}$', '{block} ')
None
>>> print re.search('}$', '{block}\n')
<re.MatchObject instance at 80adfa8>
```

To match a literal `\$`, use `$` or enclose it inside a character class, as in `[$]`.

`\A`

Matches only at the start of the string. When not in `MULTILINE` mode, `\A` and `^` are effectively the same. In `MULTILINE` mode, they're different: `\A` still matches only at the beginning of the string, but `^` may match at any location inside the string that follows a newline character.

`\Z`

Matches only at the end of the string.

`\b`

Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a
sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete word; it won't match when it's contained inside another word.

```python
>>> p = re.compile(r'class')
>>> print p.search('class')
MatchData object at 80c8f28
>>> print p.search('the declassified algorithm')
None
>>> print p.search('one subclass is')
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, `\b` is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the `\b` to a backspace, and your RE won't match as you expect it to. The following example looks the same as our previous RE, but omits the `r` in front of the RE string.

```python
>>> p = re.compile('\bclass\b')
>>> print p.search('no class at all')
None
>>> print p.search('the declassified algorithm')
None
>>> print p.search('one subclass is')
None
```

Second, inside a character class, where there's no use for this assertion, `\b` represents the backspace character, for compatibility with Python's string literals.

Another zero-width assertion, this is the opposite of `\b`, only matching when the current position is not at a word boundary.
Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a ':', like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header's value.

Groups are marked by the '(', ')' metacharacters. '(', and ')' have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a repeating qualifier, such as *, +, ?, or {m,n}. For example, (ab)* will match zero or more repetitions of ab.

```
>>> p = re.compile('(ab)*')
>>> print p.match('abababab').span()
(0, 10)
```

Groups indicated with '(', ')' also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to group(), start(), end(), and span(). Groups are numbered starting with 0. Group 0 is always present; it's the whole RE, so MatchObject methods all have group 0 as their default argument. Later we'll see how to express groups that don't capture
the span of text that they match.

>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

>>> p = re.compile('(a(b)c)d')
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those groups.

>>> m.group(2,1,2)
('b', 'abc', 'b')

The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

>>> m.groups()
('abc', 'b')

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise.
Remember that Python’s string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```python
>>> p = re.compile(r'\b\w+\s+\1')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren’t often useful for just searching through a string — there are few text formats which repeat data in this way — but you’ll soon find out that they’re very useful when performing string substitutions.

### Non-capturing and Named Groups

Elaborate REs may use many groups, both to capture substrings of interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we’ll look at that first.

Perl 5 added several additional features to standard regular expressions, and the Python `re` module supports most of them. It would have been difficult to choose new single-keystroke metacharacters or new special sequences beginning with `\` to represent the new features without making Perl’s regular expressions confusingly different from standard REs. If you chose `&` as a new metacharacter, for example, old expressions would be assuming that `&` was a regular character and wouldn’t have escaped it by writing `\&` or `[&]`.

The solution chosen by the Perl developers was to use `(?...)` as the extension syntax. `?` immediately after a parenthesis was a syntax
error because the ? would have nothing to repeat, so this didn’t introduce any compatibility problems. The characters immediately after the ? indicate what extension is being used, so (?=foo) is one thing (a positive lookahead assertion) and (?:foo) is something else (a non-capturing group containing the subexpression foo).

Python adds an extension syntax to Perl’s extension syntax. If the first character after the question mark is a P, you know that it’s an extension that’s specific to Python. Currently there are two such extensions: (?P<name>...) defines a named group, and (?P=name) is a backreference to a named group. If future versions of Perl 5 add similar features using a different syntax, the re module will be changed to support the new syntax, while preserving the Python-specific syntax for compatibility’s sake.

Now that we’ve looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs. Since groups are numbered from left to right and a complex expression may use many groups, it can become difficult to keep track of the correct numbering. Modifying such a complex RE is annoying, too: insert a new group near the beginning and you change the numbers of everything that follows it.

Sometimes you’ll want to use a group to collect a part of a regular expression, but aren’t interested in retrieving the group’s contents. You can make this fact explicit by using a non-capturing group: (?::...), where you can replace the ... with any other regular expression.

```python
g>>> m = re.match("([abc])+", "abc")
g>>> m.groups()
('c',)
g>>> m = re.match("(?:[abc])+", "abc")
g>>> m.groups()
()```
Except for the fact that you can’t retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as *, and nest it within other groups (capturing or non-capturing). (?:...) is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there’s no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: (?P<name>...). name is, obviously, the name of the group. Named groups also behave exactly like capturing groups, and additionally associate a name with a group. The MatchObject methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group’s name. Named groups are still given numbers, so you can retrieve information about a group in two ways:

```python
>>> p = re.compile(r'(?P<word>\b\w+\b)')
>>> m = p.search( '((((Lots of punctuation )))' )
>>> m.group('word')
'Lots'
>>> m.group(1)
'Lots'
```

Named groups are handy because they let you use easily-remembered names, instead of having to remember numbers. Here’s an example RE from the imaplib module:

```python
InternalDate = re.compile(r'INTERNALDATE "' +'(?P<day>[ 123][0-9])-?(?P<mon>[A-Z][a-z][a-z])-'
```
It’s obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(\...)` refers to the number of the group. There’s naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called `name` should again be matched at the current point. The regular expression for finding doubled words, `(^\b\w+)\s+(?P=word)` can also be written as `(?P<word>\b\w+)\s+(?P=word):

```python
>>> p = re.compile(r'(?P<word>\b\w+)\s+(?P=word)')
>>> p.search('Paris in the the spring').group()
'the the'
```

Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

(\?=...)

Positive lookahead assertion. This succeeds if the contained regular expression, represented here by ..., successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn’t advance at all; the rest of the pattern is tried right where the assertion started.

(?!...)

Negative lookahead assertion. This is the opposite of the positive
assertion; it succeeds if the contained expression doesn’t match at the current position in the string.

To make this concrete, let’s look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a .. For example, in news.rc, news is the base name, and rc is the filename’s extension.

The pattern to match this is quite simple:

```
.*[.].*$
```

Notice that the . needs to be treated specially because it’s a metacharacter; I’ve put it inside a character class. Also notice the trailing $; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches foo.bar and autoexec.bat and sendmail.cf and printers.conf.

Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not bat? Some incorrect attempts:

```
.*[.][^b].*$
```

The first attempt above tries to exclude bat by requiring that the first character of the extension is not a b. This is wrong, because the pattern also doesn’t match foo.bar.

```
.*[.][^b].[.][^a].|[.][^t])$
```

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn’t b; the second character isn’t a; or the third character isn’t t. This accepts foo.bar and rejects autoexec.bat, but it requires a three-letter extension and won’t
accept a filename with a two-letter extension such as `sendmail.cf`. We'll complicate the pattern again in an effort to fix it.

```
.*[.]([^b].?.?|[^a].?.?|..?[^t]?)$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as `sendmail.cf`.

The pattern's getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both `bat` and `exe` as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

```
.*[.](?!bat$).*$
```

The negative lookahead means: if the expression `bat` doesn't match at this point, try the rest of the pattern; if `bat$` does match, the whole pattern will fail. The trailing `$` is required to ensure that something like `sample.batch`, where the extension only starts with `bat`, will be allowed.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either `bat` or `exe`:

```
.*[.](?!bat$|exe$).*$
```
Modifying Strings

Up to this point, we’ve simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>split()</td>
<td>Split the string into a list, splitting it wherever the RE matches</td>
</tr>
<tr>
<td>sub()</td>
<td>Find all substrings where the RE matches, and replace them with a different string</td>
</tr>
<tr>
<td>subn()</td>
<td>Does the same thing as <code>sub()</code>, but returns the new string and the number of replacements</td>
</tr>
</tbody>
</table>

Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It’s similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; `split()` only supports splitting by whitespace or by a fixed string. As you’d expect, there’s a module-level `re.split()` function, too.

```
.split(string[, maxsplit=0])
```

Split `string` by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If `maxsplit` is nonzero, at most `maxsplit` splits are performed.

You can limit the number of splits made, by passing a value for `maxsplit`. When `maxsplit` is nonzero, at most `maxsplit` splits will be made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any
sequence of non-alphanumeric characters.

```python
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split().')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of', 'split().']
```

Sometimes you’re not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```python
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'([^\W]+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '...', 'is', '', 'a', '', 'test', '.', '']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```python
>>> re.split('([^\W]+)', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('([^\W]+)', 'Words, words, words.')
['Words', '', '', 'words', '', '', 'words', '.', '', '']
>>> re.split('([^\W]+)', 'Words, words, words.', 1)
['Words', 'words, words.']
```

## Search and Replace

Another common task is to find all the matches for a pattern, and replace them with a different string. The `sub()` method takes a replacement value, which can be either a string or a function, and the string to be processed.

```
sub(replacement, string[, count=0])
```
Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in `string` by the replacement `replacement`. If the pattern isn’t found, `string` is returned unchanged.

The optional argument `count` is the maximum number of pattern occurrences to be replaced; `count` must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here’s a simple example of using the `sub()` method. It replaces colour names with the word `colour`:

```python
>>> p = re.compile( '(blue|white|red)' )
>>> p.sub( 'colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub( 'colour', 'blue socks and red shoes', count=1)
'colour socks and red shoes'
```

The `subn()` method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```python
>>> p = re.compile( '(blue|white|red)' )
>>> p.subn( 'colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn( 'colour', 'no colours at all')
('no colours at all', 0)
```

Empty matches are replaced only when they’re not adjacent to a previous match.

```python
>>> p = re.compile( 'x*' )
>>> p.sub( '-', 'abxd')
'-a-b-d-
```

If `replacement` is a string, any backslash escapes in it are processed. That is, \n is converted to a single newline character, \r is converted
to a carriage return, and so forth. Unknown escapes such as \j are left alone. Backreferences, such as \6, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word section followed by a string enclosed in {, }, and changes section to subsection:

```python
>>> p = re.compile('section{ ( [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First} section{second}')
'subsection{First} subsection{second}'
```

There’s also a syntax for referring to named groups as defined by the (?P<name>...) syntax. \g<name> will use the substring matched by the group named name, and \g<number> uses the corresponding group number. \g<2> is therefore equivalent to \2, but isn't ambiguous in a replacement string such as \g<2>0. (\20 would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character '0'.) The following substitutions are all equivalent, but use all three variations of the replacement string.

```python
>>> p = re.compile('section{ (?P<name> [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<1>}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<name>}','section{First}')
'subsection{First}'
```

replacement can also be a function, which gives you even more control. If replacement is a function, the function is called for every non-overlapping occurrence of pattern. On each call, the function is passed a MatchObject argument for the match and can use this information to compute the desired replacement string and return it.
In the following example, the replacement function translates decimals into hexadecimal:

```python
>>> def hexrepl(match):
...     "Return the hex string for a decimal number"
...     value = int(match.group())
...     return hex(value)
...
```  

```text
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user code.
Call 0xffd2 for printing, 0xc000 for user code.')
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level `re.sub()` function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns 'x x'.
Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn’t intuitive and at times they don’t behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the re module is a mistake. If you're matching a fixed string, or a single character class, and you're not using any re features such as the IGNORECASE flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they're usually much faster, because the implementation is a single small C loop that's been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace word with deed. re.sub() seems like the function to use for this, but consider the replace() method. Note that replace() will also replace word inside words, turning swordfish into sdeedfish, but the naive RE word would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be \bword\b, in order to require that word have a word boundary on either side. This takes the job beyond replace()'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character. You might do this with something like re.sub('\\n', ' ', s), but translate() is capable of doing both tasks and will be faster than
any regular expression operation can be.

In short, before turning to the `re` module, consider whether your problem can be solved with a faster and simpler string method.

**match() versus search()**

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn't start at zero, `match()` will *not* report it.

```python
>>> print re.match('super', 'superstition').span()
(0, 5)
>>> print re.match('super', 'insuperable')
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```python
>>> print re.search('super', 'superstition').span()
(0, 5)
>>> print re.search('super', 'insuperable').span()
(2, 7)
```

Sometimes you'll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `Row` must match starting with a `'R'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'R'` is found.
Adding `.*` defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use `re.search()` instead.

**Greedy versus Non-Greedy**

When repeating a regular expression, as in `a*`, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you’re trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn’t work because of the greedy nature of `.*`.

```python
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print re.match('.*', s).span()
(0, 32)
>>> print re.match('.*', s).group()
<html><head><title>Title</title>
```

The RE matches the `<` in `<html>`, and the `.*` consumes the rest of the string. There’s still more left in the RE, though, and the `>` can’t match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the `>`. The final match extends from the `<` in `<html>` to the `>` in `</title>`, which isn’t what you want.

In this case, the solution is to use the non-greedy qualifiers `*?`, `+?`, `??`, or `{m,n}?`, which match as *little* text as possible. In the above example, the `>` is tried immediately after the first `<` matches, and when it fails, the engine advances a character at a time, retrying the `>` at every step. This produces just the right result:

```python
>>> print re.match('<.*?>', s).group()
```
(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you've written a regular expression that handles all of the possible cases, the patterns will be very complicated. Use an HTML or XML parser module for such tasks.)

Not Using re.VERBOSE

By now you've probably noticed that regular expressions are a very compact notation, but they're not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the re.VERBOSE flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The re.VERBOSE flag has several effects. Whitespace in the regular expression that isn't inside a character class is ignored. This means that an expression such as dog | cat is equivalent to the less readable dog|cat, but [a b] will still match the characters 'a', 'b', or a space. In addition, you can also put comments inside a RE; comments extend from a # character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```python
pat = re.compile(r""
\s* (?P<header>[^:]+)
\s* : (?P<value>.*?)
# Skip leading whitespace
# Header name
# Whitespace, and a colon
# The header's value -- *? used to
# lose the following trailing whitespace
"""
```

This is far more readable than:

```python
pat = re.compile(r'^\s*(?P<header>[^:]+)\s*:\s*(?P<value>.*)\s*$')
```

```python
\s*$ # Trailing whitespace to end-of-line
""", re.VERBOSE)
```
Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren’t covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's Mastering Regular Expressions, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java's flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python's now-removed `regex` module, which won't help you much.) Consider checking it out from your library.

**Footnotes**

[1] Introduced in Python 2.2.2.
Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It’s not really a tutorial - you’ll still have work to do in getting things operational. It doesn’t cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.
Sockets

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things working. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

I'm only going to talk about INET sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that “socket” can mean a number of subtly different things, depending on context. So first, let's make a distinction between a “client” socket - an endpoint of a conversation, and a “server” socket, which is more like a switchboard operator. The client application (your browser, for example) uses “client” sockets exclusively; the web server it's talking to uses both “server” sockets and “client” sockets.

History

Of the various forms of IPC (Inter Process Communication), sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.
They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the Internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other schemes).
Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```python
# create an INET, STREAMing socket
s = socket.socket(
    socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80
# - the normal http port
s.connect(('www.mcmillan-inc.com', 80))
```

When the `connect` completes, the socket `s` can now be used to send in a request for the text of this page. The same socket will read the reply, and then be destroyed. That's right - destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”.

```python
# create an INET, STREAMing socket
serversocket = socket.socket(
    socket.AF_INET, socket.SOCK_STREAM)
# bind the socket to a public host,
# and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind(('', 80))` or `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a “server” socket, but one that was only visible within the same machine.

A second thing to note: low number ports are usually reserved for
“well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to listen tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

OK, now we have a “server” socket, listening on port 80. Now we enter the mainloop of the web server:

```python
while 1:
    #accept connections from outside
    (clientsocket, address) = serversocket.accept()
    #now do something with the clientsocket
    #in this case, we'll pretend this is a threaded server
    ct = client_thread(clientsocket)
    ct.run()
```

There’s actually 3 general ways in which this loop could work - dispatching a thread to handle clientsocket, create a new process to handle clientsocket, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active clientsockets using select. More about that later. The important thing to understand now is this: this is all a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each clientsocket is created in response to some other “client” socket doing a connect() to the host and port we’re bound to. As soon as we’ve created that clientsocket, we go back to listening for more connections. The two “clients” are free to chat it up - they are using some dynamically allocated port which will be recycled when the conversation ends.

**IPC**

If you need fast IPC between two processes on one machine, you
should look into whatever form of shared memory the platform offers. A simple protocol based around shared memory and locks or semaphores is by far the fastest technique.

If you do decide to use sockets, bind the “server” socket to 'localhost'. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.
Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, as the designer, you will have to decide what the rules of etiquette are for a conversation. Normally, the connecting socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use send and recv, or you can transform your client socket into a file-like beast and use read and write. The latter is the way Java presents their sockets. I'm not going to talk about it here, except to warn you that you need to use flush on sockets. These are buffered “files”, and a common mistake is to write something, and then read for a reply. Without a flush in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come the major stumbling block of sockets - send and recv operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (send) or emptied (recv). They then tell you how many bytes they handled. It is your responsibility to call them again until your message has been completely dealt with.

When a recv returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data successfully; I'll talk about that some on the next page.
A protocol like HTTP uses a socket for only one transfer. The client sends a request, the reads a reply. That’s it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that there is no “EOT” (End of Transfer) on a socket. I repeat: if a socket `send` or `recv` returns after handling 0 bytes, the connection has been broken. If the connection has not been broken, you may wait on a `recv` forever, because the socket will not tell you that there’s nothing more to read (for now). Now if you think about that a bit, you’ll come to realize a fundamental truth of sockets: messages must either be fixed length (yuck), or be delimited (shrug), or indicate how long they are (much better), or end by shutting down the connection. The choice is entirely yours, (but some ways are righter than others).

Assuming you don’t want to end the connection, the simplest solution is a fixed length message:

class mysocket:
    '''demonstration class only
    - coded for clarity, not efficiency
    '''

    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(
                socket.AF_INET, socket.SOCK_STREAM)
        else:
            self.sock = sock

    def connect(self, host, port):
        self.sock.connect((host, port))

    def mysend(self, msg):
        totalsent = 0
        while totalsent < MSGLEN:
            sent = self.sock.send(msg[totalsent:])
            if sent == 0:
raise RuntimeError("socket connection broken")
totalsent = totalsent + sent

def myreceive(self):
    msg = ''
    while len(msg) < MSGLEN:
        chunk = self.sock.recv(MSGLEN-len(msg))
        if chunk == '':
            raise RuntimeError("socket connection broken")
        msg = msg + chunk
    return msg

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded \0 characters). It's mostly the receiving code that gets more complex. (And in C, it's not much worse, except you can't use `strlen` if the message has embedded \0s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv`s - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you'll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you've received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with it's length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you'll get away with it; but
in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

## Binary Data

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, a Motorola chip will represent a 16 bit integer with the value 1 as the two hex bytes 00 01. Intel and DEC, however, are byte-reversed - that same 1 is 01 00. Socket libraries have calls for converting 16 and 32 bit integers - `ntohl`, `htonl`, `nthos`, `htons` where “n” means network and “h” means host, “s” means short and “l” means long. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.

In these days of 32 bit machines, the ascii representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, all those longs have the value 0, or maybe 1. The string “0” would be two bytes, while binary is four. Of course, this doesn't fit well with fixed-length messages. Decisions, decisions.
Disconnecting

Strictly speaking, you’re supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean “I’m not going to send anymore, but I’ll still listen”, or “I’m not listening, good riddance!”. Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server “This client is done sending, but can still receive.” The server can detect “EOF” by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it’s needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you’re just being slow. *Please close* your sockets when you’re done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. SOCKSTREAM is a reliable protocol, and it will wait a long, long time before giving up on a connection. If you’re using threads, the entire thread is essentially
dead. There’s not much you can do about it. As long as you aren’t doing something dumb, like holding a lock while doing a blocking read, the thread isn’t really consuming much in the way of resources. Do not try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.
If you've understood the preceeding, you already know most of what you need to know about the mechanics of using sockets. You'll still use the same calls, in much the same ways. It's just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(0)` to make it non-blocking. In C, it's more complex, (for one thing, you'll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable Posix flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it's the exact same idea. You do this after creating the socket, but before using it. (Actually, if you're nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don't believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let's skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C.

```
ready_to_read, ready_to_write, in_error = 
select.select( 
    potential_readers, 
    potential_writers, 
    potential_errs, 
    timeout)
```
You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They have the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in. And if you put a socket in more than one input list, it will only be (at most) in one output list.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return `something`. Same idea for the writable list. You'll be able to send `something`. Maybe not all you want to, but `something` is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a “server” socket, put it in the potential_readers list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the potential_writers list. If it shows up in the writable list, you have a decent chance that it has connected.

One very nasty problem with `select`: if somewhere in those input lists of sockets is one which has died a nasty death, the `select` will fail. You then need to loop through every single socket in all those lists and do a `select([sock],[],[],0)` until you find the bad one. That timeout of 0 means it won’t take long, but it’s ugly.
Actually, `select` can be handy even with blocking sockets. It’s one way of determining whether you will block - the socket returns as readable when there’s something in the buffers. However, this still doesn’t help with the problem of determining whether the other end is done, or just busy with something else.

**Portability alert:** On Unix, `select` works both with the sockets and files. Don’t try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets. Face it, if you want any kind of performance, your code will look very different on Windows than on Unix.

**Performance**

There’s no question that the fastest sockets code uses non-blocking sockets and `select` to multiplex them. You can put together something that will saturate a LAN connection without putting any strain on the CPU. The trouble is that an app written this way can’t do much of anything else - it needs to be ready to shuffle bytes around at all times.

Assuming that your app is actually supposed to do something more than that, threading is the optimal solution, (and using non-blocking sockets will be faster than using blocking sockets). Unfortunately, threading support in Unixes varies both in API and quality. So the normal Unix solution is to fork a subprocess to deal with each connection. The overhead for this is significant (and don’t do this on Windows - the overhead of process creation is enormous there). It also means that unless each subprocess is completely independent, you’ll need to use another form of IPC, say a pipe, or shared memory and semaphores, to communicate between the parent and child processes.
Finally, remember that even though blocking sockets are somewhat slower than non-blocking, in many cases they are the “right” solution. After all, if your app is driven by the data it receives over a socket, there's not much sense in complicating the logic just so your app can wait on `select` instead of `recv`. 
Python lists have a built-in `list.sort()` method that modifies the list in-place and a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.
Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```python
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method of a list. It modifies the list in-place (and returns `None` to avoid confusion). Usually it’s less convenient than `sorted()` - but if you don’t need the original list, it’s slightly more efficient.

```python
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```python
[1, 2, 3, 4, 5]
```
Key Functions

Starting with Python 2.4, both `list.sort()` and `sorted()` added a `key` parameter to specify a function to be called on each list element prior to making comparisons.

For example, here's a case-insensitive string comparison:

```python
>>> sorted("This is a test string from Andrew".split(), key=str.lower)
['a', 'Andrew', 'from', 'is', 'string', 'test', 'This']
```

The value of the `key` parameter should be a function that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object's indices as keys. For example:

```python
>>> student_tuples = [
    ('john', 'A', 15),
    ('jane', 'B', 12),
    ('dave', 'B', 10),
]

>>> sorted(student_tuples, key=lambda student: student[2])  # sort by age
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The same technique works for objects with named attributes. For example:

```python
class Student:
    def __init__(self, name, grade, age):
        self.name = name
        self.grade = grade
        self.age = age
    def __repr__(self):
```
return repr((self.name, self.grade, self.age))

>>> student_objects = [Student('john', 'A', 15), Student('jane', 'B', 12), Student('dave', 'B', 10), ]
>>> sorted(student_objects, key=lambda student: student.age)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The operator module has `operator.itemgetter()`, `operator.attrgetter()`, and starting in Python 2.5 a `operator.methodcaller()` function.

Using those functions, the above examples become simpler and faster:

```python
>>> from operator import itemgetter, attrgetter

>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

The operator module functions allow multiple levels of sorting. For example, to sort by `grade` then by `age`:

```python
>>> sorted(student_tuples, key=itemgetter(1,2))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]

>>> sorted(student_objects, key=attrgetter('grade', 'age'))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```
Ascending and Descending

Both `list.sort()` and `sorted()` accept a `reverse` parameter with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse `age` order:

```python
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

```python
>>> sorted(student_objects, key=attrgetter('age'), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```
Sort Stability and Complex Sorts

Starting with Python 2.2, sorts are guaranteed to be stable. That means that when multiple records have the same key, their original order is preserved.

```python
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)]
>>> sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for blue retain their original order so that ('blue', 1) is guaranteed to precede ('blue', 2).

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending grade and then ascending age, do the age sort first and then sort again using grade:

```python
>>> s = sorted(student_objects, key=attrgetter('age'))  # sort on secondary key
>>> sorted(s, key=attrgetter('grade'), reverse=True)  # now sort on primary key, descending
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The Timsort algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.
The Old Way Using Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by grade using the DSU approach:

```python
>>> decorated = [(student.grade, i, student) for i, student in enumerate(student_objects)]
>>> decorated.sort()
>>> [student for grade, i, student in decorated]  # undecorate
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index $i$ in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.

Another name for this idiom is Schwartzian transform, after Randal
L. Schwartz, who popularized it among Perl programmers.

For large lists and lists where the comparison information is expensive to calculate, and Python versions before 2.4, DSU is likely to be the fastest way to sort the list. For 2.4 and later, key functions provide the same functionality.
**The Old Way Using the `cmp` Parameter**

Many constructs given in this HOWTO assume Python 2.4 or later. Before that, there was no `sorted()` builtin and `list.sort()` took no keyword arguments. Instead, all of the Py2.x versions supported a `cmp` parameter to handle user specified comparison functions.

In Py3.0, the `cmp` parameter was removed entirely (as part of a larger effort to simplify and unify the language, eliminating the conflict between rich comparisons and the `__cmp__() magic method)

In Py2.x, sort allowed an optional function which can be called for doing the comparisons. That function should take two arguments to be compared and then return a negative value for less-than, return zero if they are equal, or return a positive value for greater-than. For example, we can do:

```python
>>> def numeric_compare(x, y):
    return x - y
>>> sorted([5, 2, 4, 1, 3], cmp=numeric_compare)
[1, 2, 3, 4, 5]
```

Or you can reverse the order of comparison with:

```python
>>> def reverse_numeric(x, y):
    return y - x
>>> sorted([5, 2, 4, 1, 3], cmp=reverse_numeric)
[5, 4, 3, 2, 1]
```

When porting code from Python 2.x to 3.x, the situation can arise when you have the user supplying a comparison function and you need to convert that to a key function. The following wrapper makes that easy to do:

```python
def cmp_to_key(mycmp):
    'Convert a cmp= function into a key= function'
```
class K(object):
    def __init__(self, obj, *args):
        self.obj = obj
    def __lt__(self, other):
        return mycmp(self.obj, other.obj) < 0
    def __gt__(self, other):
        return mycmp(self.obj, other.obj) > 0
    def __eq__(self, other):
        return mycmp(self.obj, other.obj) == 0
    def __le__(self, other):
        return mycmp(self.obj, other.obj) <= 0
    def __ge__(self, other):
        return mycmp(self.obj, other.obj) >= 0
    def __ne__(self, other):
        return mycmp(self.obj, other.obj) != 0
    return K

To convert to a key function, just wrap the old comparison function:

```python
gt = mycmp
```

```python
>>> sorted([5, 2, 4, 1, 3], key=cmp_to_key(reverse_numeric))
[5, 4, 3, 2, 1]
```

In Python 2.7, the `functools.cmp_to_key()` function was added to the `functools` module.
Odd and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function.

- The `reverse` parameter still maintains sort stability (i.e. records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the builtin `reversed()` function twice:

  ```python
  >>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)
  >>> assert sorted(data, reverse=True) == list(reversed(sorted(reversed(data))))
  ```

- The sort routines are guaranteed to use `__lt__()` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

  ```python
  >>> Student.__lt__ = lambda self, other: self.age < other.age
  >>> sorted(student_objects)
  [(['dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
  ```

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

  ```python
  >>> students = ['dave', 'john', 'jane']
  >>> newgrades = {'john': 'F', 'jane':'A', 'dave': 'C'}
  >>> sorted(students, key=newgrades.__getitem__)
  ['jane', 'dave', 'john']
  ```
This HOWTO discusses Python 2.x's support for Unicode, and explains various problems that people commonly encounter when trying to work with Unicode. (This HOWTO has not yet been updated to cover the 3.x versions of Python.)
Introduction to Unicode

History of Character Codes

In 1968, the American Standard Code for Information Interchange, better known by its acronym ASCII, was standardized. ASCII defined numeric codes for various characters, with the numeric values running from 0 to 127. For example, the lowercase letter ‘a’ is assigned 97 as its code value.

ASCII was an American-developed standard, so it only defined unaccented characters. There was an ‘e’, but no ‘é’ or ‘Í’. This meant that languages which required accented characters couldn’t be faithfully represented in ASCII. (Actually the missing accents matter for English, too, which contains words such as ‘ naïve’ and ‘café’, and some publications have house styles which require spellings such as ‘coöperate’.)

For a while people just wrote programs that didn’t display accents. I remember looking at Apple ][ BASIC programs, published in French-language publications in the mid-1980s, that had lines like these:

```
PRINT "FICHIER EST COMPLETE."
PRINT "CARACTERE NON ACCEPTE."
```

Those messages should contain accents, and they just look wrong to someone who can read French.

In the 1980s, almost all personal computers were 8-bit, meaning that bytes could hold values ranging from 0 to 255. ASCII codes only went up to 127, so some machines assigned values between 128 and 255 to accented characters. Different machines had different codes, however, which led to problems exchanging files. Eventually various commonly used sets of values for the 128-255 range
emerged. Some were true standards, defined by the International Standards Organization, and some were de facto conventions that were invented by one company or another and managed to catch on.

255 characters aren't very many. For example, you can't fit both the accented characters used in Western Europe and the Cyrillic alphabet used for Russian into the 128-255 range because there are more than 127 such characters.

You could write files using different codes (all your Russian files in a coding system called KOI8, all your French files in a different coding system called Latin1), but what if you wanted to write a French document that quotes some Russian text? In the 1980s people began to want to solve this problem, and the Unicode standardization effort began.

Unicode started out using 16-bit characters instead of 8-bit characters. 16 bits means you have $2^{16} = 65,536$ distinct values available, making it possible to represent many different characters from many different alphabets; an initial goal was to have Unicode contain the alphabets for every single human language. It turns out that even 16 bits isn't enough to meet that goal, and the modern Unicode specification uses a wider range of codes, 0-1,114,111 (0x10ffff in base-16).

There's a related ISO standard, ISO 10646. Unicode and ISO 10646 were originally separate efforts, but the specifications were merged with the 1.1 revision of Unicode.

(This discussion of Unicode’s history is highly simplified. I don’t think the average Python programmer needs to worry about the historical details; consult the Unicode consortium site listed in the References for more information.)

**Definitions**
A **character** is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘È’ and ‘Í’. Characters are abstractions, and vary depending on the language or context you’re talking about. For example, the symbol for ohms (Ω) is usually drawn much like the capital letter omega (Ω) in the Greek alphabet (they may even be the same in some fonts), but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point is an integer value, usually denoted in base 16. In the standard, a code point is written using the notation U+12ca to mean the character with value 0x12ca (4810 decimal). The Unicode standard contains a lot of tables listing characters and their corresponding code points:

<table>
<thead>
<tr>
<th>Code Point</th>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0061</td>
<td>'a'</td>
<td>LATIN SMALL LETTER A</td>
</tr>
<tr>
<td>0062</td>
<td>'b'</td>
<td>LATIN SMALL LETTER B</td>
</tr>
<tr>
<td>0063</td>
<td>'c'</td>
<td>LATIN SMALL LETTER C</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
</tr>
<tr>
<td>007B</td>
<td>'{'</td>
<td>LEFT CURLY BRACKET</td>
</tr>
</tbody>
</table>

Strictly, these definitions imply that it’s meaningless to say ‘this is character U+12ca’. U+12ca is a code point, which represents some particular character; in this case, it represents the character ‘ETHIOPIC SYLLABLE WI’. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn’t need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.
To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 to 0x10ffff. This sequence needs to be represented as a set of bytes (meaning, values from 0-255) in memory. The rules for translating a Unicode string into a sequence of bytes are called an encoding.

The first encoding you might think of is an array of 32-bit integers. In this representation, the string “Python” would look like this:

```
P
  0x50

0  1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17 18 19 20 21 22 23
```

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by zero bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn't matter too much (desktop computers have megabytes of RAM, and strings aren’t usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It's not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.
4. Many Internet standards are defined in terms of textual data, and can’t handle content with embedded zero bytes.

Generally people don’t use this encoding, instead choosing other encodings that are more efficient and convenient. UTF-8 is probably the most commonly supported encoding; it will be discussed below.

Encodings don’t have to handle every possible Unicode character,
and most encodings don't. For example, Python's default encoding is the 'ascii' encoding. The rules for converting a Unicode string into the ASCII encoding are simple; for each code point:

1. If the code point is < 128, each byte is the same as the value of the code point.
2. If the code point is 128 or greater, the Unicode string can't be represented in this encoding. (Python raises a UnicodeEncodeError exception in this case.)

Latin-1, also known as ISO-8859-1, is a similar encoding. Unicode code points 0-255 are identical to the Latin-1 values, so converting to this encoding simply requires converting code points to byte values; if a code point larger than 255 is encountered, the string can't be encoded into Latin-1.

Encodings don't have to be simple one-to-one mappings like Latin-1. Consider IBM's EBCDIC, which was used on IBM mainframes. Letter values weren't in one block: ‘a’ through ‘i’ had values from 129 to 137, but ‘j’ through ‘r’ were 145 through 153. If you wanted to use EBCDIC as an encoding, you'd probably use some sort of lookup table to perform the conversion, but this is largely an internal detail.

UTF-8 is one of the most commonly used encodings. UTF stands for "Unicode Transformation Format", and the '8' means that 8-bit numbers are used in the encoding. (There's also a UTF-16 encoding, but it's less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is <128, it's represented by the corresponding byte value.
2. If the code point is between 128 and 0x7ff, it's turned into two byte values between 128 and 255.
3. Code points >0x7ff are turned into three- or four-byte sequences, where each byte of the sequence is between 128
and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a string of bytes containing no embedded zero bytes. This avoids byte-ordering issues, and means UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of code points are turned into two bytes, and values less than 128 occupy only a single byte.
5. If bytes are corrupted or lost, it's possible to determine the start of the next UTF-8-encoded code point and resynchronize. It's also unlikely that random 8-bit data will look like valid UTF-8.

References

The Unicode Consortium site at <http://www.unicode.org> has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. <http://www.unicode.org/history/> is a chronology of the origin and development of Unicode.

Another good introductory article was written by Joel Spolsky <http://www.joelonsoftware.com/articles/Unicode.html>. If this introduction didn’t make things clear to you, you should try reading this alternate article before continuing.
Wikipedia entries are often helpful; see the entries for “character encoding” [http://en.wikipedia.org/wiki/Character_encoding] and UTF-8 [http://en.wikipedia.org/wiki/UTF-8], for example.
Python 2.x’s Unicode Support

Now that you’ve learned the rudiments of Unicode, we can look at Python’s Unicode features.

The Unicode Type

Unicode strings are expressed as instances of the `unicode` type, one of Python’s repertoire of built-in types. It derives from an abstract type called `basestring`, which is also an ancestor of the `str` type; you can therefore check if a value is a string type with `isinstance(value, basestring)`. Under the hood, Python represents Unicode strings as either 16- or 32-bit integers, depending on how the Python interpreter was compiled.

The `unicode()` constructor has the signature `unicode(string[, encoding, errors])`. All of its arguments should be 8-bit strings. The first argument is converted to Unicode using the specified encoding; if you leave off the `encoding` argument, the ASCII encoding is used for the conversion, so characters greater than 127 will be treated as errors:

```python
>>> unicode('abcdef')
u'abcdef'
>>> s = unicode('abcdef')
>>> type(s)
<type 'unicode'>
>>> unicode('abcdef' + chr(255))
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeDecodeError: 'ascii' codec can't decode byte 0xff in position 6:
  ordinal not in range(128)
```

The `errors` argument specifies the response when the input string
can’t be converted according to the encoding’s rules. Legal values for this argument are ‘strict’ (raise a UnicodeDecodeError exception), ‘replace’ (add U+FFFD, ‘REPLACEMENT CHARACTER’), or ‘ignore’ (just leave the character out of the Unicode result). The following examples show the differences:

```python
>>> unicode('\x80abc', errors='strict')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeDecodeError: 'ascii' codec can't decode byte 0x80 in position 0:
  ordinal not in range(128)
>>> unicode('\x80abc', errors='replace')
u'\ufffdabc'
>>> unicode('\x80abc', errors='ignore')
u'abc'
```

Encodings are specified as strings containing the encoding’s name. Python 2.7 comes with roughly 100 different encodings; see the Python Library Reference at Standard Encodings for a list. Some encodings have multiple names; for example, ‘latin-1’, ‘iso_8859_1’ and ‘8859’ are all synonyms for the same encoding.

One-character Unicode strings can also be created with the unichr() built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in ord() function that takes a one-character Unicode string and returns the code point value:

```python
>>> unichr(40960)
u'\u0000'
>>> ord(u'\u0000')
40960
```

Instances of the unicode type have many of the same methods as the 8-bit string type for operations such as searching and formatting:

```python
>>> s = u'Was ever feather so lightly blown to and fro as this
```
Note that the arguments to these methods can be Unicode strings or 8-bit strings. 8-bit strings will be converted to Unicode before carrying out the operation; Python's default ASCII encoding will be used, so characters greater than 127 will cause an exception:

```python
>>> s.find('Was\x9f')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeDecodeError: 'ascii' codec can't decode byte 0x9f in position 3
>>> s.find(u'Was\x9f')
-1
```

Much Python code that operates on strings will therefore work with Unicode strings without requiring any changes to the code. (Input and output code needs more updating for Unicode; more on this later.)

Another important method is `.encode([encoding], [errors='strict'])`, which returns an 8-bit string version of the Unicode string, encoded in the requested encoding. The `errors` parameter is the same as the parameter of the `unicode()` constructor, with one additional possibility; as well as ‘strict’, ‘ignore’, and ‘replace’, you can also pass ‘xmlcharrefreplace’ which uses XML’s character references. The following example shows the different results:
Python's 8-bit strings have a `decode([encoding], [errors])` method that interprets the string using the given encoding:

```python
>>> u = unichr(40960) + u'abcd' + unichr(1972)  # Assemble a string
>>> utf8_version = u.encode('utf-8')  # Encode as UTF-8
>>> type(utf8_version), utf8_version
(<type 'str'>, '\xea\x80\x80abcd\xde\xb4')
>>> u2 = utf8_version.decode('utf-8')  # Decode using
>>> u == u2  # The two strings match
True
```

The low-level routines for registering and accessing the available encodings are found in the `codecs` module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, so I'm not going to describe the `codecs` module here. If you need to implement a completely new encoding, you'll need to learn about the `codecs` module interfaces, but implementing encodings is a specialized task that also won't be covered here. Consult the Python documentation to learn more about this module.

The most commonly used part of the `codecs` module is the `codecs.open()` function which will be discussed in the section on input and output.
In Python source code, Unicode literals are written as strings prefixed with the ‘u’ or ‘U’ character: `u'abcdefghijk'`. Specific code points can be written using the \u escape sequence, which is followed by four hex digits giving the code point. The \U escape sequence is similar, but expects 8 hex digits, not 4.

Unicode literals can also use the same escape sequences as 8-bit strings, including \x, but \x only takes two hex digits so it can’t express an arbitrary code point. Octal escapes can go up to U+01ff, which is octal 777.

```python
>>> s = u"a\xac\u1234\u20ac\U00008000"
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you’re using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `unichr()` built-in function, but this is even more tedious.

Ideally, you’d want to be able to write literals in your language’s natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing Unicode literals in any encoding, but you have to declare the encoding being used. This is done by including a
special comment as either the first or second line of the source file:

```python
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = u'abcdé'
print ord(u[-1])
```

The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports `coding`. The `-*-` symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don't include such a comment, the default encoding used will be ASCII. Versions of Python before 2.4 were Euro-centric and assumed Latin-1 as a default encoding for string literals; in Python 2.4, characters greater than 127 still work but result in a warning. For example, the following program has no encoding declaration:

```python
#!/usr/bin/env python
u = u'abcdé'
print ord(u[-1])
```

When you run it with Python 2.4, it will output the following warning:

```
amk:~$ python2.4 p263.py
sys:1: DeprecationWarning: Non-ASCII character '\xe9'
in file p263.py on line 2, but no encoding declared;
see http://www.python.org/peps.pep-0263.html for details
```

Python 2.5 and higher are stricter and will produce a syntax error:

```
amk:~$ python2.5 p263.py
File "~/tmp/p263.py", line 2
SyntaxError: Non-ASCII character '\xc3' in file ~/tmp/p263.py
on line 2, but no encoding declared; see
http://www.python.org/peps.pep-0263.html for details
```
Unicode Properties

The Unicode specification includes a database of information about code points. For each code point that's defined, the information includes the character's name, its category, the numeric value if applicable (Unicode has characters representing the Roman numerals and fractions such as one-third and four-fifths). There are also properties related to the code point's use in bidirectional text and other display-related properties.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```python
import unicodedata

u = unichr(233) + unichr(0x0bf2) + unichr(3972) + unichr(6000)

for i, c in enumerate(u):
    print i, '%04x' % ord(c), unicodedata.category(c),
    print unicodedata.name(c)

# Get numeric value of second character
print unicodedata.numeric(u[1])
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, 'Ll'
means ‘Letter, lowercase’, ‘\texttt{No}’ means “Number, other”, ‘\texttt{Mn}’ is “Mark, nonspacing”, and ‘\texttt{So}’ is “Symbol, other”. See <http://www.unicode.org/reports/tr44/#General_Category_Vvalues> for a list of category codes.

Marc-André Lemburg gave a presentation at EuroPython 2002 titled “Python and Unicode”. A PDF version of his slides is available at <http://downloads.egenix.com/python/Unicode-EPC2002-Talk.pdf>, and is an excellent overview of the design of Python’s Unicode features.
Once you’ve written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It’s possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It’s possible to do all the work yourself: open a file, read an 8-bit string from it, and convert the string with `unicode(str, encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1K or 4K), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2Gb file, you need 2Gb of RAM. (More, really, since for at least a moment you’d need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the `codecs` module...
includes a version of the `open()` function that returns a file-like object that assumes the file's contents are in a specified encoding and accepts Unicode parameters for methods such as `.read()` and `.write()`.

The function’s parameters are `open(filename, mode='rb', encoding=None, errors='strict', buffering=1)`. `mode` can be `'r'`, `'w'`, or `'a'`, just like the corresponding parameter to the regular built-in `open()` function; add a `'+'` to update the file. `buffering` is similarly parallel to the standard function’s parameter. `encoding` is a string giving the encoding to use; if it’s left as `None`, a regular Python file object that accepts 8-bit strings is returned. Otherwise, a wrapper object is returned, and data written to or read from the wrapper object will be converted as needed. `errors` specifies the action for encoding errors and can be one of the usual values of ‘strict’, ‘ignore’, and ‘replace’.

Reading Unicode from a file is therefore simple:

```python
import codecs
f = codecs.open('unicode.rst', encoding='utf-8')
for line in f:
    print repr(line)
```

It’s also possible to open files in update mode, allowing both reading and writing:

```python
f = codecs.open('test', encoding='utf-8', mode='w+')
f.write(u'\u4500 blah blah blah
')
f.seek(0)
print repr(f.readline()[:1])
f.close()
```

Unicode character U+FEFF is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such
as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as 'utf-16-le' and 'utf-16-be' for little-endian and big-endian encodings, that specify one particular byte ordering and don’t skip the BOM.

### Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. For example, Mac OS X uses UTF-8 while Windows uses a configurable encoding; on Windows, Python uses the name “mbcs” to refer to whatever the currently configured encoding is. On Unix systems, there will only be a filesystem encoding if you’ve set the `LANG` or `LC_CTYPE` environment variables; if you haven't, the default encoding is ASCII.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there’s not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```python
filename = u'filename\u4500abc'
f = open(filename, 'w')
f.write('blah\n')
f.close()
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

`os.listdir()`, which returns filenames, raises an issue: should it
return the Unicode version of filenames, or should it return 8-bit strings containing the encoded versions? os.listdir() will do both, depending on whether you provided the directory path as an 8-bit string or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing an 8-bit path will return the 8-bit versions of the filenames. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```python
fn = u'filename\u4500abc'
f = open(fn, 'w')
f.close()
import os
print os.listdir('.')
print os.listdir(u'\')
```

will produce the following output:

```
amk:~$ python t.py
['.svn', 'filename\xe4\x94\x80abc', ...]
[u'\n', u'filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

**Tips for Writing Unicode-aware Programs**

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

Software should only work with Unicode strings internally, converting to a particular encoding on output.

If you attempt to write processing functions that accept both Unicode and 8-bit strings, you will find your program vulnerable to bugs
wherever you combine the two different kinds of strings. Python’s default encoding is ASCII, so whenever a character with an ASCII value > 127 is in the input data, you’ll get a `UnicodeDecodeError` because that character can’t be handled by the ASCII encoding.

It’s easy to miss such problems if you only test your software with data that doesn’t contain any accents; everything will seem to work, but there’s actually a bug in your program waiting for the first user who attempts to use characters > 127. A second tip, therefore, is:

Include characters > 127 and, even better, characters > 255 in your test data.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you’re doing this, be careful to check the string once it’s in the form that will be used or stored; it’s possible for encodings to be used to disguise characters. This is especially true if the input data also specifies the encoding; many encodings leave the commonly checked-for characters alone, but Python includes some encodings such as `'base64'` that modify every single character.

For example, let’s say you have a content management system that takes a Unicode filename, and you want to disallow paths with a ‘/’ character. You might write this code:

```python
def read_file (filename, encoding):
    if '/' in filename:
        raise ValueError("'/' not allowed in filenames")
    unicode_name = filename.decode(encoding)
    f = open(unicode_name, 'r')
    # ... return contents of file ...
```

However, if an attacker could specify the `base64` encoding, they
could pass 'L2V0Yy9wYXNzd2Q=', which is the base-64 encoded form of the string '/etc/passwd', to read a system file. The above code looks for '/' characters in the encoded form and misses the dangerous character in the resulting decoded form.

Version 1.0: posted August 5 2005.

Version 1.01: posted August 7 2005. Corrects factual and markup errors; adds several links.

Version 1.03: posted June 20 2010. Notes that Python 3.x is not covered, and that the HOWTO only covers 2.x.
HOWTO Fetch Internet Resources Using urllib2

Author: Michael Foord

Note: There is an French translation of an earlier revision of this HOWTO, available at urllib2 - Le Manuel manquant.
**Introduction**

`urllib2` is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the `urlopen` function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

`urllib2` supports fetching URLs for many “URL schemes” (identified by the string before the “:” in URL - for example “ftp” is the URL scheme of “ftp://python.org/“) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations `urlopen` is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is RFC 2616. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using `urllib2`, with enough detail about HTTP to help you through. It is not intended to replace the `urllib2` docs, but is supplementary to them.

Fetching URLs

The simplest way to use urllib2 is as follows:

```python
import urllib2
response = urllib2.urlopen('http://python.org/)
html = response.read()
```

Many uses of urllib2 will be that simple (note that instead of an ‘http:’ URL we could have used an URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib2 mirrors this with a Request object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `read()` on the response:

```python
import urllib2

req = urllib2.Request('http://www.voidspace.org.uk')
response = urllib2.urlopen(req)
the_page = response.read()
```

Note that urllib2 makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

```python
req = urllib2.Request('ftp://example.com/)
```

In the case of HTTP, there are two extra things that Request objects
allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information ("metadata") about the data or the about request itself, to the server - this information is sent as HTTP "headers". Let's look at each of these in turn.

**Data**

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script [1] or other web application). With HTTP, this is often done using what's known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the **data** argument. The encoding is done using a function from the **urllib** library not from **urllib2**.

```python
import urllib
import urllib2

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = { 'name' : 'Michael Foord',
           'location' : 'Northampton',
           'language' : 'Python' }

data = urllib.urlencode(values)
req = urllib2.Request(url, data)
response = urllib2.urlopen(req)
the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission for more details).

If you do not pass the **data** argument, urllib2 uses a **GET** request. One way in which GET and POST requests differ is that POST
requests often have “side-effects”: they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to always cause side-effects, and GET requests never to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```python
>>> import urllib2
>>> import urllib
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.urlencode(data)
>>> print url_values
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib2.open(full_url)
```

Notice that the full URL is created by adding a `?` to the URL, followed by the encoded values.

**Headers**

We’ll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [2] dislike being browsed by programs, or send different versions to different browsers [3]. By default urllib2 identifies itself as Python-urllib/x.y (where x and y are the major and minor version numbers of the Python release, e.g. Python-
urllib/2.5), which may confuse the site, or just plain not work. The way a browser identifies itself is through the User-Agent header [4]. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [5].

```python
import urllib
import urllib2

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/4.0 (compatible; MSIE 5.5; Windows NT)'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python'}
headers = {'User-Agent' : user_agent}

data = urllib.urlencode(values)
req = urllib2.Request(url, data, headers)
response = urllib2.urlopen(req)
the_page = response.read()
```

The response also has two useful methods. See the section on `info` and `geturl` which comes after we have a look at what happens when things go wrong.
Handling Exceptions

`urlopen` raises `URLError` when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

**URLError**

Often, `URLError` is raised because there is no network connection (no route to the specified server), or the specified server doesn't exist. In this case, the exception raised will have a 'reason' attribute, which is a tuple containing an error code and a text error message.

e.g.

```python
>>> req = urllib2.Request('http://www.pretend_server.org')
>>> try: urllib2.urlopen(req)
>>> except URLError, e:
>>>     print e.reason
>>> (4, 'getaddrinfo failed')
```

**HTTPError**

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, `urllib2` will handle that for you). For those it can’t handle, `urlopen` will raise an `HTTPError`. Typical errors include ‘404’ (page not found), ‘403’
(request forbidden), and ‘401’ (authentication required).

See section 10 of RFC 2616 for a reference on all the HTTP error codes.

The **HTTPError** instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

## Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100-299 range indicate success, you will usually only see error codes in the 400-599 range.

**BaseHTTPServer.BaseHTTPRequestHandler.responses** is a useful dictionary of response codes in that shows all the response codes used by RFC 2616. The dictionary is reproduced here for convenience

```python
responses = {
    100: ('Continue', 'Request received, please continue'),
    101: ('Switching Protocols', 'Switching to new protocol; obey Upgrade header'),

    200: ('OK', 'Request fulfilled, document follows'),
    201: ('Created', 'Document created, URL follows'),
    202: ('Accepted', 'Request accepted, processing continues off-line'),
    203: ('Non-Authoritative Information', 'Request fulfilled from cache'),
    204: ('No Content', 'Request fulfilled, nothing follows'),
    205: ('Reset Content', 'Clear input form for further input.'),
    206: ('Partial Content', 'Partial content follows.'),

    300: ('Multiple Choices', 'Object has several resources -- see URI list'),
    301: ('Moved Permanently', 'Object moved permanently -- see URI list'),
    302: ('Found', 'Object moved temporarily -- see URI list'),
    303: ('See Other', 'Object moved -- see Method and URL list'),
    304: ('Not Modified',
```
305: ('Use Proxy',
    'You must use proxy specified in Location to access this resource.'),
307: ('Temporary Redirect',
    'Object moved temporarily -- see URI list'),
400: ('Bad Request',
    'Bad request syntax or unsupported method'),
401: ('Unauthorized',
    'No permission -- see authorization schemes'),
402: ('Payment Required',
    'No payment -- see charging schemes'),
403: ('Forbidden',
    'Request forbidden -- authorization will not help'),
404: ('Not Found', 'Nothing matches the given URI'),
405: ('Method Not Allowed',
    'Specified method is invalid for this server.'),
406: ('Not Acceptable', 'URI not available in preferred format'),
407: ('Proxy Authentication Required', 'You must authenticate with this proxy before proceeding.'),
408: ('Request Timeout', 'Request timed out; try again later'),
409: ('Conflict', 'Request conflict'),
410: ('Gone',
    'URI no longer exists and has been permanently removed'),
411: ('Length Required', 'Client must specify Content-Length'),
412: ('Precondition Failed', 'Precondition in headers is false'),
413: ('Request Entity Too Large', 'Entity is too large.'),
414: ('Request-URI Too Long', 'URI is too long.'),
415: ('Unsupported Media Type', 'Entity body in unsupported format'),
416: ('Requested Range Not Satisfiable',
    'Cannot satisfy request range.'),
417: ('Expectation Failed',
    'Expect condition could not be satisfied.'),
500: ('Internal Server Error', 'Server got itself in trouble'),
501: ('Not Implemented',
    'Server does not support this operation'),
502: ('Bad Gateway', 'Invalid responses from another server'),
503: ('Service Unavailable',
    'The server cannot process the request due to a high load'),
504: ('Gateway Timeout',
    'The gateway server did not receive a timely response'),
505: ('HTTP Version Not Supported', 'Cannot fulfill request')
}
When an error is raised the server responds by returning an HTTP error code and an error page. You can use the HTTPError instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods.

```python
>>> req = urllib2.Request('http://www.python.org/fish.html')
>>> try:
...    urllib2.urlopen(req)
>>> except HTTPError, e:
...    print e.code
...    print e.read()
...except URLError, e:
...    print 'We failed to reach a server.'
...    print 'Reason: ', e.reason
else:
...    # everything is fine
```

Wrapping it Up

So if you want to be prepared for HTTPError or URLError there are two basic approaches. I prefer the second approach.

Number 1

```python
from urllib2 import Request, urlopen, URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError, e:
    print 'The server couldn\'t fulfill the request.'
    print 'Error code: ', e.code
except URLError, e:
    print 'We failed to reach a server.'
    print 'Reason: ', e.reason
else:
    # everything is fine
```
Note: The except HTTPError must come first, otherwise except URLError will also catch an HTTPError.

Number 2

```python
from urllib2 import Request, urlopen, URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError, e:
    if hasattr(e, 'reason'):
        print 'We failed to reach a server.'
        print 'Reason: ', e.reason
    elif hasattr(e, 'code'):
        print 'The server couldn\'t fulfill the request.'
        print 'Error code: ', e.code
else:
    # everything is fine
```
info and geturl

The response returned by urlopen (or the HTTPError instance) has two useful methods info() and geturl().

**geturl** - this returns the real URL of the page fetched. This is useful because urlopen (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

**info** - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an `http.HttpMessage` instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the Quick Reference to HTTP Headers for a useful listing of HTTP headers with brief explanations of their meaning and use.
Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly-named `urllib2.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an opener object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an open method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.
Basic Authentication

To illustrate creating and installing a handler we will use the HTTPBasicAuthHandler. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial.

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a ‘realm’. The header looks like: `Www-authenticate: SCHEME realm="REALM"`.

e.g.

```
Www-authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of `HTTPBasicAuthHandler` and an opener to use this handler.

The `HTTPBasicAuthHandler` uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a HTTPPasswordMgr. Frequently one doesn’t care what the realm is. In that case, it is convenient to use `HTTPPasswordMgrWithDefaultRealm`. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing `None` as the realm argument to the `add_password` method.
The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to .add_password() will also match.

```python
# create a password manager
password_mgr = urllib2.HTTPPasswordMgrWithDefaultRealm()

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username, password)

handler = urllib2.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib2.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib2.urlopen use our opener.
urllib2.install_opener(opener)
```

**Note:** In the above example we only supplied our HTTPBasicAuthHandler to build_opener. By default openers have the handlers for normal situations — ProxyHandler, UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, HTTPErrorProcessor.

top_level_url is in fact *either* a full URL (including the ‘http:’ scheme component and the hostname and optionally the port number) e.g. “http://example.com/” or an “authority” (i.e. the hostname, optionally including the port number) e.g. “example.com” or “example.com:8080” (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example “joe@password:example.com” is not correct.
Proxies

`urllib2` will auto-detect your proxy settings and use those. This is through the `ProxyHandler` which is part of the normal handler chain. Normally that’s a good thing, but there are occasions when it may not be helpful [6]. One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a `Basic Authentication` handler:

```python
>>> proxy_support = urllib2.ProxyHandler({})
>>> opener = urllib2.build_opener(proxy_support)
>>> urllib2.install_opener(opener)
```

**Note:** Currently `urllib2` does not support fetching of `https` locations through a proxy. However, this can be enabled by extending `urllib2` as shown in the recipe [7].
Sockets and Layers

The Python support for fetching resources from the web is layered. urllib2 uses the httplib library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has no timeout and can hang. Currently, the socket timeout is not exposed at the httplib or urllib2 levels. However, you can set the default timeout globally for all sockets using

```python
import socket
import urllib2

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib2.urlopen now uses the default timeout
# we have set in the socket module
req = urllib2.Request('http://www.voidspace.org.uk')
response = urllib2.urlopen(req)
```
This document was reviewed and revised by John Lee.

[1] For an introduction to the CGI protocol see Writing Web Applications in Python. Like Google for example. The proper way to use google from a program is to use PyGoogle of course. See Voidspace Google for some examples of using the Google API.

[2] Browser sniffling is a very bad practise for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

[3] The user agent for MSIE 6 is ‘Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)’

[4] For details of more HTTP request headers, see Quick Reference to HTTP Headers.

[5] In my case I have to use a proxy to access the internet at work. If you attempt to fetch localhost URLs through this proxy it blocks them. IE is set to use the proxy, which urllib2 picks up on. In order to test scripts with a localhost server, I have to prevent urllib2 from using the proxy.

HOWTO Use Python in the web

Author: Marek Kubica

Abstract

This document shows how Python fits into the web. It presents some ways to integrate Python with a web server, and general practices useful for developing web sites.

Programming for the Web has become a hot topic since the rise of “Web 2.0”, which focuses on user-generated content on web sites. It has always been possible to use Python for creating web sites, but it was a rather tedious task. Therefore, many frameworks and helper tools have been created to assist developers in creating faster and more robust sites. This HOWTO describes some of the methods used to combine Python with a web server to create dynamic content. It is not meant as a complete introduction, as this topic is far too broad to be covered in one single document. However, a short overview of the most popular libraries is provided.

See also: While this HOWTO tries to give an overview of Python in the web, it cannot always be as up to date as desired. Web development in Python is rapidly moving forward, so the wiki page on Web Programming may be more in sync with recent development.
The Low-Level View

When a user enters a web site, their browser makes a connection to the site’s web server (this is called the request). The server looks up the file in the file system and sends it back to the user’s browser, which displays it (this is the response). This is roughly how the underlying protocol, HTTP, works.

Dynamic web sites are not based on files in the file system, but rather on programs which are run by the web server when a request comes in, and which generate the content that is returned to the user. They can do all sorts of useful things, like display the postings of a bulletin board, show your email, configure software, or just display the current time. These programs can be written in any programming language the server supports. Since most servers support Python, it is easy to use Python to create dynamic web sites.

Most HTTP servers are written in C or C++, so they cannot execute Python code directly – a bridge is needed between the server and the program. These bridges, or rather interfaces, define how programs interact with the server. There have been numerous attempts to create the best possible interface, but there are only a few worth mentioning.

Not every web server supports every interface. Many web servers only support old, now-obsolete interfaces; however, they can often be extended using third-party modules to support newer ones.

Common Gateway Interface

This interface, most commonly referred to as “CGI”, is the oldest, and is supported by nearly every web server out of the box. Programs using CGI to communicate with their web server need to
be started by the server for every request. So, every request starts a new Python interpreter – which takes some time to start up – thus making the whole interface only usable for low load situations.

The upside of CGI is that it is simple – writing a Python program which uses CGI is a matter of about three lines of code. This simplicity comes at a price: it does very few things to help the developer.

Writing CGI programs, while still possible, is no longer recommended. With WSGI, a topic covered later in this document, it is possible to write programs that emulate CGI, so they can be run as CGI if no better option is available.

See also: The Python standard library includes some modules that are helpful for creating plain CGI programs:

- **cgi** – Handling of user input in CGI scripts
- **cgitb** – Displays nice tracebacks when errors happen in CGI applications, instead of presenting a “500 Internal Server Error” message

The Python wiki features a page on CGI scripts with some additional information about CGI in Python.

### Simple script for testing CGI

To test whether your web server works with CGI, you can use this short and simple CGI program:

```
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

# enable debugging
import cgitb
```
Depending on your web server configuration, you may need to save this code with a `.py` or `.cgi` extension. Additionally, this file may also need to be in a `cgi-bin` folder, for security reasons.

You might wonder what the `cgitb` line is about. This line makes it possible to display a nice traceback instead of just crashing and displaying an “Internal Server Error” in the user's browser. This is useful for debugging, but it might risk exposing some confidential data to the user. You should not use `cgitb` in production code for this reason. You should always catch exceptions, and display proper error pages – end-users don’t like to see nondescript “Internal Server Errors” in their browsers.

### Setting up CGI on your own server

If you don't have your own web server, this does not apply to you. You can check whether it works as-is, and if not you will need to talk to the administrator of your web server. If it is a big host, you can try filing a ticket asking for Python support.

If you are your own administrator or want to set up CGI for testing purposes on your own computers, you have to configure it by yourself. There is no single way to configure CGI, as there are many web servers with different configuration options. Currently the most widely used free web server is Apache HTTPd, or Apache for short. Apache can be easily installed on nearly every system using the system’s package management tool. `lighttpd` is another alternative and is said to have better performance. On many systems this server can also be installed using the package management tool, so
manually compiling the web server may not be needed.

- On Apache you can take a look at the Dynamic Content with CGI tutorial, where everything is described. Most of the time it is enough just to set `+ExecCGI`. The tutorial also describes the most common gotchas that might arise.
- On lighttpd you need to use the CGI module, which can be configured in a straightforward way. It boils down to setting `cgi.assign` properly.

### Common problems with CGI scripts

Using CGI sometimes leads to small annoyances while trying to get these scripts to run. Sometimes a seemingly correct script does not work as expected, the cause being some small hidden problem that’s difficult to spot.

Some of these potential problems are:

- The Python script is not marked as executable. When CGI scripts are not executable most web servers will let the user download it, instead of running it and sending the output to the user. For CGI scripts to run properly on Unix-like operating systems, the `+x` bit needs to be set. Using `chmod a+x your_script.py` may solve this problem.
- On a Unix-like system, The line endings in the program file must be Unix style line endings. This is important because the web server checks the first line of the script (called shebang) and tries to run the program specified there. It gets easily confused by Windows line endings (Carriage Return & Line Feed, also called CRLF), so you have to convert the file to Unix line endings (only Line Feed, LF). This can be done automatically by uploading the file via FTP in text mode instead of binary mode, but the preferred way is just telling your editor to save the files with Unix line endings. Most editors support this.
• Your web server must be able to read the file, and you need to make sure the permissions are correct. On unix-like systems, the server often runs as user and group `www-data`, so it might be worth a try to change the file ownership, or making the file world readable by using `chmod a+r your_script.py`.

• The web server must know that the file you’re trying to access is a CGI script. Check the configuration of your web server, as it may be configured to expect a specific file extension for CGI scripts.

• On Unix-like systems, the path to the interpreter in the shebang (`#!/usr/bin/env python`) must be correct. This line calls `/usr/bin/env` to find Python, but it will fail if there is no `/usr/bin/env`, or if Python is not in the web server’s path. If you know where your Python is installed, you can also use that full path. The commands `whereis python` and `type -p python` could help you find where it is installed. Once you know the path, you can change the shebang accordingly: `#!/usr/bin/python`.

• The file must not contain a BOM (Byte Order Mark). The BOM is meant for determining the byte order of UTF-16 and UTF-32 encodings, but some editors write this also into UTF-8 files. The BOM interferes with the shebang line, so be sure to tell your editor not to write the BOM.

• If the web server is using `mod_python`, `mod_python` may be having problems. `mod_python` is able to handle CGI scripts by itself, but it can also be a source of issues.

---

**mod_python**

People coming from PHP often find it hard to grasp how to use Python in the web. Their first thought is mostly `mod_python`, because they think that this is the equivalent to `mod_php`. Actually, there are many differences. What `mod_python` does is embed the interpreter into the Apache process, thus speeding up requests by
not having to start a Python interpreter for each request. On the other hand, it is not “Python intermixed with HTML” in the way that PHP is often intermixed with HTML. The Python equivalent of that is a template engine. `mod_python` itself is much more powerful and provides more access to Apache internals. It can emulate CGI, work in a “Python Server Pages” mode (similar to JSP) which is “HTML intermingled with Python”, and it has a “Publisher” which designates one file to accept all requests and decide what to do with them.

`mod_python` does have some problems. Unlike the PHP interpreter, the Python interpreter uses caching when executing files, so changes to a file will require the web server to be restarted. Another problem is the basic concept – Apache starts child processes to handle the requests, and unfortunately every child process needs to load the whole Python interpreter even if it does not use it. This makes the whole web server slower. Another problem is that, because `mod_python` is linked against a specific version of `libpython`, it is not possible to switch from an older version to a newer (e.g. 2.4 to 2.5) without recompiling `mod_python`. `mod_python` is also bound to the Apache web server, so programs written for `mod_python` cannot easily run on other web servers.

These are the reasons why `mod_python` should be avoided when writing new programs. In some circumstances it still might be a good idea to use `mod_python` for deployment, but WSGI makes it possible to run WSGI programs under `mod_python` as well.

**FastCGI and SCGI**

FastCGI and SCGI try to solve the performance problem of CGI in another way. Instead of embedding the interpreter into the web server, they create long-running background processes. There is still a module in the web server which makes it possible for the web server to “speak” with the background process. As the background
process is independent of the server, it can be written in any language, including Python. The language just needs to have a library which handles the communication with the webserver.

The difference between FastCGI and SCGI is very small, as SCGI is essentially just a “simpler FastCGI”. As the web server support for SCGI is limited, most people use FastCGI instead, which works the same way. Almost everything that applies to SCGI also applies to FastCGI as well, so we'll only cover the latter.

These days, FastCGI is never used directly. Just like mod_python, it is only used for the deployment of WSGI applications.

### See also:

- **FastCGI, SCGI, and Apache: Background and Future** is a discussion on why the concept of FastCGI and SCGI is better that that of mod_python.

### Setting up FastCGI

Each web server requires a specific module.

- Apache has both mod_fastcgi and mod_fcgid. mod_fastcgi is the original one, but it has some licensing issues, which is why it is sometimes considered non-free. mod_fcgid is a smaller, compatible alternative. One of these modules needs to be loaded by Apache.
- lighttpd ships its own FastCGI module as well as an SCGI module.
- nginx also supports FastCGI.

Once you have installed and configured the module, you can test it with the following WSGI-application:
This is a simple WSGI application, but you need to install **flup** first, as flup handles the low level FastCGI access.

**See also:** There is some documentation on setting up Django with FastCGI, most of which can be reused for other WSGI-compliant frameworks and libraries. Only the `manage.py` part has to be changed, the example used here can be used instead. Django does more or less the exact same thing.

**mod_wsgi**

**mod_wsgi** is an attempt to get rid of the low level gateways. Given that FastCGI, SCGI, and mod_python are mostly used to deploy WSGI applications, mod_wsgi was started to directly embed WSGI applications into the Apache web server. mod_wsgi is specifically designed to host WSGI applications. It makes the deployment of WSGI applications much easier than deployment using other low level methods, which need glue code. The downside is that mod_wsgi is limited to the Apache web server; other servers would
need their own implementations of mod_wsgi.

mod_wsgi supports two modes: embedded mode, in which it integrates with the Apache process, and daemon mode, which is more FastCGI-like. Unlike FastCGI, mod_wsgi handles the worker-processes by itself, which makes administration easier.
WSGI has already been mentioned several times, so it has to be something important. In fact it really is, and now it is time to explain it.

The *Web Server Gateway Interface*, or WSGI for short, is defined in [PEP 333](https://www.python.org/dev/peps/pep-0333/) and is currently the best way to do Python web programming. While it is great for programmers writing frameworks, a normal web developer does not need to get in direct contact with it. When choosing a framework for web development it is a good idea to choose one which supports WSGI.

The big benefit of WSGI is the unification of the application programming interface. When your program is compatible with WSGI – which at the outer level means that the framework you are using has support for WSGI – your program can be deployed via any web server interface for which there are WSGI wrappers. You do not need to care about whether the application user uses mod_python or FastCGI or mod_wsgi – with WSGI your application will work on any gateway interface. The Python standard library contains its own WSGI server, *wsgiref*, which is a small web server that can be used for testing.

A really great WSGI feature is middleware. Middleware is a layer around your program which can add various functionality to it. There is quite a bit of *middleware* already available. For example, instead of writing your own session management (HTTP is a stateless protocol, so to associate multiple HTTP requests with a single user your application must create and manage such state via a session), you can just download middleware which does that, plug it in, and get on with coding the unique parts of your application. The same thing with compression – there is existing middleware which handles
compressing your HTML using gzip to save on your server’s bandwidth. Authentication is another a problem easily solved using existing middleware.

Although WSGI may seem complex, the initial phase of learning can be very rewarding because WSGI and the associated middleware already have solutions to many problems that might arise while developing web sites.

### WSGI Servers

The code that is used to connect to various low level gateways like CGI or mod_python is called a WSGI server. One of these servers is flup, which supports FastCGI and SCGI, as well as AJP. Some of these servers are written in Python, as flup is, but there also exist others which are written in C and can be used as drop-in replacements.

There are many servers already available, so a Python web application can be deployed nearly anywhere. This is one big advantage that Python has compared with other web technologies.

**See also:** A good overview of WSGI-related code can be found in the WSGI wiki, which contains an extensive list of WSGI servers which can be used by any application supporting WSGI.

You might be interested in some WSGI-supporting modules already contained in the standard library, namely:

- **wsgiref** – some tiny utilities and servers for WSGI

### Case study: MoinMoin
What does WSGI give the web application developer? Let’s take a look at an application that’s been around for a while, which was written in Python without using WSGI.

One of the most widely used wiki software packages is MoinMoin. It was created in 2000, so it predates WSGI by about three years. Older versions needed separate code to run on CGI, mod_python, FastCGI and standalone.

It now includes support for WSGI. Using WSGI, it is possible to deploy MoinMoin on any WSGI compliant server, with no additional glue code. Unlike the pre-WSGI versions, this could include WSGI servers that the authors of MoinMoin know nothing about.
The term MVC is often encountered in statements such as “framework foo supports MVC”. MVC is more about the overall organization of code, rather than any particular API. Many web frameworks use this model to help the developer bring structure to their program. Bigger web applications can have lots of code, so it is a good idea to have an effective structure right from the beginning. That way, even users of other frameworks (or even other languages, since MVC is not Python-specific) can easily understand the code, given that they are already familiar with the MVC structure.

MVC stands for three components:

- **The model.** This is the data that will be displayed and modified. In Python frameworks, this component is often represented by the classes used by an object-relational mapper.
- **The view.** This component’s job is to display the data of the model to the user. Typically this component is implemented via templates.
- **The controller.** This is the layer between the user and the model. The controller reacts to user actions (like opening some specific URL), tells the model to modify the data if necessary, and tells the view code what to display,

While one might think that MVC is a complex design pattern, in fact it is not. It is used in Python because it has turned out to be useful for creating clean, maintainable web sites.

**Note:** While not all Python frameworks explicitly support MVC, it is often trivial to create a web site which uses the MVC pattern by separating the data logic (the model) from the user interaction logic (the controller) and the templates (the view). That's why it is
important not to write unnecessary Python code in the templates – it works against the MVC model and creates chaos in the code base, making it harder to understand and modify.

**See also:** The English Wikipedia has an article about the Model-View-Controller pattern. It includes a long list of web frameworks for various programming languages.
Ingredients for Websites

Websites are complex constructs, so tools have been created to help web developers make their code easier to write and more maintainable. Tools like these exist for all web frameworks in all languages. Developers are not forced to use these tools, and often there is no "best" tool. It is worth learning about the available tools because they can greatly simplify the process of developing a web site.

See also: There are far more components than can be presented here. The Python wiki has a page about these components, called Web Components.

Templates

Mixing of HTML and Python code is made possible by a few libraries. While convenient at first, it leads to horribly unmaintainable code. That's why templates exist. Templates are, in the simplest case, just HTML files with placeholders. The HTML is sent to the user's browser after filling in the placeholders.

Python already includes two ways to build simple templates:

```python
>>> template = "<html><body><h1>Hello %s!</h1></body></html>"
>>> print template % "Reader"
<html><body><h1>Hello Reader!</h1></body></html>
```

```python
>>> from string import Template
>>> template = Template("<html><body><h1>Hello ${name}</h1></body></html>")
>>> print template.substitute(dict(name='Dinsdale'))
<html><body><h1>Hello Dinsdale!</h1></body></html>
```

To generate complex HTML based on non-trivial model data,
conditional and looping constructs like Python’s `for` and `if` are generally needed. Template engines support templates of this complexity.

There are a lot of template engines available for Python which can be used with or without a framework. Some of these define a plaintext programming language which is easy to learn, partly because it is limited in scope. Others use XML, and the template output is guaranteed to be always be valid XML. There are many other variations.

Some frameworks ship their own template engine or recommend one in particular. In the absence of a reason to use a different template engine, using the one provided by or recommended by the framework is a good idea.

Popular template engines include:

- Mako
- Genshi
- Jinja

See also: There are many template engines competing for attention, because it is pretty easy to create them in Python. The page Templating in the wiki lists a big, ever-growing number of these. The three listed above are considered “second generation” template engines and are a good place to start.

Data persistence

Data persistence, while sounding very complicated, is just about storing data. This data might be the text of blog entries, the postings on a bulletin board or the text of a wiki page. There are, of course, a number of different ways to store information on a web server.
Often, relational database engines like MySQL or PostgreSQL are used because of their good performance when handling very large databases consisting of millions of entries. There is also a small database engine called SQLite, which is bundled with Python in the sqlite3 module, and which uses only one file. It has no other dependencies. For smaller sites SQLite is just enough.

Relational databases are queried using a language called SQL. Python programmers in general do not like SQL too much, as they prefer to work with objects. It is possible to save Python objects into a database using a technology called ORM (Object Relational Mapping). ORM translates all object-oriented access into SQL code under the hood, so the developer does not need to think about it. Most frameworks use ORMs, and it works quite well.

A second possibility is storing data in normal, plain text files (sometimes called “flat files”). This is very easy for simple sites, but can be difficult to get right if the web site is performing many updates to the stored data.

A third possibility are object oriented databases (also called “object databases”). These databases store the object data in a form that closely parallels the way the objects are structured in memory during program execution. (By contrast, ORMs store the object data as rows of data in tables and relations between those rows.) Storing the objects directly has the advantage that nearly all objects can be saved in a straightforward way, unlike in relational databases where some objects are very hard to represent.

Frameworks often give hints on which data storage method to choose. It is usually a good idea to stick to the data store recommended by the framework unless the application has special requirements better satisfied by an alternate storage mechanism.

ZODB and Durus, two object oriented databases
Frameworks

The process of creating code to run web sites involves writing code to provide various services. The code to provide a particular service often works the same way regardless of the complexity or purpose of the web site in question. Abstracting these common solutions into reusable code produces what are called “frameworks” for web development. Perhaps the most well-known framework for web development is Ruby on Rails, but Python has its own frameworks. Some of these were partly inspired by Rails, or borrowed ideas from Rails, but many existed a long time before Rails.

Originally Python web frameworks tended to incorporate all of the services needed to develop web sites as a giant, integrated set of tools. No two web frameworks were interoperable: a program developed for one could not be deployed on a different one without considerable re-engineering work. This led to the development of “minimalist” web frameworks that provided just the tools to communicate between the Python code and the http protocol, with all other services to be added on top via separate components. Some ad hoc standards were developed that allowed for limited interoperability between frameworks, such as a standard that allowed different template engines to be used interchangeably.

Since the advent of WSGI, the Python web framework world has been evolving toward interoperability based on the WSGI standard. Now many web frameworks, whether “full stack” (providing all the tools one needs to deploy the most complex web sites) or minimalist, or anything in between, are built from collections of reusable components that can be used with more than one framework.

The majority of users will probably want to select a “full stack” framework that has an active community. These frameworks tend to be well documented, and provide the easiest path to producing a
fully functional web site in minimal time.

**Some notable frameworks**

There are an incredible number of frameworks, so they cannot all be covered here. Instead we will briefly touch on some of the most popular.

**Django**

*Django* is a framework consisting of several tightly coupled elements which were written from scratch and work together very well. It includes an ORM which is quite powerful while being simple to use, and has a great online administration interface which makes it possible to edit the data in the database with a browser. The template engine is text-based and is designed to be usable for page designers who cannot write Python. It supports template inheritance and filters (which work like Unix pipes). Django has many handy features bundled, such as creation of RSS feeds or generic views, which make it possible to create web sites almost without writing any Python code.

It has a big, international community, the members of which have created many web sites. There are also a lot of add-on projects which extend Django's normal functionality. This is partly due to Django's well written online documentation and the *Django book*.

**Note:** Although Django is an MVC-style framework, it names the elements differently, which is described in the *Django FAQ*.

**TurboGears**

Another popular web framework for Python is *TurboGears*. TurboGears takes the approach of using already existing
components and combining them with glue code to create a seamless experience. TurboGears gives the user flexibility in choosing components. For example the ORM and template engine can be changed to use packages different from those used by default.

The documentation can be found in the TurboGears wiki, where links to screencasts can be found. TurboGears has also an active user community which can respond to most related questions. There is also a TurboGears book published, which is a good starting point.

The newest version of TurboGears, version 2.0, moves even further in direction of WSGI support and a component-based architecture. TurboGears 2 is based on the WSGI stack of another popular component-based web framework, Pylons.

### Zope

The Zope framework is one of the “old original” frameworks. Its current incarnation in Zope2 is a tightly integrated full-stack framework. One of its most interesting feature is its tight integration with a powerful object database called the ZODB (Zope Object Database). Because of its highly integrated nature, Zope wound up in a somewhat isolated ecosystem: code written for Zope wasn’t very usable outside of Zope, and vice-versa. To solve this problem the Zope 3 effort was started. Zope 3 re-engineers Zope as a set of more cleanly isolated components. This effort was started before the advent of the WSGI standard, but there is WSGI support for Zope 3 from the Repoze project. Zope components have many years of production use behind them, and the Zope 3 project gives access to these components to the wider Python community. There is even a separate framework based on the Zope components: Grok.

Zope is also the infrastructure used by the Plone content management system, one of the most powerful and popular content
management systems available.

Other notable frameworks

Of course these are not the only frameworks that are available. There are many other frameworks worth mentioning.

Another framework that’s already been mentioned is Pylons. Pylons is much like TurboGears, but with an even stronger emphasis on flexibility, which comes at the cost of being more difficult to use. Nearly every component can be exchanged, which makes it necessary to use the documentation of every single component, of which there are many. Pylons builds upon Paste, an extensive set of tools which are handy for WSGI.

And that’s still not everything. The most up-to-date information can always be found in the Python wiki.

See also: The Python wiki contains an extensive list of web frameworks.

Most frameworks also have their own mailing lists and IRC channels, look out for these on the projects’ web sites. There is also a general “Python in the Web” IRC channel on freenode called #python.web.
1. Extending IronPython with C#
1.1. A Simple Example
2. Parsing and Tokenizing

Parser **CreateParser**(CompilerContext *context*, PythonOptions *options*)

- Creates a new parser using the given compiler context and options.

PythonAst **ParseFile**(bool *makeModule*)

PythonAst **ParseFile**(bool *makeModule*, bool *returnValue*)

PythonAst **ParseInteractiveCode**(out ScriptCodeParseResult *properties*)

- Parse one or more lines of interactive input

- Returns null if input is not yet valid but could be with more lines

PythonAst **ParseSingleStatement**()

PythonAst **ParseTopExpression**()

static int **GetNextAutoIndentSize**(string *text*, int *autoIndentTabWidth*)

- Given the interactive text input for a compound statement, calculate what the indentation level of the next line should be

**ErrorSink** *ErrorSink* { get; set; }

**ParserSink** *ParserSink* { get; set; }

**public int** *ErrorCode* { get; }

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants, on the Mac, and on PCs under MS-DOS, Windows, Windows NT, and OS/2.

To find out more, start with *The Python Tutorial*. The *Beginner's Guide to Python* links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF’s mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF’s home page is at [http://www.python.org/psf/](http://www.python.org/psf/).

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via the [PSF donation page](http://www.python.org/psf/donate/).

Are there copyright restrictions on the use of Python?
You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it’s OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See the PSF license page to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult the Trademark Usage Policy for more information.

Why was Python created in the first place?

Here’s a very brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of Modula-3 and read the Modula-3 report. Modula-3 is the origin of the syntax and semantics used for exceptions, and some other Python features.
I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn’t easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the Misc/HISTORY file.

What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating differences between files), Internet protocols (HTTP, FTP, SMTP, XML-RPC, POP, IMAP, CGI programming), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for The Python Standard Library to get an
idea of what's available. A wide variety of third-party extensions are also available. Consult the Python Package Index to find packages of interest to you.

How does the Python version numbering scheme work?

Python versions are numbered A.B.C or A.B. A is the major version number – it is only incremented for really major changes in the language. B is the minor version number, incremented for less earth-shattering changes. C is the micro-level – it is incremented for each bugfix release. See PEP 6 for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren't yet finalized; it's not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix. The suffix for an alpha version is “aN” for some small number N, the suffix for a beta version is “bN” for some small number N, and the suffix for a release candidate version is “cN” for some small number N. In other words, all versions labeled 2.0aN precede the versions labeled 2.0bN, which precede versions labeled 2.0cN, and those precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the Subversion trunk. In practice, after a final minor release is made, the Subversion
trunk is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

How do I obtain a copy of the Python source?

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the Developer FAQ for more information on getting the source code and compiling it.

How do I get documentation on Python?

The standard documentation for the current stable version of Python is available at http://docs.python.org/. PDF, plain text, and downloadable HTML versions are also available at http://docs.python.org/download.html.

The documentation is written in reStructuredText and processed by the Sphinx documentation tool. The reStructuredText source for the documentation is part of the Python source distribution.

I’ve never programmed before. Is there a Python
tutorial?

There are numerous tutorials and books available. The standard documentation includes *The Python Tutorial*.

Consult the *Beginner's Guide* to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, *python-list*. The newsgroup and mailing list are gatewayed into each other – if you can read news it's unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in *comp.lang.python.announce*, a low-traffic moderated list that receives about five postings per day. It's available as the *python-announce* mailing list.

More info about other mailing lists and newsgroups can be found at [http://www.python.org/community/lists/](http://www.python.org/community/lists/).

How do I get a beta test version of Python?

You can also access the development version of Python through Subversion. See http://www.python.org/dev/faq/ for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, please use the Roundup installation at http://bugs.python.org/.

You must have a Roundup account to report bugs; this makes it possible for us to contact you if we have follow-up questions. It will also enable Roundup to send you updates as we act on your bug. If you had previously used SourceForge to report bugs to Python, you can obtain your Roundup password through Roundup’s password reset procedure.

For more information on how Python is developed, consult the Python Developer’s Guide.

Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.

The very first article about Python was written in 1991 and is now quite outdated.

Are there any books on Python?

Yes, there are many, and more are being published. See the
You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

**Where in the world is www.python.org located?**

It’s currently in Amsterdam, graciously hosted by XS4ALL. Thanks to Thomas Wouters for his work in arranging python.org’s hosting.

**Why is it called Python?**

When he began implementing Python, Guido van Rossum was also reading the published scripts from “Monty Python’s Flying Circus”, a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

**Do I have to like “Monty Python’s Flying Circus”?**

No, but it helps. :)

**Python in the real world**

**How stable is Python?**

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. Currently there are usually around 18 months between major releases.

The developers issue “bugfix” releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 2.5.3, 2.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it’s guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the Python download page. There are two recommended production-ready versions at this point in time, because at the moment there are two branches of stable releases: 2.x and 3.x. Python 3.x may be less useful than 2.x, since currently there is more third party software available for Python 2 than for Python 3. Python 2 code will generally not run unchanged in Python 3.

**How many people are using Python?**

There are probably tens of thousands of users, though it's difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it's available from many different sites and packaged with many Linux distributions, so download statistics don’t tell the whole story either.
The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

Have any significant projects been done in Python?

See http://python.org/about/success for a list of projects that use Python. Consulting the proceedings for past Python conferences will reveal contributions from many different companies and organizations.

High-profile Python projects include the Mailman mailing list manager and the Zope application server. Several Linux distributions, most notably Red Hat, have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

What new developments are expected for Python in the future?

See http://www.python.org/dev/peps/ for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled “Python X.Y Release Schedule”, where X.Y is a version that hasn’t been publicly released yet.

New development is discussed on the python-dev mailing list.

Is it reasonable to propose incompatible changes to Python?

In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be
frowned upon. Even if you can provide a conversion program, there’s still the problem of updating all documentation; many books have been written about Python, and we don’t want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. PEP 5 describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

Is Python Y2K (Year 2000) Compliant?

As of August, 2003 no major problems have been reported and Y2K compliance seems to be a non-issue.

Python does very few date calculations and for those it does perform relies on the C library functions. Python generally represents times either as seconds since 1970 or as a \((\text{year}, \text{month}, \text{day}, \ldots)\) tuple where the year is expressed with four digits, which makes Y2K bugs unlikely. So as long as your C library is okay, Python should be okay. Of course, it’s possible that a particular application written in Python makes assumptions about 2-digit years.

Because Python is available free of charge, there are no absolute guarantees. If there are unforeseen problems, liability is the user’s problem rather than the developers’, and there is nobody you can sue for damages. The Python copyright notice contains the following disclaimer:

4. PSF is making Python 2.3 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR
PURPOSE OR THAT THE USE OF PYTHON 2.3 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 2.3 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.3, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

The good news is that if you encounter a problem, you have full source available to track it down and fix it. This is one advantage of an open source programming environment.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While
learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students’ first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be assigned programming projects very early in the course that do something. Assignments aren’t restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students’ reach.

Python’s interactive interpreter enables students to test language features while they’re programming. They can keep a window with the interpreter running while they enter their program’s source in another window. If they can’t remember the methods for a list, they can do something like this:

```
>>> L = []
>>> dir(L)
['append', 'count', 'extend', 'index', 'insert', 'pop', 'remove'
'reverse', 'sort']
>>> help(L.append)
Help on built-in function append:

    append(...)  
       L.append(object) -- append object to end

>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as he’s programming.
There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. PythonWin is a Windows-specific IDE. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult http://www.python.org/editors/ for a full list of Python editing environments.

If you want to discuss Python's use in education, you may be interested in joining the edu-sig mailing list.
Starting with Python2.3, the distribution includes the *PyBSDDB package* <http://pybsddb.sf.net/> as a replacement for the old bsddb module. It includes functions which provide backward compatibility at the API level, but requires a newer version of the underlying Berkeley DB library. Files created with the older bsddb module can’t be opened directly using the new module.

Using your old version of Python and a pair of scripts which are part of Python 2.3 (db2pickle.py and pickle2db.py, in the Tools/scripts directory) you can convert your old database files to the new format. Using your old Python version, run the db2pickle.py script to convert it to a pickle, e.g.:

```
python2.2 <pathto>/db2pickley.py database.db database.pck
```

Rename your database file:

```
mv database.db olddatabase.db
```

Now convert the pickle file to a new format database:

```
python <pathto>/pickle2db.py database.db database.pck
```

The precise commands you use will vary depending on the particulars of your installation. For full details about operation of these two scripts check the doc string at the start of each one.

    - When I edit an imported module and reimport it, the changes don’t show up. Why does this happen?
General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

The pdb module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is documented in the Library Reference Manual. You can also write your own debugger by using the code for pdb as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as Tools/scripts/idle), includes a graphical debugger. There is documentation for the IDLE debugger at http://www.python.org/idle/doc/idle2.html#Debugger.

PythonWin is a Python IDE that includes a GUI debugger based on pdb. The Pythonwin debugger colors breakpoints and has quite a few cool features such as debugging non-Pythonwin programs. Pythonwin is available as part of the Python for Windows Extensions project and as a part of the ActivePython distribution (see http://www.activestate.com/Products/ActivePython/index.html).

Boa Constructor is an IDE and GUI builder that uses wxWidgets. It offers visual frame creation and manipulation, an object inspector, many views on the source like object browsers, inheritance hierarchies, doc string generated html documentation, an advanced debugger, integrated help, and Zope support.

Eric is an IDE built on PyQt and the Scintilla editing component.
Pydb is a version of the standard Python debugger pdb, modified for use with DDD (Data Display Debugger), a popular graphical debugger front end. Pydb can be found at http://bashdb.sourceforge.net/pydb/ and DDD can be found at http://www.gnu.org/software/ddd.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE (http://wingware.com/)
- Komodo IDE (http://www.activestate.com/Products/Komodo)

**Is there a tool to help find bugs or perform static analysis?**

Yes.

PyChecker is a static analysis tool that finds bugs in Python source code and warns about code complexity and style. You can get PyChecker from http://pychecker.sf.net.

Pylint is another tool that checks if a module satisfies a coding standard, and also makes it possible to write plug-ins to add a custom feature. In addition to the bug checking that PyChecker performs, Pylint offers some additional features such as checking line length, whether variable names are well-formed according to your coding standard, whether declared interfaces are fully implemented, and more. http://www.logilab.org/card/pylint_manual provides a full list of Pylint’s features.

**How can I create a stand-alone binary from a Python script?**

You don’t need the ability to compile Python to C code if all you want
is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as `Tools/freeze`. It converts Python byte code to C arrays; a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

Obviously, freeze requires a C compiler. There are several other utilities which don’t. One is Thomas Heller's py2exe (Windows only) at

http://www.py2exe.org/

Another is Christian Tismer’s SQFREEZE which appends the byte code to a specially-prepared Python interpreter that can find the byte code in the executable.

Other tools include Fredrik Lundh’s Squeeze and Anthony Tuininga’s cx_Freeze.
Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as **PEP 8**.

My program is too slow. How do I speed it up?

That’s a tough one, in general. There are many tricks to speed up Python code; consider rewriting parts in C as a last resort.

In some cases it’s possible to automatically translate Python to C or x86 assembly language, meaning that you don’t have to modify your code to gain increased speed.

**Pyrex** can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms.

**Psyco** is a just-in-time compiler that translates Python code into x86 assembly language. If you can use it, Psyco can provide dramatic speedups for critical functions.

The rest of this answer will discuss various tricks for squeezing a bit more speed out of Python code. _Never_ apply any optimization tricks unless you know you need them, after profiling has indicated that a particular function is the heavily executed hot spot in the code. Optimizations almost always make the code less clear, and you shouldn’t pay the costs of reduced clarity (increased development time, greater likelihood of bugs) unless the resulting performance benefit is worth it.

There is a page on the wiki devoted to performance tips.

Guido van Rossum has written up an anecdote related to optimization at [http://www.python.org/doc/essays/list2str.html](http://www.python.org/doc/essays/list2str.html).
One thing to notice is that function and (especially) method calls are rather expensive; if you have designed a purely OO interface with lots of tiny functions that don’t do much more than get or set an instance variable or call another method, you might consider using a more direct way such as directly accessing instance variables. Also see the standard module `profile` which makes it possible to find out where your program is spending most of its time (if you have some patience – the profiling itself can slow your program down by an order of magnitude).

Remember that many standard optimization heuristics you may know from other programming experience may well apply to Python. For example it may be faster to send output to output devices using larger writes rather than smaller ones in order to reduce the overhead of kernel system calls. Thus CGI scripts that write all output in “one shot” may be faster than those that write lots of small pieces of output.

Also, be sure to use Python’s core features where appropriate. For example, slicing allows programs to chop up lists and other sequence objects in a single tick of the interpreter’s mainloop using highly optimized C implementations. Thus to get the same effect as:

```python
L2 = []
for i in range[3]:
    L2.append(L1[i])
```

it is much shorter and far faster to use

```python
L2 = list(L1[:3]) # "list" is redundant if L1 is a list.
```

Note that the functionally-oriented built-in functions such as `map()`, `zip()`, and friends can be a convenient accelerator for loops that perform a single task. For example to pair the elements of two lists together:
or to compute a number of sines:

```python
>>> map(math.sin, (1, 2, 3, 4))
[0.841470984808, 0.909297426826, 0.14112000806, -0.756802495308]
```

The operation completes very quickly in such cases.

Other examples include the `join()` and `split()` methods of string objects. For example if s1..s7 are large (10K+) strings then `"".join([s1,s2,s3,s4,s5,s6,s7])` may be far faster than the more obvious `s1+s2+s3+s4+s5+s6+s7`, since the “summation” will compute many subexpressions, whereas `join()` does all the copying in one pass. For manipulating strings, use the `replace()` and the `format()` methods on string objects. Use regular expressions only when you’re not dealing with constant string patterns. You may still use the old `% operations` string % tuple and string % dictionary.

Be sure to use the `list.sort()` built-in method to do sorting, and see the sorting mini-HOWTO for examples of moderately advanced usage. `list.sort()` beats other techniques for sorting in all but the most extreme circumstances.

Another common trick is to “push loops into functions or methods.” For example suppose you have a program that runs slowly and you use the profiler to determine that a Python function `ff()` is being called lots of times. If you notice that `ff()`:

```python
def ff(x):
    ... # do something with x computing result...
    return result
```

tends to be called in loops like:

```python
for x in ...
    ff(x)
```
list = map(ff, oldlist)

or:

for x in sequence:
    value = ff(x)
    ... # do something with value...

then you can often eliminate function call overhead by rewriting `ff()` to:

```python
def ffseq(seq):
    resultseq = []
    for x in seq:
        ... # do something with x computing result...
        resultseq.append(result)
    return resultseq
```

and rewrite the two examples to `list = ffseq(oldlist)` and to:

```python
for value in ffseq(sequence):
    ... # do something with value...
```

Single calls to `ff(x)` translate to `ffseq([x])[0]` with little penalty. Of course this technique is not always appropriate and there are other variants which you can figure out.

You can gain some performance by explicitly storing the results of a function or method lookup into a local variable. A loop like:

```python
for key in token:
    dict[key] = dict.get(key, 0) + 1
```

resolves `dict.get` every iteration. If the method isn't going to change, a slightly faster implementation is:

```python
dict_get = dict.get  # look up the method once
for key in token:
```
Default arguments can be used to determine values once, at compile time instead of at run time. This can only be done for functions or objects which will not be changed during program execution, such as replacing

```python
def degree_sin(deg):
    return math.sin(deg * math.pi / 180.0)
```

with

```python
def degree_sin(deg, factor=math.pi/180.0, sin=math.sin):
    return sin(deg * factor)
```

Because this trick uses default arguments for terms which should not be changed, it should only be used when you are not concerned with presenting a possibly confusing API to your users.
Core Language

Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the UnboundLocalError in previously working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```python
>>> x = 10
>>> def bar():
...    print x
>>> bar()
10
```

works, but this code:

```python
>>> x = 10
>>> def foo():
...    print x
...    x += 1
```

results in an UnboundLocalError:

```
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before assignment
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any similarly named variable in the outer scope. Since the last statement in foo assigns a new value to \( x \), the compiler recognizes it as a local
variable. Consequently when the earlier `print x` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it `global`:

```python
>>> x = 10
>>> def foobar():
...    global x
...    print x
...    x += 1
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```python
>>> print x
11
```

**What are the rules for local and global variables in Python?**

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a new value anywhere within the function's body, it's assumed to be a local. If a variable is ever assigned a new value inside the function, the variable is implicitly local, and you need to explicitly declare it as `global`.

Though a bit surprising at first, a moment's consideration explains this. On one hand, requiring `global` for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you'd be using `global` all the time. You'd have to declare as global every reference to a built-in
function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

**How do I share global variables across modules?**

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

**config.py:**

```python
x = 0  # Default value of the 'x' configuration setting
```

**mod.py:**

```python
import config
config.x = 1
```

**main.py:**

```python
import config
import mod
print config.x
```

Note that using a module is also the basis for implementing the Singleton design pattern, for the same reason.

**What are the “best practices” for using import in a module?**

In general, don't use `from modulename import *`. Doing so clutters
the importer’s namespace. Some people avoid this idiom even with the few modules that were designed to be imported in this manner. Modules designed in this manner include Tkinter, and threading.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It’s good practice if you import modules in the following order:

1. standard library modules – e.g. sys, os, getopt, re
2. third-party library modules (anything installed in Python’s site-packages directory) – e.g. mx.DateTime, ZODB, PIL.Image, etc.
3. locally-developed modules

Never use relative package imports. If you’re writing code that’s in the package.sub.m1 module and want to import package.sub.m2, do not just write import m2, even though it’s legal. Write from package.sub import m2 instead. Relative imports can lead to a module being initialized twice, leading to confusing bugs. See PEP 328 for details.

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “import <module>” form of import. They fail when the 2nd module wants to grab a name out of the first (“from module import name”) and the import is at the top level. That’s because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the
import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

If only instances of a specific class use a module, then it is reasonable to import the module in the class's `__init__` method and then assign the module to an instance variable so that the module is always available (via that instance variable) during the life of the object. Note that to delay an import until the class is instantiated, the import must be inside a method. Putting the import inside the class but outside of any method still causes the import to occur when the module is initialized.

---

**How can I pass optional or keyword parameters from one function to another?**

Collect the arguments using the `*` and `**` specifiers in the function's
parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using * and **:

```python
def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
    g(x, *args, **kwargs)
```

In the unlikely case that you care about Python versions older than 2.0, use `apply()`:

```python
def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
    apply(g, (x,)+args, kwargs)
```

How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:

```python
def func2(a, b):
    a = 'new-value'  # a and b are local names
    b = b + 1        # assigned to new objects
    return a, b     # return new values
x, y = 'old-value', 99
x, y = func2(x, y)
print x, y         # output: new-value 100
```
This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```python
def func1(a):
    a[0] = 'new-value'  # 'a' references a mutable list
    a[1] = a[1] + 1     # changes a shared object

args = ['old-value', 99]
func1(args)
print args[0], args[1]  # output: new-value 100
```

4. By passing in a dictionary that gets mutated:

```python
def func3(args):
    args['a'] = 'new-value'  # args is a mutable diction
    args['b'] = args['b'] + 1  # change it in-place

args = {'a': 'old-value', 'b': 99}
func3(args)
print args['a'], args['b']
```

5. Or bundle up values in a class instance:

```python
class callByRef:
    def __init__(self, **args):
        for (key, value) in args.items():
            setattr(self, key, value)

def func4(args):
    args.a = 'new-value'  # args is a mutable callByR
    args.b = args.b + 1   # change object in-place

args = callByRef(a='old-value', b=99)
func4(args)
print args.a, args.b
```

There's almost never a good reason to get this complicated.
Your best choice is to return a tuple containing the multiple results.

How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a,b)` which returns a function $f(x)$ that computes the value $a*x+b$. Using nested scopes:

```python
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:

```python
class linear:
    def __init__(self, a, b):
        self.a, self.b = a, b
    def __call__(self, x):
        return self.a * x + self.b
```

In both cases,

```python
taxes = linear(0.3, 2)
```

gives a callable object where $\text{taxes}(10e6) == 0.3 \times 10e6 + 2$.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

```python
class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
```
Object can encapsulate state for several methods:

```python
class counter:
    value = 0

    def set(self, x):
        self.value = x

    def up(self):
        self.value = self.value + 1

    def down(self):
        self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

**How do I copy an object in Python?**

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:

```python
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```python
new_1 = l[:]
```

**How can I find the methods or attributes of an**
object?

For an instance \( x \) of a user-defined class, \( \text{dir}(x) \) returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

How can my code discover the name of an object?

Generally speaking, it can’t, because objects don’t really have names. Essentially, assignment always binds a name to a value; The same is true of \texttt{def} and \texttt{class} statements, but in that case the value is a callable. Consider the following code:

```python
class A:
    pass

B = A

a = B()
b = a
print b
<__main__.A instance at 0x16D07CC>
print a
<__main__.A instance at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name \( B \) the created instance is still reported as an instance of class \( A \). However, it is impossible to say whether the instance’s name is \( a \) or \( b \), since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy
in answer to this question:

The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn’t really care – so the only way to find out what it’s called is to ask all your neighbours (namespaces) if it’s their cat (object)...

....and don’t be surprised if you'll find that it's known by many names, or no name at all!

What’s up with the comma operator’s precedence?

Comma is not an operator in Python. Consider this session:

```python
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```python
>>> ("a" in "b"), "a"
```

not:

```python
>>> "a" in ("b", "a")
```

The same is true of the various assignment operators (=, += etc). They are not truly operators but syntactic delimiters in assignment statements.

Is there an equivalent of C’s “?:” ternary operator?

Yes, this feature was added in Python 2.5. The syntax would be as follows:
[on_true] if [expression] else [on_false]

x, y = 50, 25
small = x if x < y else y

For versions previous to 2.5 the answer would be ‘No’.

In many cases you can mimic \( a \ ? \ b : c \) with \( a \ and \ b \ or \ c \), but there’s a flaw: if \( b \) is zero (or empty, or \texttt{None} – anything that tests false) then \( c \) will be selected instead. In many cases you can prove by looking at the code that this can’t happen (e.g. because \( b \) is a constant or has a type that can never be false), but in general this can be a problem.

Tim Peters (who wishes it was Steve Majewski) suggested the following solution: \((a \ and \ [b] \ or \ [c])[0]\). Because \([b]\) is a singleton list it is never false, so the wrong path is never taken; then applying \([0]\) to the whole thing gets the \( b \ or \ c \) that you really wanted. Ugly, but it gets you there in the rare cases where it is really inconvenient to rewrite your code using ‘if’.

The best course is usually to write a simple \texttt{if...else} statement. Another solution is to implement the \texttt{?:} operator as a function:

```python
def q(cond, on_true, on_false):
    if cond:
        if not isfunction(on_true):
            return on_true
        else:
            return on_true()
    else:
        if not isfunction(on_false):
            return on_false
        else:
            return on_false()
```

In most cases you’ll pass \( b \) and \( c \) directly: \texttt{q(a, b, c)}. To avoid
evaluating b or c when they shouldn’t be, encapsulate them within a lambda function, e.g.: q(a, lambda: b, lambda: c).

It has been asked why Python has no if-then-else expression. There are several answers: many languages do just fine without one; it can easily lead to less readable code; no sufficiently “Pythonic” syntax has been discovered; a search of the standard library found remarkably few places where using an if-then-else expression would make the code more understandable.

In 2002, PEP 308 was written proposing several possible syntaxes and the community was asked to vote on the issue. The vote was inconclusive. Most people liked one of the syntaxes, but also hated other syntaxes; many votes implied that people preferred no ternary operator rather than having a syntax they hated.

Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting lambda within lambda. See the following three examples, due to Ulf Bartelt:

```python
# Primes < 1000
print filter(None, map(lambda y: y*reduce(lambda x, y: x*y != 0, map(lambda x, y: y%x, range(2, int(pow(y, 0.5)+1))), 1), range(2, 1000))

# First 10 Fibonacci numbers
print map(lambda x, f=lambda x, f: (f(x-1, f)+f(x-2, f)) if x>1 else f(0, f), range(10))

# Mandelbrot set
print (lambda Ru, Ro, Iu, Io, IM, Sx, Sy: reduce(lambda x, y: x+y, map(lambda xc, yc, x, y, k, f=lambda xc, yc, x, y, k, f: (k<=0) or (x*x+y*y >= 4.0) or 1+f(xc, yc, x*x-y*y+xc, 2.0*x*y+yc, k-1, f):f(xc, yc, x, y, k, 64+F(Ru+x*(Ro-Ru)/Sx, yc, 0, 0, i)), range(Sx))):L(Iu+y*(Io-Iu)/Sy), range(Sy))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24)
```

```bash
# ___ ___/   ___ ___/  |   |   __ lines on screen
```
<table>
<thead>
<tr>
<th>V</th>
<th>V</th>
<th>_____ columns on screen</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>maximum of &quot;iterations&quot;</td>
</tr>
<tr>
<td></td>
<td></td>
<td>range on y axis</td>
</tr>
<tr>
<td></td>
<td></td>
<td>range on x axis</td>
</tr>
</tbody>
</table>

Don't try this at home, kids!
How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```python
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```python
>>> a = 0xa5
>>> a
165
>>> b = 0xB2
>>> b
178
```

Why does -22 // 10 return -3?

It’s primarily driven by the desire that \( i \% j \) have the same sign as \( j \). If you want that, and also want:

\[
i == (i \div j) * j + (i \% j)
\]

then integer division has to return the floor. C also requires that identity to hold, and then compilers that truncate \( i \div j \) need to make \( i \% j \) have the same sign as \( i \).
There are few real use cases for $i \% j$ when $j$ is negative. When $j$ is positive, there are many, and in virtually all of them it’s more useful for $i \% j$ to be $\geq 0$. If the clock says 10 now, what did it say 200 hours ago? $-190 \% 12 == 2$ is useful; $-190 \% 12 == -10$ is a bug waiting to bite.

**Note:** On Python 2, $a / b$ returns the same as $a // b$ if `__future__.division` is not in effect. This is also known as “classic” division.

### How do I convert a string to a number?

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python’s rules: a leading ‘0’ indicates octal, and ‘0x’ indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because Python regards numbers starting with ‘0’ as octal (base 8).
How do I convert a number to a string?

To convert, e.g., the number 144 to the string ‘144’, use the built-in type constructor \texttt{str()}. If you want a hexadecimal or octal representation, use the built-in functions \texttt{hex()} or \texttt{oct()}. For fancy formatting, see the \textit{Format String Syntax} section, e.g. \texttt{"{:04d}".format(144)} yields ‘0144’ and \texttt{"{:3f}".format(1/3)} yields ‘0.333’. You may also use \textit{the \% operator} on strings. See the library reference manual for details.

How do I modify a string in place?

You can’t, because strings are immutable. If you need an object with this ability, try converting the string to a list or use the array module:

\begin{verbatim}
>>> s = "Hello, world"
>>> a = list(s)
>>> print a
['H', 'e', 'l', 'l', 'o', ',', ' ', 'w', 'o', 'r', 'l', 'd']
>>> a[7:] = list("there!")
>>> ".join(a)
'Hello, there!'

>>> import array
>>> a = array.array('c', s)
>>> print a
array('c', 'Hello, world')
>>> a[0] = 'y'; print a
array('c', 'yello world')
>>> a.tostring()
yello, world
\end{verbatim}

How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions.
The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```python
def a():
    pass

def b():
    pass

dispatch = {'go': a, 'stop': b}  # Note lack of parens for func
dispatch[get_input()]()  # Note trailing parens to call func
```

- Use the built-in function `getattr()`:

```python
import foo
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.

This is used in several places in the standard library, like this:

```python
class Foo:
    def do_foo(self):
        ...

    def do_bar(self):
        ...

f = getattr(foo_instance, 'do_' + opname)
f()
```

- Use `locals()` or `eval()` to resolve the function name:

```python
def myFunc():
    print "hello"

fname = "myFunc"
```
Note: Using `eval()` is slow and dangerous. If you don’t have absolute control over the contents of the string, someone could pass a string that resulted in an arbitrary function being executed.

Is there an equivalent to Perl’s `chomp()` for removing trailing newlines from strings?

Starting with Python 2.2, you can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other trailing whitespace. If the string `S` represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```python
>>> lines = ("line 1 \r\n"
... "\r\n"
... "\r\n")
>>> lines.rstrip("\n\r")
'line 1 '  
```

Since this is typically only desired when reading text one line at a time, using `S.rstrip()` this way works well.

For older versions of Python, there are two partial substitutes:

- If you want to remove all trailing whitespace, use the `rstrip()` method of string objects. This removes all trailing whitespace, not just a single newline.
- Otherwise, if there is only one line in the string `S`, use
Is there a scanf() or sscanf() equivalent?

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the \texttt{split()} method of string objects and then convert decimal strings to numeric values using \texttt{int()} or \texttt{float()}. \texttt{split()} supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C’s \texttt{sscanf()} and better suited for the task.

What does ‘UnicodeError: ASCII [decoding,encoding] error: ordinal not in range(128)’ mean?

This error indicates that your Python installation cannot handle 8-bit ASCII strings. There are a couple ways to fix or work around the problem.

If your programs must handle data in arbitrary character set encodings, the environment the application runs in will generally identify the encoding of the data it is handing you. You need to convert the input to Unicode data using that encoding. For example, a program that handles email or web input will typically find character set encoding information in Content-Type headers. This can then be used to properly convert input data to Unicode. Assuming the string referred to by \texttt{value} is encoded as UTF-8:

\begin{verbatim}
value = unicode(value, "utf-8")
\end{verbatim}
will return a Unicode object. If the data is not correctly encoded as UTF-8, the above call will raise a `UnicodeError` exception.

If you only want strings converted to Unicode which have non-ASCII data, you can try converting them first assuming an ASCII encoding, and then generate Unicode objects if that fails:

```python
try:
    x = unicode(value, "ascii")
except UnicodeError:
    value = unicode(value, "utf-8")
else:
    # value was valid ASCII data
    pass
```

It's possible to set a default encoding in a file called `sitecustomize.py` that's part of the Python library. However, this isn't recommended because changing the Python-wide default encoding may cause third-party extension modules to fail.

Note that on Windows, there is an encoding known as “mbcs”, which uses an encoding specific to your current locale. In many cases, and particularly when working with COM, this may be an appropriate default encoding to use.
Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields (`'a', 'b', 'c'`). If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `s[::1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.

How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function, which is new in Python 2.4:
for x in reversed(sequence):
    ... # do something with x...

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

With Python 2.3, you can use an extended slice syntax:

```python
for x in sequence[::-1]:
    ... # do something with x...
```

**How do you remove duplicates from a list?**

See the Python Cookbook for a long discussion of many ways to do this:

```
http://aspn.activestate.com/ASPN/Cookbook/Python/Recipe/52560
```

If you don't mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```python
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
            last = mylist[i]
```

If all elements of the list may be used as dictionary keys (i.e. they are all hashable) this is often faster

```python
d = {}
for x in mylist:
    d[x] = 1
mylist = list(d.keys())
```

In Python 2.5 and later, the following is possible instead:
mylist = list(set(mylist))

This converts the list into a set, thereby removing duplicates, and then back into a list.

How do you make an array in Python?

Use a list:

["this", 1, "is", "an", "array"]

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The array module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that the Numeric extensions and others define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate cons cells using tuples:

lisp_list = ("like", ("this", ("example", None)) )

If mutability is desired, you could use lists instead of tuples. Here the analogue of lisp car is lisp_list[0] and the analogue of cdr is lisp_list[1]. Only do this if you're sure you really need to, because it's usually a lot slower than using Python lists.

How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

A = [[None] * 2] * 3
This looks correct if you print it:

```python
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```python
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with * doesn't create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```python
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```python
w, h = 2, 3
A = [[None] * w for i in range(h)]
```

Or, you can use an extension that provides a matrix datatype; **Numeric Python** is the best known.

How do I apply a method to a sequence of objects?

Use a list comprehension:
result = [obj.method() for obj in mylist]

More generically, you can try the following function:

def method_map(objects, method, arguments):
    """method_map([a,b], "meth", (1,2)) gives [a.meth(1,2), b.meth(1,2)]""
    nobjects = len(objects)
    methods = map(getattr, objects, [method]*nobjects)
    return map(apply, methods, [arguments]*nobjects)
Dictionaries

How can I get a dictionary to display its keys in a consistent order?

You can’t. Dictionaries store their keys in an unpredictable order, so the display order of a dictionary’s elements will be similarly unpredictable.

This can be frustrating if you want to save a printable version to a file, make some changes and then compare it with some other printed dictionary. In this case, use the `pprint` module to pretty-print the dictionary; the items will be presented in order sorted by the key.

A more complicated solution is to subclass `dict` to create a `SortedDict` class that prints itself in a predictable order. Here’s one simpleminded implementation of such a class:

```python
class SortedDict(dict):
    def __repr__(self):
        keys = sorted(self.keys())
        result = ('{{!r}: {!r}'' for k in keys
        return '{{{}}}'.format('', ', '.join(result))

    __str__ = __repr__
```

This will work for many common situations you might encounter, though it’s far from a perfect solution. The largest flaw is that if some values in the dictionary are also dictionaries, their values won’t be presented in any particular order.

I want to do a complicated sort: can you do a Schwartzian Transform in Python?
The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, just use the `key` argument for the `sort()` method:

```python
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

The `key` argument is new in Python 2.4, for older versions this kind of sorting is quite simple to do with list comprehensions. To sort a list of strings by their uppercase values:

```python
tmp1 = [(x.upper(), x) for x in L]  # Schwartzian transform
tmp1.sort()
Usorted = [x[1] for x in tmp1]
```

To sort by the integer value of a subfield extending from positions 10-15 in each string:

```python
tmp2 = [(int(s[10:15]), s) for s in L]  # Schwartzian transform
tmp2.sort()
Isorted = [x[1] for x in tmp2]
```

Note that `Isorted` may also be computed by

```python
def intfield(s):
    return int(s[10:15])

def Icmp(s1, s2):
    return cmp(intfield(s1), intfield(s2))

Isorted = L[:]
Isorted.sort(Icmp)
```

but since this method calls `intfield()` many times for each element of `L`, it is slower than the Schwartzian Transform.
How can I sort one list by values from another list?

Merge them into a single list of tuples, sort the resulting list, and then pick out the element you want.

```python
>>> list1 = ['what', 'I'm', 'sorting', 'by']
>>> list2 = ['something', 'else', 'to', 'sort']
>>> pairs = zip(list1, list2)
>>> pairs
[('what', 'something'), ('I'm', 'else'), ('sorting', 'to'), ('by', 'sort')]
```
```python
>>> pairs.sort()
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```

An alternative for the last step is:

```python
>>> result = []
>>> for p in pairs: result.append(p[1])
```

If you find this more legible, you might prefer to use this instead of the final list comprehension. However, it is almost twice as slow for long lists. Why? First, the `append()` operation has to reallocate memory, and while it uses some tricks to avoid doing that each time, it still has to do it occasionally, and that costs quite a bit. Second, the expression “result.append” requires an extra attribute lookup, and third, there’s a speed reduction from having to make all those function calls.
**Objects**

**What is a class?**

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic Mailbox class that provides basic accessor methods for a mailbox, and subclasses such as MboxMailbox, MaildirMailbox, OutlookMailbox that handle various specific mailbox formats.

**What is a method?**

A method is a function on some object \(x\) that you normally call as \(x\).name(arguments...). Methods are defined as functions inside the class definition:

```python
class C:
    def meth (self, arg):
        return arg * 2 + self.attribute
```

**What is self?**

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as `x.meth(a, b, c)` for some instance `x` of the class in which the
definition occurs; the called method will think it is called as `meth(x, a, b, c)`.

See also *Why must ‘self’ be used explicitly in method definitions and calls?*

**How do I check if an object is an instance of a given class or of a subclass of it?**

Use the built-in function `isinstance(obj, cls)`. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python’s built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, long, float, complex))`.

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object’s class and doing a different thing based on what class it is. For example, if you have a function that does something:

```python
def search(obj):
    if isinstance(obj, Mailbox):
        # ... code to search a mailbox
    elif isinstance(obj, Document):
        # ... code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes and just call it:

```python
class Mailbox:
    def search(self):
        # ... code to search a mailbox
```
What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let’s say you have an object \( x \) and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you're interested in changing and delegates all other methods to the corresponding method of \( x \).

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```python
class UpperOut:
    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
        return getattr(self._outfile, name)
```

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self._outfile.write()` method. All other methods are delegated to the underlying `self._outfile` object. The delegation is accomplished via the `__getattr__` method; consult the language reference for more information about controlling attribute access.
Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```python
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for `self` without causing an infinite recursion.

**How do I call a method defined in a base class from a derived class that overrides it?**

If you’re using new-style classes, use the built-in `super()` function:

```python
class Derived(Base):
    def meth(self):
        super(Derived, self).meth()
```

If you’re using classic classes: For a class definition such as `class Derived(Base): ...` you can call method `meth()` defined in `Base` (or one of `Base`’s base classes) as `Base.meth(self, arguments...)`. Here, `Base.meth` is an unbound method, so you need to provide the `self` argument.

**How can I organize my code to make it easier to change the base class?**

You could define an alias for the base class, assign the real base class to it before your class definition, and use the alias throughout.
your class. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```python
BaseAlias = <real base class>

class Derived(BaseAlias):
    def meth(self):
        BaseAlias.meth(self)
    ...
```

### How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value to the attribute, you have to explicitly use the class name in the assignment:

```python
class C:
    count = 0  # number of times C.__init__ called

    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count  # or return self.count
```

c.count also refers to C.count for any c such that isinstance(c, C) holds, unless overridden by c itself or by some class on the base-class search path from c.__class__ back to C.

Caution: within a method of C, an assignment like self.count = 42 creates a new and unrelated instance named “count” in self's own
dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

C.count = 314

Static methods are possible since Python 2.2:

class C:
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
    static = staticmethod(static)

With Python 2.4's decorators, this can also be written as

class C:
    @staticmethod
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:

def getcount():
    return C.count

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you’d write
In Python you have to write a single constructor that catches all cases using default arguments. For example:

class C:
    def __init__(self, i=None):
        if i is None:
            print "No arguments"
        else:
            print "Argument is", i

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.

def __init__(self, *args):
    ...

The same approach works for all method definitions.

I try to use __spam and I get an error about _SomeClassName__spam.

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with __classname__spam, where classname is the current class name with any leading underscores stripped.

This doesn’t guarantee privacy: an outside user can still deliberately access the “_classname__spam” attribute, and private values are visible in the object’s __dict__. Many Python programmers never
bother to use private variable names at all.

My class defines \_\_del\_\_ but it is not called when I delete the object.

There are several possible reasons for this.

The del statement does not necessarily call \_\_del\_\_() – it simply decrements the object's reference count, and if this reaches zero \_\_del\_\_() is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your \_\_del\_\_() method may be called at an inconvenient and random time. This is inconvenient if you're trying to reproduce a problem. Worse, the order in which object's \_\_del\_\_() methods are executed is arbitrary. You can run \texttt{gc.collect()} to force a collection, but there are pathological cases where objects will never be collected.

Despite the cycle collector, it's still a good idea to define an explicit \texttt{close()} method on objects to be called whenever you're done with them. The \texttt{close()} method can then remove attributes that refer to subobjects. Don't call \_\_del\_\_() directly – \_\_del\_\_() should call \texttt{close()} and \texttt{close()} should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the \texttt{weakref} module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need
them!).

If the object has ever been a local variable in a function that caught an expression in an except clause, chances are that a reference to the object still exists in that function's stack frame as contained in the stack trace. Normally, calling \texttt{sys\_exc\_clear()} will take care of this by clearing the last recorded exception.

Finally, if your \texttt{\_del\_()} method raises an exception, a warning message is printed to \texttt{sys\_stderr}.

**How do I get a list of all instances of a given class?**

Python does not keep track of all instances of a class (or of a built-in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.
How do I create a .pyc file?

When a module is imported for the first time (or when the source is more recent than the current compiled file) a .pyc file containing the compiled code should be created in the same directory as the .py file.

One reason that a .pyc file may not be created is permissions problems with the directory. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server. Creation of a .pyc file is automatic if you’re importing a module and Python has the ability (permissions, free space, etc...) to write the compiled module back to the directory.

Running Python on a top level script is not considered an import and no .pyc will be created. For example, if you have a top-level module abc.py that imports another module xyz.py, when you run abc, xyz.pyc will be created since xyz is imported, but no abc.pyc file will be created since abc.py isn’t being imported.

If you need to create abc.pyc – that is, to create a .pyc file for a module that is not imported – you can, using the py_compile and compileall modules.

The py_compile module can manually compile any module. One way is to use the compile() function in that module interactively:

```python
>>> import py_compile
>>> py_compile.compile('abc.py')
```

This will write the .pyc to the same location as abc.py (or you can
override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the `compileall` module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```bash
python -m compileall .
```

**How do I find the current module name?**

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```python
def main():
    print 'Running test...'  
...
if __name__ == '__main__':
    main()
```

**How can I have modules that mutually import each other?**

Suppose you have the following modules:

**foo.py:**

```python
from bar import bar_var
foo_var = 1
```

**bar.py:**
The problem is that the interpreter will perform the following steps:

- main imports foo
- Empty globals for foo are created
- foo is compiled and starts executing
- foo imports bar
- Empty globals for bar are created
- bar is compiled and starts executing
- bar imports foo (which is a no-op since there already is a module named foo)
- bar.foo_var = foo.foo_var

The last step fails, because Python isn’t done with interpreting foo yet and the global symbol dictionary for foo is still empty.

The same thing happens when you use import foo, and then try to access foo.foo_var in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of from <module> import ..., and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as <module>.<name>.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don’t need imported base classes)
- import statements
• active code (including globals that are initialized from imported values).

van Rossum doesn’t like this approach much because the imports appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

```python
__import__('x.y.z') returns <module 'x'>; how do I get z?
```

Try:

```python
__import__('x.y.z').y.z
```

For more realistic situations, you may have to do something like

```python
m = __import__(s)
for i in s.split('.')[1:]:
    m = getattr(m, i)
```

See `importlib` for a convenience function called `import_module()`.

**When I edit an imported module and reimport it, the changes don’t show up. Why does this happen?**

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn’t, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force rereading of a changed module, do this:
import modname
reload(modname)

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

    from modname import some_objects

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will not be updated to use the new class definition. This can result in the following paradoxical behaviour:

```python
>>> import cls
>>> c = cls.C()            # Create an instance of C
>>> reload(cls)
<module 'cls' from 'cls.pyc'>
>>> isinstance(c, cls.C)  # isinstance is false?!?
False
```

The nature of the problem is made clear if you print out the class objects:

```python
>>> c.__class__
<class cls.C at 0x7352a0>
>>> cls.C
<class cls.C at 0x4198d0>
```
Design and History FAQ
Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
    x++;  
    y--;  
z++;  
```

Only the `x++` statement is executed if the condition is true, but the indentation leads you to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place the braces. If you’re used to reading and writing code that uses one style, you will feel at least slightly uneasy when reading (or being required to write) another style.

Many coding styles place begin/end brackets on a line by themself. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20-30 lines). 20 lines of Python can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations
and the high-level data types are also responsible – but the indentation-based syntax certainly helps.
Why am I getting strange results with simple arithmetic operations?

See the next question.
Why are floating point calculations so inaccurate?

People are often very surprised by results like this:

```python
>>> 1.2 - 1.0
0.199999999999999996
```

and think it is a bug in Python. It's not. This has nothing to do with Python, but with how the underlying C platform handles floating point numbers, and ultimately with the inaccuracies introduced when writing down numbers as a string of a fixed number of digits.

The internal representation of floating point numbers uses a fixed number of binary digits to represent a decimal number. Some decimal numbers can't be represented exactly in binary, resulting in small roundoff errors.

In decimal math, there are many numbers that can't be represented with a fixed number of decimal digits, e.g. $1/3 = 0.3333333333.......$

In base 2, $1/2 = 0.1$, $1/4 = 0.01$, $1/8 = 0.001$, etc. .2 equals 2/10 equals 1/5, resulting in the binary fractional number $0.001100110011001...$

Floating point numbers only have 32 or 64 bits of precision, so the digits are cut off at some point, and the resulting number is $0.199999999999999996$ in decimal, not 0.2.

A floating point number's `repr()` function prints as many digits are necessary to make `eval(repr(f)) == f` true for any float `f`. The `str()` function prints fewer digits and this often results in the more sensible number that was probably intended:
One of the consequences of this is that it is error-prone to compare the result of some computation to a float with `==`. Tiny inaccuracies may mean that `==` fails. Instead, you have to check that the difference between the two numbers is less than a certain threshold:

```python
epsilon = 0.0000000000001  # Tiny allowed error
expected_result = 0.4

if expected_result - epsilon <= computation() <= expected_result + epsilon:
    ...
```

Please see the chapter on *floating point arithmetic* in the Python tutorial for more information.
Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as "elemental" as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.
Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it's more obvious that you are using a method or instance attribute instead of a local variable. Reading self.x or self.meth() makes it absolutely clear that an instance variable or method is used even if you don’t know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you’d have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an m_ prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the :: operator – in Python you can write baseclass.methodname(self, <argument list>). This is particularly useful for __init__() methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren’t explicitly declared global), there has to be some way to tell the interpreter that an assignment was meant to assign to an instance
variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn’t have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don’t have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.
Why can’t I use an assignment in an expression?

Many people used to C or Perl complain that they want to use this C idiom:

```c
while (line = readline(f)) {
    // do something with line
}
```

where in Python you’re forced to write this:

```python
while True:
    line = f.readline()
    if not line:
        break
... # do something with line
```

The reason for not allowing assignment in Python expressions is a common, hard-to-find bug in those other languages, caused by this construct:

```c
if (x = 0) {
    // error handling
}
else {
    // code that only works for nonzero x
}
```

The error is a simple typo: `x = 0`, which assigns 0 to the variable `x`, was written while the comparison `x == 0` is certainly what was intended.

Many alternatives have been proposed. Most are hacks that save some typing but use arbitrary or cryptic syntax or keywords, and fail the simple criterion for language change proposals: it should
intuitively suggest the proper meaning to a human reader who has not yet been introduced to the construct.

An interesting phenomenon is that most experienced Python programmers recognize the `while True` idiom and don’t seem to be missing the assignment in expression construct much; it’s only newcomers who express a strong desire to add this to the language.

There’s an alternative way of spelling this that seems attractive but is generally less robust than the “while True” solution:

```python
line = f.readline()
while line:
    ... # do something with line...
    line = f.readline()
```

The problem with this is that if you change your mind about exactly how you get the next line (e.g. you want to change it into `sys.stdin.readline()`) you have to remember to change two places in your program – the second occurrence is hidden at the bottom of the loop.

The best approach is to use iterators, making it possible to loop through objects using the `for` statement. For example, in the current version of Python file objects support the iterator protocol, so you can now write simply:

```python
for line in f:
    ... # do something with line...
```
Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?

The major reason is history. Functions were used for those operations that were generic for a group of types and which were intended to work even for objects that didn’t have methods at all (e.g. tuples). It is also convenient to have a function that can readily be applied to an amorphous collection of objects when you use the functional features of Python (map(), apply() et al).

In fact, implementing len(), max(), min() as a built-in function is actually less code than implementing them as methods for each type. One can quibble about individual cases but it’s a part of Python, and it's too late to make such fundamental changes now. The functions have to remain to avoid massive code breakage.

Note: For string operations, Python has moved from external functions (the string module) to methods. However, len() is still a function.
**Why is join() a string method instead of a list or tuple method?**

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
", ".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split(" ")
```

is an instruction to a string literal to return the substrings delimited by
the given separator (or, by default, arbitrary runs of white space). In this case a Unicode string returns a list of Unicode strings, an ASCII string returns a list of ASCII strings, and everyone is happy.

join() is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself.

Because this is a string method it can work for Unicode strings as well as plain ASCII strings. If join() were a method of the sequence types then the sequence types would have to decide which type of string to return depending on the type of the separator.

If none of these arguments persuade you, then for the moment you can continue to use the join() function from the string module, which allows you to write

```
string.join(['1', '2', '4', '8', '16'], ',', ',')
```
How fast are exceptions?

A try/except block is extremely efficient. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```python
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn’t the case, you coded it like this:

```python
if mydict.has_key(key):
    value = mydict[key]
else:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

**Note:** In Python 2.0 and higher, you can code this as `value = mydict.setdefault(key, getvalue(key))`. 
Why isn’t there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. There have been some proposals for switch statement syntax, but there is no consensus (yet) on whether and how to do range tests. See PEP 275 for complete details and the current status.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to functions to call. For example:

```python
def function_1(...):
    ...
functions = {'a': function_1,
              'b': function_2,
              'c': self.method_1,
              ...
}
func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```python
def visit_a(self,...):
    ...
    ...
def dispatch(self, value):
    method_name = 'visit_' + str(value)
    method = getattr(self, method_name)
    method()
```

It’s suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming
from an untrusted source, an attacker would be able to call any method on your object.
Can’t you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is Stackless Python, which has a completely redesigned interpreter loop that avoids the C stack. It’s still experimental but looks very promising. Although it is binary compatible with standard Python, it’s still unclear whether Stackless will make it into the core – maybe it’s just too revolutionary.
Why can’t lambda forms contain statements?

Python lambda forms cannot contain statements because Python’s syntactic framework can’t handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you’re too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda form instead of a locally-defined function is that you don’t need to invent a name for the function – but that’s just a local variable to which the function object (which is exactly the same type of object that a lambda form yields) is assigned!
Can Python be compiled to machine code, C or some other language?

Not easily. Python's high level data types, dynamic typing of objects and run-time invocation of the interpreter (using `eval()` or `exec`) together mean that a “compiled” Python program would probably consist mostly of calls into the Python run-time system, even for seemingly simple operations like `x+1`.

Several projects described in the Python newsgroup or at past Python conferences have shown that this approach is feasible, although the speedups reached so far are only modest (e.g. 2x). Jython uses the same strategy for compiling to Java bytecode. (Jim Hugunin has demonstrated that in combination with whole-program analysis, speedups of 1000x are feasible for small demo programs. See the proceedings from the 1997 Python conference for more information.)

Internally, Python source code is always translated into a bytecode representation, and this bytecode is then executed by the Python virtual machine. In order to avoid the overhead of repeatedly parsing and translating modules that rarely change, this byte code is written into a file whose name ends in “.pyc” whenever a module is parsed. When the corresponding .py file is changed, it is parsed and translated again and the .pyc file is rewritten.

There is no performance difference once the .pyc file has been loaded, as the bytecode read from the .pyc file is exactly the same as the bytecode created by direct translation. The only difference is that loading code from a .pyc file is faster than parsing and translating a .py file, so the presence of precompiled .pyc files improves the start-up time of Python scripts. If desired, the Lib/compileall.py module can be used to create valid .pyc files for a
given set of modules.

Note that the main script executed by Python, even if its filename ends in .py, is not compiled to a .pyc file. It is compiled to bytecode, but the bytecode is not saved to a file. Usually main scripts are quite short, so this doesn’t cost much speed.

There are also several programs which make it easier to intermingle Python and C code in various ways to increase performance. See, for example, Psyco, Pyrex, PyInline, Py2Cmod, and Weave.
How does Python manage memory?

The details of Python memory management depend on the implementation. The standard C implementation of Python uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The `gc` module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Jython relies on the Java runtime so the JVM's garbage collector is used. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

Sometimes objects get stuck in tracebacks temporarily and hence are not deallocated when you might expect. Clear the tracebacks with:

```python
import sys
sys.exc_clear()
sys.exc_traceback = sys.last_traceback = None
```

Tracebacks are used for reporting errors, implementing debuggers and related things. They contain a portion of the program state extracted during the handling of an exception (usually the most recent exception).

In the absence of circularities and tracebacks, Python programs do not need to manage memory explicitly.

Why doesn't Python use a more traditional garbage collection scheme? For one thing, this is not a C standard feature and hence
it’s not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for *most* common platforms, not for all of them, and although it is mostly transparent, it isn’t completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it’s fine to replace the standard malloc() and free() with versions provided by the GC library, an application embedding Python may want to have its own substitute for malloc() and free(), and may not want Python’s. Right now, Python works with anything that implements malloc() and free() properly.

In Jython, the following code (which is fine in CPython) will probably run out of file descriptors long before it runs out of memory:

```python
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Using the current reference counting and destructor scheme, each new assignment to f closes the previous file. Using GC, this is not guaranteed. If you want to write code that will work with any Python implementation, you should explicitly close the file or use the `with` statement; this will work regardless of GC:

```python
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
```
Why isn’t all memory freed when Python exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.
Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they're small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can't replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements. Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.
How are lists implemented?

Python's lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array's length in a list head structure.

This makes indexing a list \texttt{a[i]} an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don't require an actual resize.
How are dictionaries implemented?

Python’s dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key; for example, “Python” hashes to -539294296 while “python”, a string that differs by a single bit, hashes to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you’re storing keys that all have different hash values, this means that dictionaries take constant time – O(1), in computer science notation – to retrieve a key. It also means that no sorted order of the keys is maintained, and traversing the array as the `.keys()` and `.items()` do will output the dictionary’s content in some arbitrary jumbled order.
Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can’t tell that it was being used as a dictionary key, it can’t move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won’t be found because its hash value is different. If you tried to look up the old value it wouldn’t be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function $\text{tuple}(L)$ creates a tuple with the same entries as the list $L$. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn’t work because if you construct a new list with the same value it won’t be found; e.g.:

  ```python
  mydict = {[1, 2]: '12'}
  print mydict[[1, 2]]
  ```

  would raise a KeyError exception because the id of the $[1, 2]$ used in the second line differs from that in the first line. In other words, dictionary keys should be compared using $==$, not using $\text{is}$.

- Make a copy when using a list as a key. This doesn’t work because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an
infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it’s not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a `__eq__()` and a `__hash__()` method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```python
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list
    def __eq__(self, other):
        return self.the_list == other.the_list
    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
                result = result + (hash(el) % 99999999) * 1001 +
            except Exception:
                result = (result % 7777777) + i * 333
        return result
```

Note that the hash computation is complicated by the possibility that
some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if $o_1 == o_2$ (ie $o_1.__eq__(o_2)$ is True) then $hash(o_1) == hash(o_2)$ (ie, $o_1.__hash__() == o_2.__hash__()$), regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of ListWrapper, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don’t do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.
Why doesn’t list.sort() return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won’t be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

In Python 2.4 a new built-in function – `sorted()` – has been added. This function creates a new list from a provided iterable, sorts it and returns it. For example, here’s how to iterate over the keys of a dictionary in sorted order:

```python
for key in sorted(mydict):
    ... # do whatever with mydict[key]...
```
How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections` modules defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components. There is also a tool, PyChecker, which can be used to find problems due to subclassing.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would. In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `append()` method is expected to add new elements to the end of
some internal list; an interface specification cannot test that your `append()` implementation will actually do this correctly, but it's trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code with an eye to making it easily tested. One increasingly popular technique, test-directed development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.
Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```python
def foo(mydict={}):  # Danger: shared reference to one dict for ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don't write:

```python
def foo(mydict={}):
    ...
```
This feature can be useful. When you have a function that’s time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called “memoizing”, and can be implemented like this:

```python
def expensive(arg1, arg2, _cache={}):
    if (arg1, arg2) in _cache:
        return _cache[(arg1, arg2)]

    # Calculate the value
    result = ... expensive computation ...
    _cache[(arg1, arg2)] = result    # Store result in the cache
    return result
```

You could use a global variable containing a dictionary instead of the default value; it’s a matter of taste.
Why is there no goto?

You can use exceptions to provide a “structured goto” that even works across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```python
class label: pass  # declare a label
try:
    ...
    if (condition): raise label()  # goto label
    ...
except label:  # where to goto
    pass
    ...
```

This doesn’t allow you to jump into the middle of a loop, but that’s usually considered an abuse of goto anyway. Use sparingly.
Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```python
f = open("/mydir/file.txt")  # works fine!
```

If you’re trying to build a pathname for a DOS command, try e.g. one of

```python
dir = r"\this\is\my\dos\dir" "\"
dir = r"\this\is\my\dos\dir\ "[:-1]
dir = "\this\is\my\dos\dir\"
```
Why doesn’t Python have a “with” statement for attribute assignments?

Python has a ‘with’ statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some language have a construct that looks like this:

```python
with obj:
    a = 1 # equivalent to obj.a = 1
    total = total + 1 # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it’s possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler always knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```python
def foo(a):
    with a:
        print x
```

The snippet assumes that “a” must have a member attribute called “x”. However, there is nothing in Python that tells the interpreter this. What should happen if “a” is, let us say, an integer? If there is a global variable named “x”, will it be used inside the with block? As
you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```python
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```python
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.
Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```python
if a == b
    print a
```

versus

```python
if a == b:
    print a
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.
Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```python
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7],  # last trailing comma is optional but good style
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it’s easier to add more elements because you don’t have to remember to add a comma to the previous line. The lines can also be sorted in your editor without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```python
x = [
    "fee",
    "fie",
    "foo",
    "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check *the Library Reference* to see if there’s a relevant standard library module. (Eventually you’ll learn what’s in the standard library and will able to skip this step.)

For third-party packages, search the Python Package Index or try Google or another Web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

Where is the math.py (socket.py, regex.py, etc.) source file?

If you can’t find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like mathmodule.c, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:
How do I make a Python script executable on Unix?

You need to do two things: the script file's mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the “env” program. Almost all Unix variants support the following, assuming the Python interpreter is in a directory on the user's $PATH:

```
#!/usr/bin/env python
```

*Don't* do this for CGI scripts. The $PATH variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.

Occasionally, a user's environment is so full that the `/usr/bin/env` program fails; or there's no env program at all. In that case, you can try the following hack (due to Alex Rezinsky):
The minor disadvantage is that this defines the script's __doc__ string. However, you can fix that by adding

```python
__doc__ = """...Whatever..."""
```

Is there a curses/termcap package for Python?

For Unix variants: The standard Python source distribution comes with a curses module in the Modules/ subdirectory, though it's not compiled by default (note that this is not available in the Windows distribution – there is no curses module for Windows).

The curses module supports basic curses features as well as many additional functions from ncsurses and SYSV curses such as colour, alternative character set support, pads, and mouse support. This means the module isn’t compatible with operating systems that only have BSD curses, but there don’t seem to be any currently maintained OSes that fall into this category.

For Windows: use the consolelib module.

Is there an equivalent to C’s onexit() in Python?

The `atexit` module provides a register function that is similar to C’s onexit.

Why don’t my signal handlers work?

The most common problem is that the signal handler is declared with the wrong argument list. It is called as
handler(signum, frame)

so it should be declared with two arguments:

def handler(signum, frame):
    ...
How do I test a Python program or component?

Python comes with two testing frameworks. The `doctest` module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The `unittest` module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

For testing, it helps to write the program so that it may be easily tested by using good modular design. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```python
if __name__ == '__main__':
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of functions and class behaviours you should write test functions that exercise the behaviours. A test suite can be associated with each module which automates a sequence of tests. This sounds like a lot of work, but since Python is so terse and flexible it’s surprisingly easy. You can make coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it
easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```python
if __name__ == "__main__":
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

**How do I create documentation from doc strings?**

The [pydoc](https://docs.python.org/3/library/pydoc.html) module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is [epydoc](https://epydoc.sourceforge.net/). [Sphinx](https://www.sphinx-doc.org/) can also include docstring content.

**How do I get a single keypress at a time?**

For Unix variants: There are several solutions. It’s straightforward to do this using curses, but curses is a fairly large module to learn. Here’s a solution without curses:

```python
import termios, fcntl, sys, os
fd = sys.stdin.fileno()
oldterm = termios.tcgetattr(fd)
newattr = termios.tcgetattr(fd)
termios.tcsetattr(fd, termios.TCSANOW, newattr)
oldflags = fcntl.fcntl(fd, fcntl.F_GETFL)
fcntl.fcntl(fd, fcntl.F_SETFL, oldflags | os.O_NONBLOCK)

try:
    while 1:
```
try:
c = sys.stdin.read(1)
print "Got character", repr(c)
except IOError: pass
finally:
termios.tcsetattr(fd, termios.TCSAFLUSH, oldterm)
fcntl.fcntl(fd, fcntl.F_SETFL, oldflags)

You need the termios and the fcntl module for any of this to work, and I've only tried it on Linux, though it should work elsewhere. In this code, characters are read and printed one at a time.

termios.tcsetattr() turns off stdin's echoing and disables canonical mode. fcntl.fcntl() is used to obtain stdin's file descriptor flags and modify them for non-blocking mode. Since reading stdin when it is empty results in an IOError, this error is caught and ignored.
Threads

How do I program using threads?

Be sure to use the `threading` module and not the `thread` module. The `threading` module builds convenient abstractions on top of the low-level primitives provided by the `thread` module.

Aahz has a set of slides from his threading tutorial that are helpful; see http://www.pythoncraft.com/OSCON2001/.

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```python
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), i))
    T.start()

time.sleep(10)  # <-----------------------------!
```

But now (on many platforms) the threads don’t run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn’t start a new thread until the previous thread is blocked.
A simple fix is to add a tiny sleep to the start of the run function:

```python
def thread_task(name, n):
    time.sleep(0.001)  # <---------------------!
    for i in range(n): print name, i

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), i))
    T.start()

time.sleep(10)
```

Instead of trying to guess how long a `time.sleep()` delay will be enough, it’s better to use some kind of semaphore mechanism. One idea is to use the `Queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

**How do I parcel out work among a bunch of worker threads?**

Use the `Queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects with `.put(obj)` to add an item to the queue and `.get()` to return an item. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here’s a trivial example:

```python
import threading, Queue, time

# The worker thread gets jobs off the queue. When the queue is
# assumes there will be no more work and exits.
# (Realistically workers will run until terminated.)
def worker ():
    print 'Running worker'
    time.sleep(0.1)
```
while True:
    try:
        arg = q.get(block=False)
    except Queue.Empty:
        print 'Worker', threading.currentThread(), 'queue empty'
        break
    else:
        print 'Worker', threading.currentThread(), 'running with argument', arg
        time.sleep(0.5)

# Create queue
q = Queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker %i' % (i+1))
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)

# Give threads time to run
print 'Main thread sleeping'
time.sleep(5)

When run, this will produce the following output:

    Running worker Running worker Running worker Running worker Running worker Main thread sleeping Worker
    <Thread(worker 1, started)> running with argument 0 Worker
    <Thread(worker 2, started)> running with argument 1 Worker
    <Thread(worker 3, started)> running with argument 2 Worker
    <Thread(worker 4, started)> running with argument 3 Worker
    <Thread(worker 5, started)> running with argument 4 Worker
    <Thread(worker 1, started)> running with argument 5 ...

Consult the module's documentation for more details; the Queue class provides a featureful interface.
What kinds of global value mutation are thread-safe?

A global interpreter lock (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setcheckinterval()`. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```
L.append(x)  
L1.extend(L2)  
x = L[i]  
x = L.pop()  
L1[i:j] = L2  
L.sort()  
x = y  
x.field = y  
D[x] = y  
D1.update(D2)  
D.keys()  
```

These aren’t:

```
i = i+1  
L.append(L[-1])  
L[i] = L[j]  
D[x] = D[x] + 1  
```
Operations that replace other objects may invoke those other objects’ `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!

**Can’t we get rid of the Global Interpreter Lock?**

The Global Interpreter Lock (GIL) is often seen as a hindrance to Python’s deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the “free threading” patches) that removed the GIL and replaced it with fine-grained locking. Unfortunately, even on Windows (where locks are very efficient) this ran ordinary Python code about twice as slow as the interpreter using the GIL. On Linux the performance loss was even worse because pthread locks aren’t as efficient.

Since then, the idea of getting rid of the GIL has occasionally come up but nobody has found a way to deal with the expected slowdown, and users who don’t use threads would not be happy if their code ran at half the speed. Greg’s free threading patch set has not been kept up-to-date for later Python versions.

This doesn’t mean that you can’t make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done.
It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn’t be able to share objects. Unfortunately, this isn’t likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?
How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`, use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don’t exist. `os.removedirs(path)` will remove intermediate directories as long as they’re empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "r+"), and use `f.truncate(offset)`; offset defaults to the current seek position. There’s also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on MacOS 9 it doesn’t copy the resource fork and Finder info.

How do I read (or write) binary data?

To read or write complex binary data formats, it’s best to use the...
**struct** module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```python
import struct
f = open(filename, "rb")  # Open in binary mode for portability
s = f.read(8)
x, y, z = struct.unpack(">hhl", s)
```

The ‘>’ in the format string forces big-endian data; the letter ‘h’ reads one “short integer” (2 bytes), and ‘l’ reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the **array** module.

---

I can’t seem to use os.read() on a pipe created with os.popen(); why?

**os.read()** is a low-level function which takes a file descriptor, a small integer representing the opened file. **os.popen()** creates a high-level file object, the same type returned by the built-in **open()** function. Thus, to read n bytes from a pipe p created with **os.popen()**, you need to use `p.read(n)`.

---

How do I run a subprocess with pipes connected to both input and output?

Use the **popen2** module. For example:

```python
import popen2
```
fromchild, tochild = popen2.popen2("command")
tochild.write("input\n")
tochild.flush()
output = fromchild.readline()

Warning: in general it is unwise to do this because you can easily cause a deadlock where your process is blocked waiting for output from the child while the child is blocked waiting for input from you. This can be caused because the parent expects the child to output more text than it does, or it can be caused by data being stuck in stdout buffers due to lack of flushing. The Python parent can of course explicitly flush the data it sends to the child before it reads any output, but if the child is a naive C program it may have been written to never explicitly flush its output, even if it is interactive, since flushing is normally automatic.

Note that a deadlock is also possible if you use popen3() to read stdout and stderr. If one of the two is too large for the internal buffer (increasing the buffer size does not help) and you read() the other one first, there is a deadlock, too.

Note on a bug in popen2: unless your program calls wait() or waitpid(), finished child processes are never removed, and eventually calls to popen2 will fail because of a limit on the number of child processes. Calling os.waitpid() with the os.WNOHANG option can prevent this; a good place to insert such a call would be before calling popen2 again.

In many cases, all you really need is to run some data through a command and get the result back. Unless the amount of data is very large, the easiest way to do this is to write it to a temporary file and run the command with that temporary file as input. The standard module tempfile exports a mktemp() function to generate unique temporary file names.
import tempfile
import os

class Popen3:
    r""
    This is a deadlock-safe version of popen that returns an object with errorlevel, out (a string) and err (a string (capturestderr may not work under windows.) Example: print Popen3('grep spam','\n
here spam

').out
    r""
    def __init__(self,command,input=None,capturestderr=None):
        outfile=tempfile.mktemp()
        command="( %s ) > %s" % (command,outfile)
        if input:
            infile=tempfile.mktemp()
            open(infile,"w").write(input)
            command=command+" <"+infile
        if capturestderr:
            errfile=tempfile.mktemp()
            command=command+" 2>"+errfile
        self.errorlevel=os.system(command) >> 8
        self.out=open(outfile,"r").read()
        os.remove(outfile)
        if input:
            os.remove(infile)
        if capturestderr:
            self.err=open(errfile,"r").read()
            os.remove(errfile)

Note that many interactive programs (e.g. vi) don’t work well with pipes substituted for standard input and output. You will have to use pseudo ttys (“ptys”) instead of pipes. Or you can use a Python interface to Don Libes’ “expect” library. A Python extension that interfaces to expect is called “expy” and available from http://expectpy.sourceforge.net. A pure Python solution that works like expect is pexpect.

How do I access the serial (RS232) port?

For Win32, POSIX (Linux, BSD, etc.), Jython:
Why doesn’t closing sys.stdout (stdin, stderr) really close it?

Python file objects are a high-level layer of abstraction on top of C streams, which in turn are a medium-level layer of abstraction on top of (among other things) low-level C file descriptors.

For most file objects you create in Python via the built-in file constructor, f.close() marks the Python file object as being closed from Python’s point of view, and also arranges to close the underlying C stream. This also happens automatically in f’s destructor, when f becomes garbage.

But stdin, stdout and stderr are treated specially by Python, because of the special status also given to them by C. Running sys.stdout.close() marks the Python-level file object as being closed, but does not close the associated C stream.

To close the underlying C stream for one of these three, you should first be sure that’s what you really want to do (e.g., you may confuse extension modules trying to do I/O). If it is, use os.close:

```
    os.close(0)  # close C's stdin stream
    os.close(1)  # close C's stdout stream
    os.close(2)  # close C's stderr stream
```
What WWW tools are there for Python?

See the chapters titled *Internet Protocols and Support* and *Internet Data Handling* in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

How can I mimic CGI form submission (METHOD=POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses httpplib:

```python
#!/usr/local/bin/python

import httpplib, sys, time

### build the query string
qs = "First=Josephine&MI=Q&Last=Public"

### connect and send the server a path
httpobj = httpplib.HTTP('www.some-server.out-there', 80)
httpobj.putrequest('POST', '/cgi-bin/some-cgi-script')
### now generate the rest of the HTTP headers...
httpobj.putheader('Accept', '*/*')
```
httpobj.putheader('Connection', 'Keep-Alive')
httpobj.putheader('Content-type', 'application/x-www-form-urlencoded')
httpobj.putheader('Content-length', '%d' % len(qs))
httpobj.endheaders()
httpobj.send(qs)
###
find out what the server said in response...
reply, msg, hdrs = httpobj.getreply()
if reply != 200:
    sys.stdout.write(httpobj.getfile().read())

Note that in general for URL-encoded POST operations, query strings must be quoted by using `urllib.quote()`. For example to send name="Guy Steele, Jr.":

```python
>>> from urllib import quote
>>> x = quote("Guy Steele, Jr.")
>>> x
'Guy%20Steele,%20Jr.'
>>> query_string = "name=\"+x
>>> query_string
'name=Guy%20Steele,%20Jr.'
```

What module should I use to help with generating HTML?

There are many different modules available:

- HTMLgen is a class library of objects corresponding to all the HTML 3.2 markup tags. It's used when you are writing in Python and wish to synthesize HTML pages for generating a web or for CGI forms, etc.
- DocumentTemplate and Zope Page Templates are two different systems that are part of Zope.
- Quixote’s PTL uses Python syntax to assemble strings of text.

Consult the Web Programming wiki pages for more links.
How do I send mail from a Python script?

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```python
import sys, smtplib
fromaddr = raw_input("From: ")
toaddrs = raw_input("To: ").split(',')
print "Enter message, end with \^D:",
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
sender.quit()
```

A Unix-only alternative uses sendmail. The location of the sendmail program varies between systems; sometimes it is `/usr/lib/sendmail`, sometime `/usr/sbin/sendmail`. The sendmail manual page will help you out. Here's some sample code:

```python
SENDMAIL = "/usr/sbin/sendmail" # sendmail location
import os
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n") # blank line separating headers from body
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print "Sendmail exit status", sts
```
How do I avoid blocking in the connect() method of a socket?

The select module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the connect(), you will either connect immediately (unlikely) or get an exception that contains the error number as .errno. errno.EINPROGRESS indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the connect_ex() method to avoid creating an exception. It will just return the errno value. To poll, you can call connect_ex() again later – 0 or errno.EISCONN indicate that you're connected – or you can pass this socket to select to check if it's writable.
Databases

Are there any interfaces to database packages in Python?

Yes.

Python 2.3 includes the `bsddb` package which provides an interface to the BerkeleyDB library. Interfaces to disk-based hashes such as `DBM` and `GDBM` are also included with standard Python.

Support for most relational databases is available. See the DatabaseProgramming wiki page for details.

How do you implement persistent objects in Python?

The `pickle` library module solves this in a very general way (though you still can't store things like open files, sockets or windows), and the `shelve` library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects. For better performance, you can use the `cPickle` module.

A more awkward way of doing things is to use pickle's little sister, marshal. The `marshal` module provides very fast ways to store noncircular basic Python types to files and strings, and back again. Although marshal does not do fancy things like store instances or handle shared references properly, it does run extremely fast. For example loading a half megabyte of data may take less than a third of a second. This often beats doing something more complex and general such as using gdbm with pickle/shelve.
Why is cPickle so slow?

The default format used by the pickle module is a slow one that results in readable pickles. Making it the default, but it would break backward compatibility:

```python
largeString = 'z' * (100 * 1024)
myPickle = cPickle.dumps(largeString, protocol=1)
```

If my program crashes with a bsddb (or anydbm) database open, it gets corrupted. How come?

Databases opened for write access with the bsddb module (and often by the anydbm module, since it will preferentially use bsddb) must explicitly be closed using the `.close()` method of the database. The underlying library caches database contents which need to be converted to on-disk form and written.

If you have initialized a new bsddb database but not written anything to it before the program crashes, you will often wind up with a zero-length file and encounter an exception the next time the file is opened.

I tried to open Berkeley DB file, but bsddb produces bsddb.error: (22, ‘Invalid argument’). Help! How can I restore my data?

Don’t panic! Your data is probably intact. The most frequent cause for the error is that you tried to open an earlier Berkeley DB file with a later version of the Berkeley DB library.

Many Linux systems now have all three versions of Berkeley DB available. If you are migrating from version 1 to a newer version use db_dump185 to dump a plain text version of the database. If you are
migrating from version 2 to version 3 use db2_dump to create a plain text version of the database. In either case, use db_load to create a new native database for the latest version installed on your computer. If you have version 3 of Berkeley DB installed, you should be able to use db2_load to create a native version 2 database.

You should move away from Berkeley DB version 1 files because the hash file code contains known bugs that can corrupt your data.
How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```python
import random
random.random()
```

This returns a random floating point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).
- `uniform(a, b)` chooses a floating point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses random element from a given sequence
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly

There’s also a `Random` class you can instantiate to create independent multiple random number generators.

Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document *IronPython .NET API Reference Manual*.

Most intermediate or advanced Python books will also cover this topic.
Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.
Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you’re trying to do.

If you need more speed, Psyco generates x86 assembly code from Python bytecode. You can use Psyco to compile the most time-critical functions in your code, and gain a significant improvement with very little effort, as long as you’re running on a machine with an x86-compatible processor.

Pyrex is a compiler that accepts a slightly modified form of Python and generates the corresponding C code. Pyrex makes it possible to write an extension without having to learn Python’s C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library’s data types and functions with a tool such as SWIG. SIP, CXX Boost, or Weave are also alternatives for wrapping C++ libraries.
How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in Python/pythonrun.c.
How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.
How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyList_Size()` and `PyList_GetItem()`.

For strings, `PyString_Size()` returns its length and `PyString_AsString()` a pointer to its value. Note that Python strings may contain null bytes so C's `strlen()` should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use `PyString_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called 'abstract' interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like `PySequence_Size()`, `PySequence_GetItem()`, etc.) as well as many other useful protocols.
How do I use Py_BuildValue() to create a tuple of arbitrary length?

You can’t. Use \texttt{t = PyTuple_New(n)} instead, and fill it with objects using \texttt{PyTuple_SetItem(t, i, o)} – note that this “eats” a reference count of \texttt{o}, so you have to \texttt{Py_INCREF()} it. Lists have similar functions \texttt{PyList_New(n)} and \texttt{PyList_SetItem(l, i, o)}. Note that you \textit{must} set all the tuple items to some value before you pass the tuple to Python code – \texttt{PyTuple_New(n)} initializes them to \texttt{NULL}, which isn’t a valid Python value.
How do I call an object's method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```c
PyObject *
PyObject_CallMethod(PyObject *object, char *method_name,
                    char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`‘ing the return value.

To call, e.g., a file object’s “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```c
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
    ... an exception occurred ... 
}
else {
    Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` always wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”. 

How do I catch the output from PyErr_Print() (or anything that prints to stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `StringIO` class in the standard library.

Sample code and use for catching stdout:

```python
>>> class StdoutCatcher:
...     def __init__(self):
...         self.data = ''
...     def write(self, stuff):
...         self.data = self.data + stuff
...
>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print 'foo'
>>> print 'hello world!'
>>> sys.stderr.write(sys.stdout.data)
foo
hello world!
```
How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```python
global module
global PyImport_ImportModule

module = PyImport_ImportModule("<modulename>);
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn’t enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```python
global PyObject_GetAttrString

global attr

attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.
How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading the “Extending and Embedding” document. Realize that for the Python run-time system, there isn’t a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, you can look at SIP, CXX, Boost, Weave or SWIG
I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)
How do I debug an extension?

When using GDB with dynamically loaded extensions, you can’t set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
(gdb) run myscript.py
(gdb) continue # repeat until your extension is loaded
(gdb) finish   # so that your extension is loaded
(gdb) br myfunction.c:50
(gdb) continue
```
I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don’t include the /usr/lib/python2.x/config/ directory, which contains various files required for compiling Python extensions.

For Red Hat, install the python-devel RPM to get the necessary files.

For Debian, run `apt-get install python-dev`. 
What does “SystemError: _PyImport_FixupExtension: module yourmodule not loaded” mean?

This means that you have created an extension module named “yourmodule”, but your module init function does not initialize with that name.

Every module init function will have a line similar to:

```
module = Py_InitModule("yourmodule", yourmodule_functions);
```

If the string passed to this function is not the same name as your extension module, the SystemError exception will be raised.
How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter’s behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn’t close your parentheses or triple string quotes), but it gives you a syntax error message immediately when the input is invalid.

In Python you can use the codeop module, which approximates the parser’s behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call PyRun_InteractiveLoop() (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the PyOS_ReadlineFunctionPointer() to point at your custom input function. See Modules/readline.c and Parser/myreadline.c for more hints.

However sometimes you have to run the embedded Python interpreter in the same thread as your rest application and you can’t allow the PyRun_InteractiveLoop() to stop while waiting for user input. The one solution then is to call PyParser_ParseString() and test for e.error equal to E_EOF, which means the input is incomplete). Here’s a sample code fragment, untested, inspired by code from Alex Farber:

```
#include <Python.h>
#include <node.h>
#include <errcode.h>
#include <grammar.h>
#include <parsetok.h>
#include <compile.h>
```
int testcomplete(char *code)
    /* code should end in \n */
    /* return -1 for error, 0 for incomplete, 1 for complete */
{
    node *n;
    perrdetail e;

    n = PyParser_ParseString(code, &PyParser_Grammar, Py_file_input, &e);
    if (n == NULL) {
        if (e.error == E_EOF)
            return 0;
        return -1;
    }
    PyNode_Free(n);
    return 1;
}

Another solution is trying to compile the received string with
Py_CompileString(). If it compiles without errors, try to execute the
returned code object by calling PyEval_EvalCode(). Otherwise save
the input for later. If the compilation fails, find out if it’s an error or just
more input is required - by extracting the message string from the
exception tuple and comparing it to the string “unexpected EOF
while parsing”. Here is a complete example using the GNU readline
library (you may want to ignore SIGINT while calling readline()):

#include <stdio.h>
#include <readline.h>
#include <Python.h>
#include <object.h>
#include <compile.h>
#include <eval.h>

int main (int argc, char* argv[])
{
    int i, j, done = 0; /* lengths of li
    char ps1[] = ">>> ";
    char ps2[] = "... ";
    char *prompt = ps1;
    char *msg, *line, *code = NULL;
PyObject *src, *glb, *loc;

Py_Initialize();
loc = PyDict_New();
glb = PyDict_New();
PyDict_SetItemString (glb, "__builtins__", PyEval_GetBuiltins());

while (!done)
{
    line = readline (prompt);
    
    if (NULL == line) /* CTRL-D pressed */
    {
        done = 1;
    }
    else
    {
        i = strlen (line);
        
        if (i > 0)
            add_history (line); /* save non-empty
        
        if (NULL == code) /* nothing in code */
            j = 0;
        else
            j = strlen (code);
        
        code = realloc (code, i + j + 2);
        if (NULL == code) /* out of memory */
            exit (1);

        if (0 == j) /* code was empty */
            code[0] = '\0'; /* keep strncat happy */
        
        strncat (code, line, i); /* append line to code */
        code[i + j] = '\n'; /* append '\n' to code */
        code[i + j + 1] = '\0';
        
        src = Py_CompileString (code, "<stdin>", Py_single_input);
        if (NULL != src) /* compiled just */
        {
            if (ps1 == prompt || /* ">>> " or */
                '\n' == code[i + j - 1]) /* "... " and do */
                /* so execute it */
                dum = PyEval_EvalCode ((PyCodeObject *)src, glb, loc)
Py_XDECREF (dum);
Py_XDECREF (src);
free (code);
code = NULL;
if (PyErr_Occurred ())
    PyErr_Print ();
prompt = ps1;
}
	/* syntax error */
else if (PyErr_ExceptionMatches (PyExc_SyntaxError))
{
    PyErr_Fetch (&exc, &val, &trb); /* clears exception! */
    if (PyArg_ParseTuple (val, "sO", &msg, &obj) &&
        !strcmp (msg, "unexpected EOF while parsing")) /* E_EOF */
    {
        Py_XDECREF (exc);
        Py_XDECREF (val);
        Py_XDECREF (trb);
        prompt = ps2;
    }
    else /* some other syntax error */
    {
        PyErr_Restore (exc, val, trb);
        PyErr_Print ();
        free (code);
code = NULL;
prompt = ps1;
    }
}
else /* some non-syntax error */
{
    PyErr_Print ();
    free (code);
code = NULL;
prompt = ps1;
}
free (line);
}

Py_XDECREF(glb);
Py_XDECREF(loc);
Py_Finalize();
exit(0);
How do I find undefined g++ symbols __builtin_new or __pure_virtual?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the Python Modules Makefile), and link your extension module using g++ (e.g., g++ -shared -o mymodule.so mymodule.o).
Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

In Python 2.2, you can inherit from built-in classes such as `int`, `list`, `dict`, etc.

The Boost Python Library (BPL, http://www.boost.org/libs/python/doc/index.html) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).
When importing module X, why do I get “undefined symbol: PyUnicodeUCS2*”? 

You are using a version of Python that uses a 4-byte representation for Unicode characters, but some C extension module you are importing was compiled using a Python that uses a 2-byte representation for Unicode characters (the default).

If instead the name of the undefined symbol starts with PyUnicodeUCS4, the problem is the reverse: Python was built using 2-byte Unicode characters, and the extension module was compiled using a Python with 4-byte Unicode characters.

This can easily occur when using pre-built extension packages. RedHat Linux 7.x, in particular, provided a “python2” binary that is compiled with 4-byte Unicode. This only causes the link failure if the extension uses any of the PyUnicode_*() functions. It is also a problem if an extension uses any of the Unicode-related format specifiers for Py_BuildValue() (or similar) or parameter specifications for PyArg_ParseTuple().

You can check the size of the Unicode character a Python interpreter is using by checking the value of sys.maxunicode:

```python
>>> import sys
>>> if sys.maxunicode > 65535:
...     print 'UCS4 build'
... else:
...     print 'UCS2 build'
```

The only way to solve this problem is to use extension modules compiled with a Python binary built using the same size for Unicode characters.

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance. There are also differences between Windows 95, 98, NT, ME, 2000 and XP which can add to the confusion.

Unless you use some sort of integrated development environment, you will end up typing Windows commands into what is variously referred to as a “DOS window” or “Command prompt window”. Usually you can create such a window from your Start menu; under Windows 2000 the menu selection is Start ▶ Programs ▶ Accessories ▶ Command Prompt. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

C:>

The letter may be different, and there might be other things after it, so you might just as easily see something like:

D:\Steve\Projects\Python>
depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python interpreter. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “python” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `python` and hitting return. You should then see something like:

```plaintext
Python 2.2 (#28, Dec 21 2001, 12:21:22) [MSC 32 bit (Intel)] on
Type "help", "copyright", "credits" or "license" for more infor
```  

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```plaintext
>>> print "Hello"
Hello
>>> "Hello" * 3
HelloHelloHello
```  

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, hold the Ctrl key down while you enter a Z, then hit the “Enter” key to get back to your Windows command prompt.
You may also find that you have a Start-menu entry such as Start ▶ Programs ▶ Python 2.2 ▶ Python (command line) that results in you seeing the >>> prompt in a new window. If so, the window will disappear after you enter the Ctrl-Z character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

If the python command, instead of displaying the interpreter prompt >>>, gives you a message like:

```
'python' is not recognized as an internal or external command, operable program or batch file.
```

or:
```
Bad command or filename
```

then you need to make sure that your computer knows where to find the Python interpreter. To do this you will have to modify a setting called PATH, which is a list of directories where Windows will look for programs.

You should arrange for Python’s installation directory to be added to the PATH of every command window as it starts. If you installed Python fairly recently then the command

```
dir C:\py*
```

will probably tell you where it is installed; the usual location is something like C:\Python23. Otherwise you will be reduced to a
search of your whole disk ... use Tools ▶ Find or hit the Search button and look for “python.exe”. Supposing you discover that Python is installed in the C:\Python23 directory (the default at the time of writing), you should make sure that entering the command

c:\Python23\python

starts up the interpreter as above (and don’t forget you'll need a “CTRL-Z” and an “Enter” to get out of it). Once you have verified the directory, you need to add it to the start-up routines your computer goes through. For older versions of Windows the easiest way to do this is to edit the C:\AUTOEXEC.BAT file. You would want to add a line like the following to AUTOEXEC.BAT:

PATH C:\Python23;%PATH%

For Windows NT, 2000 and (I assume) XP, you will need to add a string such as

;C:\Python23

to the current setting for the PATH environment variable, which you will find in the properties window of “My Computer” under the “Advanced” tab. Note that if you have sufficient privilege you might get a choice of installing the settings either for the Current User or for System. The latter is preferred if you want everybody to be able to run Python on the machine.

If you aren't confident doing any of these manipulations yourself, ask for help! At this stage you may want to reboot your system to make absolutely sure the new setting has taken effect. You probably won’t need to reboot for Windows NT, XP or 2000. You can also avoid it in earlier versions by editing the file C:\WINDOWS\COMMAND\CMDINIT.BAT instead of AUTOEXEC.BAT.
You should now be able to start a new command window, enter `python` at the `C:\>` (or whatever) prompt, and see the `>>>` prompt that indicates the Python interpreter is reading interactive commands.

Let's suppose you have a program called `pytest.py` in directory `C:\Steve\Projects\Python`. A session to run that program might look like this:

```
C:\> cd \Steve\Projects\Python
C:\Steve\Projects\Python> python pytest.py
```

Because you added a file name to the command to start the interpreter, when it starts up it reads the Python script in the named file, compiles it, executes it, and terminates, so you see another `C:\>` prompt. You might also have entered

```
C:\> python \Steve\Projects\Python\pytest.py
```

if you hadn’t wanted to change your current directory.

Under NT, 2000 and XP you may well find that the installation process has also arranged that the command `pytest.py` (or, if the file isn’t in the current directory, `C:\Steve\Projects\Python\pytest.py`) will automatically recognize the “.py” extension and run the Python interpreter on the named file. Using this feature is fine, but some versions of Windows have bugs which mean that this form isn’t exactly equivalent to using the interpreter explicitly, so be careful.

The important things to remember are:

1. Start Python from the Start Menu, or make sure the PATH is set correctly so Windows can find the Python interpreter.
should give you a ‘>>>’ prompt from the Python interpreter. Don’t forget the CTRL-Z and ENTER to terminate the interpreter (and, if you started the window from the Start Menu, make the window disappear).

2. Once this works, you run programs with commands:

```
python {program-file}
```

3. When you know the commands to use you can build Windows shortcuts to run the Python interpreter on any of your scripts, naming particular working directories, and adding them to your menus. Take a look at

```
python --help
```

if your needs are complex.

4. Interactive mode (where you see the >>> prompt) is best used for checking that individual statements and expressions do what you think they will, and for developing code by experiment.
How do I make Python scripts executable?

On Windows 2000, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (D:\Program Files\Python\python.exe "%1" %*). This is enough to make scripts executable from the command prompt as ‘foo.py’. If you’d rather be able to execute the script by simple typing ‘foo’ with no extension you need to add .py to the PATHEXT environment variable.

On Windows NT, the steps taken by the installer as described above allow you to run a script with ‘foo.py’, but a longtime bug in the NT command processor prevents you from redirecting the input or output of any script executed in this way. This is often important.

The incantation for making a Python script executable under WinNT is to give the file an extension of .cmd and add the following as the first line:

@setlocal enableextensions & python -x %~f0 %* & goto :EOF
Why does Python sometimes take so long to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.
“Freeze” is a program that allows you to ship a Python program as a single stand-alone executable file. It is not a compiler; your programs don’t run any faster, but they are more easily distributable, at least to platforms with the same OS and CPU. Read the README file of the freeze program for more disclaimers.

You can use freeze on Windows, but you must download the source tree (see http://www.python.org/download/source). The freeze program is in the Tools\freeze subdirectory of the source tree.

You need the Microsoft VC++ compiler, and you probably need to build Python. The required project files are in the PCbuild directory.
Is a *.pyd file the same as a DLL?

Yes, .pyd files are dll’s, but there are a few differences. If you have a DLL named foo.pyd, then it must have a function initfoo(). You can then write Python “import foo”, and Python will search for foo.pyd (as well as foo.py, foo.pyc) and if it finds it, will attempt to call initfoo() to initialize it. You do not link your .exe with foo.lib, as that would cause Windows to require the DLL to be present.

Note that the search path for foo.pyd is PYTHONPATH, not the same as the path that Windows uses to search for foo.dll. Also, foo.pyd need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, foo.pyd is required if you want to say import foo. In a DLL, linkage is declared in the source code with __declspec(dllexport). In a .pyd, linkage is defined in a list of available functions.
How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do _not_ build Python into your .exe file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL’s. (This is the first key undocumented fact.) Instead, link to `pythonNN.dll`; it is typically installed in `C:\Windows\System`. NN is the Python version, a number such as “23” for Python 2.3.

   You can link to Python statically or dynamically. Linking statically means linking against `pythonNN.lib`, while dynamically linking means linking against `pythonNN.dll`. The drawback to dynamic linking is that your app won’t run if `pythonNN.dll` does not exist on your system. (General note: `pythonNN.lib` is the so-called “import lib” corresponding to `python.dll`. It merely defines symbols for the linker.)

   Linking dynamically greatly simplifies link options; everything happens at run time. Your code must load `pythonNN.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `pythonNN.dll` (that is, Python’s C API’s) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python’s C API.

   Borland note: convert `pythonNN.lib` to OMF format using `Coff2Omf.exe` first.
2. If you use SWIG, it is easy to create a Python “extension module” that will make the app’s data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link into your .exe file (!) You do _not_ have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

```c
#include "python.h"
...
Py_Initialize(); // Initialize Python.
initmyAppc(); // Initialize (import) the helper class.
PyRun_SimpleString("import myApp") ; // Import the shadow
```

5. There are two problems with Python’s C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

Problem 1: The so-called “Very High Level” functions that take FILE * arguments will not work in a multi-compiler environment because each compiler’s notion of a struct FILE will be different. From an implementation standpoint these are very _low_ level
functions.

Problem 2: SWIG generates the following code when generating wrappers to `void` functions:

```c
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

Alas, `Py_None` is a macro that expands to a reference to a complex data structure called `_Py_NoneStruct` inside `pythonNN.dll`. Again, this code will fail in a mult-compiler environment. Replace such code by:

```c
return Py_BuildValue("");
```

It may be possible to use SWIG’s `%typemap` command to make the change automatically, though I have not been able to get this to work (I’m a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app’s windowing system. Rather, you (or the `wxPythonWindow` class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python’s i/o to _any_ object that supports read and write, so all you need is a Python object (defined in your extension module) that contains read() and write() methods.
How do I use Python for CGI?

On the Microsoft IIS server or on the Win95 MS Personal Web Server you set up Python in the same way that you would set up any other scripting engine.

Run regedt32 and go to:

```
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W3SVC\Parameters
```

and enter the following line (making any specific changes that your system may need):

```
.py :REG_SZ: c:\<path to python>\python.exe -u %s %s
```

This line will allow you to call your script with a simple reference like: [http://yourserv..](http://yourserv..) provided “scripts” is an “executable” directory for your server (which it usually is by default). The `-u` flag specifies unbuffered and binary mode for stdin - needed when working with binary data.

In addition, it is recommended that using “.py” may not be a good idea for the file extensions when used in this context (you might want to reserve `*.py` for support modules and use `*.cgi` or `*.cgp` for “main program” scripts).

In order to set up Internet Information Services 5 to use Python for CGI processing, please see the following links:

- [http://www.e-coli.net/pyiis_server.html](http://www.e-coli.net/pyiis_server.html) (for Win2k Server)
- [http://www.e-coli.net/pyiis.html](http://www.e-coli.net/pyiis.html) (for Win2k pro)

Configuring Apache is much simpler. In the Apache configuration file `httpd.conf`, add the following line at the end of the file:
Then, give your Python CGI-scripts the extension .py and put them in the cgi-bin directory.
How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, PEP 8, recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take Tools ▶ Options ▶ Tabs, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

If you suspect mixed tabs and spaces are causing problems in leading whitespace, run Python with the -t switch or run Tools/Scripts/tabnanny.py to check a directory tree in batch mode.
How do I check for a keypress without blocking?

Use the msvcrt module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.
How do I emulate os.kill() in Windows?

Prior to Python 2.7 and 3.2, to terminate a process, you can use ctypes:

```python
import ctypes

def kill(pid):
    """kill function for Win32""
    kernel32 = ctypes.windll.kernel32
    handle = kernel32.OpenProcess(1, 0, pid)
    return (0 != kernel32.TerminateProcess(handle, 0))
```

In 2.7 and 3.2, `os.kill()` is implemented similar to the above function, with the additional feature of being able to send CTRL+C and CTRL+BREAK to console subprocesses which are designed to handle those signals. See `os.kill()` for further details.
Why does os.path.isdir() fail on NT shared directories?

The solution appears to be always append the "\" on the end of shared drives.

```python
>>> import os
>>> os.path.isdir( '\\\rorschach\public')
0
>>> os.path.isdir( '\\\rorschach\public\')
1
```

It helps to think of share points as being like drive letters. Example:

```
k: is not a directory
k:\ is a directory
k:\media is a directory
k:\media\ is not a directory
```

The same rules apply if you substitute “k:” with “\conkyfoo”:

```
\\conky\foo  is not a directory
\\conky\foo\ is a directory
\\conky\foo\media is a directory
\\conky\foo\media\ is not a directory
```
cgi.py (or other CGI programming) doesn’t work sometimes on NT or win95!

Be sure you have the latest python.exe, that you are using python.exe rather than a GUI version of Python and that you have configured the server to execute

"...\python.exe -u ..."

for the CGI execution. The -u (unbuffered) option on NT and Win95 prevents the interpreter from altering newlines in the standard input and output. Without it post/multipart requests will seem to have the wrong length and binary (e.g. GIF) responses may get garbled (resulting in broken images, PDF files, and other binary downloads failing).
Why doesn't `os.popen()` work in PythonWin on NT?

The reason that `os.popen()` doesn't work from within PythonWin is due to a bug in Microsoft's C Runtime Library (CRT). The CRT assumes you have a Win32 console attached to the process.

You should use the `win32pipe` module's `popen()` instead which doesn't depend on having an attached Win32 console.

Example:

```python
import win32pipe
f = win32pipe.popen('dir /c c:\
print f.readlines()
f.close()
```
Why doesn't os.popen()/win32pipe.popen() work on Win9x?

There is a bug in Win9x that prevents os.popen/win32pipe.popen* from working. The good news is there is a way to work around this problem. The Microsoft Knowledge Base article that you need to lookup is: Q150956. You will find links to the knowledge base at: http://support.microsoft.com/.
PyRun_SimpleFile() crashes on Windows but not on Unix; why?

This is very sensitive to the compiler vendor, version and (perhaps) even options. If the FILE* structure in your embedding program isn't the same as is assumed by the Python interpreter it won't work.

The Python 1.5.* DLLs (python15.dll) are all compiled with MS VC++ 5.0 and with multithreading-DLL options (/MD).

If you can't change compilers or flags, try using Py_RunSimpleString(). A trick to get it to run an arbitrary file is to construct a call to execfile() with the name of your file as argument.

Also note that you can not mix-and-match Debug and Release versions. If you wish to use the Debug Multithreaded DLL, then your module must have an “_d” appended to the base name.
Importing _tkinter fails on Windows 95/98: why?

Sometimes, the import of _tkinter fails on Windows 95 or 98, complaining with a message like the following:

```
ImportError: DLL load failed: One of the library files needed to run this application cannot be found.
```

It could be that you haven’t installed Tcl/Tk, but if you did install Tcl/Tk, and the Wish application works correctly, the problem may be that its installer didn’t manage to edit the autoexec.bat file correctly. It tries to add a statement that changes the PATH environment variable to include the Tcl/Tk ‘bin’ subdirectory, but sometimes this edit doesn’t quite work. Opening it with notepad usually reveals what the problem is.

(One additional hint, noted by David Szafranski: you can’t use long filenames here; e.g. use `C:\PROGRA~1\Tcl\bin` instead of `C:\Program Files\Tcl\bin`.)
How do I extract the downloaded documentation on Windows?

Sometimes, when you download the documentation package to a Windows machine using a web browser, the file extension of the saved file ends up being .EXE. This is a mistake; the extension should be .TGZ.

Simply rename the downloaded file to have the .TGZ extension, and WinZip will be able to handle it. (If your copy of WinZip doesn’t, get a newer one from http://www.winzip.com.)
Missing cw3215mt.dll (or missing cw3215.dll)

Sometimes, when using Tkinter on Windows, you get an error that cw3215mt.dll or cw3215.dll is missing.

Cause: you have an old Tcl/Tk DLL built with cygwin in your path (probably C:\Windows). You must use the Tcl/Tk DLLs from the standard Tcl/Tk installation (Python 1.5.2 comes with one).
Warning about CTL3D32 version from installer

The Python installer issues a warning like this:

```
This version uses `CTL3D32.DLL` which is not the correct version.
This version is used for Windows NT applications only.
```

Tim Peters:

This is a Microsoft DLL, and a notorious source of problems. The message means what it says: you have the wrong version of this DLL for your operating system. The Python installation did not cause this – something else you installed previous to this overwrote the DLL that came with your OS (probably older shareware of some sort, but there's no way to tell now). If you search for “CTL3D32” using any search engine (AltaVista, for example), you'll find hundreds and hundreds of web pages complaining about the same problem with all sorts of installation programs. They'll point you to ways to get the correct version reinstalled on your system (since Python doesn’t cause this, we can’t fix it).

David A Burton has written a little program to fix this. Go to http://www.burtonsys.com/downloads.html and click on “ctl3dfix.zip”.

    - I can't get key bindings to work in Tkinter: why?
What platform-independent GUI toolkits exist for Python?

Depending on what platform(s) you are aiming at, there are several.

Tkinter

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called Tkinter. This is probably the easiest to install and use. For more info about Tk, including pointers to the source, see the Tcl/Tk home page at http://www.tcl.tk. Tcl/Tk is fully portable to the MacOS, Windows, and Unix platforms.

wxWidgets

wxWidgets (http://www.wxwidgets.org) is a free, portable GUI class library written in C++ that provides a native look and feel on a number of platforms, with Windows, MacOS X, GTK, X11, all listed as current stable targets. Language bindings are available for a number of languages including Python, Perl, Ruby, etc.

wxPython (http://www.wxpython.org) is the Python binding for wxwidgets. While it often lags slightly behind the official wxWidgets releases, it also offers a number of features via pure Python extensions that are not available in other language bindings. There is an active wxPython user and developer community.

Both wxWidgets and wxPython are free, open source, software with permissive licences that allow their use in commercial products as well as in freeware or shareware.

Qt
There are bindings available for the Qt toolkit (PyQt) and for KDE (PyKDE). If you're writing open source software, you don't need to pay for PyQt, but if you want to write proprietary applications, you must buy a PyQt license from Riverbank Computing and (up to Qt 4.4; Qt 4.5 upwards is licensed under the LGPL license) a Qt license from Trolltech.

**Gtk+**

PyGtk bindings for the Gtk+ toolkit have been implemented by James Henstridge; see <http://www.pygtk.org>.

**FLTK**

Python bindings for the FLTK toolkit, a simple yet powerful and mature cross-platform windowing system, are available from the PyFLTK project.

**FOX**

A wrapper for the FOX toolkit called FXpy is available. FOX supports both Unix variants and Windows.

**OpenGL**

For OpenGL bindings, see PyOpenGL.
What platform-specific GUI toolkits exist for Python?

The Mac port by Jack Jansen has a rich and ever-growing set of modules that support the native Mac toolbox calls. The port supports MacOS X’s Carbon libraries.

By installing the PyObjc Objective-C bridge, Python programs can use MacOS X’s Cocoa libraries. See the documentation that comes with the Mac port.

Pythonwin by Mark Hammond includes an interface to the Microsoft Foundation Classes and a Python programming environment that’s written mostly in Python using the MFC classes.
How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the `TCL_LIBRARY` and `TK_LIBRARY` environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (http://tix.sourceforge.net/).

Build Tix with SAM enabled, perform the appropriate call to `Tclsam_init()`, etc. inside Python's `Modules/tkappinit.c`, and link with `libtclsam` and `libtksam` (you might include the Tix libraries as well).

Can I have Tk events handled while waiting for I/O?

Yes, and you don’t even need threads! But you'll have to restructure your I/O code a bit. Tk has the equivalent of Xt's `XtAddInput()` call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. Here's what you need:

```python
from Tkinter import tkinter
tkinter.createfilehandler(file, mask, callback)
```
The file may be a Python file or socket object (actually, anything with a fileno() method), or an integer file descriptor. The mask is one of the constants tkinter.READABLE or tkinter.WRITABLE. The callback is called as follows:

```
callback(file, mask)
```

You must unregister the callback when you're done, using

```
tkinter.deletefilehandler(file)
```

Note: since you don’t know how many bytes are available for reading, you can’t use the Python file object’s read or readline methods, since these will insist on reading a predefined number of bytes. For sockets, the `recv()` or `recvfrom()` methods will work fine; for other files, use `os.read(file.fileno(), maxbytecount)`.

I can’t get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the `bind()` method don’t get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn’t have “keyboard focus”. Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the takefocus option).
“Why is Python Installed on my Computer?” FAQ
What is Python?

Python is a programming language. It’s used for many different applications. It’s used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it's also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the Beginner's Guide to Python.
Why is Python installed on my machine?

If you find Python installed on your system but don’t remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you’ll have to figure out who’s been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. For a home computer, the most common such application is PySol, a solitaire game that includes over 1000 different games and variations.
- Some Windows machines also have Python installed. At this writing we’re aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq’s administrative tools are written in Python.
- All Apple computers running Mac OS X have Python installed; it’s included in the base installation.
Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application’s uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.
The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

The default Python prompt of the interactive shell when entering code for an indented code block or within a pair of matching left and right delimiters (parentheses, square brackets or curly braces).

2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as `lib2to3`; a standalone entry point is provided as `Tools/scripts/2to3`. See `2to3 - Automated Python 2 to 3 code translation`.

abstract base class

Abstract Base Classes (abbreviated ABCs) complement duck-typing by providing a way to define interfaces when other techniques like `hasattr()` would be clumsy. Python comes with many built-in ABCs for data structures (in the `collections` module), numbers (in the `numbers` module), and streams (in the `io` module). You can create your own ABC with the `abc` module.

argument

A value passed to a function or method, assigned to a named local variable in the function body. A function or method may have both positional arguments and keyword arguments in its definition. Positional and keyword arguments may be variable-
length: * accepts or passes (if in the function definition or call) several positional arguments in a list, while ** does the same for keyword arguments in a dictionary.

Any expression may be used within the argument list, and the evaluated value is passed to the local variable.

attribute
A value associated with an object which is referenced by name using dotted expressions. For example, if an object `o` has an attribute `a` it would be referenced as `o.a`.

BDFL
Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python's creator.

bytecode
Python source code is compiled into bytecode, the internal representation of a Python program in the interpreter. The bytecode is also cached in `.pyc` and `.pyo` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a virtual machine that executes the machine code corresponding to each bytecode.

class
A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

classic class
Any class which does not inherit from `object`. See new-style class. Classic classes will be removed in Python 3.0.

coercion
The implicit conversion of an instance of one type to another
during an operation which involves two arguments of the same type. For example, \texttt{int(3.15)} converts the floating point number to the integer 3, but in \texttt{3+4.5}, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a \texttt{TypeError}. Coercion between two operands can be performed with the \texttt{coerce} built-in function; thus, \texttt{3+4.5} is equivalent to calling \texttt{operator.add(*coerce(3, 4.5))} and results in \texttt{operator.add(3.0, 4.5)}. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., \texttt{float(3)+4.5} rather than just \texttt{3+4.5}.

**complex number**

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of \(-1\)), often written \texttt{i} in mathematics or \texttt{j} in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a \texttt{j} suffix, e.g., \texttt{3+1j}. To get access to complex equivalents of the \texttt{math} module, use \texttt{cmath}. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

**context manager**

An object which controls the environment seen in a \texttt{with} statement by defining \texttt{__enter__()} and \texttt{__exit__()} methods. See \texttt{PEP 343}.

**CPython**

The canonical implementation of the Python programming language. The term “CPython” is used in contexts when necessary to distinguish this implementation from others such as
Jython or IronPython.

**decorator**
A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```python
def f(...):
    ...
f = staticmethod(f)

@staticmethod
def f(...):
    ...
```

See *the documentation for function definition* for more about decorators.

**descriptor**
Any *new-style* object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors’ methods, see *Implementing Descriptors*.
An associative array, where arbitrary keys are mapped to values. The use of `dict` closely resembles that for `list`, but the keys can be any object with a `__hash__()` function, not just integers. Called a hash in Perl.

**docstring**
A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

**duck-typing**
A pythonic programming style which determines an object’s type by inspection of its method or attribute signature rather than by explicit relationship to some type object (“If it looks like a duck and quacks like a duck, it must be a duck.”) By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs `hasattr()` tests or **EAFP** programming.

**EAFP**
Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the **LBYL** style common to many other languages such as C.

**expression**
A piece of syntax which can be evaluated to some value. In other
words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as print or if. Assignments are also statements, not expressions.

extension module
A module written in C#, using IronPython’s C# API to interact with the core and with user code.

finder
An object that tries to find the loader for a module. It must implement a method named find_module(). See PEP 302 for details.

function
A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also argument and method.

__future__
A pseudo module which programmers can use to enable new language features which are not compatible with the current interpreter. For example, the expression \( \frac{11}{4} \) currently evaluates to 2. If the module in which it is executed had enabled true division by executing:

```python
from __future__ import division
```

the expression \( \frac{11}{4} \) would evaluate to 2.75. By importing the __future__ module and evaluating its variables, you can see when a new feature was first added to the language and when it will become the default:

```bash
>>> import __future__
```
garbage collection

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles.

generator

A function which returns an iterator. It looks like a normal function except that values are returned to the caller using a `yield` statement instead of a `return` statement. Generator functions often contain one or more `for` or `while` loops which `yield` elements back to the caller. The function execution is stopped at the `yield` keyword (returning the result) and is resumed there when the next element is requested by calling the `next()` method of the returned iterator.

generator expression

An expression that returns an iterator. It looks like a normal expression followed by a `for` expression defining a loop variable, `range`, and an optional `if` expression. The combined expression generates values for an enclosing function:

```python
>>> sum(i*i for i in range(10))  # sum of squares 0, 1, 4, ..., 81
285
```

GIL

See global interpreter lock.

global interpreter lock

The lock used by Python threads to assure that only one thread executes in the CPython virtual machine at a time. This simplifies the CPython implementation by assuring that no two processes
can access the same memory at the same time. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines. Efforts have been made in the past to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity), but so far none have been successful because performance suffered in the common single-processor case.

**hashable**

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` or `__cmp__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

All of Python’s immutable built-in objects are hashable, while no mutable containers (such as lists or dictionaries) are. Objects which are instances of user-defined classes are hashable by default; they all compare unequal, and their hash value is their `id()`.

**IDLE**

An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python. Good for beginners, it also serves as clear example code for those wanting to implement a moderately sophisticated, multi-platform GUI application.

**immutable**

An object with a fixed value. Immutable objects include numbers,
strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

**integer division**

Mathematical division discarding any remainder. For example, the expression $11/4$ currently evaluates to $2$ in contrast to the $2.75$ returned by float division. Also called *floor division*. When dividing two integers the outcome will always be another integer (having the floor function applied to it). However, if one of the operands is another numeric type (such as a *float*), the result will be coerced (see *coercion*) to a common type. For example, an integer divided by a float will result in a float value, possibly with a decimal fraction. Integer division can be forced by using the `//` operator instead of the `/` operator. See also `__future__`.

**importer**

An object that both finds and loads a module; both a *finder* and *loader* object.

**interactive**

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer’s main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

**interpreted**

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter
development/debug cycle than compiled ones, though their programs generally also run more slowly. See also *interactive*.

**iterable**

A container object capable of returning its members one at a time. Examples of iterables include all sequence types (such as `list`, `str`, and `tuple`) and some non-sequence types like `dict` and `file` and objects of any classes you define with an `__iter__()` or `__getitem__()` method. Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, `...`). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also `iterator`, `sequence`, and `generator`.

**iterator**

An object representing a stream of data. Repeated calls to the iterator's `next()` method return successive items in the stream. When no more data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `next()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration.
pass, making it appear like an empty container.

More information can be found in *Iterator Types*.

**keyword argument**
Arguments which are preceded with a `variable_name=` in the call. The variable name designates the local name in the function to which the value is assigned. `**` is used to accept or pass a dictionary of keyword arguments. See *argument*.

**lambda**
An anonymous inline function consisting of a single expression which is evaluated when the function is called. The syntax to create a lambda function is `lambda [arguments]: expression`

**LBYL**
Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the *EAFP* approach and is characterized by the presence of many if statements.

**list**
A built-in Python sequence. Despite its name it is more akin to an array in other languages than to a linked list since access to elements are O(1).

**list comprehension**
A compact way to process all or part of the elements in a sequence and return a list with the results.
```python
def example():
    result = ['0x%02x' % x for x in range(256) if x % 2 == 0]
    return result
```

The if clause is optional. If omitted, all elements in `range(256)` are processed.

**loader**
An object that loads a module. It must define a method named
A loader is typically returned by a `finder`. See PEP 302 for details.

**mapping**

A container object (such as `dict`) which supports arbitrary key lookups using the special method `__getitem__()`.

**metaclass**

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in *Customizing class creation*.

**method**

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first argument (which is usually called `self`). See `function` and `nested scope`.

**mutable**

Mutable objects can change their value but keep their `id()`. See also `immutable`.

**named tuple**

Any tuple-like class whose indexable elements are also accessible using named attributes (for example, `time.localtime()` returns a tuple-like object where the `year` is
accessible either with an index such as \texttt{t[0]} or with a named attribute like \texttt{t.tm\_year}).

A named tuple can be a built-in type such as \texttt{time.struct\_time}, or it can be created with a regular class definition. A full featured named tuple can also be created with the factory function \texttt{collections.namedtuple()}. The latter approach automatically provides extra features such as a self-documenting representation like \texttt{Employee(name='jones', title='programmer')}.

\textbf{namespace}

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions \texttt{\_\_builtin\_.open()} and \texttt{os.open()} are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing \texttt{random.seed()} or \texttt{itertools.izip()} makes it clear that those functions are implemented by the \texttt{random} and \texttt{itertools} modules, respectively.

\textbf{nested scope}

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes work only for reference and not for assignment which will always write to the innermost scope. In contrast, local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace.

\textbf{new-style class}

Any class which inherits from \texttt{object}. This includes all built-in
types like `list` and `dict`. Only new-style classes can use Python’s newer, versatile features like `_slots_`, descriptors, properties, and `_getattribute_()`.

More information can be found in *New-style and classic classes*.

**object**

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any *new-style class*.

**positional argument**

The arguments assigned to local names inside a function or method, determined by the order in which they were given in the call. `*` is used to either accept multiple positional arguments (when in the definition), or pass several arguments as a list to a function. See *argument*.

**Python 3000**

Nickname for the next major Python version, 3.0 (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

**Pythonic**

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a *for* statement. Many other languages don’t have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```python
for i in range(len(food)):
    print food[i]
```

As opposed to the cleaner, Pythonic method:
for piece in food:
    print piece

reference count
The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. The sys module defines a getrefcount() function that programmers can call to return the reference count for a particular object.

__slots__
A declaration inside a new-style class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

sequence
An iterable which supports efficient element access using integer indices via the __getitem__() special method and defines a len() method that returns the length of the sequence. Some built-in sequence types are list, str, tuple, and unicode. Note that dict also supports __getitem__() and __len__(), but is considered a mapping rather than a sequence because the lookups use arbitrary immutable keys rather than integers.

slice
An object usually containing a portion of a sequence. A slice is created using the subscript notation, [] with colons between numbers when several are given, such as in variable_name[1:3:5]. The bracket (subscript) notation uses slice objects internally (or in older versions, __getslice__() and __setslice__()).
special method
A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in *Special method names*.

statement
A statement is part of a suite (a “block” of code). A statement is either an *expression* or a one of several constructs with a keyword, such as *if*, *while* or *print*.

triple-quoted string
A string which is bound by three instances of either a quotation mark (") or an apostrophe ('). While they don’t provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

type
The type of a Python object determines what kind of object it is; every object has a type. An object’s type is accessible as its *__class__* attribute or can be retrieved with *type(obj)*.

view
The objects returned from *dict.viewkeys()*, *dict.viewvalues()*, and *dict.viewitems()* are called dictionary views. They are lazy sequences that will see changes in the underlying dictionary. To force the dictionary view to become a full list use *list(dictview)*. See *Dictionary view objects*.

virtual machine
A computer defined entirely in software. Python’s virtual machine executes the *bytecode* emitted by the bytecode compiler.
Zen of Python

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing “import this” at the interactive prompt.
About these documents

These documents are generated from `reStructuredText` sources by `Sphinx`, a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain takes place on the `docs@python.org` mailing list. We’re always looking for volunteers wanting to help with the docs, so feel free to send a mail there!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the `Docutils` project for creating `reStructuredText` and the Docutils suite;
- Fredrik Lundh for his `Alternative Python Reference` project from which Sphinx got many good ideas.

See `Reporting Bugs` for information how to report bugs in this documentation, or Python itself.
Contributors to the Python Documentation

This section lists people who have contributed in some way to the Python documentation. It is probably not complete – if you feel that you or anyone else should be on this list, please let us know (send email to docs@python.org), and we'll be glad to correct the problem.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!
Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.
Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please send an e-mail to docs@python.org describing the bug and where you found it. If you have a suggestion how to fix it, include that as well.

docs@python.org is a mailing list run by volunteers; your request will be noticed, even if it takes a while to be processed.

Of course, if you want a more persistent record of your issue, you can use the issue tracker for documentation bugs as well.
Using the Python issue tracker

Bug reports for Python itself should be submitted via the Python Bug Tracker (http://bugs.python.org/). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the top of the page.

If the problem you’re reporting is not already in the bug tracker, go back to the Python Bug Tracker and log in. If you don’t already have a tracker account, select the “Register” link or, if you use OpenID, one of the OpenID provider logos in the sidebar. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit a bug. Select the “Create New” link in the sidebar to open the bug reporting form.

The submission form has a number of fields. For the “Title” field, enter a very short description of the problem; less than ten words is good. In the “Type” field, select the type of your problem; also select the “Component” and “Versions” to which the bug relates.

In the “Comment” field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).
Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug. See http://www.python.org/dev/workflow/ for a detailed description of the issue workflow.

IronPython is an implementation of the Python programming language on .NET. The .NET Framework is a managed programming model for Windows; Microsoft standardized part of it in ECMA several years ago as the Common Language Infrastructure and C# Language Specification standards.

IronPython includes both the IronPython runtime licensed under the Microsoft Public License and the Python standard library whose licensing is described below.
History of Python

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn’t mean that we’re distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don’t.

Thanks to the many outside volunteers who have worked under Guido’s direction to make these releases possible.
IronPython License

Apache License Version 2.0, January 2004
http://www.apache.org/licenses/

TERMS AND CONDITIONS FOR USE, REPRODUCTION, AND DISTRIBUTION

1. Definitions.

“License” shall mean the terms and conditions for use, reproduction, and distribution as defined by Sections 1 through 9 of this document.

“Licensor” shall mean the copyright owner or entity authorized by the copyright owner that is granting the License.

“Legal Entity” shall mean the union of the acting entity and all other entities that control, are controlled by, or are under common control with that entity. For the purposes of this definition, “control” means (i) the power, direct or indirect, to cause the direction or management of such entity, whether by contract or otherwise, or (ii) ownership of fifty percent (50%) or more of the outstanding shares, or (iii) beneficial ownership of such entity.

“You” (or “Your”) shall mean an individual or Legal Entity exercising permissions granted by this License.

“Source” form shall mean the preferred form for making modifications, including but not limited to software source code, documentation source, and configuration files.

“Object” form shall mean any form resulting from mechanical transformation or translation of a Source form, including but not limited to compiled object code, generated documentation, and conversions to other media types.
“Work” shall mean the work of authorship, whether in Source or Object form, made available under the License, as indicated by a copyright notice that is included in or attached to the work (an example is provided in the Appendix below).

“Derivative Works” shall mean any work, whether in Source or Object form, that is based on (or derived from) the Work and for which the editorial revisions, annotations, elaborations, or other modifications represent, as a whole, an original work of authorship. For the purposes of this License, Derivative Works shall not include works that remain separable from, or merely link (or bind by name) to the interfaces of, the Work and Derivative Works thereof.

“Contribution” shall mean any work of authorship, including the original version of the Work and any modifications or additions to that Work or Derivative Works thereof, that is intentionally submitted to Licensor for inclusion in the Work by the copyright owner or by an individual or Legal Entity authorized to submit on behalf of the copyright owner. For the purposes of this definition, “submitted” means any form of electronic, verbal, or written communication sent to the Licensor or its representatives, including but not limited to communication on electronic mailing lists, source code control systems, and issue tracking systems that are managed by, or on behalf of, the Licensor for the purpose of discussing and improving the Work, but excluding communication that is conspicuously marked or otherwise designated in writing by the copyright owner as “Not a Contribution.”

“Contributor” shall mean Licensor and any individual or Legal Entity on behalf of whom a Contribution has been received by Licensor and subsequently incorporated within the Work.

2. Grant of Copyright License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free,
irrevocable copyright license to reproduce, prepare Derivative Works of, publicly display, publicly perform, sublicense, and distribute the Work and such Derivative Works in Source or Object form.

3. Grant of Patent License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable (except as stated in this section) patent license to make, have made, use, offer to sell, sell, import, and otherwise transfer the Work, where such license applies only to those patent claims licensable by such Contributor that are necessarily infringed by their Contribution(s) alone or by combination of their Contribution(s) with the Work to which such Contribution(s) was submitted. If You institute patent litigation against any entity (including a cross-claim or counterclaim in a lawsuit) alleging that the Work or a Contribution incorporated within the Work constitutes direct or contributory patent infringement, then any patent licenses granted to You under this License for that Work shall terminate as of the date such litigation is filed.

4. Redistribution. You may reproduce and distribute copies of the Work or Derivative Works thereof in any medium, with or without modifications, and in Source or Object form, provided that You meet the following conditions:

You must give any other recipients of the Work or Derivative Works a copy of this License; and

You must cause any modified files to carry prominent notices stating that You changed the files; and

You must retain, in the Source form of any Derivative Works that You distribute, all copyright, patent, trademark, and attribution notices from the Source form of the Work, excluding those notices that do not pertain to any part of the Derivative Works; and
If the Work includes a “NOTICE” text file as part of its distribution, then any Derivative Works that You distribute must include a readable copy of the attribution notices contained within such NOTICE file, excluding those notices that do not pertain to any part of the Derivative Works, in at least one of the following places: within a NOTICE text file distributed as part of the Derivative Works; within the Source form or documentation, if provided along with the Derivative Works; or, within a display generated by the Derivative Works, if and wherever such third-party notices normally appear. The contents of the NOTICE file are for informational purposes only and do not modify the License. You may add Your own attribution notices within Derivative Works that You distribute, alongside or as an addendum to the NOTICE text from the Work, provided that such additional attribution notices cannot be construed as modifying the License. You may add Your own copyright statement to Your modifications and may provide additional or different license terms and conditions for use, reproduction, or distribution of Your modifications, or for any such Derivative Works as a whole, provided Your use, reproduction, and distribution of the Work otherwise complies with the conditions stated in this License.

5. Submission of Contributions. Unless You explicitly state otherwise, any Contribution intentionally submitted for inclusion in the Work by You to the Licensor shall be under the terms and conditions of this License, without any additional terms or conditions. Notwithstanding the above, nothing herein shall supersede or modify the terms of any separate license agreement you may have executed with Licensor regarding such Contributions.

6. Trademarks. This License does not grant permission to use the trade names, trademarks, service marks, or product names of the Licensor, except as required for reasonable and customary use in describing the origin of the Work and reproducing the content of the NOTICE file.
7. Disclaimer of Warranty. Unless required by applicable law or agreed to in writing, Licensor provides the Work (and each Contributor provides its Contributions) on an “AS IS” BASIS, WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied, including, without limitation, any warranties or conditions of TITLE, NON-INFRINGEMENT, MERCHANTABILITY, or FITNESS FOR A PARTICULAR PURPOSE. You are solely responsible for determining the appropriateness of using or redistributing the Work and assume any risks associated with Your exercise of permissions under this License.

8. Limitation of Liability. In no event and under no legal theory, whether in tort (including negligence), contract, or otherwise, unless required by applicable law (such as deliberate and grossly negligent acts) or agreed to in writing, shall any Contributor be liable to You for damages, including any direct, indirect, special, incidental, or consequential damages of any character arising as a result of this License or out of the use or inability to use the Work (including but not limited to damages for loss of goodwill, work stoppage, computer failure or malfunction, or any and all other commercial damages or losses), even if such Contributor has been advised of the possibility of such damages.

9. Accepting Warranty or Additional Liability. While redistributing the Work or Derivative Works thereof, You may choose to offer, and charge a fee for, acceptance of support, warranty, indemnity, or other liability obligations and/or rights consistent with this License. However, in accepting such obligations, You may act only on Your own behalf and on Your sole responsibility, not on behalf of any other Contributor, and only if You agree to indemnify, defend, and hold each Contributor harmless for any liability incurred by, or claims asserted against, such Contributor by reason of your accepting any such warranty or additional liability.
See FAQ for answers to frequently asked questions about this license.
PSF LICENSE AGREEMENT FOR PYTHON 2.7.4a1

1. This LICENSE AGREEMENT is between the Python Software Foundation (“PSF”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 2.7.4a1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.7.4a1 alone or in any derivative version, provided, however, that PSF’s License Agreement and PSF’s notice of copyright, i.e., “Copyright © 2001-2010 Python Software Foundation; All Rights Reserved” are retained in Python 2.7.4a1 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.7.4a1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.7.4a1.

4. PSF is making Python 2.7.4a1 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.7.4a1 WILL
NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 2.7.4a1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.7.4a1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.7.4a1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT
VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in
any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any
derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an “AS IS” basis. BEOPEN MAKES NO REPRESENTATIONS OR
WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND
DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR
PURPOSE OR THAT THE USE OF THE SOFTWARE WILL
NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY
OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL,
SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A
RESULT OF USING, MODIFYING OR DISTRIBUTING THE
SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF
ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a
material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in
all respects by the law of the State of California, excluding
conflict of law provisions. Nothing in this License Agreement
shall be deemed to create any relationship of agency,
partnership, or joint venture between BeOpen and Licensee.
This License Agreement does not grant permission to use
BeOpen trademarks or trade names in a trademark sense to
endorse or promote products or services of Licensee, or any
third party. As an exception, the “BeOpen Python” logos
available at http://www.pythonlabs.com/logos.html may be used
according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee
agrees to be bound by the terms and conditions of this License
Agreement.
CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (“CNRI”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI’s License Agreement and CNRI’s notice of copyright, i.e., “Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved” are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI’s License Agreement, Licensee may substitute the following text (omitting the quotes): “Python 1.6.1 is made available subject to the terms and conditions in CNRI’s License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013.”

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an “AS IS” basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF
EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia’s conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the “ACCEPT” button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.
ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

MD5 message digest algorithm

The source code for the `md5` module contains the following notice:

Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved.

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any damages arising from the use of this software.

Permission is granted to anyone to use this software for any purpose, including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must not claim that you wrote the original software. If you use this software in a product, an acknowledgment in the product documentation would be appreciated but is not required.
2. Altered source versions must be plainly marked as such, and not misrepresented as being the original software.
3. This notice may not be removed or altered from any source distribution.

L. Peter Deutsch
ghost@aladdin.com

Independent implementation of MD5 (RFC 1321).

This code implements the MD5 Algorithm defined in RFC 1321, whose text is available at
http://www.ietf.org/rfc/rfc1321.txt

The code is derived from the text of the RFC, including the test (section A.5) but excluding the rest of Appendix A. It does not include any code or documentation that is identified in the RFC as being copyrighted.

The original and principal author of md5.h is L. Peter Deutsch <ghost@aladdin.com>. Other authors are noted in the change history that follows (in reverse chronological order):

2002-04-13 lpd Removed support for non-ANSI compilers; removed references to Ghostscript; clarified derivation from RFC
now handles byte order either statically or dynamically.
1999-11-04 lpd Edited comments slightly for automatic TOC extr
Asynchronous socket services

The `asynchat` and `asyncore` modules contain the following notice:

strtod and dtoa

The file `Python/dtoa.c`, which supplies C functions `dtoa` and `strtod` for conversion of C doubles to and from strings, is derived from the file of the same name by David M. Gay, currently available from http://www.netlib.org/fp/. The original file, as retrieved on March 16, 2009, contains the following copyright and licensing notice:

What’s New in Python

The “What’s New in Python” series of essays takes tours through the most important changes between major Python versions. They are a “must read” for anyone wishing to stay up-to-date after a new release.

- **What’s New in Python 2.7**
  - The Future for Python 2.x
  - Python 3.1 Features
  - PEP 372: Adding an Ordered Dictionary to collections
  - PEP 378: Format Specifier for Thousands Separator
  - PEP 389: The argparse Module for Parsing Command Lines
  - PEP 391: Dictionary-Based Configuration For Logging
  - PEP 3106: Dictionary Views
  - PEP 3137: The memoryview Object
  - Other Language Changes
  - New and Improved Modules
  - Build and C API Changes
  - Other Changes and Fixes
  - Porting to Python 2.7
  - Acknowledgements

- **What’s New in Python 2.6**
  - Python 3.0
  - PEP 343: The ‘with’ statement
  - PEP 366: Explicit Relative Imports From a Main Module
  - PEP 370: Per-user site-packages Directory
  - PEP 3101: Advanced String Formatting
  - PEP 3105: print As a Function
  - PEP 3110: Exception-Handling Changes
  - PEP 3112: Byte Literals
  - PEP 3116: New I/O Library
○ PEP 3119: Abstract Base Classes
○ PEP 3127: Integer Literal Support and Syntax
○ PEP 3129: Class Decorators
○ PEP 3141: A Type Hierarchy for Numbers
○ Other Language Changes
○ New and Improved Modules
○ Deprecations and Removals
○ Acknowledgements

bullet What’s New in Python 2.5 (IronPython 2.0)
○ PEP 308: Conditional Expressions
○ PEP 309: Partial Function Application
○ PEP 314: Metadata for Python Software Packages v1.1
○ PEP 328: Absolute and Relative Imports
○ PEP 338: Executing Modules as Scripts
○ PEP 341: Unified try/except/finally
○ PEP 342: New Generator Features
○ PEP 343: The ‘with’ statement
○ PEP 352: Exceptions as New-Style Classes
○ PEP 357: The ‘__index__’ method
○ Other Language Changes
○ New, Improved, and Removed Modules
○ Porting to IronPython 2.0
○ Acknowledgements
Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python’s elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, http://www.python.org/, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see The Python Standard Library. The Python Language Reference gives a more formal definition of the language. To write extensions in C or C++, read IronPython .NET API Reference Manual and c-api-index. There are also several books covering Python in depth.
This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python’s most noteworthy features, and will give you a good idea of the language’s flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in *The Python Standard Library*.

The *Glossary* is also worth going through.

- **1. Whetting Your Appetite**
- **2. Using the Python Interpreter**
  - 2.1. Invoking the Interpreter
    - 2.1.1. Argument Passing
    - 2.1.2. Interactive Mode
  - 2.2. The Interpreter and Its Environment
    - 2.2.1. Error Handling
    - 2.2.2. Executable Python Scripts
    - 2.2.3. Source Code Encoding
    - 2.2.4. The Interactive Startup File
- **3. An Informal Introduction to Python**
  - 3.1. Using Python as a Calculator
    - 3.1.1. Numbers
    - 3.1.2. Strings
    - 3.1.3. Unicode Strings
    - 3.1.4. Lists

• 14. Floating Point Arithmetic: Issues and Limitations
  ○ 14.1. Representation Error
Using Python

This part of the documentation is devoted to general information on the setup of the Python environment on different platform, the invocation of the interpreter and things that make working with Python easier.

- **1. Command line and environment**
  - 1.1. Command line
    - 1.1.1. Interface options
    - 1.1.2. Generic options
    - 1.1.3. Miscellaneous options
    - 1.1.4. Options you shouldn’t use
  - 1.2. Environment variables
    - 1.2.1. Debug-mode variables
While The Python Language Reference describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python's standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifics into platform-neutral APIs.

The Python installers for the Windows platform usually includes the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is a growing collection of several thousand components (from individual programs and modules to packages and entire application development frameworks), available from the Python Package Index.

- 1. Introduction
2. Built-in Functions
3. Non-essential Built-in Functions
4. Built-in Constants
   - 4.1. Constants added by the site module
5. Built-in Types
   - 5.1. Truth Value Testing
   - 5.2. Boolean Operations — and, or, not
   - 5.3. Comparisons
   - 5.4. Numeric Types — int, float, long, complex
   - 5.5. Iterator Types
   - 5.6. Sequence Types — str, unicode, list, tuple, buffer, xrange
   - 5.7. Set Types — set, frozenset
   - 5.8. Mapping Types — dict
   - 5.9. File Objects
   - 5.10. memoryview type
   - 5.11. Context Manager Types
   - 5.12. Other Built-in Types
   - 5.13. Special Attributes
6. Built-in Exceptions
   - 6.1. Exception hierarchy
7. String Services
   - 7.1. string — Common string operations
   - 7.2. re — Regular expression operations
   - 7.3. struct — Interpret strings as packed binary data
   - 7.4. difflib — Helpers for computing deltas
   - 7.5. StringIO — Read and write strings as files
   - 7.6. cStringIO — Faster version of StringIO
   - 7.7. textwrap — Text wrapping and filling
   - 7.8. codecs — Codec registry and base classes
   - 7.9. unicodedata — Unicode Database
   - 7.10. stringprep — Internet String Preparation
7.11. fpformat — Floating point conversions

8. Data Types

8.1. datetime — Basic date and time types
8.2. calendar — General calendar-related functions
8.3. collections — High-performance container datatypes
8.4. heapq — Heap queue algorithm
8.5. bisect — Array bisection algorithm
8.6. array — Efficient arrays of numeric values
8.7. sets — Unordered collections of unique elements
8.8. sched — Event scheduler
8.9. mutex — Mutual exclusion support
8.10. queue — A synchronized queue class
8.11. weakref — Weak references
8.12. UserDict — Class wrapper for dictionary objects
8.13. UserList — Class wrapper for list objects
8.14. UserString — Class wrapper for string objects
8.15. types — Names for built-in types
8.16. new — Creation of runtime internal objects
8.17. copy — Shallow and deep copy operations
8.18. pprint — Data pretty printer
8.19. repr — Alternate repr() implementation

9. Numeric and Mathematical Modules

9.1. numbers — Numeric abstract base classes
9.2. math — Mathematical functions
9.3. cmath — Mathematical functions for complex numbers
9.4. decimal — Decimal fixed point and floating point arithmetic
9.5. fractions — Rational numbers
9.6. random — Generate pseudo-random numbers
9.7. itertools — Functions creating iterators for efficient looping
9.8. `functools` — Higher order functions and operations on callable objects
9.9. `operator` — Standard operators as functions

10. File and Directory Access
- 10.1. `os.path` — Common pathname manipulations
- 10.2. `fileinput` — Iterate over lines from multiple input streams
- 10.3. `stat` — Interpreting `stat()` results
- 10.4. `statvfs` — Constants used with `os.statvfs()`
- 10.5. `filecmp` — File and Directory Comparisons
- 10.6. `tempfile` — Generate temporary files and directories
- 10.7. `glob` — Unix style pathname pattern expansion
- 10.8. `fnmatch` — Unix filename pattern matching
- 10.9. `linecache` — Random access to text lines
- 10.10. `shutil` — High-level file operations
- 10.11. `dircache` — Cached directory listings

11. Data Persistence
- 11.1. `pickle` — Python object serialization
- 11.2. `cPickle` — A faster `pickle`
- 11.3. `copy_reg` — Register `pickle` support functions
- 11.4. `shelve` — Python object persistence
- 11.5. `marshal` — Internal Python object serialization
- 11.6. `anydbm` — Generic access to DBM-style databases
- 11.7. `whichdb` — Guess which DBM module created a database
- 11.8. `dbhash` — DBM-style interface to the BSD database library
- 11.9. `dumbdbm` — Portable DBM implementation
- 11.10. `sqlite3` — DB-API 2.0 interface for SQLite databases

12. Data Compression and Archiving
12.1. zlib — Compression compatible with gzip
12.2. gzip — Support for gzip files
12.3. bz2 — Compression compatible with bzip2
12.4. zipfile — Work with ZIP archives
12.5. tarfile — Read and write tar archive files

• 13. File Formats
  13.1. csv — CSV File Reading and Writing
  13.2. ConfigParser — Configuration file parser
  13.3. robotparser — Parser for robots.txt
  13.4. netrc — netrc file processing
  13.5. xdrlib — Encode and decode XDR data
  13.6. plistlib — Generate and parse Mac OS X .plist files

• 14. Cryptographic Services
  14.1. hashlib — Secure hashes and message digests
  14.2. hmac — Keyed-Hashing for Message Authentication
  14.3. md5 — MD5 message digest algorithm
  14.4. sha — SHA-1 message digest algorithm

• 15. Generic Operating System Services
  15.1. os — Miscellaneous operating system interfaces
  15.2. io — Core tools for working with streams
  15.3. time — Time access and conversions
  15.4. argparse — Parser for command line options, arguments and sub-commands
  15.5. optparse — Parser for command line options
  15.6. getopt — C-style parser for command line options
  15.7. logging — Logging facility for Python
  15.8. getpass — Portable password input
  15.9. curses — Terminal handling for character-cell displays
  15.10. curses.textpad — Text input widget for curses programs
• 15.11. curses.wrapper — Terminal handler for curses programs
• 15.12. curses.ascii — Utilities for ASCII characters
• 15.13. curses.panel — A panel stack extension for curses
• 15.14. platform — Access to underlying platform’s identifying data
• 15.15. errno — Standard errno system symbols
• 15.16. ctypes — A foreign function library for Python

• 16. Optional Operating System Services
  • 16.1. select — Waiting for I/O completion
  • 16.2. threading — Higher-level threading interface
  • 16.3. thread — Multiple threads of control
  • 16.4. dummy_threading — Drop-in replacement for the threading module
  • 16.5. dummy_thread — Drop-in replacement for the thread module
  • 16.6. multiprocessing — Process-based “threading” interface
  • 16.7. rlcompleter — Completion function for GNU readline

• 17. Interprocess Communication and Networking
  • 17.1. subprocess — Subprocess management
  • 17.2. socket — Low-level networking interface
  • 17.3. ssl — SSL wrapper for socket objects
  • 17.4. signal — Set handlers for asynchronous events
  • 17.5. popen2 — Subprocesses with accessible I/O streams
  • 17.6. asyncore — Asynchronous socket handler
  • 17.7. asynchat — Asynchronous socket command/response handler

• 18. Internet Data Handling
  • 18.1. email — An email and MIME handling package
  • 18.2. json — JSON encoder and decoder
- 18.3. mailcap — Mailcap file handling
- 18.4. mailbox — Manipulate mailboxes in various formats
- 18.5. mhlib — Access to MH mailboxes
- 18.6. mimeutils — Tools for parsing MIME messages
- 18.7. mimetypes — Map filenames to MIME types
- 18.8. MimeWriter — Generic MIME file writer
- 18.9. mimify — MIME processing of mail messages
- 18.10. multfile — Support for files containing distinct parts
- 18.11. rfc822 — Parse RFC 2822 mail headers
- 18.12. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings
- 18.13. binhex — Encode and decode binhex4 files
- 18.14. binascii — Convert between binary and ASCII
- 18.15. quopri — Encode and decode MIME quoted-printable data
- 18.16. uu — Encode and decode uuencode files

- 19. Structured Markup Processing Tools
  - 19.1. HTMLParser — Simple HTML and XHTML parser
  - 19.2. sgmllib — Simple SGML parser
  - 19.3. htmllib — A parser for HTML documents
  - 19.4. htmlentitydefs — Definitions of HTML general entities
  - 19.5. xml.parsers.expat — Fast XML parsing using Expat
  - 19.6. xml.dom — The Document Object Model API
  - 19.7. xml.dom.minidom — Lightweight DOM implementation
  - 19.8. xml.dom.pulldom — Support for building partial DOM trees
  - 19.9. xml.sax — Support for SAX2 parsers
  - 19.10. xml.sax.handler — Base classes for SAX handlers
  - 19.11. xml.sax.saxutils — SAX Utilities
19.12. `xml.sax.xmlreader` — Interface for XML parsers
19.13. `xml.etree.ElementTree` — The ElementTree XML API

20. Internet Protocols and Support
20.1. `webbrowser` — Convenient Web-browser controller
20.2. `cgi` — Common Gateway Interface support
20.3. `cgitb` — Traceback manager for CGI scripts
20.4. `wsgiref` — WSGI Utilities and Reference Implementation
20.5. `urllib` — Open arbitrary resources by URL
20.6. `urllib2` — extensible library for opening URLs
20.7. `httplib` — HTTP protocol client
20.8. `ftplib` — FTP protocol client
20.9. `poplib` — POP3 protocol client
20.10. `imaplib` — IMAP4 protocol client
20.11. `nntplib` — NNTP protocol client
20.12. `smtplib` — SMTP protocol client
20.13. `smtpd` — SMTP Server
20.14. `telnetlib` — Telnet client
20.15. `uuid` — UUID objects according to RFC 4122
20.16. `urlparse` — Parse URLs into components
20.17. `SocketServer` — A framework for network servers
20.18. `BaseHTTPServer` — Basic HTTP server
20.19. `SimpleHTTPServer` — Simple HTTP request handler
20.20. `CGIHTTPServer` — CGI-capable HTTP request handler
20.21. `cookielib` — Cookie handling for HTTP clients
20.22. `Cookie` — HTTP state management
20.23. `xmlrpclib` — XML-RPC client access
20.24. `SimpleXMLRPCServer` — Basic XML-RPC server
20.25. `DocXMLRPCServer` — Self-documenting XML-RPC
server

- **21. Multimedia Services**
  - 21.1. `audioop` — Manipulate raw audio data
  - 21.2. `imageop` — Manipulate raw image data
  - 21.3. `aifc` — Read and write AIFF and AIFC files
  - 21.4. `sunau` — Read and write Sun AU files
  - 21.5. `wave` — Read and write WAV files
  - 21.6. `chunk` — Read IFF chunked data
  - 21.7. `colors` — Conversions between color systems
  - 21.8. `imghdr` — Determine the type of an image
  - 21.9. `sndhdr` — Determine type of sound file

- **22. Internationalization**
  - 22.1. `gettext` — Multilingual internationalization services
  - 22.2. `locale` — Internationalization services

- **23. Program Frameworks**
  - 23.1. `cmd` — Support for line-oriented command interpreters
  - 23.2. `shlex` — Simple lexical analysis

- **24. Development Tools**
  - 24.1. `pydoc` — Documentation generator and online help system
  - 24.2. `doctest` — Test interactive Python examples
  - 24.3. `unittest` — Unit testing framework
  - 24.4. `2to3` - Automated Python 2 to 3 code translation
  - 24.5. `test` — Regression tests package for Python
  - 24.6. `test.test_support` — Utility functions for tests

- **25. Debugging and Profiling**
  - 25.1. `bdb` — Debugger framework
  - 25.2. `pdb` — The Python Debugger
  - 25.3. Debugger Commands
  - 25.4. The Python Profilers
  - 25.5. `hotshot` — High performance logging profiler
  - 25.6. `timeit` — Measure execution time of small code
snippets
- 25.7. trace — Trace or track Python statement execution

- 26. Python Runtime Services
  - 26.1. sys — System-specific parameters and functions
  - 26.2. sysconfig — Provide access to Python’s configuration information
  - 26.3. __builtin__ — Built-in objects
  - 26.4. future_builtins — Python 3 builtins
  - 26.5. __main__ — Top-level script environment
  - 26.6. warnings — Warning control
  - 26.7. contextlib — Utilities for with-statement contexts
  - 26.8. abc — Abstract Base Classes
  - 26.9. atexit — Exit handlers
  - 26.10. traceback — Print or retrieve a stack traceback
  - 26.11. __future__ — Future statement definitions
  - 26.12. gc — Garbage Collector interface
  - 26.13. inspect — Inspect live objects
  - 26.14. site — Site-specific configuration hook
  - 26.15. user — User-specific configuration hook
  - 26.16. distutils — Building and installing Python modules

- 27. Custom Python Interpreters
  - 27.1. code — Interpreter base classes
  - 27.2. codeop — Compile Python code

- 28. Restricted Execution
  - 28.1. rexec — Restricted execution framework
  - 28.2. Bastion — Restricting access to objects

- 29. Importing Modules
  - 29.1. imp — Access the import internals
  - 29.2. importlib — Convenience wrappers for __import__()
29.5. **pkgutil** — Package extension utility
29.6. **modulefinder** — Find modules used by a script
29.7. **runpy** — Locating and executing Python modules

- **30. Python Language Services**
  - 30.1. **parser** — Access Python parse trees
  - 30.2. Abstract Syntax Trees
  - 30.3. **symtable** — Access to the compiler’s symbol tables
  - 30.4. **symbol** — Constants used with Python parse trees
  - 30.5. **token** — Constants used with Python parse trees
  - 30.6. **keyword** — Testing for Python keywords
  - 30.7. **tokenize** — Tokenizer for Python source
  - 30.8. **tabnanny** — Detection of ambiguous indentation
  - 30.9. **pyclbr** — Python class browser support
  - 30.10. **py_compile** — Compile Python source files
  - 30.11. **compileall** — Byte-compile Python libraries
  - 30.12. **dis** — Disassembler for Python bytecode
  - 30.13. **pickletools** — Tools for pickle developers

- **31. Python compiler package**
  - 31.1. The basic interface
  - 31.2. Limitations
  - 31.3. Python Abstract Syntax
  - 31.4. Using Visitors to Walk ASTs
  - 31.5. Bytecode Generation

- **32. Miscellaneous Services**
  - 32.1. **formatter** — Generic output formatting

- **33. MS Windows Specific Services**
  - 33.1. **_winreg** — Windows registry access

- **34. Undocumented Modules**
  - 34.1. Miscellaneous useful utilities
  - 34.2. Platform specific modules
  - 34.3. Multimedia
  - 34.4. Obsolete
34.5. SGI-specific Extension modules
This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in *The Python Standard Library*. For an informal introduction to the language, see *The Python Tutorial*. For C or C++ programmers, two additional manuals exist: *IronPython .NET API Reference Manual* describes the high-level picture of how to write a Python extension module.

Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project’s HOWTO collection, this collection is an effort to foster documentation that’s more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- Python Advocacy HOWTO
- Porting Extension Modules to 3.0
- Curses Programming with Python
- Descriptor HowTo Guide
- Idioms and Anti-Idioms in Python
- Functional Programming HOWTO
- Regular Expression HOWTO
- Socket Programming HOWTO
- Sorting HOW TO
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using urllib2
- HOWTO Use Python in the web
IronPython Hosting

Provides information on IronPython and DLR Hosting APIs.

The DLR hosting APIs provide a common way for hosting scripting languages on .NET. IronPython provides some specific extensions to these APIs to make getting started and performing IronPython specific behaviors simpler. This section provides an overview of both the DLR specific APIs and the IronPython extensions. For deeply interacting with IronPython please see :_extending-index

Installing Python Modules

Abstract

This document describes the Python Distribution Utilities ("Distutils") from the end-user’s point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.
Introduction

Although Python's extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don't need to know Python to read this document; there will be some brief forays into using Python's interactive mode to explore your installation, but that's it. If you're looking for information on how to distribute your own Python modules so that others may use them, see the Distributing Python Modules manual.

Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based
Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` it if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything—you might not even need to read any instructions (although it's always a good idea to do so anyways).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

The new standard: Distutils

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running

```
python setup.py install
```

If all these things are true, then you already know how to build and
install the modules you’ve just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don’t really need this manual. Or rather, the above command is everything you need to get out of this manual.
As described in section *The new standard: Distutils*, building and installing a module distribution using the Distutils is usually one simple command:

```
python setup.py install
```

On Unix, you’d run this command from a shell prompt; on Windows, you have to open a command prompt window (“DOS box”) and do it there; on Mac OS X, you open a **Terminal** window to get a shell prompt.

### Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you’ve just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -  # unpacks into directory
cd foo-1.0
python setup.py install
```

On Windows, you’d probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as `unzip` or `pkunzip`) to unpack the archive. Then, open a command prompt window (“DOS box”), and run:

```
cd C:\Temp\foo-1.0
```
Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```
python setup.py build
python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the `build` command is responsible for putting the files to install into a `build directory`. By default, this is `build` under the distribution root; if you’re excessively concerned with speed, or want
to keep the source tree pristine, you can change the build directory with the --build-base option. For example:

```
python setup.py build --build-base=/tmp/pybuild/foo-1.0
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section Distutils Configuration Files.) Normally, this isn’t necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
   temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.<plat>` directory holds temporary files generated by the compile/link process that don’t actually get installed. In either case, the `lib` (or `lib.<plat>`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.

**How installation works**

After the `build` command runs (whether you run it explicitly, or the `install` command does it for you), the work of the `install` command is
relatively simple: all it has to do is copy everything under build/lib (or build/lib.plat) to your chosen installation directory.

If you don’t choose an installation directory—i.e., if you just run setup.py install—then the install command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Standard installation location</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unix (pure)</td>
<td>prefix/lib/pythonX.Y/site-packages</td>
<td>/usr/local/lib/pythonX.Y/site-packages</td>
</tr>
<tr>
<td>Unix (non-pure)</td>
<td>exec-prefix/lib/pythonX.Y/site-packages</td>
<td>/usr/local/lib/pythonX.Y/site-packages</td>
</tr>
<tr>
<td>Windows</td>
<td>prefix</td>
<td>C:\Python</td>
</tr>
</tbody>
</table>

Notes:

1. Most Linux distributions include Python as a standard part of the system, so prefix and exec-prefix are usually both /usr on Linux. If you build Python yourself on Linux (or any Unix-like system), the default prefix and exec-prefix are /usr/local.

2. The default installation directory on Windows was C:\Program Files\Python under Python 1.6a1, 1.5.2, and earlier.

prefix and exec-prefix stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and Mac OS X. You can find out what your Python installation uses for prefix and exec-prefix by running Python in interactive
mode and typing a few simple commands. Under Unix, just type `python` at the shell prompt. Under Windows, choose Start ▷ Programs ▷ Python X.Y ▷ Python (command line). Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my prefix and exec-prefix:

```
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

If you don’t want to install modules to the standard location, or if you don’t have permission to write there, then you need to read about alternate installations in section Alternate Installation. If you want to customize your installation directories more heavily, see section Custom Installation on custom installations.
Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils `install` command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the `install` command picks a set of directories (called an *installation scheme*) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme's name is derived from the idea of a “home” directory on Unix, since it's not unusual for a Unix user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system their installing for.

Installing a new module distribution is as simple as

```bash
python setup.py install --home=<dir>
```

where you can supply any directory you like for the `--home` option.
On Unix, lazy typists can just type a tilde (~); the `install` command will expand this to your home directory:

```
python setup.py install --home=~
```

The `--home` option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td><code>home/lib/python</code></td>
<td><code>--install-purelib</code></td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td><code>home/lib/python</code></td>
<td><code>--install-platlib</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>home/bin</code></td>
<td><code>--install-scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>home/share</code></td>
<td><code>--install-data</code></td>
</tr>
</tbody>
</table>

*Changed in version 2.4:* The `--home` option used to be supported only on Unix.

**Alternate installation: Unix (the prefix scheme)**

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that's why the “home scheme” comes first. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python
modules from source, you probably want them to go in `/usr/local/lib/python2.X` rather than `/usr/lib/python2.X`. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.X`, but those modules would have to be installed to, say, `/mnt/@server/export/lib/python2.X`. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@server/export
```

In either case, the `--prefix` option defines the installation base, and the `--exec-prefix` option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If `--exec-prefix` is not supplied, it defaults to `--prefix`. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>--install-purelib</code></td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>--install-platlib</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix/bin</code></td>
<td><code>--install-scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix/share</code></td>
<td><code>--install-data</code></td>
</tr>
</tbody>
</table>

There is no requirement that `--prefix` or `--exec-prefix` actually point to an alternate Python installation; if the directories listed above do not
already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with `--prefix` and `--exec-prefix` supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix scheme, but every time you run `python setup.py install` without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your `--prefix` and `--exec-prefix` don't even point to an alternate Python installation, this is immaterial.)

### Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under Unix, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows. Files are installed as
follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td>prefix</td>
<td>--install-purelib</td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td>prefix</td>
<td>--install-platlib</td>
</tr>
<tr>
<td>scripts</td>
<td>prefix\Scripts</td>
<td>--install-scripts</td>
</tr>
<tr>
<td>data</td>
<td>prefix\Data</td>
<td>--install-data</td>
</tr>
</tbody>
</table>
Custom Installation

Sometimes, the alternate installation schemes described in section *Alternate Installation* just don’t do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you're creating a *custom installation scheme*.

You probably noticed the column of “override options” in the tables describing the alternate installation schemes above. Those options are how you define a custom installation scheme. These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same—they only differ when you use the Unix “prefix scheme” and supply different *--prefix* and *--exec-prefix* options.)

For example, say you’re installing a module distribution to your home directory under Unix—but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the *--install-scripts* option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another Unix example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the *--install-scripts* option:
python setup.py install --install-scripts=/usr/local/bin

(This performs an installation using the “prefix scheme,” where the prefix is whatever your Python interpreter was installed with—/usr/local/python in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of prefix, rather than right in prefix itself. This is almost as easy as customizing the script installation directory—you just have to remember that there are two types of modules to worry about, pure modules and non-pure modules (i.e., modules from a non-pure distribution). For example:

```
python setup.py install --install-purelib=Site --install-platlib=Site
```

The specified installation directories are relative to prefix. Of course, you also have to ensure that these directories are in Python’s module search path, such as by putting a .pth file in prefix. See section Modifying Python’s Search Path to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under python in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~
    --install-purelib=python/lib
    --install-platlib=python/lib.$PLAT
    --install-scripts=python/scripts
    --install-data=python/data
```
or, equivalently,

```
python setup.py install --home=~/.python \
   --install-purelib=lib \
   --install-platlib='lib.$PLAT' \
   --install-scripts=scripts \
   --install-data=data
```

$\text{PLAT}$ is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section Distutils Configuration Files):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are not equivalent if you supply a different installation base directory when you run the setup script. For example,

```
python setup.py install --install-base=/tmp
```
would install pure modules to /tmp/python/lib in the first case, and to /tmp/lib in the second case. (For the second case, you probably want to supply an installation base of /tmp/python.)

You probably noticed the use of $HOME and $PLAT in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as $PLAT. (And of course, on systems that don’t have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section Distutils Configuration Files for details.

### Modifying Python’s Search Path

When the Python interpreter executes an import statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the sys module and printing the value of sys.path.

$ python
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> import sys
>>> sys.path

The null string in sys.path represents the current working directory.
The expected convention for locally installed packages is to put them in the `.../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `.../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can’t use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the `site` module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```python
import sys
sys.path.append('/www/python/)
```

However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You’d have to remember that it was
modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. `PYTHONHOME` sets an alternate value for the prefix of the Python installation. For example, if `PYTHONHOME` is set to `/www/python`, the search path will be set to `['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/plat-linux2', ...]`.

The `PYTHONPATH` variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if `PYTHONPATH` is set to `/www/python:/opt/py`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the `site` module removes paths that don't exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.
**Distutils Configuration Files**

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

**Location and names of config files**

The names and locations of the configuration files vary slightly across platforms. On Unix and Mac OS X, the three configuration files (in the order they are processed) are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td><code>prefix/lib/pythonver/distutils/distutils.cfg</code></td>
<td>(1)</td>
</tr>
<tr>
<td>personal</td>
<td><code>$HOME/.pydistutils.cfg</code></td>
<td>(2)</td>
</tr>
<tr>
<td>local</td>
<td><code>setup.cfg</code></td>
<td>(3)</td>
</tr>
</tbody>
</table>

And on Windows, the configuration files are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>

</tbody>
</table>

On all platforms, the “personal” file can be temporarily disabled by passing the `–no-user-cfg` option.
Notes:

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to `prefix/lib/python1.5/site-packages/distutils`, so the system configuration file should be put there under Python 1.5.2.
2. On Unix, if the `HOME` environment variable is not defined, the user’s home directory will be determined with the `getpwuid()` function from the standard `pwd` module. This is done by the `os.path.expanduser()` function used by Distutils.
3. I.e., in the current directory (usually the location of the setup script).
4. (See also note (1).) Under Python 1.6 and later, Python’s default “installation prefix” is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the default prefix was `C:\Program Files\Python`, and the Distutils were not part of the standard library—so the system configuration file would be `C:\Program Files\Python\distutils\distutils.cfg` in a standard Python 1.5.2 installation under Windows.
5. On Windows, if the `HOME` environment variable is not defined, `USERPROFILE` then `HOMEDRIVE` and `HOMEPATH` will be tried. This is done by the `os.path.expanduser()` function used by Distutils.

Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a `global` section for global options that affect every command. Each section consists of one option per line, specified as
For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the `build*` commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the `build` command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the `--help` option, e.g.:
and you can find out the complete list of global options by using `--help` without a command:

```
python setup.py --help
```

See also the “Reference” section of the “Distributing Python Modules” manual.
Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

### Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn't been tested on your platform, or if you're trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let's examine each of the fields in turn.

- *module* is the name of the extension module to be built, and
should be a valid Python identifier. You can’t just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.

- **sourcefile** is anything that’s likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.c`, `.cc`, and `.cpp` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- **cpparg** is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.
- **library** is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the `Setup` file and running `python setup.py build`. For example, if the module defined by the line

```
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you’ll have to supply multiple `-Xcompiler` options; for example, to pass `-x c++` the `Setup` file would have to contain `-Xcompiler -x -Xcompiler c++`. 
Compiler flags can also be supplied through setting the $CFLAGS$ environment variable. If set, the contents of $CFLAGS$ will be added to the compiler flags specified in the setup file.

Using non-Microsoft compilers on Windows

Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland's object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python's library `python25.lib` into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn’t find such a special library it uses the default name (`foo.lib`.) [1]

To let Distutils compile your extension with Borland C++ you now
have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

See also:

**C++Builder Compiler**
Information about the free C++ compiler from Borland, including links to the download pages.

**Creating Python Extensions Using Borland's Free Compiler**
Document describing how to use Borland's free command-line C++ compiler to build Python.

**GNU C / Cygwin / MinGW**

These instructions only apply if you're using a version of Python prior to 2.4.1 with a MinGW prior to 3.0.0 (with binutils-2.13.90-20030111-1).

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. [2] For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

These compilers require some special libraries. This task is more complex than for Borland's C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at [http://www.emmestech.com/software/pexports-0.43/download_pexports.html](http://www.emmestech.com/software/pexports-0.43/download_pexports.html)).
pexports python25.dll >python25.def

The location of an installed python25.dll will depend on the installation options and the version and language of Windows. In a “just for me” installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.

/cygwin/bin/dlltool --dllname python25.dll --def python25.def --output-lib libpython25.a

The resulting library has to be placed in the same directory as python25.lib. (Should be the libs directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

To let Distutils compile your extension with Cygwin you now have to type

python setup.py build --compiler=cygwin

and for Cygwin in no-cygwin mode [3] or for MinGW type:

python setup.py build --compiler=mingw32

If you want to use any of these options/compilers as default, you should consider to write it in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

See also:
Building Python modules on MS Windows platform with MinGW

Information about building the required libraries for the MinGW environment.

Footnotes

[1] This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

Check http://sources.redhat.com/cygwin/ and http://www.mingw.org/ for more information

[3] Then you have no POSIX emulation available, but you also don't need cygwin1.dll.
This document describes the Python Distribution Utilities ("Distutils") from the module developer’s point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

- **1. An Introduction to Distutils**
  - 1.1. Concepts & Terminology

11.28. **distutils.command.bdist_dumb** — Build a “dumb” installer
11.29. **distutils.command.bdist_msi** — Build a Microsoft Installer binary package
11.30. **distutils.command.bdist_rpm** — Build a binary distribution as a Redhat RPM and SRPM
11.31. **distutils.command.bdist_wininst** — Build a Windows installer
11.32. **distutils.command.sdist** — Build a source distribution
11.33. **distutils.command.build** — Build all files of a package
11.34. **distutils.command.build_clib** — Build any C libraries in a package
- 11.35. distutils.command.build_ext — Build any extensions in a package
- 11.36. distutils.command.build_py — Build the .py/.pyc files of a package
- 11.37. distutils.command.build_scripts — Build the scripts of a package
- 11.38. distutils.command.clean — Clean a package build area
- 11.39. distutils.command.config — Perform package configuration
- 11.40. distutils.command.install — Install a package
- 11.41. distutils.command.install_data — Install data files from a package
- 11.42. distutils.command.install_headers — Install C/C++ header files from a package
- 11.43. distutils.command.install_lib — Install library files from a package
- 11.44. distutils.command.install_scripts — Install script files from a package
- 11.45. distutils.command.register — Register a module with the Python Package Index
- 11.46. Creating a new Distutils command
The Python language has a substantial body of documentation, much of it contributed by various authors. The markup used for the Python documentation is reStructuredText, developed by the docutils project, amended by custom directives and using a toolset named Sphinx to postprocess the HTML output.

This document describes the style guide for our documentation as well as the custom reStructuredText markup introduced by Sphinx to support Python documentation and how it should be used.

**Note:** If you’re interested in contributing to Python’s documentation, there’s no need to write reStructuredText if you’re not so inclined; plain text contributions are more than welcome as well. Send an e-mail to docs@python.org or open an issue on the tracker.

      5.2.2. Literals
      5.2.3. Parenthesized forms
      5.2.4. List displays
      5.2.5. Displays for sets and dictionaries
      5.2.6. Generator expressions
      5.2.7. Dictionary displays
      5.2.8. Set displays
      5.2.9. String conversions
      5.2.10. Yield expressions
   5.3. Primaries
      5.3.1. Attribute references
      5.3.2. Subscriptions
      5.3.3. Slicings
      5.3.4. Calls
   5.4. The power operator
   5.5. Unary arithmetic and bitwise operations
   5.6. Binary arithmetic operations
   5.7. Shifting operations
   5.8. Binary bitwise operations
   5.9. Comparisons
   5.10. Boolean operations
   5.11. Conditional Expressions
   5.12. Lambdas
   5.13. Expression lists
   5.14. Evaluation order
   5.15. Summary
6. Simple statements
   - 6.1. Expression statements
   - 6.2. Assignment statements
     - 6.2.1. Augmented assignment statements
   - 6.3. The `assert` statement
   - 6.4. The `pass` statement
   - 6.5. The `del` statement
   - 6.6. The `print` statement
   - 6.7. The `return` statement
   - 6.8. The `yield` statement
   - 6.9. The `raise` statement
   - 6.10. The `break` statement
   - 6.11. The `continue` statement
   - 6.12. The `import` statement
     - 6.12.1. Future statements
   - 6.13. The `global` statement
   - 6.14. The `exec` statement

7. Compound statements
   - 7.1. The `if` statement
   - 7.2. The `while` statement
   - 7.3. The `for` statement
   - 7.4. The `try` statement
   - 7.5. The `with` statement
   - 7.6. Function definitions
   - 7.7. Class definitions

8. Top-level components
   - 8.1. Complete Python programs
   - 8.2. File input
   - 8.3. Interactive input
   - 8.4. Expression input

9. Full Grammar specification
   - The Python Standard Library
1. Introduction
2. Built-in Functions
3. Non-essential Built-in Functions
4. Built-in Constants
   - 4.1. Constants added by the site module
5. Built-in Types
   - 5.1. Truth Value Testing
   - 5.2. Boolean Operations — and, or, not
   - 5.3. Comparisons
   - 5.4. Numeric Types — int, float, long, complex
     - 5.4.1. Bit-string Operations on Integer Types
     - 5.4.2. Additional Methods on Integer Types
     - 5.4.3. Additional Methods on Float
   - 5.5. Iterator Types
     - 5.5.1. Generator Types
   - 5.6. Sequence Types — str, unicode, list, tuple, buffer, xrange
     - 5.6.1. String Methods
     - 5.6.2. String Formatting Operations
     - 5.6.3. XRange Type
     - 5.6.4. Mutable Sequence Types
   - 5.7. Set Types — set, frozenset
   - 5.8. Mapping Types — dict
     - 5.8.1. Dictionary view objects
   - 5.9. File Objects
   - 5.10. memoryview type
   - 5.11. Context Manager Types
   - 5.12. Other Built-in Types
     - 5.12.1. Modules
     - 5.12.2. Classes and Class Instances
     - 5.12.3. Functions
     - 5.12.4. Methods
     - 5.12.5. Code Objects
- 5.12.6. Type Objects
- 5.12.7. The Null Object
- 5.12.8. The Ellipsis Object
- 5.12.9. Boolean Values
- 5.12.10. Internal Objects
- 5.13. Special Attributes
- 6. Built-in Exceptions
  - 6.1. Exception hierarchy
- 7. String Services
  - 7.1. `string` — Common string operations
    - 7.1.1. String constants
    - 7.1.2. String Formatting
    - 7.1.3. Format String Syntax
      - 7.1.3.1. Format Specification Mini-Language
      - 7.1.3.2. Format examples
    - 7.1.4. Template strings
    - 7.1.5. String functions
    - 7.1.6. Deprecated string functions
  - 7.2. `re` — Regular expression operations
    - 7.2.1. Regular Expression Syntax
    - 7.2.2. Matching vs Searching
    - 7.2.3. Module Contents
    - 7.2.4. Regular Expression Objects
    - 7.2.5. Match Objects
    - 7.2.6. Examples
      - 7.2.6.1. Checking For a Pair
      - 7.2.6.2. Simulating `scanf()`
      - 7.2.6.3. Avoiding recursion
      - 7.2.6.4. `search()` vs. `match()`
      - 7.2.6.5. Making a Phonebook
      - 7.2.6.6. Text Munging
      - 7.2.6.7. Finding all Adverbs
      - 7.2.6.8. Finding all Adverbs and their Positions
- 7.2.6.9. Raw String Notation
- 7.3. struct — Interpret strings as packed binary data
  - 7.3.1. Functions and Exceptions
  - 7.3.2. Format Strings
    - 7.3.2.1. Byte Order, Size, and Alignment
    - 7.3.2.2. Format Characters
    - 7.3.2.3. Examples
  - 7.3.3. Classes
- 7.4. difflib — Helpers for computing deltas
  - 7.4.1. SequenceMatcher Objects
  - 7.4.2. SequenceMatcher Examples
  - 7.4.3. Differ Objects
  - 7.4.4. Differ Example
  - 7.4.5. A command-line interface to difflib
- 7.5. StringIO — Read and write strings as files
- 7.6. cStringIO — Faster version of StringIO
- 7.7. textwrap — Text wrapping and filling
- 7.8. codecs — Codec registry and base classes
  - 7.8.1. Codec Base Classes
    - 7.8.1.1. Codec Objects
    - 7.8.1.2. IncrementalEncoder Objects
    - 7.8.1.3. IncrementalDecoder Objects
    - 7.8.1.4. StreamWriter Objects
    - 7.8.1.5. StreamReader Objects
    - 7.8.1.6. StreamReaderWriter Objects
    - 7.8.1.7. StreamRecoder Objects
  - 7.8.2. Encodings and Unicode
  - 7.8.3. Standard Encodings
    - 7.8.4. encodings.idna — Internationalized Domain Names in Applications
  - 7.8.5. encodings.utf_8_sig — UTF-8 codec with BOM signature
- 7.9. unicodedata — Unicode Database
7.10. stringprep — Internet String Preparation
7.11. fpformat — Floating point conversions

8. Data Types

8.1. datetime — Basic date and time types
  8.1.1. Available Types
  8.1.2. timedelta Objects
  8.1.3. date Objects
  8.1.4. datetime Objects
  8.1.5. time Objects
  8.1.6. tzinfo Objects
  8.1.7. strftime() and strptime() Behavior

8.2. calendar — General calendar-related functions

8.3. collections — High-performance container datatypes
  8.3.1. ABCs - abstract base classes
  8.3.2. counter objects
  8.3.3. deque objects
    8.3.3.1. deque Recipes
  8.3.4. defaultdict objects
    8.3.4.1. defaultdict Examples
  8.3.5. namedtuple() Factory Function for Tuples with Named Fields
  8.3.6. OrderedDict objects

8.4. heapq — Heap queue algorithm
  8.4.1. Theory

8.5. bisect — Array bisection algorithm
  8.5.1. Examples

8.6. array — Efficient arrays of numeric values

8.7. sets — Unordered collections of unique elements
  8.7.1. Set Objects
  8.7.2. Example
  8.7.3. Protocol for automatic conversion to
immutable
- 8.7.4. Comparison to the built-in set types
- 8.8. sched — Event scheduler
  - 8.8.1. Scheduler Objects
- 8.9. mutex — Mutual exclusion support
  - 8.9.1. Mutex Objects
- 8.10. queue — A synchronized queue class
  - 8.10.1. Queue Objects
- 8.11. weakref — Weak references
  - 8.11.1. Weak Reference Objects
  - 8.11.2. Example
- 8.12. UserDict — Class wrapper for dictionary objects
- 8.13. UserList — Class wrapper for list objects
- 8.15. types — Names for built-in types
- 8.16. new — Creation of runtime internal objects
- 8.17. copy — Shallow and deep copy operations
- 8.18. pprint — Data pretty printer
  - 8.18.1. PrettyPrinter Objects
  - 8.18.2. pprint Example
- 8.19. repr — Alternate repr() implementation
  - 8.19.1. Repr Objects
  - 8.19.2. Subclassing Repr Objects
- 9. Numeric and Mathematical Modules
  - 9.1. numbers — Numeric abstract base classes
    - 9.1.1. The numeric tower
    - 9.1.2. Notes for type implementors
      - 9.1.2.1. Adding More Numeric ABCs
      - 9.1.2.2. Implementing the arithmetic operations
  - 9.2. math — Mathematical functions
    - 9.2.1. Number-theoretic and representation
functions

- 9.2.2. Power and logarithmic functions
- 9.2.3. Trigonometric functions
- 9.2.4. Angular conversion
- 9.2.5. Hyperbolic functions
- 9.2.6. Special functions
- 9.2.7. Constants

- 9.3. cmath — Mathematical functions for complex numbers
  - 9.3.1. Conversions to and from polar coordinates
  - 9.3.2. Power and logarithmic functions
  - 9.3.3. Trigonometric functions
  - 9.3.4. Hyperbolic functions
  - 9.3.5. Classification functions
  - 9.3.6. Constants

- 9.4. decimal — Decimal fixed point and floating point arithmetic
  - 9.4.1. Quick-start Tutorial
  - 9.4.2. Decimal objects
    - 9.4.2.1. Logical operands
  - 9.4.3. Context objects
  - 9.4.4. Signals
  - 9.4.5. Floating Point Notes
    - 9.4.5.1. Mitigating round-off error with increased precision
    - 9.4.5.2. Special values
  - 9.4.6. Working with threads
  - 9.4.7. Recipes
  - 9.4.8. Decimal FAQ

- 9.5. fractions — Rational numbers

- 9.6. random — Generate pseudo-random numbers

- 9.7. itertools — Functions creating iterators for efficient looping
  - 9.7.1. Itertool functions
- 9.7.2. Recipes
- 9.8. functools — Higher order functions and operations on callable objects
  - 9.8.1. partial Objects
- 9.9. operator — Standard operators as functions
  - 9.9.1. Mapping Operators to Functions
- 10. File and Directory Access
  - 10.1. os.path — Common pathname manipulations
  - 10.2. fileinput — Iterate over lines from multiple input streams
  - 10.3. stat — Interpreting stat() results
  - 10.4. statvfs — Constants used with os.statvfs()
  - 10.5. filecmp — File and Directory Comparisons
    - 10.5.1. The dircmp class
  - 10.6. tempfile — Generate temporary files and directories
  - 10.7. glob — Unix style pathname pattern expansion
  - 10.8. fnmatch — Unix filename pattern matching
  - 10.9. linecache — Random access to text lines
  - 10.10. shutil — High-level file operations
    - 10.10.1. Directory and files operations
      - 10.10.1.1. copytree example
    - 10.10.2. Archives operations
      - 10.10.2.1. Archiving example
  - 10.11. dircache — Cached directory listings
- 11. Data Persistence
  - 11.1. pickle — Python object serialization
    - 11.1.1. Relationship to other Python modules
    - 11.1.2. Data stream format
    - 11.1.3. Usage
    - 11.1.4. What can be pickled and unpickled?
    - 11.1.5. The pickle protocol
- 11.1.5.1. Pickling and unpickling normal class instances
- 11.1.5.2. Pickling and unpickling extension types
- 11.1.5.3. Pickling and unpickling external objects
- 11.1.6. Subclassing Unpicklers
- 11.1.7. Example
- 11.2. cPickle — A faster pickle
- 11.3. copy_reg — Register pickle support functions
- 11.4. shelve — Python object persistence
  - 11.4.1. Restrictions
  - 11.4.2. Example
- 11.5. marshal — Internal Python object serialization
- 11.6. anydbm — Generic access to DBM-style databases
- 11.7. whichdb — Guess which DBM module created a database
- 11.8. dbhash — DBM-style interface to the BSD database library
  - 11.8.1. Database Objects
- 11.9. dumbdbm — Portable DBM implementation
  - 11.9.1. Dumbdbm Objects
- 11.10. sqlite3 — DB-API 2.0 interface for SQLite databases
  - 11.10.1. Module functions and constants
  - 11.10.2. Connection Objects
  - 11.10.3. Cursor Objects
  - 11.10.4. Row Objects
  - 11.10.5. SQLite and Python types
    - 11.10.5.1. Introduction
    - 11.10.5.2. Using adapters to store additional Python types in SQLite databases
- 11.10.5.2.1. Letting your object adapt itself
- 11.10.5.2.2. Registering an adapter callable
- 11.10.5.3. Converting SQLite values to custom Python types
- 11.10.5.4. Default adapters and converters
- 11.10.6. Controlling Transactions
- 11.10.7. Using sqlite3 efficiently
  - 11.10.7.1. Using shortcut methods
  - 11.10.7.2. Accessing columns by name instead of by index
  - 11.10.7.3. Using the connection as a context manager
- 12. Data Compression and Archiving
  - 12.1. zlib — Compression compatible with gzip
  - 12.2. gzip — Support for gzip files
    - 12.2.1. Examples of usage
  - 12.3. bz2 — Compression compatible with bzip2
    - 12.3.1. (De)compression of files
    - 12.3.2. Sequential (de)compression
    - 12.3.3. One-shot (de)compression
  - 12.4. zipfile — Work with ZIP archives
    - 12.4.1. ZipFile Objects
    - 12.4.2. PyZipFile Objects
    - 12.4.3. ZipInfo Objects
  - 12.5. tarfile — Read and write tar archive files
    - 12.5.1. TarFile Objects
    - 12.5.2. TarInfo Objects
    - 12.5.3. Examples
    - 12.5.4. Supported tar formats
    - 12.5.5. Unicode issues
- 13. File Formats
13.1. csv — CSV File Reading and Writing
   - 13.1.1. Module Contents
   - 13.1.2. Dialects and Formatting Parameters
   - 13.1.3. Reader Objects
   - 13.1.4. Writer Objects
   - 13.1.5. Examples

13.2. ConfigParser — Configuration file parser
   - 13.2.1. RawConfigParser Objects
   - 13.2.2. ConfigParser Objects
   - 13.2.3. SafeConfigParser Objects
   - 13.2.4. Examples

13.3. robotparser — Parser for robots.txt

13.4. netrc — netrc file processing
   - 13.4.1. netrc Objects

13.5. xdrlib — Encode and decode XDR data
   - 13.5.1. Packer Objects
   - 13.5.2. Unpacker Objects
   - 13.5.3. Exceptions

13.6. plistlib — Generate and parse Mac OS X .plist files
   - 13.6.1. Examples

14. Cryptographic Services
   - 14.1. hashlib — Secure hashes and message digests
   - 14.2. hmac — Keyed-Hashing for Message Authentication
   - 14.3. md5 — MD5 message digest algorithm
   - 14.4. sha — SHA-1 message digest algorithm

15. Generic Operating System Services
   - 15.1. os — Miscellaneous operating system interfaces
     - 15.1.1. Process Parameters
     - 15.1.2. File Object Creation
     - 15.1.3. File Descriptor Operations
       - 15.1.3.1. open() flag constants
15.1.4. Files and Directories
15.1.5. Process Management
15.1.6. Miscellaneous System Information
15.1.7. Miscellaneous Functions

15.2. io — Core tools for working with streams
  15.2.1. Module Interface
  15.2.2. I/O Base Classes
  15.2.3. Raw File I/O
  15.2.4. Buffered Streams
  15.2.5. Text I/O

15.3. time — Time access and conversions

15.4. argparse — Parser for command line options, arguments and sub-commands
  15.4.1. Example
    15.4.1.1. Creating a parser
    15.4.1.2. Adding arguments
    15.4.1.3. Parsing arguments
  15.4.2. ArgumentParser objects
    15.4.2.1. description
    15.4.2.2. epilog
    15.4.2.3. add_help
    15.4.2.4. prefix_chars
    15.4.2.5. fromfile_prefix_chars
    15.4.2.6. argument_default
    15.4.2.7. parents
    15.4.2.8. formatter_class
    15.4.2.9. conflict_handler
    15.4.2.10. prog
    15.4.2.11. usage
  15.4.3. The add_argument() method
    15.4.3.1. name or flags
    15.4.3.2. action
    15.4.3.3. nargs
    15.4.3.4. const
- 15.4.3.5. default
- 15.4.3.6. type
- 15.4.3.7. choices
- 15.4.3.8. required
- 15.4.3.9. help
- 15.4.3.10. metavar
- 15.4.3.11. dest

- 15.4.4. The parse_args() method
  - 15.4.4.1. Option value syntax
  - 15.4.4.2. Invalid arguments
  - 15.4.4.3. Arguments containing "-"
  - 15.4.4.4. Argument abbreviations
  - 15.4.4.5. Beyond sys.argv
  - 15.4.4.6. Custom namespaces

- 15.4.5. Other utilities
  - 15.4.5.1. Sub-commands
  - 15.4.5.2. FileType objects
  - 15.4.5.3. Argument groups
  - 15.4.5.4. Mutual exclusion
  - 15.4.5.5. Parser defaults
  - 15.4.5.6. Printing help
  - 15.4.5.7. Partial parsing
  - 15.4.5.8. Customizing file parsing

- 15.4.6. Upgrading optparse code

- 15.5. optparse — Parser for command line options

- 15.5.1. Background
  - 15.5.1.1. Terminology
  - 15.5.1.2. What are options for?
  - 15.5.1.3. What are positional arguments for?

- 15.5.2. Tutorial
  - 15.5.2.1. Understanding option actions
  - 15.5.2.2. The store action
  - 15.5.2.3. Handling boolean (flag) options
  - 15.5.2.4. Other actions
- 15.5.2.5. Default values
- 15.5.2.6. Generating help
- 15.5.2.7. Printing a version string
- 15.5.2.8. How optparse handles errors
- 15.5.2.9. Putting it all together

- 15.5.3. Reference Guide
  - 15.5.3.1. Creating the parser
  - 15.5.3.2. Populating the parser
  - 15.5.3.3. Defining options
  - 15.5.3.4. Option attributes
  - 15.5.3.5. Standard option actions
  - 15.5.3.6. Standard option types
  - 15.5.3.7. Parsing arguments
  - 15.5.3.8. Querying and manipulating your option parser
  - 15.5.3.9. Conflicts between options
  - 15.5.3.10. Cleanup
  - 15.5.3.11. Other methods

- 15.5.4. Option Callbacks
  - 15.5.4.1. Defining a callback option
  - 15.5.4.2. How callbacks are called
  - 15.5.4.3. Raising errors in a callback
  - 15.5.4.4. Callback example 1: trivial callback
  - 15.5.4.5. Callback example 2: check option order
  - 15.5.4.6. Callback example 3: check option order (generalized)
  - 15.5.4.7. Callback example 4: check arbitrary condition
  - 15.5.4.8. Callback example 5: fixed arguments
  - 15.5.4.9. Callback example 6: variable arguments

- 15.5.5. Extending optparse
- 15.5.5.1. Adding new types
- 15.5.5.2. Adding new actions
- 15.6. getopt — C-style parser for command line options
- 15.7. logging — Logging facility for Python
  - 15.7.1. Logging tutorial
    - 15.7.1.1. Simple examples
    - 15.7.1.2. Loggers
    - 15.7.1.3. Handlers
    - 15.7.1.4. Formatters
    - 15.7.1.5. Configuring Logging
    - 15.7.1.6. Configuring Logging for a Library
  - 15.7.2. Logging Levels
  - 15.7.3. Useful Handlers
  - 15.7.4. Module-Level Functions
  - 15.7.5. Logger Objects
  - 15.7.6. Basic example
  - 15.7.7. Logging to multiple destinations
  - 15.7.8. Exceptions raised during logging
  - 15.7.9. Adding contextual information to your logging output
  - 15.7.10. Logging to a single file from multiple processes
  - 15.7.11. Sending and receiving logging events across a network
  - 15.7.12. Using arbitrary objects as messages
  - 15.7.13. Optimization
  - 15.7.14. Handler Objects
    - 15.7.14.2. FileHandler
    - 15.7.14.3. NullHandler
    - 15.7.14.4. WatchedFileHandler
    - 15.7.14.5. RotatingFileHandler
    - 15.7.14.6. TimedRotatingFileHandler
- 15.7.14.7. SocketHandler
- 15.7.14.10. NTEventLogHandler
- 15.7.14.11. SMTPHandler
- 15.7.14.13. HTTPHandler

- 15.7.15. Formatter Objects
- 15.7.16. Filter Objects
- 15.7.17. LogRecord Objects
- 15.7.18. LoggerAdapter Objects
- 15.7.19. Thread Safety
- 15.7.20. Integration with the warnings module

- 15.7.21. Configuration
  - 15.7.21.1. Configuration functions
  - 15.7.21.2. Configuration dictionary schema
    - 15.7.21.2.1. Dictionary Schema Details
    - 15.7.21.2.2. Incremental Configuration
    - 15.7.21.2.3. Object connections
    - 15.7.21.2.4. User-defined objects
    - 15.7.21.2.5. Access to external objects
    - 15.7.21.2.6. Access to internal objects
  - 15.7.21.3. Configuration file format
  - 15.7.21.4. Configuration server example
- 15.7.22. More examples
  - 15.7.22.1. Multiple handlers and formatters
  - 15.7.22.2. Using logging in multiple modules

- 15.8. getpass — Portable password input
- 15.9. curses — Terminal handling for character-cell displays
  - 15.9.1. Functions
  - 15.9.2. Window Objects
  - 15.9.3. Constants
- 15.10. curses.textpad — Text input widget for curses
15.10.1. Textbox objects

15.11. curses.wrapper — Terminal handler for curses programs

15.12. curses.ascii — Utilities for ASCII characters

15.13. curses.panel — A panel stack extension for curses
   - 15.13.1. Functions
   - 15.13.2. Panel Objects

15.14. platform — Access to underlying platform’s identifying data
     - 15.14.3.1. Win95/98 specific
   - 15.14.5. Unix Platforms

15.15. errno — Standard errno system symbols

15.16. ctypes — A foreign function library for Python
   - 15.16.1. ctypes tutorial
     - 15.16.1.1. Loading dynamic link libraries
     - 15.16.1.2. Accessing functions from loaded dlls
     - 15.16.1.3. Calling functions
     - 15.16.1.4. Fundamental data types
     - 15.16.1.5. Calling functions, continued
     - 15.16.1.6. Calling functions with your own custom data types
     - 15.16.1.7. Specifying the required argument types (function prototypes)
     - 15.16.1.8. Return types
     - 15.16.1.9. Passing pointers (or: passing parameters by reference)
- 15.16.1.10. Structures and unions
- 15.16.1.11. Structure/union alignment and byte order
- 15.16.1.12. Bit fields in structures and unions
- 15.16.1.13. Arrays
- 15.16.1.15. Type conversions
- 15.16.1.16. Incomplete Types
- 15.16.1.17. Callback functions
- 15.16.1.18. Accessing values exported from dlls
- 15.16.1.19. Surprises
- 15.16.1.20. Variable-sized data types
- 15.16.2. ctypes reference
  - 15.16.2.1. Finding shared libraries
  - 15.16.2.2. Loading shared libraries
  - 15.16.2.3. Foreign functions
  - 15.16.2.4. Function prototypes
  - 15.16.2.5. Utility functions
  - 15.16.2.6. Data types
  - 15.16.2.7. Fundamental data types
  - 15.16.2.8. Structured data types
  - 15.16.2.9. Arrays and pointers
- 16. Optional Operating System Services
  - 16.1. select — Waiting for I/O completion
    - 16.1.1. Edge and Level Trigger Polling (epoll) Objects
    - 16.1.2. Polling Objects
    - 16.1.3. Kqueue Objects
    - 16.1.4. Kevent Objects
  - 16.2. threading — Higher-level threading interface
    - 16.2.1. Thread Objects
    - 16.2.2. Lock Objects
    - 16.2.3. RLock Objects
16.2.4. Condition Objects
16.2.5. Semaphore Objects
  - 16.2.5.1. Semaphore Example
16.2.6. Event Objects
16.2.7. Timer Objects
16.2.8. Using locks, conditions, and semaphores in the with statement
16.2.9. Importing in threaded code

16.3. thread — Multiple threads of control
16.4. dummy_threading — Drop-in replacement for the threading module
16.5. dummy_thread — Drop-in replacement for the thread module
16.6. multiprocessing — Process-based “threading” interface
  - 16.6.1. Introduction
    - 16.6.1.1. The Process class
    - 16.6.1.2. Exchanging objects between processes
    - 16.6.1.3. Synchronization between processes
    - 16.6.1.4. Sharing state between processes
    - 16.6.1.5. Using a pool of workers
  - 16.6.2. Reference
    - 16.6.2.1. Process and exceptions
    - 16.6.2.2. Pipes and Queues
    - 16.6.2.3. Miscellaneous
    - 16.6.2.4. Connection Objects
    - 16.6.2.5. Synchronization primitives
    - 16.6.2.6. Shared ctypes Objects
      - 16.6.2.6.1. The multiprocessing.sharedctypes module
    - 16.6.2.7. Managers
      - 16.6.2.7.1. Namespace objects
16.6.2.7.2. Customized managers
16.6.2.7.3. Using a remote manager
16.6.2.8. Proxy Objects
   16.6.2.8.1. Cleanup
16.6.2.9. Process Pools
16.6.2.10. Listeners and Clients
   16.6.2.10.1. Address Formats
16.6.2.11. Authentication keys
16.6.2.12. Logging
16.6.2.13. The multiprocessing.dummy module
16.6.3. Programming guidelines
   16.6.3.1. All platforms
   16.6.3.2. Windows
16.6.4. Examples
16.7. rlcompleter — Completion function for GNU readline
   16.7.1. Completer Objects
17. Interprocess Communication and Networking
   17.1. subprocess — Subprocess management
      17.1.1. Using the subprocess Module
         17.1.1.1. Convenience Functions
         17.1.1.2. Exceptions
         17.1.1.3. Security
      17.1.2. Popen Objects
      17.1.3. Replacing Older Functions with the subprocess Module
         17.1.3.1. Replacing /bin/sh shell backquote
         17.1.3.2. Replacing shell pipeline
         17.1.3.3. Replacing os.system()
         17.1.3.4. Replacing the os.spawn family
         17.1.3.5. Replacing os.popen(), os.popen2(), os.popen3()
         17.1.3.6. Replacing functions from the popen2
module

- **17.2. socket** — Low-level networking interface
  - 17.2.1. Socket Objects
  - 17.2.2. Example

- **17.3. ssl** — SSL wrapper for socket objects
  - 17.3.1. Functions, Constants, and Exceptions
  - 17.3.2. SSLSocket Objects
  - 17.3.3. Certificates
  - 17.3.4. Examples
    - 17.3.4.1. Testing for SSL support
    - 17.3.4.2. Client-side operation
    - 17.3.4.3. Server-side operation

- **17.4. signal** — Set handlers for asynchronous events
  - 17.4.1. Example

- **17.5. popen2** — Subprocesses with accessible I/O streams
  - 17.5.1. Popen3 and Popen4 Objects
  - 17.5.2. Flow Control Issues

- **17.6. asyncore** — Asynchronous socket handler
  - 17.6.1. asyncore Example basic HTTP client

- **17.7. asynchat** — Asynchronous socket command/response handler
  - 17.7.1. asynchat - Auxiliary Classes
  - 17.7.2. asynchat Example

- **18. Internet Data Handling**
  - **18.1. email** — An email and MIME handling package
    - 18.1.1. email: Representing an email message
    - 18.1.2. email: Parsing email messages
      - 18.1.2.1. FeedParser API
      - 18.1.2.2. Parser class API
      - 18.1.2.3. Additional notes
    - 18.1.3. email: Generating MIME documents
    - 18.1.4. email: Creating email and MIME objects
from scratch

- 18.1.5. email: Internationalized headers
- 18.1.6. email: Representing character sets
- 18.1.7. email: Encoders
- 18.1.8. email: Exception and Defect classes
- 18.1.9. email: Miscellaneous utilities
- 18.1.10. email: Iterators
- 18.1.11. email: Examples
- 18.1.12. Package History
- 18.1.13. Differences from mimelib

- 18.2. json — JSON encoder and decoder
  - 18.2.1. Basic Usage
  - 18.2.2. Encoders and decoders

- 18.3. mailcap — Mailcap file handling

- 18.4. mailbox — Manipulate mailboxes in various formats
  - 18.4.1. Mailbox objects
    - 18.4.1.1. Maildir
    - 18.4.1.2. mbox
    - 18.4.1.3. MH
    - 18.4.1.4. Babyl
    - 18.4.1.5. MMDF
  - 18.4.2. Message objects
    - 18.4.2.1. MaildirMessage
    - 18.4.2.2. mboxMessage
    - 18.4.2.3. MHMessage
    - 18.4.2.4. BabylMessage
    - 18.4.2.5. MMDFMessage
  - 18.4.3. Exceptions
  - 18.4.4. Deprecated classes and methods
  - 18.4.5. Examples
18.5. **mhlib** — Access to MH mailboxes
   - 18.5.1. MH Objects
   - 18.5.2. Folder Objects
   - 18.5.3. Message Objects

18.6. **mimetools** — Tools for parsing MIME messages
   - 18.6.1. Additional Methods of Message Objects

18.7. **mimetypes** — Map filenames to MIME types
   - 18.7.1. MimeTypes Objects

18.8. **MimeWriter** — Generic MIME file writer
   - 18.8.1. MimeWriter Objects

18.9. **mimify** — MIME processing of mail messages

18.10. **multifile** — Support for files containing distinct parts
   - 18.10.1. MultiFile Objects
   - 18.10.2. MultiFile Example

18.11. **rfc822** — Parse RFC 2822 mail headers
   - 18.11.1. Message Objects
   - 18.11.2. AddressList Objects

18.12. **base64** — RFC 3548: Base16, Base32, Base64 Data Encodings

18.13. **binhex** — Encode and decode binhex4 files
   - 18.13.1. Notes

18.14. **binascii** — Convert between binary and ASCII

18.15. **quopri** — Encode and decode MIME quoted-printable data

18.16. **uu** — Encode and decode uuencode files

19. Structured Markup Processing Tools
   - 19.1. **HTMLParser** — Simple HTML and XHTML parser
     - 19.1.1. Example HTML Parser Application
   - 19.2. **sgmllib** — Simple SGML parser
   - 19.3. **htmlib** — A parser for HTML documents
     - 19.3.1. HTMLParser Objects
- **19.4. `htmlentitydefs`** — Definitions of HTML general entities
- **19.5. `xml.parsers.expat`** — Fast XML parsing using Expat
  - 19.5.1. XMLParser Objects
  - 19.5.2. ExpatError Exceptions
  - 19.5.3. Example
  - 19.5.4. Content Model Descriptions
  - 19.5.5. Expat error constants
- **19.6. `xml.dom`** — The Document Object Model API
  - 19.6.1. Module Contents
  - 19.6.2. Objects in the DOM
    - 19.6.2.1. DOMImplementation Objects
    - 19.6.2.2. Node Objects
    - 19.6.2.3. NodeList Objects
    - 19.6.2.4. DocumentType Objects
    - 19.6.2.5. Document Objects
    - 19.6.2.6. Element Objects
    - 19.6.2.7. Attr Objects
    - 19.6.2.8. NamedNodeMap Objects
    - 19.6.2.9. Comment Objects
    - 19.6.2.10. Text and CDATASection Objects
    - 19.6.2.11. ProcessingInstruction Objects
    - 19.6.2.12. Exceptions
  - 19.6.3. Conformance
    - 19.6.3.1. Type Mapping
    - 19.6.3.2. Accessor Methods
- **19.7. `xml.dom.minidom`** — Lightweight DOM implementation
  - 19.7.1. DOM Objects
  - 19.7.2. DOM Example
    - 19.7.3. minidom and the DOM standard
- **19.8. `xml.dom.pulldom`** — Support for building partial DOM trees
- 19.8.1. DOMEventStream Objects
- 19.9. xml.sax — Support for SAX2 parsers
  - 19.9.1. SAXException Objects
- 19.10. xml.sax.handler — Base classes for SAX handlers
  - 19.10.1. ContentHandler Objects
  - 19.10.2. DTDHandler Objects
  - 19.10.3. EntityResolver Objects
  - 19.10.4. ErrorHandler Objects
- 19.11. xml.sax.saxutils — SAX Utilities
- 19.12. xml.sax.xmlreader — Interface for XML parsers
  - 19.12.1. XMLReader Objects
  - 19.12.2. IncrementalParser Objects
  - 19.12.3. Locator Objects
  - 19.12.4. InputSource Objects
  - 19.12.5. The Attributes Interface
  - 19.12.6. The AttributesNS Interface
- 19.13. xml.etree.ElementTree — The ElementTree XML API
  - 19.13.1. Functions
  - 19.13.2. Element Objects
  - 19.13.3. ElementTree Objects
  - 19.13.4. QName Objects
  - 19.13.5. TreeBuilder Objects
  - 19.13.6. XMLParser Objects
- 20. Internet Protocols and Support
  - 20.1. webbrowser — Convenient Web-browser controller
    - 20.1.1. Browser Controller Objects
  - 20.2. cgi — Common Gateway Interface support
    - 20.2.1. Introduction
    - 20.2.2. Using the cgi module
    - 20.2.3. Higher Level Interface
- 20.2.4. Old classes
- 20.2.5. Functions
- 20.2.6. Caring about security
- 20.2.7. Installing your CGI script on a Unix system
- 20.2.8. Testing your CGI script
- 20.2.9. Debugging CGI scripts
- 20.2.10. Common problems and solutions

- 20.3. cgitb — Traceback manager for CGI scripts

- 20.4. wsgiref — WSGI Utilities and Reference Implementation
  - 20.4.1. wsgiref.util — WSGI environment utilities
  - 20.4.2. wsgiref.headers — WSGI response header tools
  - 20.4.3. wsgiref.simple_server — a simple WSGI HTTP server
  - 20.4.4. wsgiref.validate — WSGI conformance checker
  - 20.4.5. wsgiref.handlers — server/gateway base classes
  - 20.4.6. Examples

- 20.5. urllib — Open arbitrary resources by URL
  - 20.5.1. High-level interface
  - 20.5.2. Utility functions
  - 20.5.3. URL Opener objects
  - 20.5.4. urllib Restrictions
  - 20.5.5. Examples

- 20.6. urllib2 — extensible library for opening URLs
  - 20.6.1. Request Objects
  - 20.6.2. OpenerDirector Objects
  - 20.6.3. BaseHandler Objects
  - 20.6.4. HTTPRedirectHandler Objects
  - 20.6.5. HTTPCookieProcessor Objects
  - 20.6.6. ProxyHandler Objects
- 20.6.7. HTTPPasswordMgr Objects
- 20.6.8. AbstractBasicAuthHandler Objects
- 20.6.9. HTTPBasicAuthHandler Objects
- 20.6.10. ProxyBasicAuthHandler Objects
- 20.6.11. AbstractDigestAuthHandler Objects
- 20.6.12. HTTPDigestAuthHandler Objects
- 20.6.13. ProxyDigestAuthHandler Objects
- 20.6.14. HTTPHandler Objects
- 20.6.15. HTTPSHandler Objects
- 20.6.16. FileHandler Objects
- 20.6.17. FTPHandler Objects
- 20.6.18. CacheFTPHandler Objects
- 20.6.19. UnknownHandler Objects
- 20.6.20. HTTPErrorProcessor Objects
- 20.6.21. Examples

- 20.7. httplib — HTTP protocol client
  - 20.7.1. HTTPConnection Objects
  - 20.7.2. HTTPResponse Objects
  - 20.7.3. Examples

- 20.8. ftplib — FTP protocol client
  - 20.8.1. FTP Objects
  - 20.8.2. FTP_TLS Objects

- 20.9. poplib — POP3 protocol client
  - 20.9.1. POP3 Objects
  - 20.9.2. POP3 Example

- 20.10. imaplib — IMAP4 protocol client
  - 20.10.1. IMAP4 Objects
  - 20.10.2. IMAP4 Example

- 20.11. nntplib — NNTP protocol client
  - 20.11.1. NNTP Objects

- 20.12. smtplib — SMTP protocol client
  - 20.12.1. SMTP Objects
  - 20.12.2. SMTP Example
- 20.13. smtplib — SMTP Server
  - 20.13.1. SMTPServer Objects
  - 20.13.2. DebuggingServer Objects
  - 20.13.3. PureProxy Objects
  - 20.13.4. MailmanProxy Objects
- 20.14. telnetlib — Telnet client
  - 20.14.1. Telnet Objects
  - 20.14.2. Telnet Example
- 20.15. uuid — UUID objects according to RFC 4122
  - 20.15.1. Example
- 20.16. urlparse — Parse URLs into components
  - 20.16.1. Results of urlparse() and urlsplit()
- 20.17. SocketServer — A framework for network servers
  - 20.17.1. Server Creation Notes
  - 20.17.2. Server Objects
  - 20.17.3. RequestHandler Objects
  - 20.17.4. Examples
    - 20.17.4.1. SocketServer.TCPServer Example
    - 20.17.4.2. SocketServer.UDPServer Example
    - 20.17.4.3. Asynchronous Mixins
- 20.18. BaseHTTPServer — Basic HTTP server
  - 20.18.1. More examples
- 20.19. SimpleHTTPServer — Simple HTTP request handler
- 20.20. CGIHTTPServer — CGI-capable HTTP request handler
- 20.21. cookielib — Cookie handling for HTTP clients
  - 20.21.2. FileCookieJar subclasses and cooperation with web browsers
  - 20.21.3. CookiePolicy Objects
  - 20.21.4. DefaultCookiePolicy Objects
20.21.5. Cookie Objects
20.21.6. Examples

20.22. Cookie — HTTP state management
- 20.22.1. Cookie Objects
- 20.22.2. Morsel Objects
- 20.22.3. Example

20.23. xmlrpclib — XML-RPC client access
- 20.23.1. ServerProxy Objects
- 20.23.2. Boolean Objects
- 20.23.3. DateTime Objects
- 20.23.4. Binary Objects
- 20.23.5. Fault Objects
- 20.23.6. ProtocolError Objects
- 20.23.7. MultiCall Objects
- 20.23.8. Convenience Functions
- 20.23.9. Example of Client Usage
- 20.23.10. Example of Client and Server Usage

20.24. SimpleXMLRPCServer — Basic XML-RPC server
- 20.24.1. SimpleXMLRPCServer Objects
  - 20.24.1.1. SimpleXMLRPCServer Example
- 20.24.2. CGIXMLRPCRequestHandler

20.25. DocXMLRPCServer — Self-documenting XML-RPC server
- 20.25.1. DocXMLRPCServer Objects
- 20.25.2. DocCGIXMLRPCRequestHandler

21. Multimedia Services
- 21.1. audioop — Manipulate raw audio data
- 21.2. imageop — Manipulate raw image data
- 21.3. aifc — Read and write AIFF and AIFC files
- 21.4. sunau — Read and write Sun AU files
  - 21.4.1. AU_read Objects
  - 21.4.2. AU_write Objects
- 21.5. wave — Read and write WAV files
21.5.1. Wave_read Objects
21.5.2. Wave_write Objects

21.6. chunk — Read IFF chunked data
21.7. colorsys — Conversions between color systems
21.8. imghdr — Determine the type of an image
21.9. sndhdr — Determine type of sound file

22. Internationalization
22.1. gettext — Multilingual internationalization services
   22.1.1. GNU gettext API
   22.1.2. Class-based API
      22.1.2.1. The NullTranslations class
      22.1.2.2. The GNUTranslations class
      22.1.2.3. Solaris message catalog support
      22.1.2.4. The Catalog constructor
   22.1.3. Internationalizing your programs and modules
      22.1.3.1. Localizing your module
      22.1.3.2. Localizing your application
      22.1.3.3. Changing languages on the fly
      22.1.3.4. Deferred translations
      22.1.3.5. gettext() vs. lgettext()
   22.1.4. Acknowledgements
22.2. locale — Internationalization services
   22.2.1. Background, details, hints, tips and caveats
   22.2.2. For extension writers and programs that embed Python
   22.2.3. Access to message catalogs

23. Program Frameworks
23.1. cmd — Support for line-oriented command interpreters
   23.1.1. Cmd Objects
- 23.2. **shlex** — Simple lexical analysis
  - 23.2.1. shlex Objects
  - 23.2.2. Parsing Rules
- 24. Development Tools
  - 24.1. **pydoc** — Documentation generator and online help system
  - 24.2. **doctest** — Test interactive Python examples
    - 24.2.1. Simple Usage: Checking Examples in Docstrings
    - 24.2.2. Simple Usage: Checking Examples in a Text File
    - 24.2.3. How It Works
      - 24.2.3.1. Which Docstrings Are Examined?
      - 24.2.3.2. How are Docstring Examples Recognized?
      - 24.2.3.3. What’s the Execution Context?
      - 24.2.3.4. What About Exceptions?
      - 24.2.3.5. Option Flags and Directives
      - 24.2.3.6. Warnings
  - 24.2.4. Basic API
  - 24.2.5. Unitest API
  - 24.2.6. Advanced API
    - 24.2.6.1. DocTest Objects
    - 24.2.6.2. Example Objects
    - 24.2.6.3. DocTestFinder objects
    - 24.2.6.4. DocTestParser objects
    - 24.2.6.5. DocTestRunner objects
    - 24.2.6.6. OutputChecker objects
  - 24.2.7. Debugging
  - 24.2.8. Soapbox
- 24.3. **unittest** — Unit testing framework
  - 24.3.1. Basic example
  - 24.3.2. Command Line Interface
    - 24.3.2.1. failfast, catch and buffer command
24.3.3. Test Discovery
24.3.4. Organizing test code
24.3.5. Re-using old test code
24.3.6. Skipping tests and expected failures
24.3.7. Classes and functions
   24.3.7.1. Test cases
   24.3.7.2. Grouping tests
   24.3.7.3. Loading and running tests
      24.3.7.3.1. load_tests Protocol
24.3.8. Class and Module Fixtures
   24.3.8.1. setUpClass and tearDownClass
   24.3.8.2. setUpModule and tearDownModule
24.3.9. Signal Handling
24.4. 2to3 - Automated Python 2 to 3 code translation
   24.4.1. Using 2to3
   24.4.2. Fixers
   24.4.3. lib2to3 - 2to3's library
24.5. test — Regression tests package for Python
   24.5.1. Writing Unit Tests for the test package
   24.5.2. Running tests using test.regrtest
24.6. test.test_support — Utility functions for tests
25. Debugging and Profiling
   25.1. bdb — Debugger framework
   25.2. pdb — The Python Debugger
   25.3. Debugger Commands
   25.4. The Python Profilers
      25.4.1. Introduction to the profilers
      25.4.2. Instant User’s Manual
      25.4.3. What Is Deterministic Profiling?
      25.4.4. Reference Manual – profile and cProfile
         25.4.4.1. The stats Class
      25.4.5. Limitations
25.4.6. Calibration
25.4.7. Extensions — Deriving Better Profilers

25.5. hotshot — High performance logging profiler
  25.5.1. Profile Objects
  25.5.2. Using hotshot data
  25.5.3. Example Usage

25.6. timeit — Measure execution time of small code snippets
  25.6.1. Command Line Interface
  25.6.2. Examples

25.7. trace — Trace or track Python statement execution
  25.7.1. Command Line Usage
  25.7.2. Programming Interface

26. Python Runtime Services
  26.1. sys — System-specific parameters and functions
  26.2. sysconfig — Provide access to Python’s configuration information
    26.2.1. Configuration variables
    26.2.2. Installation paths
    26.2.3. Other functions
  26.3. __builtin__ — Built-in objects
  26.4. future_builtins — Python 3 builtins
  26.5. __main__ — Top-level script environment
  26.6. warnings — Warning control
    26.6.1. Warning Categories
    26.6.2. The Warnings Filter
    26.6.3. Temporarily Suppressing Warnings
    26.6.4. Testing Warnings
    26.6.5. Updating Code For New Versions of Python
    26.6.6. Available Functions
    26.6.7. Available Context Managers
- 26.7. `contextlib` — Utilities for with-statement contexts
- 26.8. `abc` — Abstract Base Classes
- 26.9. `atexit` — Exit handlers
  - 26.9.1. `atexit` Example
- 26.10. `traceback` — Print or retrieve a stack traceback
  - 26.10.1. Traceback Examples
- 26.11. `__future__` — Future statement definitions
- 26.12. `gc` — Garbage Collector interface
- 26.13. `inspect` — Inspect live objects
  - 26.13.1. Types and members
  - 26.13.2. Retrieving source code
  - 26.13.3. Classes and functions
  - 26.13.4. The interpreter stack
- 26.14. `site` — Site-specific configuration hook
- 26.15. `user` — User-specific configuration hook
- 26.16. `distutils` — Building and installing Python modules
- 27. Custom Python Interpreters
  - 27.1. `code` — Interpreter base classes
    - 27.1.1. Interactive Interpreter Objects
    - 27.1.2. Interactive Console Objects
  - 27.2. `codeop` — Compile Python code
- 28. Restricted Execution
  - 28.1. `reexec` — Restricted execution framework
    - 28.1.1. RExec Objects
    - 28.1.2. Defining restricted environments
    - 28.1.3. An example
  - 28.2. `Bastion` — Restricting access to objects
- 29. Importing Modules
  - 29.1. `imp` — Access the `import` internals
    - 29.1.1. Examples
29.2. `importlib` — Convenience wrappers for `__import__()`
29.3. `importutil` — Import utilities
   - 29.3.1. Examples
29.4. `zipimport` — Import modules from Zip archives
   - 29.4.1. `zipimporter` Objects
   - 29.4.2. Examples
29.5. `pkgutil` — Package extension utility
29.6. `modulefinder` — Find modules used by a script
   - 29.6.1. Example usage of `ModuleFinder`
29.7. `runpy` — Locating and executing Python modules

30. Python Language Services
30.1. `parser` — Access Python parse trees
   - 30.1.1. Creating ST Objects
   - 30.1.2. Converting ST Objects
   - 30.1.3. Queries on ST Objects
   - 30.1.4. Exceptions and Error Handling
   - 30.1.5. ST Objects
   - 30.1.6. Examples
     - 30.1.6.1. Emulation of `compile()`
     - 30.1.6.2. Information Discovery
30.2. Abstract Syntax Trees
   - 30.2.1. Node classes
   - 30.2.2. Abstract Grammar
   - 30.2.3. `ast` Helpers
30.3. `symtable` — Access to the compiler’s symbol tables
   - 30.3.1. Generating Symbol Tables
   - 30.3.2. Examining Symbol Tables
30.4. `symbol` — Constants used with Python parse trees
30.5. `token` — Constants used with Python parse trees
- 30.6. **keyword** — Testing for Python keywords
- 30.7. **tokenize** — Tokenizer for Python source
- 30.8. **tabnanny** — Detection of ambiguous indentation
- 30.9. **pyclbr** — Python class browser support
  - 30.9.1. Class Objects
  - 30.9.2. Function Objects
- 30.10. **py_compile** — Compile Python source files
- 30.11. **compileall** — Byte-compile Python libraries
- 30.12. **dis** — Disassembler for Python bytecode
  - 30.12.1. Python Bytecode Instructions
- 30.13. **pickletools** — Tools for pickle developers

      10.1.2. install_scripts

11. API Reference
   11.1. distutils.core — Core Distutils functionality
   11.2. distutils.ccompiler — CCompiler base class
   11.3. distutils.unixccompiler — Unix C Compiler
   11.4. distutils.msvccompiler — Microsoft Compiler
   11.5. distutils.bcppcompiler — Borland Compiler
   11.6. distutils.cygwincompiler — Cygwin Compiler
   11.7. distutils.emxccompiler — OS/2 EMX Compiler
   11.8. distutils.archive_util — Archiving utilities
   11.9. distutils.dep_util — Dependency checking
   11.10. distutils.dir_util — Directory tree operations
   11.11. distutils.file_util — Single file operations
   11.12. distutils.util — Miscellaneous other utility functions
   11.13. distutils.dist — The Distribution class
   11.14. distutils.extension — The Extension class
   11.15. distutils.debug — Distutils debug mode
   11.16. distutils.errors — Distutils exceptions
   11.17. distutils.fancy_getopt — Wrapper around the standard getopt module
   11.18. distutils.filelist — The FileList class
   11.19. distutils.log — Simple PEP 282-style logging
   11.20. distutils.spawn — Spawn a sub-process
   11.21. distutils.sysconfig — System configuration information
   11.22. distutils.text_file — The TextFile class
- 11.23. **distutils.version** — Version number classes
- 11.24. **distutils.cmd** — Abstract base class for Distutils commands
- 11.25. **distutils.command** — Individual Distutils commands
- 11.26. **distutils.command.bdist** — Build a binary installer
- 11.27. **distutils.command.bdist_packager** — Abstract base class for packagers
- 11.28. **distutils.command.bdist_dumb** — Build a “dumb” installer
- 11.29. **distutils.command.bdist_msi** — Build a Microsoft Installer binary package
- 11.30. **distutils.command.bdist_rpm** — Build a binary distribution as a Redhat RPM and SRPM
- 11.31. **distutils.command.bdist_wininst** — Build a Windows installer
- 11.32. **distutils.command.sdist** — Build a source distribution
- 11.33. **distutils.command.build** — Build all files of a package
- 11.34. **distutils.command.build_clib** — Build any C libraries in a package
- 11.35. **distutils.command.build_ext** — Build any extensions in a package
- 11.36. **distutils.command.build_py** — Build the .py/.pyc files of a package
- 11.37. **distutils.command.build_scripts** — Build the scripts of a package
- 11.38. **distutils.command.clean** — Clean a package build area
- 11.39. **distutils.command.config** — Perform package
configuration

- **11.40. distutils.command.install** — Install a package
- **11.41. distutils.command.install_data** — Install data files from a package
- **11.42. distutils.command.install_headers** — Install C/C++ header files from a package
- **11.43. distutils.command.install_lib** — Install library files from a package
- **11.44. distutils.command.install_scripts** — Install script files from a package
- **11.45. distutils.command.register** — Register a module with the Python Package Index
- **11.46. Creating a new Distutils command**

    - Why does Python use indentation for grouping of statements?
    - Why am I getting strange results with simple arithmetic operations?
    - Why are floating point calculations so inaccurate?
    - Why are Python strings immutable?
• Why must ‘self’ be used explicitly in method definitions and calls?
• Why can’t I use an assignment in an expression?
• Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?
• Why is join() a string method instead of a list or tuple method?
• How fast are exceptions?
• Why isn’t there a switch or case statement in Python?
• Can’t you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?
• Why can’t lambda forms contain statements?
• Can Python be compiled to machine code, C or some other language?
• How does Python manage memory?
• Why isn’t all memory freed when Python exits?
• Why are there separate tuple and list data types?
• How are lists implemented?
• How are dictionaries implemented?
• Why must dictionary keys be immutable?
• Why doesn’t list.sort() return the sorted list?
• How do you specify and enforce an interface spec in Python?
• Why are default values shared between objects?
• Why is there no goto?
• Why can’t raw strings (r-strings) end with a backslash?
• Why doesn’t Python have a “with” statement for attribute assignments?
• Why are colons required for the if/while/def/class statements?
• Why does Python allow commas at the end of lists and tuples?

Memory-mapped file objects behave like both strings and like file objects. Unlike normal string objects, however, these are mutable. You can use mmap objects in most places where strings are expected; for example, you can use the `re` module to search through a memory-mapped file. Since they're mutable, you can change a single character by doing `obj[index] = 'a'`, or change a substring by assigning to a slice: `obj[i1:i2] = '...'`. You can also read and write data starting at the current file position, and `seek()` through the file to different positions.

A memory-mapped file is created by the `mmap` constructor, which is different on Unix and on Windows. In either case you must provide a file descriptor for a file opened for update. If you wish to map an existing Python file object, use its `fileno()` method to obtain the correct value for the `fileno` parameter. Otherwise, you can open the file using the `os.open()` function, which returns a file descriptor directly (the file still needs to be closed when done).

For both the Unix and Windows versions of the constructor, `access` may be specified as an optional keyword parameter. `access` accepts one of three values: `ACCESS_READ`, `ACCESS_WRITE`, or `ACCESS_COPY` to specify read-only, write-through or copy-on-write memory respectively. `access` can be used on both Unix and Windows. If `access` is not specified, Windows mmap returns a write-through mapping. The initial memory values for all three access types are taken from the specified file. Assignment to an `ACCESS_READ` memory map raises a `TypeError` exception. Assignment to an `ACCESS_WRITE` memory map affects both memory and the underlying file. Assignment to an `ACCESS_COPY` memory map affects memory but
does not update the underlying file.

*Changed in version 2.5:* To map anonymous memory, -1 should be passed as the fileno along with the length.

*Changed in version 2.6:* mmap.mmap has formerly been a factory function creating mmap objects. Now mmap.mmap is the class itself.

```python
class mmap.mmap(fileno, length[, tagname[, access[, offset]]]])
```

*(Windows version)* Maps length bytes from the file specified by the file handle fileno, and creates a mmap object. If length is larger than the current size of the file, the file is extended to contain length bytes. If length is 0, the maximum length of the map is the current size of the file, except that if the file is empty Windows raises an exception (you cannot create an empty mapping on Windows).

*tagname*, if specified and not `None`, is a string giving a tag name for the mapping. Windows allows you to have many different mappings against the same file. If you specify the name of an existing tag, that tag is opened, otherwise a new tag of this name is created. If this parameter is omitted or `None`, the mapping is created without a name. Avoiding the use of the tag parameter will assist in keeping your code portable between Unix and Windows.

*offset* may be specified as a non-negative integer offset. mmap references will be relative to the offset from the beginning of the file. *offset* defaults to 0. *offset* must be a multiple of the ALLOCATIONGRANULARITY.

```python
class mmap.mmap(fileno, length[, flags[, prot[, access[, offset]]]])
```

*(Unix version)* Maps length bytes from the file specified by the file descriptor fileno, and returns a mmap object. If length is 0, the
maximum length of the map will be the current size of the file when `mmap` is called.

`flags` specifies the nature of the mapping. `MAP_PRIVATE` creates a private copy-on-write mapping, so changes to the contents of the mmap object will be private to this process, and `MAP_SHARED` creates a mapping that’s shared with all other processes mapping the same areas of the file. The default value is `MAP_SHARED`.

`prot`, if specified, gives the desired memory protection; the two most useful values are `PROT_READ` and `PROT_WRITE`, to specify that the pages may be read or written. `prot` defaults to `PROT_READ` | `PROT_WRITE`.

`access` may be specified in lieu of `flags` and `prot` as an optional keyword parameter. It is an error to specify both `flags`, `prot` and `access`. See the description of `access` above for information on how to use this parameter.

`offset` may be specified as a non-negative integer offset. mmap references will be relative to the offset from the beginning of the file. `offset` defaults to 0. `offset` must be a multiple of the PAGESIZE or ALLOCATIONGRANULARITY.

This example shows a simple way of using `mmap`:

```python
import mmap

# write a simple example file
with open("hello.txt", "w") as f:
    f.write("Hello Python!\n")

with open("hello.txt", "r+") as f:
    # memory-map the file, size 0 means whole file
    map = mmap.mmap(f.fileno(), 0)
    # read content via standard file methods
```
print map.readline()  # prints "Hello Python!"
# read content via slice notation
print map[:5]  # prints "Hello"
# update content using slice notation;
# note that new content must have same size
map[6:] = " world!\n"
# ... and read again using standard file methods
map.seek(0)
print map.readline()  # prints "Hello world!"
# close the map
map.close()

The next example demonstrates how to create an anonymous map and exchange data between the parent and child processes:

```python
import mmap
import os

map = mmap.mmap(-1, 13)
map.write("Hello world!")

pid = os.fork()

if pid == 0:  # In a child process
    map.seek(0)
    print map.readline()

map.close()
```

Memory-mapped file objects support the following methods:

**mmap.close()**

Close the file. Subsequent calls to other methods of the object will result in an exception being raised.

**mmap.find(string[, start[, end]])**

Returns the lowest index in the object where the substring `string` is found, such that `string` is contained in the range `[start, end]`. Optional arguments `start` and `end` are interpreted as in slice notation. Returns `-1` on failure.
**mmap.flush([offset, size])**

Flushes changes made to the in-memory copy of a file back to disk. Without use of this call there is no guarantee that changes are written back before the object is destroyed. If `offset` and `size` are specified, only changes to the given range of bytes will be flushed to disk; otherwise, the whole extent of the mapping is flushed.

*(Windows version)* A nonzero value returned indicates success; zero indicates failure.

*(Unix version)* A zero value is returned to indicate success. An exception is raised when the call failed.

**mmap.move(dest, src, count)**

Copy the `count` bytes starting at offset `src` to the destination index `dest`. If the mmap was created with `ACCESS_READ`, then calls to move will throw a `TypeError` exception.

**mmap.read(num)**

Return a string containing up to `num` bytes starting from the current file position; the file position is updated to point after the bytes that were returned.

**mmap.read_byte()**

Returns a string of length 1 containing the character at the current file position, and advances the file position by 1.

**mmap.readline()**

Returns a single line, starting at the current file position and up to the next newline.

**mmap.resize(newsize)**

Resizes the map and the underlying file, if any. If the mmap
was created with `ACCESS_READ` or `ACCESS_COPY`, resizing the map will throw a `TypeError` exception.

```python
mmap.rfind(string[, start[, end]])
```

Returns the highest index in the object where the substring `string` is found, such that `string` is contained in the range `[start, end]`. Optional arguments `start` and `end` are interpreted as in slice notation. Returns `-1` on failure.

```python
mmap.seek(pos[, whence])
```

Set the file's current position. `whence` argument is optional and defaults to `os.SEEK_SET` or `0` (absolute file positioning); other values are `os.SEEK_CUR` or `1` (seek relative to the current position) and `os.SEEK_END` or `2` (seek relative to the file's end).

```python
mmap.size()
```

Return the length of the file, which can be larger than the size of the memory-mapped area.

```python
mmap.tell()
```

Returns the current position of the file pointer.

```python
mmap.write(string)
```

Write the bytes in `string` into memory at the current position of the file pointer; the file position is updated to point after the bytes that were written. If the mmap was created with `ACCESS_READ`, then writing to it will throw a `TypeError` exception.

```python
mmap.write_byte(byte)
```

Write the single-character string `byte` into memory at the current position of the file pointer; the file position is advanced by `1`. If the mmap was created with `ACCESS_READ`, then writing to it will throw a `TypeError` exception.
The `ttk` module provides access to the Tk themed widget set, which has been introduced in Tk 8.5. If Python is not compiled against Tk 8.5 code may still use this module as long as Tile is installed. However, some features provided by the new Tk, like anti-aliased font rendering under X11, window transparency (on X11 you will need a composition window manager) will be missing.

The basic idea of `ttk` is to separate, to the extent possible, the code implementing a widget's behavior from the code implementing its appearance.

Tk Widget Styling Support
   The document which brought up theming support for Tk
Using Ttk

To start using Ttk, import its module:

```python
import ttk
```

But code like this:

```python
from Tkinter import *
```

may optionally want to use this:

```python
from Tkinter import *
from ttk import *
```

And then several ttk widgets (Button, Checkbutton, Entry, Frame, Label, LabelFrame, Menubutton, PanedWindow, Radiobutton, Scale and Scrollbar) will automatically substitute for the Tk widgets.

This has the direct benefit of using the new widgets, giving better look & feel across platforms, but be aware that they are not totally compatible. The main difference is that widget options such as “fg”, “bg” and others related to widget styling are no longer present in Ttk widgets. Use ttk.Style to achieve the same (or better) styling.

See also:

Converting existing applications to use the Tile widgets

A text which talks in Tcl terms about differences typically found when converting applications to use the new widgets.
Ttk Widgets

Ttk comes with 17 widgets, 11 of which already exist in Tkinter: Button, Checkbutton, Entry, Frame, Label, LabelFrame, Menubutton, PanedWindow, Radiobutton, Scale and Scrollbar. The 6 new widget classes are: Combobox, Notebook, Progressbar, Separator, Sizegrip and Treeview. All of these classes are subclasses of Widget.

As said previously, you will notice changes in look-and-feel as well in the styling code. To demonstrate the latter, a very simple example is shown below.

Tk code:

```python
l1 = Tkinter.Label(text="Test", fg="black", bg="white")
l2 = Tkinter.Label(text="Test", fg="black", bg="white")
```

Corresponding Ttk code:

```python
style = ttk.Style()
style.configure("BW.TLabel", foreground="black", background="white")
l1 = ttk.Label(text="Test", style="BW.TLabel")
l2 = ttk.Label(text="Test", style="BW.TLabel")
```

For more information about TtkStyling read the style class documentation.
**Widget**

`ttk.Widget` defines standard options and methods supported by Tk themed widgets and is not supposed to be directly instantiated.

**Standard Options**

All the `ttk` widgets accept the following options:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>class</td>
<td>Specifies the window class. The class is used when querying the option database for the window's other options, to determine the default bindtags for the window, and to select the widget's default layout and style. This is a read-only option which may only be specified when the window is created.</td>
</tr>
<tr>
<td>cursor</td>
<td>Specifies the mouse cursor to be used for the widget. If set to the empty string (the default), the cursor is inherited from the parent widget.</td>
</tr>
<tr>
<td>takefocus</td>
<td>Determines whether the window accepts the focus during keyboard traversal. 0, 1 or an empty string is returned. If 0, the window should be skipped entirely during keyboard traversal. If 1, the window should receive the input focus as long as it is viewable. An empty string means that the traversal scripts make the decision about whether or not to focus on the window.</td>
</tr>
<tr>
<td>style</td>
<td>May be used to specify a custom widget style.</td>
</tr>
</tbody>
</table>

**Scrollable Widget Options**

The following options are supported by widgets that are controlled by a scrollbar.
<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xscrollcommand</td>
<td>Used to communicate with horizontal scrollbars.</td>
</tr>
<tr>
<td></td>
<td>When the view in the widget's window changes, the widget will generate a Tcl command based on the scrollcommand.</td>
</tr>
<tr>
<td></td>
<td>Usually this option consists of the Scrollbar.set() method of some scrollbar. This will cause the scrollbar to be updated whenever the view in the window changes.</td>
</tr>
<tr>
<td>yscrollcommand</td>
<td>Used to communicate with vertical scrollbars.</td>
</tr>
<tr>
<td></td>
<td>For more information, see above.</td>
</tr>
</tbody>
</table>

**Label Options**

The following options are supported by labels, buttons and other button-like widgets.

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>text</td>
<td>Specifies a text string to be displayed inside the widget.</td>
</tr>
<tr>
<td>textvariable</td>
<td>Specifies a name whose value will be used in place of the text option resource.</td>
</tr>
<tr>
<td>underline</td>
<td>If set, specifies the index (0-based) of a character to underline in the text string. The underline character is used for mnemonic activation.</td>
</tr>
</tbody>
</table>
| image       | Specifies an image to display. This is a list of 1 or more elements. The first element is the default image name. The rest of the list is a sequence of statespec/value pairs as defined by Style.map(), specifying different images to use when the widget is in a particular state or a combination of states. All images in the list should have the same
size.

<table>
<thead>
<tr>
<th>compound</th>
<th>Specifies how to display the image relative to the text, in the case both text and image options are present. Valid values are:</th>
</tr>
</thead>
<tbody>
<tr>
<td>• text: display text only</td>
<td></td>
</tr>
<tr>
<td>• image: display image only</td>
<td></td>
</tr>
<tr>
<td>• top, bottom, left, right: display image above, below, left of, or right of the text, respectively.</td>
<td></td>
</tr>
<tr>
<td>• none: the default. display the image if present, otherwise the text.</td>
<td></td>
</tr>
</tbody>
</table>

| width | If greater than zero, specifies how much space, in character widths, to allocate for the text label; if less than zero, specifies a minimum width. If zero or unspecified, the natural width of the text label is used. |

## Compatibility Options

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>state</td>
<td>May be set to “normal” or “disabled” to control the “disabled” state bit. This is a write-only option: setting it changes the widget state, but the <code>Widget.state()</code> method does not affect this option.</td>
</tr>
</tbody>
</table>

## Widget States

The widget state is a bitmap of independent state flags.

<table>
<thead>
<tr>
<th>flag</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>active</td>
<td>The mouse cursor is over the widget and pressing a mouse button will cause some action to occur.</td>
</tr>
<tr>
<td>disabled</td>
<td>Widget is disabled under program control.</td>
</tr>
<tr>
<td>focus</td>
<td>Widget has keyboard focus.</td>
</tr>
<tr>
<td>State</td>
<td>Description</td>
</tr>
<tr>
<td>------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>pressed</td>
<td>Widget is being pressed.</td>
</tr>
<tr>
<td>selected</td>
<td>“On”, “true”, or “current” for things like Checkbuttons and radiobuttons.</td>
</tr>
<tr>
<td>background</td>
<td>Windows and Mac have a notion of an “active” or foreground window. The <em>background</em> state is set for widgets in a background window, and cleared for those in the foreground window.</td>
</tr>
<tr>
<td>readonly</td>
<td>Widget should not allow user modification.</td>
</tr>
<tr>
<td>alternate</td>
<td>A widget-specific alternate user display format.</td>
</tr>
<tr>
<td>invalid</td>
<td>The widget’s value is invalid.</td>
</tr>
</tbody>
</table>

A state specification is a sequence of state names, optionally prefixed with an exclamation point indicating that the bit is off.

**ttk.Widget**

Besides the methods described below, the `ttk.Widget` class supports the `Tkinter.Widget.cget()` and `Tkinter.Widget.configure()` methods.

```python
class ttk.Widget
    identify(x, y)
        Returns the name of the element at position x, y, or the empty string if the point does not lie within any element.

        x and y are pixel coordinates relative to the widget.

    instate(statespec[, callback=None[, *args[, **kw]]]])
        Test the widget’s state. If a callback is not specified, returns True if the widget state matches `statespec` and False otherwise. If callback is specified then it is called with `args` if widget state matches `statespec`.

    state([statespec= None])
```
Modify or read widget state. If `statespec` is specified, sets the widget state accordingly and returns a new `statespec` indicating which flags were changed. If `statespec` is not specified, returns the currently-enabled state flags.

`statespec` will usually be a list or a tuple.
## Combobox

The `ttk.Combobox` widget combines a text field with a pop-down list of values. This widget is a subclass of `Entry`.

Besides the methods inherited from `Widget` (`Widget.cget()`, `Widget.configure()`, `Widget.identify()`, `Widget.instate()`, and `Widget.state()`), and those inherited from `Entry` (`Entry.bbox()`, `Entry.delete()`, `Entry.icursor()`, `Entry.index()`, `Entry.inset()`, `Entry.selection()`, `Entry.xview()`), this class has some other methods, described at `ttk.Combobox`.

## Options

This widget accepts the following options:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>exportselection</td>
<td>Boolean value. If set, the widget selection is linked to the Window Manager selection (which can be returned by invoking <code>Misc.selection_get()</code>, for example).</td>
</tr>
<tr>
<td>justify</td>
<td>Specifies how the text is aligned within the widget. One of “left”, “center”, or “right”.</td>
</tr>
<tr>
<td>height</td>
<td>Specifies the height of the pop-down listbox, in rows.</td>
</tr>
<tr>
<td>postcommand</td>
<td>A script (possibly registered with <code>Misc.register()</code>) that is called immediately before displaying the values. It may specify which values to display.</td>
</tr>
<tr>
<td>state</td>
<td>One of “normal”, “readonly”, or “disabled”. In the “readonly” state, the value may not be edited directly, and the user can only select one of the values from the dropdown list.</td>
</tr>
</tbody>
</table>
the “normal” state, the text field is directly editable. In the “disabled” state, no interaction is possible.

| textvariable | Specifies a name whose value is linked to the widget value. Whenever the value associated with that name changes, the widget value is updated, and vice versa. See Tkinter.StringVar. |
| values | Specifies the list of values to display in the drop-down listbox. |
| width | Specifies an integer value indicating the desired width of the entry window, in average-size characters of the widget’s font. |

Virtual events

The combobox widget generates a \<<ComboboxSelected>> virtual event when the user selects an element from the list of values.

```python
ttk.Combobox

class ttk.Combobox

    current([newindex=None])
    
    If newindex is specified, sets the combobox value to the element position newindex. Otherwise, returns the index of the current value or -1 if the current value is not in the values list.

    get()
    
    Returns the current value of the combobox.

    set(value)
    
    Sets the value of the combobox to value.
```
Notebook

The Ttk Notebook widget manages a collection of windows and displays a single one at a time. Each child window is associated with a tab, which the user may select to change the currently-displayed window.

Options

This widget accepts the following specific options:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>height</td>
<td>If present and greater than zero, specifies the desired height of the pane area (not including internal padding or tabs). Otherwise, the maximum height of all panes is used.</td>
</tr>
<tr>
<td>padding</td>
<td>Specifies the amount of extra space to add around the outside of the notebook. The padding is a list of up to four length specifications: left top right bottom. If fewer than four elements are specified, bottom defaults to top, right defaults to left, and top defaults to left.</td>
</tr>
<tr>
<td>width</td>
<td>If present and greater than zero, specifies the desired width of the pane area (not including internal padding). Otherwise, the maximum width of all panes is used.</td>
</tr>
</tbody>
</table>

Tab Options

There are also specific options for tabs:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>state</td>
<td>Either “normal”, “disabled” or “hidden”. If “disabled”, then the tab is not selectable. If</td>
</tr>
<tr>
<td>Option</td>
<td>Description</td>
</tr>
<tr>
<td>----------</td>
<td>-------------</td>
</tr>
<tr>
<td>sticky</td>
<td>Specifies how the child window is positioned within the pane area. Value is a string containing zero or more of the characters “n”, “s”, “e” or “w”. Each letter refers to a side (north, south, east or west) that the child window will stick to, as per the <code>grid()</code> geometry manager.</td>
</tr>
<tr>
<td>padding</td>
<td>Specifies the amount of extra space to add between the notebook and this pane. Syntax is the same as for the option padding used by this widget.</td>
</tr>
<tr>
<td>text</td>
<td>Specifies a text to be displayed in the tab.</td>
</tr>
<tr>
<td>image</td>
<td>Specifies an image to display in the tab. See the option image described in <code>Widget</code>.</td>
</tr>
<tr>
<td>compound</td>
<td>Specifies how to display the image relative to the text, in the case both text and image options are present. See <code>Label Options</code> for legal values.</td>
</tr>
<tr>
<td>underline</td>
<td>Specifies the index (0-based) of a character to underline in the text string. The underlined character is used for mnemonic activation if <code>Notebook.enable_traversal()</code> is called.</td>
</tr>
</tbody>
</table>

### Tab Identifiers

The `tab_id` present in several methods of `ttk.Notebook` may take any of the following forms:

- An integer between zero and the number of tabs.
- The name of a child window.
- A positional specification of the form “@x,y”, which identifies the tab.
- The literal string “current”, which identifies the currently-selected tab.
- The literal string “end”, which returns the number of tabs (only valid for `Notebook.index()`).
Virtual Events

This widget generates a `<<NotebookTabChanged>>` virtual event after a new tab is selected.

**ttk.Notebook**

```python
class ttk.Notebook
    add(child, **kw)
        Adds a new tab to the notebook.
        If window is currently managed by the notebook but hidden, it is restored to its previous position.
        See Tab Options for the list of available options.

    forget(tab_id)
        Removes the tab specified by `tab_id`, unmaps and unmanages the associated window.

    hide(tab_id)
        Hides the tab specified by `tab_id`.
        The tab will not be displayed, but the associated window remains managed by the notebook and its configuration remembered. Hidden tabs may be restored with the `add()` command.

    identify(x, y)
        Returns the name of the tab element at position `x, y`, or the empty string if none.

    index(tab_id)
        Returns the numeric index of the tab specified by `tab_id`, or the total number of tabs if `tab_id` is the string “end”.
```
**insert**(pos, child, **kw)

Inserts a pane at the specified position.

*pos* is either the string “end”, an integer index, or the name of a managed child. If *child* is already managed by the notebook, moves it to the specified position.

See Tab Options for the list of available options.

**select**(tab_id)

Selects the specified *tab_id*.

The associated child window will be displayed, and the previously-selected window (if different) is unmapped. If *tab_id* is omitted, returns the widget name of the currently selected pane.

**tab**(tab_id[, option= None[, **kw]])

Query or modify the options of the specific *tab_id*.

If *kw* is not given, returns a dictionary of the tab option values. If *option* is specified, returns the value of that *option*. Otherwise, sets the options to the corresponding values.

**tabs**()

Returns a list of windows managed by the notebook.

**enable_traversal**()

Enable keyboard traversal for a toplevel window containing this notebook.

This will extend the bindings for the toplevel window containing the notebook as follows:

- Control-Tab: selects the tab following the currently
selected one.
- Shift-Control-Tab: selects the tab preceding the currently selected one.
- Alt-K: where K is the mnemonic (underlined) character of any tab, will select that tab.

Multiple notebooks in a single toplevel may be enabled for traversal, including nested notebooks. However, notebook traversal only works properly if all panes have the notebook they are in as master.
Progressbar

The `ttk.Progressbar` widget shows the status of a long-running operation. It can operate in two modes: determinate mode shows the amount completed relative to the total amount of work to be done, and indeterminate mode provides an animated display to let the user know that something is happening.

Options

This widget accepts the following specific options:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>orient</td>
<td>One of “horizontal” or “vertical”. Specifies the orientation of the progress bar.</td>
</tr>
<tr>
<td>length</td>
<td>Specifies the length of the long axis of the progress bar (width if horizontal, height if vertical).</td>
</tr>
<tr>
<td>mode</td>
<td>One of “determinate” or “indeterminate”.</td>
</tr>
<tr>
<td>maximum</td>
<td>A number specifying the maximum value. Defaults to 100.</td>
</tr>
<tr>
<td>value</td>
<td>The current value of the progress bar. In “determinate” mode, this represents the amount of work completed. In “indeterminate” mode, it is interpreted as modulo <code>maximum</code>; that is, the progress bar completes one “cycle” when its value increases by <code>maximum</code>.</td>
</tr>
<tr>
<td>variable</td>
<td>A name which is linked to the option value. If specified, the value of the progress bar is automatically set to the value of this name whenever the latter is modified.</td>
</tr>
<tr>
<td>phase</td>
<td>Read-only option. The widget periodically increments the value of this option whenever its value is greater than 0 and, in determinate mode, less than maximum. This option may be used by the</td>
</tr>
</tbody>
</table>
current theme to provide additional animation effects.

ttk.ProgressBar

```python
class ttk.ProgressBar

start([interval])
   Begin autoincrement mode: schedules a recurring timer event that calls `Progressbar.step()` every `interval` milliseconds. If omitted, `interval` defaults to 50 milliseconds.

step([amount])
   Increments the progress bar's value by `amount`.

   `amount` defaults to 1.0 if omitted.

stop()
   Stop autoincrement mode: cancels any recurring timer event initiated by `Progressbar.start()` for this progress bar.
```
Separator

The `ttk.Separator` widget displays a horizontal or vertical separator bar.

It has no other methods besides the ones inherited from `ttk.Widget`.

Options

This widget accepts the following specific option:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>orient</td>
<td>One of “horizontal” or “vertical”. Specifies the orientation of the separator.</td>
</tr>
</tbody>
</table>
Sizegrip

The `ttk.Sizegrip` widget (also known as a grow box) allows the user to resize the containing toplevel window by pressing and dragging the grip.

This widget has neither specific options nor specific methods, besides the ones inherited from `ttk.Widget`.

Platform-specific notes

- On Mac OS X, toplevel windows automatically include a built-in size grip by default. Adding a `Sizegrip` is harmless, since the built-in grip will just mask the widget.

Bugs

- If the containing toplevel's position was specified relative to the right or bottom of the screen (e.g. ...), the `Sizegrip` widget will not resize the window.
- This widget supports only “southeast” resizing.
The `ttk.Treeview` widget displays a hierarchical collection of items. Each item has a textual label, an optional image, and an optional list of data values. The data values are displayed in successive columns after the tree label.

The order in which data values are displayed may be controlled by setting the widget option `displaycolumns`. The tree widget can also display column headings. Columns may be accessed by number or symbolic names listed in the widget option columns. See Column Identifiers.

Each item is identified by an unique name. The widget will generate item IDs if they are not supplied by the caller. There is a distinguished root item, named `{}`. The root item itself is not displayed; its children appear at the top level of the hierarchy.

Each item also has a list of tags, which can be used to associate event bindings with individual items and control the appearance of the item.

The Treeview widget supports horizontal and vertical scrolling, according to the options described in Scrollable Widget Options and the methods `Treeview.xview()` and `Treeview.yview()`.

## Options

This widget accepts the following specific options:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>columns</td>
<td>A list of column identifiers, specifying the number of columns and their names.</td>
</tr>
<tr>
<td><strong>displaycolumns</strong></td>
<td>A list of column identifiers (either symbolic or integer indices) specifying which data columns are displayed and the order in which they appear, or the string “#all”.</td>
</tr>
<tr>
<td>-------------------</td>
<td>--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td><strong>height</strong></td>
<td>Specifies the number of rows which should be visible. Note: the requested width is determined from the sum of the column widths.</td>
</tr>
<tr>
<td><strong>padding</strong></td>
<td>Specifies the internal padding for the widget. The padding is a list of up to four length specifications.</td>
</tr>
<tr>
<td><strong>selectmode</strong></td>
<td>Controls how the built-in class bindings manage the selection. One of “extended”, “browse” or “none”. If set to “extended” (the default), multiple items may be selected. If “browse”, only a single item will be selected at a time. If “none”, the selection will not be changed. Note that the application code and tag bindings can set the selection however they wish, regardless of the value of this option.</td>
</tr>
</tbody>
</table>
| **show**          | A list containing zero or more of the following values, specifying which elements of the tree to display.  

- **tree**: display tree labels in column #0.  
- **headings**: display the heading row.  

The default is “tree headings”, i.e., show all elements.  

**Note**: Column #0 always refers to the tree column, even if show=”tree” is not specified. |
## Item Options

The following item options may be specified for items in the insert and item widget commands:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>text</td>
<td>The textual label to display for the item.</td>
</tr>
<tr>
<td>image</td>
<td>A Tk Image, displayed to the left of the label.</td>
</tr>
<tr>
<td>values</td>
<td>The list of values associated with the item. Each item should have the same number of values as the widget option columns. If there are fewer values than columns, the remaining values are assumed empty. If there are more values than columns, the extra values are ignored.</td>
</tr>
<tr>
<td>open</td>
<td>True/False value indicating whether the item's children should be displayed or hidden.</td>
</tr>
<tr>
<td>tags</td>
<td>A list of tags associated with this item.</td>
</tr>
</tbody>
</table>

## Tag Options

The following options may be specified on tags:

<table>
<thead>
<tr>
<th>option</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreground</td>
<td>Specifies the text foreground color.</td>
</tr>
<tr>
<td>background</td>
<td>Specifies the cell or item background color.</td>
</tr>
<tr>
<td>font</td>
<td>Specifies the font to use when drawing text.</td>
</tr>
<tr>
<td>image</td>
<td>Specifies the item image, in case the item's image option is empty.</td>
</tr>
</tbody>
</table>

## Column Identifiers

Column identifiers take any of the following forms:
• A symbolic name from the list of columns option.
• An integer n, specifying the nth data column.
• A string of the form #n, where n is an integer, specifying the nth display column.

Notes:

• Item’s option values may be displayed in a different order than the order in which they are stored.
• Column #0 always refers to the tree column, even if show="tree" is not specified.

A data column number is an index into an item's option values list; a display column number is the column number in the tree where the values are displayed. Tree labels are displayed in column #0. If option displaycolumns is not set, then data column n is displayed in column #n+1. Again, **column #0 always refers to the tree column.**

**Virtual Events**

The Treeview widget generates the following virtual events.

<table>
<thead>
<tr>
<th>event</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;&lt;TreeviewSelect&gt;&gt;</td>
<td>Generated whenever the selection changes.</td>
</tr>
<tr>
<td>&lt;&lt;TreeviewOpen&gt;&gt;</td>
<td>Generated just before settings the focus item to open=True.</td>
</tr>
<tr>
<td>&lt;&lt;TreeviewClose&gt;&gt;</td>
<td>Generated just after setting the focus item to open=False.</td>
</tr>
</tbody>
</table>

The `Treeview.focus()` and `Treeview.selection()` methods can be used to determine the affected item or items.

**ttk.Treeview**
class ttk.Treeview

bbox(item[, column=None])

Returns the bounding box (relative to the treeview widget’s window) of the specified item in the form (x, y, width, height).

If column is specified, returns the bounding box of that cell. If the item is not visible (i.e., if it is a descendant of a closed item or is scrolled offscreen), returns an empty string.

get_children([item])

Returns the list of children belonging to item.

If item is not specified, returns root children.

set_children(item, *newchildren)

Replaces item’s child with newchildren.

Children present in item that are not present in newchildren are detached from the tree. No items in newchildren may be an ancestor of item. Note that not specifying newchildren results in detaching item’s children.

column(column[, option=None[, **kw]])

Query or modify the options for the specified column.

If kw is not given, returns a dict of the column option values. If option is specified then the value for that option is returned. Otherwise, sets the options to the corresponding values.

The valid options/values are:

- id
  Returns the column name. This is a read-only option.

- anchor: One of the standard Tk anchor values.
Specifies how the text in this column should be aligned with respect to the cell.

- **minwidth**: `width`
  The minimum width of the column in pixels. The treeview widget will not make the column any smaller than specified by this option when the widget is resized or the user drags a column.

- **stretch**: `True/False`
  Specifies whether the column’s width should be adjusted when the widget is resized.

- **width**: `width`
  The width of the column in pixels.

To configure the tree column, call this with `column = "#0"

**delete(**`*items`**)***
Delete all specified `items` and all their descendants.

The root item may not be deleted.

**detach(**`*items`**)***
Unlinks all of the specified `items` from the tree.

The items and all of their descendants are still present, and may be reinserted at another point in the tree, but will not be displayed.

The root item may not be detached.

**exists(**`item`**)***
Returns True if the specified `item` is present in the tree.

**focus(**`[item=None]`)***
If \textit{item} is specified, sets the focus item to \textit{item}. Otherwise, returns the current focus item, or '' if there is none.

\textbf{heading}(column[, option=None[, **kw]])

Query or modify the heading options for the specified \textit{column}.

If \textit{kw} is not given, returns a dict of the heading option values. If \textit{option} is specified then the value for that \textit{option} is returned. Otherwise, sets the options to the corresponding values.

The valid options/values are:

- **text**: text
  - The text to display in the column heading.

- **image**: imageName
  - Specifies an image to display to the right of the column heading.

- **anchor**: anchor
  - Specifies how the heading text should be aligned. One of the standard Tk anchor values.

- **command**: callback
  - A callback to be invoked when the heading label is pressed.

To configure the tree column heading, call this with \textit{column} = \texttt{"#0"}.

\textbf{identify}(component, x, y)

Returns a description of the specified \textit{component} under the point given by \textit{x} and \textit{y}, or the empty string if no such \textit{component} is present at that position.

\textbf{identify_row}(y)
Returns the item ID of the item at position $y$.

**identify_column($x$)**

Returns the data column identifier of the cell at position $x$.

The tree column has ID #0.

**identify_region($x$, $y$)**

Returns one of:

<table>
<thead>
<tr>
<th>region</th>
<th>meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>heading</td>
<td>Tree heading area.</td>
</tr>
<tr>
<td>separator</td>
<td>Space between two columns headings.</td>
</tr>
<tr>
<td>tree</td>
<td>The tree area.</td>
</tr>
<tr>
<td>cell</td>
<td>A data cell.</td>
</tr>
</tbody>
</table>

Availability: Tk 8.6.

**identify_element($x$, $y$)**

Returns the element at position $x$, $y$.

Availability: Tk 8.6.

**index($item$)**

Returns the integer index of $item$ within its parent's list of children.

**insert($parent$, $index$, iid=None, **kw])**

Creates a new item and returns the item identifier of the newly created item.

$parent$ is the item ID of the parent item, or the empty string to create a new top-level item. $index$ is an integer, or the value “end”, specifying where in the list of parent's children to insert the new item. If $index$ is less than or equal to zero, the new
node is inserted at the beginning; if index is greater than or equal to the current number of children, it is inserted at the end. If iid is specified, it is used as the item identifier; iid must not already exist in the tree. Otherwise, a new unique identifier is generated.

See Item Options for the list of available points.

item(item[, option[, **kw]])

Query or modify the options for the specified item.

If no options are given, a dict with options/values for the item is returned. If option is specified then the value for that option is returned. Otherwise, sets the options to the corresponding values as given by kw.

move(item, parent, index)

Moves item to position index in parent's list of children.

It is illegal to move an item under one of its descendants. If index is less than or equal to zero, item is moved to the beginning; if greater than or equal to the number of children, it is moved to the end. If item was detached it is reattached.

next(item)

Returns the identifier of item's next sibling, or '' if item is the last child of its parent.

parent(item)

Returns the ID of the parent of item, or '' if item is at the top level of the hierarchy.

prev(item)

Returns the identifier of item's previous sibling, or '' if item is the first child of its parent.
reattach(item, parent, index)
    An alias for Treeview.move().

see(item)
    Ensure that item is visible.

    Sets all of item's ancestors open option to True, and scrolls the widget if necessary so that item is within the visible portion of the tree.

selection([selop=None, items=None])
    If selop is not specified, returns selected items. Otherwise, it will act according to the following selection methods.

selection_set(items)
    items becomes the new selection.

selection_add(items)
    Add items to the selection.

selection_remove(items)
    Remove items from the selection.

selection_toggle(items)
    Toggle the selection state of each item in items.

set(item[, column=None[, value=None]])
    With one argument, returns a dictionary of column/value pairs for the specified item. With two arguments, returns the current value of the specified column. With three arguments, sets the value of given column in given item to the specified value.

tag_bind(tagname[, sequence=None[, callback=None]])
    Bind a callback for the given event sequence to the tag tagname. When an event is delivered to an item, the callbacks
for each of the item’s tags option are called.

**tag_configure**(tagname[, option=\textit{None}, **\textit{kw}])

Query or modify the options for the specified \textit{tagname}.

If \textit{kw} is not given, returns a dict of the option settings for \textit{tagname}. If \textit{option} is specified, returns the value for that \textit{option} for the specified \textit{tagname}. Otherwise, sets the options to the corresponding values for the given \textit{tagname}.

**tag_has**(tagname[, item])

If \textit{item} is specified, returns 1 or 0 depending on whether the specified \textit{item} has the given \textit{tagname}. Otherwise, returns a list of all items that have the specified tag.

Availability: Tk 8.6

**xview**(\textit{*args})

Query or modify horizontal position of the treeview.

**yview**(\textit{*args})

Query or modify vertical position of the treeview.
Ttk Styling

Each widget in ttk is assigned a style, which specifies the set of elements making up the widget and how they are arranged, along with dynamic and default settings for element options. By default the style name is the same as the widget's class name, but it may be overridden by the widget's style option. If the class name of a widget is unknown, use the method `Misc.winfo_class()` (somewidget.winfo_class()).

See also:

Tcl'2004 conference presentation
This document explains how the theme engine works

class ttk.Style
This class is used to manipulate the style database.

`configure(style, query_opt=None, **kw)`
Query or set the default value of the specified option(s) in `style`.

Each key in `kw` is an option and each value is a string identifying the value for that option.

For example, to change every default button to be a flat button with some padding and a different background color do:

```python
import ttk
import Tkinter

root = Tkinter.Tk()
```
```python
ttk.Style().configure("TButton", padding=6, relief="flat", background="#ccc")
btn = ttk.Button(text="Sample")
btn.pack()
root.mainloop()
```

```python
map(style, query_opt=None, **kw)
```

Query or sets dynamic values of the specified option(s) in `style`.

Each key in `kw` is an option and each value should be a list or a tuple (usually) containing statespecs grouped in tuples, lists, or something else of your preference. A statespec is a compound of one or more states and then a value.

An example:

```python
import Tkinter
import ttk

root = Tkinter.Tk()

style = ttk.Style()
style.map("C.TButton",
    foreground=[('pressed', 'red'), ('active', 'blue')],
    background=[('pressed', '!disabled', 'black'), ('active', 'white')]

colored_btn = ttk.Button(text="Test", style="C.TButton").pack()

root.mainloop()
```

Note that the order of the (states, value) sequences for an option matters. In the previous example, if you change the order to `[(active', 'blue'), ('pressed', 'red')]` in the foreground option, for example, you would get a blue foreground when the widget is in the active or pressed states.
**lookup**(*style, option[, state=None[, default=None]]*)

Returns the value specified for *option* in *style*.

If *state* is specified, it is expected to be a sequence of one or more states. If the *default* argument is set, it is used as a fallback value in case no specification for *option* is found.

To check what font a Button uses by default, do:

```python
import ttk
print ttk.Style().lookup("TButton", "font")
```

**layout**(*style[, layoutspec=None]*)

Define the widget layout for given *style*. If *layoutspec* is omitted, return the layout specification for given *style*.

*layoutspec*, if specified, is expected to be a list or some other sequence type (excluding strings), where each item should be a tuple and the first item is the layout name and the second item should have the format described in *Layouts*.

To understand the format, see the following example (it is not intended to do anything useful):

```python
import ttk
import Tkinter

root = Tkinter.Tk()

style = ttk.Style()
style.layout("TMenubutton", [  ("Menubutton.background", None),  ("Menubutton.button", {"children":  [("Menubutton.focus", {"children":  [("Menubutton.padding", {"children":  ["Menubutton.label", {"side": "left", "ex
```
element_create(elementname, etype, *args, **kw)

Create a new element in the current theme, of the given etype which is expected to be either “image”, “from” or “vsapi”. The latter is only available in Tk 8.6a for Windows XP and Vista and is not described here.

If “image” is used, args should contain the default image name followed by statespec/value pairs (this is the imagespec), and kw may have the following options:

- border=padding
  padding is a list of up to four integers, specifying the left, top, right, and bottom borders, respectively.

- height=height
  Specifies a minimum height for the element. If less than zero, the base image’s height is used as a default.

- padding=padding
  Specifies the element’s interior padding. Defaults to border’s value if not specified.

- sticky=spec
  Specifies how the image is placed within the final parcel. spec contains zero or more characters “n”, “s”, “w”, or “e”.
• width=width
   Specifies a minimum width for the element. If less than zero, the base image's width is used as a default.

If “from” is used as the value of etype, `element_create()` will clone an existing element. `args` is expected to contain a themename, from which the element will be cloned, and optionally an element to clone from. If this element to clone from is not specified, an empty element will be used. `kw` is discarded.

`element_names()`
Returns the list of elements defined in the current theme.

`element_options(elementname)`
Returns the list of `elementname`'s options.

`theme_create(themename[, parent=None[, settings=None]])`
Create a new theme.

It is an error if `themename` already exists. If `parent` is specified, the new theme will inherit styles, elements and layouts from the parent theme. If `settings` are present they are expected to have the same syntax used for `theme_settings()`.

`theme_settings(themename, settings)`
Temporarily sets the current theme to `themename`, apply specified `settings` and then restore the previous theme.

Each key in `settings` is a style and each value may contain the keys ‘configure’, ‘map’, ‘layout’ and ‘element create’ and they are expected to have the same format as specified by the methods `Style.configure()`, `Style.map()`, `Style.layout()` and `Style.element_create()` respectively.
As an example, let’s change the Combobox for the default theme a bit:

```python
import ttk
import Tkinter

root = Tkinter.Tk()

style = ttk.Style()
style.theme_settings("default", {
    "TCombobox": {
        "configure": {"padding": 5},
        "map": {
            "background": ["active", "green2"],
            "!disabled", "green4"
        ],
        "foreground": ["focus", "OliveDrab1"],
        "!disabled", "OliveDrab2"
    }
})

combo = ttk.Combobox().pack()

root.mainloop()
```

**theme_names()**

Returns a list of all known themes.

**theme_use([themenname])**

If *themenname* is not given, returns the theme in use. Otherwise, sets the current theme to *themenname*, refreshes all widgets and emits a <<ThemeChanged>> event.

## Layouts

A layout can be just None, if it takes no options, or a dict of options specifying how to arrange the element. The layout mechanism uses a simplified version of the pack geometry manager: given an initial cavity, each element is allocated a parcel. Valid options/values are:
- **side**: `whichside`  
  Specifies which side of the cavity to place the element; one of top, right, bottom or left. If omitted, the element occupies the entire cavity.

- **sticky**: `nswe`  
  Specifies where the element is placed inside its allocated parcel.

- **unit**: 0 or 1  
  If set to 1, causes the element and all of its descendants to be treated as a single element for the purposes of `Widget.identify()` et al. It’s used for things like scrollbar thumbs with grips.

- **children**: `[sublayout...]`  
  Specifies a list of elements to place inside the element. Each element is a tuple (or other sequence type) where the first item is the layout name, and the other is a `Layout`.
