the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized Formatters would be used with particular Handlers.

*Changed in version 2.5: extra was added.*

Logger.\texttt{info}(msg[, *args[, **kwargs]])
Logs a message with level \texttt{INFO} on this logger. The arguments are interpreted as for \texttt{debug()}.

Logger.\texttt{warning}(msg[, *args[, **kwargs]])
Logs a message with level \texttt{WARNING} on this logger. The arguments are interpreted as for \texttt{debug()}.

Logger.\texttt{error}(msg[, *args[, **kwargs]])
Logs a message with level \texttt{ERROR} on this logger. The arguments are interpreted as for \texttt{debug()}.

Logger.\texttt{critical}(msg[, *args[, **kwargs]])
Logs a message with level \texttt{CRITICAL} on this logger. The arguments are interpreted as for \texttt{debug()}.

Logger.\texttt{log}(lvl, msg[, *args[, **kwargs]])
Logs a message with integer level \texttt{lvl} on this logger. The other arguments are interpreted as for \texttt{debug()}.

Logger.\texttt{exception}(msg[, *args])
Logs a message with level \texttt{ERROR} on this logger. The arguments are interpreted as for \texttt{debug()}. Exception info is added to the logging message. This method should only be called from an
exception handler.

Logger.addFilter(filt)
    Adds the specified filter filt to this logger.

Logger.removeFilter(filt)
    Removes the specified filter filt from this logger.

Logger.filter(record)
    Applies this logger's filters to the record and returns a true value if the record is to be processed.

Logger.addHandler(hdlr)
    Adds the specified handler hdlr to this logger.

Logger.removeHandler(hdlr)
    Removes the specified handler hdlr from this logger.

Logger.findCaller()
    Finds the caller's source filename and line number. Returns the filename, line number and function name as a 3-element tuple.

    Changed in version 2.4: The function name was added. In earlier versions, the filename and line number were returned as a 2-element tuple.

Logger.handle(record)
    Handles a record by passing it to all handlers associated with this logger and its ancestors (until a false value of propagate is found). This method is used for unpickled records received from a socket, as well as those created locally. Logger-level filtering is applied using filter().

Logger.makeRecord(name, lvl, fn, lno, msg, args, exc_info[, func,
Extra]

This is a factory method which can be overridden in subclasses to create specialized LogRecord instances.

*Changed in version 2.5: func and extra were added.*
15.7.6. Basic example

*Changed in version 2.4:* formerly `basicConfig()` did not take any keyword arguments.

The `logging` package provides a lot of flexibility, and its configuration can appear daunting. This section demonstrates that simple use of the logging package is possible.

The simplest example shows logging to the console:

```python
import logging

logging.debug('A debug message')
logging.info('Some information')
logging.warning('A shot across the bows')
```

If you run the above script, you’ll see this:

```
WARNING:root:A shot across the bows
```

Because no particular logger was specified, the system used the root logger. The debug and info messages didn’t appear because by default, the root logger is configured to only handle messages with a severity of WARNING or above. The message format is also a configuration default, as is the output destination of the messages - `sys.stderr`. The severity level, the message format and destination can be easily changed, as shown in the example below:

```python
import logging

logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(levelname)s %(message)s',
                    filename='myapp.log',
                    filemode='w')

logging.debug('A debug message')
logging.info('Some information')
```
The `basicConfig()` method is used to change the configuration defaults, which results in output (written to `myapp.log`) which should look something like the following:

```
2004-07-02 13:00:08,743 DEBUG A debug message
2004-07-02 13:00:08,743 INFO Some information
2004-07-02 13:00:08,743 WARNING A shot across the bows
```

This time, all messages with a severity of DEBUG or above were handled, and the format of the messages was also changed, and output went to the specified file rather than the console.

Formatting uses standard Python string formatting - see section `String Formatting Operations`. The format string takes the following common specifiers. For a complete list of specifiers, consult the `Formatter` documentation.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>%(name)s</td>
<td>Name of the logger (logging channel).</td>
</tr>
<tr>
<td>%(levelname)s</td>
<td>Text logging level for the message ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL').</td>
</tr>
<tr>
<td>%(asctime)s</td>
<td>Human-readable time when the <code>LogRecord</code> was created. By default this is of the form “2003-07-08 16:49:45,896” (the numbers after the comma are millisecond portion of the time).</td>
</tr>
<tr>
<td>%(message)s</td>
<td>The logged message.</td>
</tr>
</tbody>
</table>

To change the date/time format, you can pass an additional keyword parameter, `datefmt`, as in the following:

```
import logging

logging.basicConfig(level=logging.DEBUG, format='%(asctime)s %(levelname)-8s %(message)s', datefmt='%Y-%m-%d %H:%M:%S')
```
which would result in output like

Fri, 02 Jul 2004 13:06:18 DEBUG A debug message
Fri, 02 Jul 2004 13:06:18 INFO Some information
Fri, 02 Jul 2004 13:06:18 WARNING A shot across the bows

The date format string follows the requirements of strftime() - see the documentation for the time module.

If, instead of sending logging output to the console or a file, you’d rather use a file-like object which you have created separately, you can pass it to basicConfig() using the stream keyword argument. Note that if both stream and filename keyword arguments are passed, the stream argument is ignored.

Of course, you can put variable information in your output. To do this, simply have the message be a format string and pass in additional arguments containing the variable information, as in the following example:

```python
import logging

logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s %(levelname)-8s %(message)s',
    datefmt='%a, %d %b %Y %H:%M:%S',
    filename='/temp/myapp.log',
    filemode='w')

logging.error('Pack my box with %d dozen %s', 5, 'liquor jugs')
```

which would result in
Pack my box with 5 dozen liquor jugs.
15.7.7. Logging to multiple destinations

Let’s say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let’s also assume that the file should contain timestamps, but the console messages should not. Here’s how you can achieve this:

```python
import logging

# set up logging to file - see previous section for more details
logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s (%(name)-12s) %(levelname)-8s %(message)s',
                    datefmt='%m-%d %H:%M',
                    filename='/tmp/myapp.log',
                    filemode='w')

# define a Handler which writes INFO messages or higher to the console
console = logging.StreamHandler()
console.setLevel(logging.INFO)

# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s %(message)s')

# tell the handler to use this format
console.setFormatter(formatter)

# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger. First to the root
logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent areas in your
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```
When you run this, on the console you will see

```
root    : INFO      Jackdaws love my big sphinx of quartz.
myapp.area1 : INFO     How quickly daft jumping zebras vex.
myapp.area2 : WARNING  Jail zesty vixen who grabbed pay from qu
myapp.area2 : ERROR     The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 root INFO    Jackdaws love my big sphinx o
10-22 22:19 myapp.area1 DEBUG Quick zephyrs blow, vexing da
10-22 22:19 myapp.area1 INFO     How quickly daft jumping zebr
10-22 22:19 myapp.area2 WARNING Jail zesty vixen who grabbed
10-22 22:19 myapp.area2 ERROR     The five boxing wizards jump
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.
The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a `Handler` subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in `Handler` checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

**Note:** The default value of `raiseExceptions` is True. This is because during development, you typically want to be notified of any exceptions that occur. It’s advised that you set `raiseExceptions` to `False` for production usage.
15.7.9. Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the `extra` parameter to achieve this, it’s not always convenient to pass the information in this way. While it might be tempting to create `Logger` instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of `Logger` instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of `Logger` instances becomes effectively unbounded.

An easy way in which you can pass contextual information to be output along with logging event information is to use the `LoggerAdapter` class. This class is designed to look like a `Logger`, so that you can call `debug()`, `info()`, `warning()`, `error()`, `exception()`, `critical()` and `log()`. These methods have the same signatures as their counterparts in `Logger`, so you can use the two types of instances interchangeably.

When you create an instance of `LoggerAdapter`, you pass it a `Logger` instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance of `LoggerAdapter`, it delegates the call to the underlying instance of `Logger` passed to its constructor, and arranges to pass the contextual information in the delegated call. Here’s a snippet from the code of `LoggerAdapter`:
def debug(self, msg, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, after adding contextual information from this adapter instance.
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)

The **process()** method of **LoggerAdapter** is where the contextual information is added to the logging output. It’s passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an “extra” key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an “extra” keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using “extra” is that the values in the dict-like object are merged into the **LogRecord** instance’s **__dict__**, allowing you to use customized strings with your **Formatter** instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass **LoggerAdapter** and override **process()** to do what you need. Here’s an example script which uses this class, which also illustrates what dict-like behaviour is needed from an arbitrary “dict-like” object for use in the constructor:

```python
import logging
class ConnInfo:
    """
    An example class which shows how an arbitrary class can be the 'extra' context information repository passed to a Logg
    """
```
def __getitem__(self, name):
    """
    To allow this instance to look like a dict.
    """
    from random import choice
    if name == "ip":
        result = choice(["127.0.0.1", "192.168.0.1"])
    elif name == "user":
        result = choice(["jim", "fred", "sheila"])
    else:
        result = self.__dict__.get(name, "?")
    return result

def __iter__(self):
    """
    To allow iteration over keys, which will be merged into the LogRecord dict before formatting and output.
    """
    keys = ["ip", "user"]
    keys.extend(self.__dict__.keys())
    return keys.__iter__()

if __name__ == "__main__":
    from random import choice
    levels = (logging.DEBUG, logging.INFO, logging.WARNING, logging.ERROR, logging.CRITICAL)
    a1 = logging.LoggerAdapter(logging.getLogger("a.b.c"),
    { "ip" : "123.231.231.123", "user" : "sheila" })
    logging.basicConfig(level=logging.DEBUG,
    format="%(asctime)-15s	%(name)-5s	%(levelname)-8s	IP:	%(ip)-15s	User:	%(user)-8s	%(message)s")
    a1.debug("A debug message")
    a1.info("An info message with %s", "some parameters")
    a2 = logging.LoggerAdapter(logging.getLogger("d.e.f"), Conn)
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
        a2.log(lvl, "A message at %s level with %d %s", lvlname, 2, "parameters")

When this script is run, the output should look something like this:

```
2008-01-18 14:49:54,023 d.e.f CRITICAL IP: 192.168.0.1 User
2008-01-18 14:49:54,033 d.e.f INFO IP: 192.168.0.1 User
2008-01-18 14:49:54,033 d.e.f WARNING IP: 192.168.0.1 User
```
New in version 2.6.

The LoggerAdapter class was not present in previous versions.
15.7.10. Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process is supported, logging to a single file from multiple processes is not supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, the best way of doing this is to have all the processes log to a `SocketHandler`, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) The following section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

If you are using a recent version of Python which includes the `multiprocessing` module, you can write your own handler which uses the `Lock` class from this module to serialize access to the file from your processes. The existing `FileHandler` and subclasses do not make use of `multiprocessing` at present, though they may do so in the future. Note that at present, the `multiprocessing` module does not provide working lock functionality on all platforms (see [http://bugs.python.org/issue3770](http://bugs.python.org/issue3770)).
15.7.11. Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```python
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
   logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler sends t
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger. First
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might represent a
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.
logger1.info('How quickly daft jumping zebras vex.
logger2.warning('Jail zesty vixen who grabbed pay from quack.
logger2.error('The five boxing wizards jump quickly.
```

At the receiving end, you can set up a receiver using the `SocketServer` module. Here is a basic working example:

```python
import cPickle
import logging
import logging.handlers
import SocketServer
```
import struct

class LogRecordStreamHandler(SocketServer.StreamRequestHandler):
    '''Handler for a streaming logging request.
    This basically logs the record using whatever logging policy is configured locally.'''

def handle(self):
    '''Handle multiple requests - each expected to be a 4-byte length, followed by the LogRecord in pickle format. Logs the record according to whatever policy is configured locally.'''
    while 1:
        chunk = self.connection.recv(4)
        if len(chunk) < 4:
            break
        slen = struct.unpack('>L', chunk)[0]
        chunk = self.connection.recv(slen)
        while len(chunk) < slen:
            chunk = chunk + self.connection.recv(slen - len(chunk))
        obj = self.unPickle(chunk)
        record = logging.makeLogRecord(obj)
        self.handleLogRecord(record)

def unPickle(self, data):
    return cPickle.loads(data)

def handleLogRecord(self, record):
    # if a name is specified, we use the named logger rather than the one implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because Logger.handle is normally called AFTER logger-level filtering. If you # to do filtering, do it at the client end to save wasted cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(SocketServer.ThreadingTCPServer):
    '''Simple TCP socket-based logging receiver suitable for testing.'''
allow_reuse_address = 1

def __init__(self, host='localhost',
    port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
    handler=LogRecordStreamHandler):
    SocketServer.ThreadingTCPServer.__init__(self, (host, port),
    handler)
    self.abort = 0
    self.timeout = 1
    self.logname = None

def serve_until_stopped(self):
    import select
    abort = 0
    while not abort:
        rd, wr, ex = select.select([self.socket.fileno()],
                                   [], [],
                                   self.timeout)

        if rd:
            self.handle_request()
        abort = self.abort

def main():
    logging.basicConfig(
        format="%d %s %s %s",
        datefmt="%m-%d-%y %H:%M:%S",
        level=logging.DEBUG)

    tcpserver = LogRecordSocketReceiver()
    print "About to start TCP server..."
    tcpserver.serve_until_stopped()

if __name__ == "__main__":
    main()
15.7.12. Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.
15.7.13. Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```python
if logger.isEnabledFor(logging.DEBUG):
    logger.debug("Message with %s, %s", expensive_func1(), expensive_func2())
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1()` and `expensive_func2()` are never made.

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don’t need:

<table>
<thead>
<tr>
<th>What you don't want to collect</th>
<th>How to avoid collecting it</th>
</tr>
</thead>
<tbody>
<tr>
<td>Information about where calls were made from.</td>
<td>Set <code>logging._srcfile</code> to <code>None</code>.</td>
</tr>
<tr>
<td>Threading information.</td>
<td>Set <code>logging.logThreads</code> to <code>0</code>.</td>
</tr>
<tr>
<td>Process information.</td>
<td>Set <code>logging.logProcesses</code> to <code>0</code>.</td>
</tr>
</tbody>
</table>

Also note that the core logging module only includes the basic handlers. If you don’t import `logging.handlers` and `logging.config`, they won’t take up any memory.
15.7.14. Handler Objects

Handlers have the following attributes and methods. Note that `Handler` is never instantiated directly; this class acts as a base for more useful subclasses. However, the `__init__()` method in subclasses needs to call `Handler.__init__()`.

`Handler. __init__(level=NOTSET)`

Initializes the `Handler` instance by setting its level, setting the list of filters to the empty list and creating a lock (using `createLock()`) for serializing access to an I/O mechanism.

`Handler.createLock()`

Initializes a thread lock which can be used to serialize access to underlying I/O functionality which may not be threadsafe.

`Handler.acquire()`

Acquires the thread lock created with `createLock()`.

`Handler.release()`

Releases the thread lock acquired with `acquire()`.

`Handler.setLevel(lvl)`

Sets the threshold for this handler to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a handler is created, the level is set to `NOTSET` (which causes all messages to be processed).

`Handler.setFormatter(form)`

Sets the `Formatter` for this handler to `form`.

`Handler.addFilter(filt)`
Adds the specified filter \texttt{filt} to this handler.

\textbf{Handler.} \texttt{removeFilter(filt)}
Removes the specified filter \texttt{filt} from this handler.

\textbf{Handler.} \texttt{filter(record)}
Applies this handler's filters to the record and returns a true value if the record is to be processed.

\textbf{Handler.} \texttt{flush()}
Ensure all logging output has been flushed. This version does nothing and is intended to be implemented by subclasses.

\textbf{Handler.} \texttt{close()}
Tidy up any resources used by the handler. This version does no output but removes the handler from an internal list of handlers which is closed when \texttt{shutdown()} is called. Subclasses should ensure that this gets called from overridden \texttt{close()} methods.

\textbf{Handler.} \texttt{handle(record)}
Conditionally emits the specified logging record, depending on filters which may have been added to the handler. Wraps the actual emission of the record with acquisition/release of the I/O thread lock.

\textbf{Handler.} \texttt{handleError(record)}
This method should be called from handlers when an exception is encountered during an \texttt{emit()} call. By default it does nothing, which means that exceptions get silently ignored. This is what is mostly wanted for a logging system - most users will not care about errors in the logging system, they are more interested in application errors. You could, however, replace this with a custom handler if you wish. The specified record is the one which was being processed when the exception occurred.
Handler.\texttt{format}(\texttt{record})

Do formatting for a record - if a formatter is set, use it. Otherwise, use the default formatter for the module.

Handler.\texttt{emit}(\texttt{record})

Do whatever it takes to actually log the specified logging record. This version is intended to be implemented by subclasses and so raises a \texttt{NotImplementedError}.

15.7.14.1. StreamHandler

The \texttt{StreamHandler} class, located in the core \texttt{logging} package, sends logging output to streams such as \texttt{sys.stdout}, \texttt{sys.stderr} or any file-like object (or, more precisely, any object which supports \texttt{write()} and \texttt{flush()} methods).

\texttt{class logging\texttt{.StreamHandler}\texttt{([\texttt{stream}]})}

Returns a new instance of the \texttt{StreamHandler} class. If \texttt{stream} is specified, the instance will use it for logging output; otherwise, \texttt{sys.stderr} will be used.

\texttt{emit}(\texttt{record})

If a formatter is specified, it is used to format the record. The record is then written to the stream with a trailing newline. If exception information is present, it is formatted using \texttt{traceback.print_exception()} and appended to the stream.

\texttt{flush()}

Flushes the stream by calling its \texttt{flush()} method. Note that the \texttt{close()} method is inherited from \texttt{Handler} and so does no output, so an explicit \texttt{flush()} call may be needed at times.

15.7.14.2. FileHandler
The `FileHandler` class, located in the core `logging` package, sends logging output to a disk file. It inherits the output functionality from `StreamHandler`.

```python
class logging.FileHandler(filename[, mode[, encoding[, delay]]])
```

Returns a new instance of the `FileHandler` class. The specified file is opened and used as the stream for logging. If `mode` is not specified, 'a' is used. If `encoding` is not `None`, it is used to open the file with that encoding. If `delay` is true, then file opening is deferred until the first call to `emit()`. By default, the file grows indefinitely.

*Changed in version 2.6: delay was added.*

```python
close()
```

Closes the file.

```python
emit(record)
```

Outputs the record to the file.

### 15.7.14.3. NullHandler

*New in version 2.7.*

The `NullHandler` class, located in the core `logging` package, does not do any formatting or output. It is essentially a “no-op” handler for use by library developers.

```python
class logging.NullHandler
```

Returns a new instance of the `NullHandler` class.

```python
emit(record)
```

This method does nothing.
See *Configuring Logging for a Library* for more information on how to use *NullHandler*.

15.7.14.4. WatchedFileHandler

*New in version 2.6.*

The *WatchedFileHandler* class, located in the *logging.handlers* module, is a *FileHandler* which watches the file it is logging to. If the file changes, it is closed and reopened using the file name.

A file change can happen because of usage of programs such as *newsyslog* and *logrotate* which perform log file rotation. This handler, intended for use under Unix/Linux, watches the file to see if it has changed since the last emit. (A file is deemed to have changed if its device or inode have changed.) If the file has changed, the old file stream is closed, and the file opened to get a new stream.

This handler is not appropriate for use under Windows, because under Windows open log files cannot be moved or renamed - logging opens the files with exclusive locks - and so there is no need for such a handler. Furthermore, *ST_INO* is not supported under Windows; *stat()* always returns zero for this value.

```
class logging.handlers.WatchedFileHandler(filename[, mode[, encoding[, delay]]])
```

Returns a new instance of the *WatchedFileHandler* class. The specified file is opened and used as the stream for logging. If *mode* is not specified, 'a' is used. If *encoding* is not *None*, it is used to open the file with that encoding. If *delay* is true, then file opening is deferred until the first call to *emit()*.

*Changed in version 2.6*: *delay* was added.
emit(record)

Outputs the record to the file, but first checks to see if the file has changed. If it has, the existing stream is flushed and closed and the file opened again, before outputting the record to the file.

15.7.14.5. RotatingFileHandler

The RotatingFileHandler class, located in the logging.handlers module, supports rotation of disk log files.

class logging.handlers.RotatingFileHandler(filename[, mode[, maxBytes[, backupCount[, encoding[, delay]]]]])

Returns a new instance of the RotatingFileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. If encoding is not None, it is used to open the file with that encoding. If delay is true, then file opening is deferred until the first call to emit(). By default, the file grows indefinitely.

You can use the maxBytes and backupCount values to allow the file to rollover at a predetermined size. When the size is about to be exceeded, the file is closed and a new file is silently opened for output. Rollover occurs whenever the current log file is nearly maxBytes in length; if maxBytes is zero, rollover never occurs. If backupCount is non-zero, the system will save old log files by appending the extensions ".1", ".2" etc., to the filename. For example, with a backupCount of 5 and a base file name of app.log, you would get app.log, app.log.1, app.log.2, up to app.log.5. The file being written to is always app.log. When this file is filled, it is closed and renamed to app.log.1, and if files app.log.1, app.log.2, etc. exist, then they are renamed to app.log.2, app.log.3 etc. respectively.
Changed in version 2.6: delay was added.

doRollover()
  Does a rollover, as described above.

emit(record)
  Outputs the record to the file, catering for rollover as described previously.

15.7.14.6. TimedRotatingFileHandler

The TimedRotatingFileHandler class, located in the logging.handlers module, supports rotation of disk log files at certain timed intervals.

```python
class logging.handlers.TimedRotatingFileHandler(filename[, when[, interval[, backupCount[, encoding[, delay[, utc]]]]]])
```

Returns a new instance of the TimedRotatingFileHandler class. The specified file is opened and used as the stream for logging. On rotating it also sets the filename suffix. Rotating happens based on the product of when and interval.

You can use the when to specify the type of interval. The list of possible values is below. Note that they are not case sensitive.

<table>
<thead>
<tr>
<th>Value</th>
<th>Type of interval</th>
</tr>
</thead>
<tbody>
<tr>
<td>'S'</td>
<td>Seconds</td>
</tr>
<tr>
<td>'M'</td>
<td>Minutes</td>
</tr>
<tr>
<td>'H'</td>
<td>Hours</td>
</tr>
<tr>
<td>'D'</td>
<td>Days</td>
</tr>
<tr>
<td>'W'</td>
<td>Week day (0=Monday)</td>
</tr>
<tr>
<td>'midnight'</td>
<td>Roll over at midnight</td>
</tr>
</tbody>
</table>
The system will save old log files by appending extensions to the filename. The extensions are date-and-time based, using the strftime format `%Y-%m-%d_%H-%M-%S` or a leading portion thereof, depending on the rollover interval.

When computing the next rollover time for the first time (when the handler is created), the last modification time of an existing log file, or else the current time, is used to compute when the next rotation will occur.

If the `utc` argument is true, times in UTC will be used; otherwise local time is used.

If `backupCount` is nonzero, at most `backupCount` files will be kept, and if more would be created when rollover occurs, the oldest one is deleted. The deletion logic uses the interval to determine which files to delete, so changing the interval may leave old files lying around.

If `delay` is true, then file opening is deferred until the first call to `emit()`.

*Changed in version 2.6: delay was added.*

**doRollover()**

Does a rollover, as described above.

**emit(record)**

Outputs the record to the file, catering for rollover as described above.

## 15.7.14.7. SocketHandler

The `SocketHandler` class, located in the `logging.handlers` module, sends logging output to a network socket. The base class uses a
TCP socket.

*class* logging.handlers.**SocketHandler**(host, port)

Returns a new instance of the SocketHandler class intended to communicate with a remote machine whose address is given by *host* and *port*.

**close()**

Closes the socket.

**emit()**

Pickles the record’s attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. If the connection was previously lost, re-establishes the connection. To unpickle the record at the receiving end into a LogRecord, use the makeLogRecord() function.

**handleError()**

Handles an error which has occurred during emit(). The most likely cause is a lost connection. Closes the socket so that we can retry on the next event.

**makeSocket()**

This is a factory method which allows subclasses to define the precise type of socket they want. The default implementation creates a TCP socket (**socket.SOCK_STREAM**).

**makePickle(record)**

Pickles the record's attribute dictionary in binary format with a length prefix, and returns it ready for transmission across the socket.

Note that pickles aren't completely secure. If you are concerned about security, you may want to override this
method to implement a more secure mechanism. For example, you can sign pickles using HMAC and then verify them on the receiving end, or alternatively you can disable unpickling of global objects on the receiving end.

\textbf{send}(\textit{packet})

Send a pickled string \textit{packet} to the socket. This function allows for partial sends which can happen when the network is busy.

\textbf{15.7.14.8. DatagramHandler}

The \texttt{DatagramHandler} class, located in the \texttt{logging.handlers} module, inherits from \texttt{SocketHandler} to support sending logging messages over UDP sockets.

\texttt{class} \texttt{logging.handlers.DatagramHandler}(\textit{host, port})

Returns a new instance of the \texttt{DatagramHandler} class intended to communicate with a remote machine whose address is given by \textit{host} and \textit{port}.

\texttt{emit()}

Pickles the record’s attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. To unpickle the record at the receiving end into a \texttt{LogRecord}, use the \texttt{makeLogRecord()} function.

\texttt{makeSocket()}

The factory method of \texttt{SocketHandler} is here overridden to create a UDP socket (\texttt{socket.SOCK_DGRAM}).

\texttt{send(s)}

Send a pickled string to a socket.
15.7.14.9. SysLogHandler

The `SysLogHandler` class, located in the `logging.handlers` module, supports sending logging messages to a remote or local Unix syslog.

```python
class logging.handlers.SysLogHandler([address[, facility[, socktype]])
```

Returns a new instance of the `SysLogHandler` class intended to communicate with a remote Unix machine whose address is given by `address` in the form of a `(host, port)` tuple. If `address` is not specified, `('localhost', 514)` is used. The address is used to open a socket. An alternative to providing a `(host, port)` tuple is providing an address as a string, for example “/dev/log”. In this case, a Unix domain socket is used to send the message to the syslog. If `facility` is not specified, `LOG_USER` is used. The type of socket opened depends on the `socktype` argument, which defaults to `socket.SOCK_DGRAM` and thus opens a UDP socket. To open a TCP socket (for use with the newer syslog daemons such as rsyslog), specify a value of `socket.SOCK_STREAM`.

*Changed in version 2.7: socktype was added.*

```python
close()
```

Closes the socket to the remote host.

```python
emit(record)
```

The record is formatted, and then sent to the syslog server. If exception information is present, it is not sent to the server.

```python
encodePriority(facility, priority)
```

Encodes the facility and priority into an integer. You can pass in strings or integers - if strings are passed, internal mapping dictionaries are used to convert them to integers.
The symbolic \texttt{LOG} values are defined in \texttt{SysLogHandler} and mirror the values defined in the \texttt{sys/syslog.h} header file.

### Priorities

<table>
<thead>
<tr>
<th>Name (string)</th>
<th>Symbolic value</th>
</tr>
</thead>
<tbody>
<tr>
<td>alert</td>
<td>\texttt{LOG_ALERT}</td>
</tr>
<tr>
<td>crit or critical</td>
<td>\texttt{LOG_CRIT}</td>
</tr>
<tr>
<td>debug</td>
<td>\texttt{LOG_DEBUG}</td>
</tr>
<tr>
<td>emerg or panic</td>
<td>\texttt{LOG_EMERG}</td>
</tr>
<tr>
<td>err or error</td>
<td>\texttt{LOG_ERR}</td>
</tr>
<tr>
<td>info</td>
<td>\texttt{LOG_INFO}</td>
</tr>
<tr>
<td>notice</td>
<td>\texttt{LOG_NOTICE}</td>
</tr>
<tr>
<td>warn or warning</td>
<td>\texttt{LOG_WARNING}</td>
</tr>
</tbody>
</table>

### Facilities

<table>
<thead>
<tr>
<th>Name (string)</th>
<th>Symbolic value</th>
</tr>
</thead>
<tbody>
<tr>
<td>auth</td>
<td>\texttt{LOG_AUTH}</td>
</tr>
<tr>

<td>\texttt{LOG_USER}</td>
</tr>
<tr>
<td>uucp</td>
<td>\texttt{LOG_UUCP}</td>
</tr>
<tr>
<td>local0</td>
<td>\texttt{LOG_LOCAL0}</td>
</tr>
<tr>
<td>local1</td>
<td>\texttt{LOG_LOCAL1}</td>
</tr>
<tr>
<td>local2</td>
<td>\texttt{LOG_LOCAL2}</td>
</tr>
</tbody>
</table>
mapPriority\((\text{levelname})\)
Maps a logging level name to a syslog priority name. You may need to override this if you are using custom levels, or if the default algorithm is not suitable for your needs. The default algorithm maps \texttt{DEBUG}, \texttt{INFO}, \texttt{WARNING}, \texttt{ERROR} and \texttt{CRITICAL} to the equivalent syslog names, and all other level names to “warning”.

15.7.14.10. NTEventLogHandler

The \texttt{NTEventLogHandler} class, located in the \texttt{logging.handlers} module, supports sending logging messages to a local Windows NT, Windows 2000 or Windows XP event log. Before you can use it, you need Mark Hammond's Win32 extensions for Python installed.

\begin{verbatim}
class logging.handlers.NTEventLogHandler(\texttt{appname}[, \texttt{dllname}[, \texttt{logtype}]]):
\end{verbatim}

Returns a new instance of the \texttt{NTEventLogHandler} class. The \texttt{appname} is used to define the application name as it appears in the event log. An appropriate registry entry is created using this name. The \texttt{dllname} should give the fully qualified pathname of a .dll or .exe which contains message definitions to hold in the log (if not specified, \texttt{win32service.pyd} is used - this is installed with the Win32 extensions and contains some basic placeholder message definitions. Note that use of these placeholders will make your event logs big, as the entire message source is held in the log. If you want slimmer logs, you have to pass in the name of
your own .dll or .exe which contains the message definitions you want to use in the event log). The `logtype` is one of 'Application', 'System' or 'Security', and defaults to 'Application'.

**close()**

At this point, you can remove the application name from the registry as a source of event log entries. However, if you do this, you will not be able to see the events as you intended in the Event Log Viewer - it needs to be able to access the registry to get the .dll name. The current version does not do this.

**emit(record)**

Determines the message ID, event category and event type, and then logs the message in the NT event log.

**getEventCategory(record)**

Returns the event category for the record. Override this if you want to specify your own categories. This version returns 0.

**getEventType(record)**

Returns the event type for the record. Override this if you want to specify your own types. This version does a mapping using the handler’s typemap attribute, which is set up in `_init_()` to a dictionary which contains mappings for DEBUG, INFO, WARNING, ERROR and CRITICAL. If you are using your own levels, you will either need to override this method or place a suitable dictionary in the handler’s typemap attribute.

**getMessageID(record)**

Returns the message ID for the record. If you are using your own messages, you could do this by having the `msg` passed to the logger being an ID rather than a format string. Then, in here, you could use a dictionary lookup to get the message.
ID. This version returns 1, which is the base message ID in win32service.pyd.

15.7.14.11. SMTPHandler

The SMTPHandler class, located in the logging.handlers module, supports sending logging messages to an email address via SMTP.

```python
class logging.handlers.SMTPHandler(mailhost, fromaddr, toaddrs, subject[, credentials])
```

Returns a new instance of the SMTPHandler class. The instance is initialized with the from and to addresses and subject line of the email. The toaddrs should be a list of strings. To specify a non-standard SMTP port, use the (host, port) tuple format for the mailhost argument. If you use a string, the standard SMTP port is used. If your SMTP server requires authentication, you can specify a (username, password) tuple for the credentials argument.

*Changed in version 2.6: credentials was added.*

```python
etit(record)
```

Formats the record and sends it to the specified addressees.

```python
getSubject(record)
```

If you want to specify a subject line which is record-dependent, override this method.

15.7.14.12. MemoryHandler

The MemoryHandler class, located in the logging.handlers module, supports buffering of logging records in memory, periodically flushing them to a target handler. Flushing occurs whenever the buffer is full, or when an event of a certain severity or greater is seen.
**MemoryHandler** is a subclass of the more general **BufferingHandler**, which is an abstract class. This buffers logging records in memory. Whenever each record is added to the buffer, a check is made by calling **shouldFlush**() to see if the buffer should be flushed. If it should, then **flush**() is expected to do the needful.

**class logging.handlers.BufferingHandler**(capacity)

Initializes the handler with a buffer of the specified capacity.

**emit**(record)

Appends the record to the buffer. If **shouldFlush**() returns true, calls **flush**() to process the buffer.

**flush**()

You can override this to implement custom flushing behavior. This version just zaps the buffer to empty.

**shouldFlush**(record)

Returns true if the buffer is up to capacity. This method can be overridden to implement custom flushing strategies.

**class logging.handlers.MemoryHandler**(capacity[, flushLevel[, target]])

Returns a new instance of the **MemoryHandler** class. The instance is initialized with a buffer size of capacity. If flushLevel is not specified, **ERROR** is used. If no target is specified, the target will need to be set using **setTarget**() before this handler does anything useful.

**close**()

Calls **flush**(), sets the target to **None** and clears the buffer.

**flush**()

For a **MemoryHandler**, flushing means just sending the buffered
records to the target, if there is one. Override if you want different behavior.

**setTarget**(target)
Sets the target handler for this handler.

**shouldFlush**(record)
Checks for buffer full or a record at the \textit{flushLevel} or higher.

### 15.7.14.13. HTTPHandler

The \texttt{HTTPHandler} class, located in the \texttt{logging.handlers} module, supports sending logging messages to a Web server, using either GET or POST semantics.

\begin{verbatim}
class logging.handlers.HTTPHandler((host, url[, method]))

Returns a new instance of the \texttt{HTTPHandler} class. The instance is initialized with a host address, url and HTTP method. The \textit{host} can be of the form \texttt{host:port}, should you need to use a specific port number. If no \textit{method} is specified, \texttt{GET} is used.

**emit**(record)
Sends the record to the Web server as an URL-encoded dictionary.
\end{verbatim}
15.7.15. Formatter Objects

Formatters have the following attributes and methods. They are responsible for converting a LogRecord to (usually) a string which can be interpreted by either a human or an external system. The base Formatter allows a formatting string to be specified. If none is supplied, the default value of '%(message)s' is used.

A Formatter can be initialized with a format string which makes use of knowledge of the LogRecord attributes - such as the default value mentioned above making use of the fact that the user’s message and arguments are pre-formatted into a LogRecord's message attribute. This format string contains standard Python %-style mapping keys. See section String Formatting Operations for more information on string formatting.

Currently, the useful mapping keys in a LogRecord are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>%(name)s</td>
<td>Name of the logger (logging channel).</td>
</tr>
<tr>
<td>%(levelname)s</td>
<td>Text logging level for the message ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL').</td>
</tr>
<tr>
<td>%(pathname)s</td>
<td>Full pathname of the source file where the logging call was issued (if available).</td>
</tr>
<tr>
<td>%(filename)s</td>
<td>Filename portion of pathname.</td>
</tr>
<tr>
<td>%(module)s</td>
<td>Module (name portion of filename).</td>
</tr>
<tr>
<td>%(funcName)s</td>
<td>Name of function containing the logging call.</td>
</tr>
<tr>
<td>%(lineno)d</td>
<td>Source line number where the logging call was issued (if available).</td>
</tr>
<tr>
<td>Field</td>
<td>Description</td>
</tr>
<tr>
<td>-----------------------</td>
<td>---------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>%(created)f</td>
<td>Time when the LogRecord was created (as returned by <code>time.time()</code>).</td>
</tr>
<tr>
<td>%(relativeCreated)d</td>
<td>Time in milliseconds when the LogRecord was created, relative to the time the logging module was loaded.</td>
</tr>
<tr>
<td>%(asctime)s</td>
<td>Human-readable time when the LogRecord was created. By default this is of the form “2003-07-08 16:49:45,896” (the numbers after the comma are millisecond portion of the time).</td>
</tr>
<tr>
<td>%(msecs)d</td>
<td>Millisecond portion of the time when the LogRecord was created.</td>
</tr>
<tr>
<td>%(thread)d</td>
<td>Thread ID (if available).</td>
</tr>
<tr>
<td>%(threadName)s</td>
<td>Thread name (if available).</td>
</tr>
<tr>
<td>%(process)d</td>
<td>Process ID (if available).</td>
</tr>
<tr>
<td>%(message)s</td>
<td>The logged message, computed as <code>msg % args</code>.</td>
</tr>
</tbody>
</table>

*Changed in version 2.5:* `funcName` was added.

```python
class logging.Formatter([fmt[, datefmt]])
```

Returns a new instance of the `Formatter` class. The instance is initialized with a format string for the message as a whole, as well as a format string for the date/time portion of a message. If no `fmt` is specified, `'%(message)s'` is used. If no `datefmt` is specified, the ISO8601 date format is used.

```python
format(record)
```

The record’s attribute dictionary is used as the operand to a string formatting operation. Returns the resulting string. Before formatting the dictionary, a couple of preparatory steps are carried out. The `message` attribute of the record is computed using `msg % args`. If the formatting string contains `'%(asctime)'`, `formatTime()` is called to format the event time.
If there is exception information, it is formatted using `formatException()` and appended to the message. Note that the formatted exception information is cached in attribute `exc_text`. This is useful because the exception information can be pickled and sent across the wire, but you should be careful if you have more than one `Formatter` subclass which customizes the formatting of exception information. In this case, you will have to clear the cached value after a formatter has done its formatting, so that the next formatter to handle the event doesn’t use the cached value but recalculates it afresh.

`formatTime(record[, datefmt])`
This method should be called from `format()` by a formatter which wants to make use of a formatted time. This method can be overridden in formatters to provide for any specific requirement, but the basic behavior is as follows: if `datefmt` (a string) is specified, it is used with `time.strftime()` to format the creation time of the record. Otherwise, the ISO8601 format is used. The resulting string is returned.

`formatException(exc_info)`
Formats the specified exception information (a standard exception tuple as returned by `sys.exc_info()`) as a string. This default implementation just uses `traceback.print_exception()`. The resulting string is returned.
Filters can be used by Handlers and Loggers for more sophisticated filtering than is provided by levels. The base filter class only allows events which are below a certain point in the logger hierarchy. For example, a filter initialized with “A.B” will allow events logged by loggers “A.B”, “A.B.C”, “A.B.C.D”, “A.B.D” etc. but not “A.BB”, “B.A.B” etc. If initialized with the empty string, all events are passed.

```python
class logging.Filter([name])

    Returns an instance of the Filter class. If name is specified, it names a logger which, together with its children, will have its events allowed through the filter. If no name is specified, allows every event.

    filter(record)

    Is the specified record to be logged? Returns zero for no, nonzero for yes. If deemed appropriate, the record may be modified in-place by this method.
```
15.7.17. LogRecord Objects

LogRecord instances are created every time something is logged. They contain all the information pertinent to the event being logged. The main information passed in is in msg and args, which are combined using msg % args to create the message field of the record. The record also includes information such as when the record was created, the source line where the logging call was made, and any exception information to be logged.

class logging. LogRecord(name, lvl, pathname, lineno, msg, args,
exc_info[, func])

Returns an instance of LogRecord initialized with interesting information. The name is the logger name; lvl is the numeric level; pathname is the absolute pathname of the source file in which the logging call was made; lineno is the line number in that file where the logging call is found; msg is the user-supplied message (a format string); args is the tuple which, together with msg, makes up the user message; and exc_info is the exception tuple obtained by calling sys.exc_info() (or None, if no exception information is available). The func is the name of the function from which the logging call was made. If not specified, it defaults to None.

Changed in version 2.5: func was added.

getMessage()

Returns the message for this LogRecord instance after merging any user-supplied arguments with the message.
15.7.18. LoggerAdapter Objects

New in version 2.6.

LoggerAdapter instances are used to conveniently pass contextual information into logging calls. For a usage example, see the section on adding contextual information to your logging output.

```python
class logging.LoggerAdapter(logger, extra)
    Returns an instance of LoggerAdapter initialized with an underlying Logger instance and a dict-like object.
```

```python
process(msg, kwargs)
    Modifies the message and/or keyword arguments passed to a logging call in order to insert contextual information. This implementation takes the object passed as extra to the constructor and adds it to kwargs using key 'extra'. The return value is a (msg, kwargs) tuple which has the (possibly modified) versions of the arguments passed in.
```

In addition to the above, LoggerAdapter supports all the logging methods of Logger, i.e. debug(), info(), warning(), error(), exception(), critical() and log(). These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

Changed in version 2.7.

The isEnabledFor() method was added to LoggerAdapter. This method delegates to the underlying logger.
The logging module is intended to be thread-safe without any special work needing to be done by its clients. It achieves this though using threading locks; there is one lock to serialize access to the module’s shared data, and each handler also creates a lock to serialize access to its underlying I/O.

If you are implementing asynchronous signal handlers using the `signal` module, you may not be able to use logging from within such handlers. This is because lock implementations in the `threading` module are not always re-entrant, and so cannot be invoked from such signal handlers.
15.7.20. Integration with the warnings module

The `captureWarnings()` function can be used to integrate logging with the `warnings` module.

```python
logging.captureWarnings(capture)
```

This function is used to turn the capture of warnings by logging on and off.

If `capture` is `True`, warnings issued by the `warnings` module will be redirected to the logging system. Specifically, a warning will be formatted using `warnings.formatwarning()` and the resulting string logged to a logger named “py.warnings” with a severity of `WARNING`.

If `capture` is `False`, the redirection of warnings to the logging system will stop, and warnings will be redirected to their original destinations (i.e. those in effect before `captureWarnings(True)` was called).
15.7.21. Configuration

15.7.21.1. Configuration functions

The following functions configure the logging module. They are located in the logging.config module. Their use is optional — you can configure the logging module using these functions or by making calls to the main API (defined in logging itself) and defining handlers which are declared either in logging or logging.handlers.

logging.dictConfig(config)

Takes the logging configuration from a dictionary. The contents of this dictionary are described in Configuration dictionary schema below.

If an error is encountered during configuration, this function will raise a ValueError, TypeError, AttributeError or ImportError with a suitably descriptive message. The following is a (possibly incomplete) list of conditions which will raise an error:

- A level which is not a string or which is a string not corresponding to an actual logging level.
- A propagate value which is not a boolean.
- An id which does not have a corresponding destination.
- A non-existent handler id found during an incremental call.
- An invalid logger name.
- Inability to resolve to an internal or external object.

Parsing is performed by the DictConfigurator class, whose constructor is passed the dictionary used for configuration, and has a configure() method. The logging.config module has a callable attribute dictConfigClass which is initially set to DictConfigurator. You can replace the value of dictConfigClass
with a suitable implementation of your own.

dictConfig() calls dictConfigClass passing the specified dictionary, and then calls the configure() method on the returned object to put the configuration into effect:

```python
def dictConfig(config):
    dictConfigClass(config).configure()
```

For example, a subclass of DictConfigurator could call DictConfigurator.__init__() in its own __init__(), then set up custom prefixes which would be usable in the subsequent configure() call. dictConfigClass would be bound to this new subclass, and then dictConfig() could be called exactly as in the default, uncustomized state.

logging.fileConfig(fname[, defaults])
Reads the logging configuration from a ConfigParser-format file named fname. This function can be called several times from an application, allowing an end user to select from various pre-canned configurations (if the developer provides a mechanism to present the choices and load the chosen configuration). Defaults to be passed to the ConfigParser can be specified in the defaults argument.

logging.listen([port])
Starts up a socket server on the specified port, and listens for new configurations. If no port is specified, the module's default DEFAULT_LOGGING_CONFIG_PORT is used. Logging configurations will be sent as a file suitable for processing by fileConfig(). Returns a Thread instance on which you can call start() to start the server, and which you can join() when appropriate. To stop the server, call stopListening().
To send a configuration to the socket, read in the configuration file and send it to the socket as a string of bytes preceded by a four-byte length string packed in binary using `struct.pack('>L', n)`.

```
logging.stopListening()
```

 Stops the listening server which was created with a call to `listen()`. This is typically called before calling `join()` on the return value from `listen()`.

### 15.7.21.2. Configuration dictionary schema

Describing a logging configuration requires listing the various objects to create and the connections between them; for example, you may create a handler named “console” and then say that the logger named “startup” will send its messages to the “console” handler. These objects aren’t limited to those provided by the `logging` module because you might write your own formatter or handler class. The parameters to these classes may also need to include external objects such as `sys.stderr`. The syntax for describing these objects and connections is defined in *Object connections* below.

### 15.7.21.2.1. Dictionary Schema Details

The dictionary passed to `dictConfig()` must contain the following keys:

- **version** - to be set to an integer value representing the schema version. The only valid value at present is 1, but having this key allows the schema to evolve while still preserving backwards compatibility.

All other keys are optional, but if present they will be interpreted as described below. In all cases below where a ‘configuring dict’ is
mentioned, it will be checked for the special '()' key to see if a custom instantiation is required. If so, the mechanism described in User-defined objects below is used to create an instance; otherwise, the context is used to determine what to instantiate.

- **formatters** - the corresponding value will be a dict in which each key is a formatter id and each value is a dict describing how to configure the corresponding Formatter instance.

  The configuring dict is searched for keys `format` and `datefmt` (with defaults of `None`) and these are used to construct a `logging.Formatter` instance.

- **filters** - the corresponding value will be a dict in which each key is a filter id and each value is a dict describing how to configure the corresponding Filter instance.

  The configuring dict is searched for the key `name` (defaulting to the empty string) and this is used to construct a `logging.Filter` instance.

- **handlers** - the corresponding value will be a dict in which each key is a handler id and each value is a dict describing how to configure the corresponding Handler instance.

  The configuring dict is searched for the following keys:

  - class (mandatory). This is the fully qualified name of the handler class.
  - level (optional). The level of the handler.
  - formatter (optional). The id of the formatter for this handler.
  - filters (optional). A list of ids of the filters for this handler.

  All other keys are passed through as keyword arguments to the handler’s constructor. For example, given the snippet:
handlers:
  console:
    class : logging.StreamHandler
    formatter: brief
    level : INFO
    filters: [allow_foo]
    stream : ext://sys.stdout
  file:
    class : logging.handlers.RotatingFileHandler
    formatter: precise
    filename: logconfig.log
    maxBytes: 1024
    backupCount: 3

the handler with id console is instantiated as a logging.StreamHandler, using sys.stdout as the underlying stream. The handler with id file is instantiated as a logging.handlers.RotatingFileHandler with the keyword arguments filename='logconfig.log', maxBytes=1024, backupCount=3.

- **loggers** - the corresponding value will be a dict in which each key is a logger name and each value is a dict describing how to configure the corresponding Logger instance.

The configuring dict is searched for the following keys:

- **level** (optional). The level of the logger.
- **propagate** (optional). The propagation setting of the logger.
- **filters** (optional). A list of ids of the filters for this logger.
- **handlers** (optional). A list of ids of the handlers for this logger.

The specified loggers will be configured according to the level, propagation, filters and handlers specified.

- **root** - this will be the configuration for the root logger. Processing
of the configuration will be as for any logger, except that the `propagate` setting will not be applicable.

- *incremental* - whether the configuration is to be interpreted as incremental to the existing configuration. This value defaults to `False`, which means that the specified configuration replaces the existing configuration with the same semantics as used by the existing `fileConfig()` API.

  If the specified value is `True`, the configuration is processed as described in the section on *Incremental Configuration*.

- *disable_existing_loggers* - whether any existing loggers are to be disabled. This setting mirrors the parameter of the same name in `fileConfig()`. If absent, this parameter defaults to `True`. This value is ignored if `incremental` is `True`.

### 15.7.21.2.2. Incremental Configuration

It is difficult to provide complete flexibility for incremental configuration. For example, because objects such as filters and formatters are anonymous, once a configuration is set up, it is not possible to refer to such anonymous objects when augmenting a configuration.

Furthermore, there is not a compelling case for arbitrarily altering the object graph of loggers, handlers, filters, formatters at run-time, once a configuration is set up; the verbosity of loggers and handlers can be controlled just by setting levels (and, in the case of loggers, propagation flags). Changing the object graph arbitrarily in a safe way is problematic in a multi-threaded environment; while not impossible, the benefits are not worth the complexity it adds to the implementation.

Thus, when the `incremental` key of a configuration dict is present
and is True, the system will completely ignore any formatters and filters entries, and process only the level settings in the handlers entries, and the level and propagate settings in the loggers and root entries.

Using a value in the configuration dict lets configurations to be sent over the wire as pickled dicts to a socket listener. Thus, the logging verbosity of a long-running application can be altered over time with no need to stop and restart the application.

15.7.21.2.3. Object connections

The schema describes a set of logging objects - loggers, handlers, formatters, filters - which are connected to each other in an object graph. Thus, the schema needs to represent connections between the objects. For example, say that, once configured, a particular logger has attached to it a particular handler. For the purposes of this discussion, we can say that the logger represents the source, and the handler the destination, of a connection between the two. Of course in the configured objects this is represented by the logger holding a reference to the handler. In the configuration dict, this is done by giving each destination object an id which identifies it unambiguously, and then using the id in the source object's configuration to indicate that a connection exists between the source and the destination object with that id.

So, for example, consider the following YAML snippet:

```yaml
formatters:
  brief:
    # configuration for formatter with id 'brief' goes here
  precise:
    # configuration for formatter with id 'precise' goes here
handlers:
  h1: #This is an id
    # configuration of handler with id 'h1' goes here
  formatter: brief
```
The ids for loggers are the logger names which would be used programmatically to obtain a reference to those loggers, e.g. foo.bar.baz. The ids for Formatters and Filters can be any string value (such as brief, precise above) and they are transient, in that they are only meaningful for processing the configuration dictionary and used to determine connections between objects, and are not persisted anywhere when the configuration call is complete.

The above snippet indicates that logger named foo.bar.baz should have two handlers attached to it, which are described by the handler ids h1 and h2. The formatter for h1 is that described by id brief, and the formatter for h2 is that described by id precise.

15.7.21.2.4. User-defined objects

The schema supports user-defined objects for handlers, filters and formatters. (Loggers do not need to have different types for different instances, so there is no support in this configuration schema for user-defined logger classes.)

Objects to be configured are described by dictionaries which detail their configuration. In some places, the logging system will be able to infer from the context how an object is to be instantiated, but when a user-defined object is to be instantiated, the system will not know how to do this. In order to provide complete flexibility for user-defined
object instantiation, the user needs to provide a ‘factory’ - a callable which is called with a configuration dictionary and which returns the instantiated object. This is signalled by an absolute import path to the factory being made available under the special key `()`. Here's a concrete example:

```
formatters:
  brief:
    format: '%(message)s'
  default:
    format: '%(asctime)s %(levelname)-8s %(name)-15s %(message)s'
    datefmt: '%Y-%m-%d %H:%M:%S'
  custom:
    (): my.package.customFormatterFactory
    bar: baz
    spam: 99.9
    answer: 42
```

The above YAML snippet defines three formatters. The first, with id `brief`, is a standard `logging.Formatter` instance with the specified format string. The second, with id `default`, has a longer format and also defines the time format explicitly, and will result in a `logging.Formatter` initialized with those two format strings. Shown in Python source form, the `brief` and `default` formatters have configuration sub-dictionaries:

```
{
  'format' : '%(message)s'
}
```

and:

```
{
  'format' : '%(asctime)s %(levelname)-8s %(name)-15s %(message)s'
  'datefmt' : '%Y-%m-%d %H:%M:%S'
}
```
respectively, and as these dictionaries do not contain the special key '()', the instantiation is inferred from the context: as a result, standard `logging.Formatter` instances are created. The configuration sub-dictionary for the third formatter, with id `custom`, is:

```python
{
    '()': 'my.package.customFormatterFactory',
    'bar': 'baz',
    'spam': 99.9,
    'answer': 42
}
```

and this contains the special key '()', which means that user-defined instantiation is wanted. In this case, the specified factory callable will be used. If it is an actual callable it will be used directly - otherwise, if you specify a string (as in the example) the actual callable will be located using normal import mechanisms. The callable will be called with the `remaining` items in the configuration sub-dictionary as keyword arguments. In the above example, the formatter with id `custom` will be assumed to be returned by the call:

```python
my.package.customFormatterFactory(bar='baz', spam=99.9, answer=42)
```

The key '()' has been used as the special key because it is not a valid keyword parameter name, and so will not clash with the names of the keyword arguments used in the call. The '()' also serves as a mnemonic that the corresponding value is a callable.

### 15.7.21.2.5. Access to external objects

There are times where a configuration needs to refer to objects external to the configuration, for example `sys.stderr`. If the configuration dict is constructed using Python code, this is straightforward, but a problem arises when the configuration is provided via a text file (e.g. JSON, YAML). In a text file, there is no
standard way to distinguish \texttt{sys.stderr} from the literal string \\
\texttt{'sys.stderr'}. To facilitate this distinction, the configuration system \\
looks for certain special prefixes in string values and treat them \\
specially. For example, if the literal string \texttt{'ext://sys.stderr'} is \\
provided as a value in the configuration, then the \texttt{ext://} will be \\
stripped off and the remainder of the value processed using normal \\
import mechanisms.

The handling of such prefixes is done in a way analogous to protocol 
handling: there is a generic mechanism to look for prefixes which 
match the regular expression \texttt{^(?P<prefix>[a-z]+)://(?P<suffix>.*).}$ whereby, if the \texttt{prefix} is recognised, the \texttt{suffix} is 
processed in a prefix-dependent manner and the result of the 
processing replaces the string value. If the prefix is not recognised, 
then the string value will be left as-is.

\section*{15.7.21.2.6. Access to internal objects}

As well as external objects, there is sometimes also a need to refer 
to objects in the configuration. This will be done implicitly by the 
configuration system for things that it knows about. For example, the 
string value \texttt{'DEBUG'} for a level in a logger or handler will 
automatically be converted to the value \texttt{logging.DEBUG}, and the 
\texttt{handlers}, \texttt{filters} and \texttt{formatter} entries will take an object id and 
resolve to the appropriate destination object.

However, a more generic mechanism is needed for user-defined 
objects which are not known to the \texttt{logging} module. For example, 
consider \texttt{logging.handlers.MemoryHandler}, which takes a \texttt{target} 
argument which is another handler to delegate to. Since the system 
already knows about this class, then in the configuration, the given 
\texttt{target} just needs to be the object id of the relevant target handler, 
and the system will resolve to the handler from the id. If, however, a
user defines a `my.package.MyHandler` which has an alternate handler, the configuration system would not know that the alternate referred to a handler. To cater for this, a generic resolution system allows the user to specify:

```yaml
handlers:
  file:
    # configuration of file handler goes here
  custom:
    (): my.package.MyHandler
    alternate: cfg://handlers.file
```

The literal string `
` will be resolved in an analogous way to strings with the `ext://` prefix, but looking in the configuration itself rather than the import namespace. The mechanism allows access by dot or by index, in a similar way to that provided by `str.format`. Thus, given the following snippet:

```yaml
handlers:
  email:
    class: logging.handlers.SMTPHandler
    mailhost: localhost
    fromaddr: my_app@domain.tld
    toaddrs:
      - support_team@domain.tld
      - dev_team@domain.tld
    subject: Houston, we have a problem.
```

in the configuration, the string `'cfg://handlers'` would resolve to the dict with key `handlers`, the string `'cfg://handlers.email'` would resolve to the dict with key `email` in the `handlers` dict, and so on. The string `'cfg://handlers.email.toaddrs[1]'` would resolve to `dev_team.domain.tld` and the string `'cfg://handlers.email.toaddrs[0]'` would resolve to the value `support_team@domain.tld`. The `subject` value could be accessed using either `'cfg://handlers.email.subject'` or, equivalently,
The latter form only needs to be used if the key contains spaces or non-alphanumeric characters. If an index value consists only of decimal digits, access will be attempted using the corresponding integer value, falling back to the string value if needed.

Given a string `cfg://handlers.myhandler.mykey.123`, this will resolve to `config_dict['handlers']['myhandler']['mykey']['123']`. If the string is specified as `cfg://handlers.myhandler.mykey[123]`, the system will attempt to retrieve the value from `config_dict['handlers']['myhandler']['mykey'][123]`, and fall back to `config_dict['handlers']['myhandler']['mykey']['123']` if that fails.

### 15.7.21.3. Configuration file format

The configuration file format understood by `fileConfig()` is based on `ConfigParser` functionality. The file must contain sections called `[loggers]`, `[handlers]` and `[formatters]` which identify by name the entities of each type which are defined in the file. For each such entity, there is a separate section which identifies how that entity is configured. Thus, for a logger named `log01` in the `[loggers]` section, the relevant configuration details are held in a section `[logger_log01]`. Similarly, a handler called `hand01` in the `[handlers]` section will have its configuration held in a section called `[handler_hand01]`, while a formatter called `form01` in the `[formatters]` section will have its configuration specified in a section called `[formatter_form01]`. The root logger configuration must be specified in a section called `[logger_root]`.

Examples of these sections in the file are given below.

```
[loggers]
```
The root logger must specify a level and a list of handlers. An example of a root logger section is given below.

```
[logger_root]
level=NOTSET
handlers=hand01
```

The `level` entry can be one of DEBUG, INFO, WARNING, ERROR, CRITICAL or NOTSET. For the root logger only, NOTSET means that all messages will be logged. Level values are `eval()`uated in the context of the `logging` package's namespace.

The `handlers` entry is a comma-separated list of handler names, which must appear in the `[handlers]` section. These names must appear in the `[handlers]` section and have corresponding sections in the configuration file.

For loggers other than the root logger, some additional information is required. This is illustrated by the following example.

```
[logger_parser]
level=DEBUG
handlers=hand01
propagate=1
qualname=compiler.parser
```

The `level` and `handlers` entries are interpreted as for the root logger, except that if a non-root logger's level is specified as NOTSET, the system consults loggers higher up the hierarchy to determine the
effective level of the logger. The propagate entry is set to 1 to indicate that messages must propagate to handlers higher up the logger hierarchy from this logger, or 0 to indicate that messages are not propagated to handlers up the hierarchy. The qualname entry is the hierarchical channel name of the logger, that is to say the name used by the application to get the logger.

Sections which specify handler configuration are exemplified by the following.

```
[handler_hand01]
class=StreamHandler
level=NOTSET
formatter=form01
args=(sys.stdout,)
```

The class entry indicates the handler’s class (as determined by `eval()` in the logging package’s namespace). The level is interpreted as for loggers, and NOTSET is taken to mean “log everything”.

*Changed in version 2.6:* Added support for resolving the handler’s class as a dotted module and class name.

The formatter entry indicates the key name of the formatter for this handler. If blank, a default formatter (`logging._defaultFormatter`) is used. If a name is specified, it must appear in the [formatters] section and have a corresponding section in the configuration file.

The args entry, when `eval()`uated in the context of the logging package’s namespace, is the list of arguments to the constructor for the handler class. Refer to the constructors for the relevant handlers, or to the examples below, to see how typical entries are constructed.

```
[handler_hand02]
class=FileHandler
```
level=DEBUG
formatter=form02
args=('python.log', 'w')

[handler_hand03]
class=handlers.SocketHandler
level=INFO
formatter=form03
args=('localhost', handlers.DEFAULT_TCP_LOGGING_PORT)

[handler_hand04]
class=handlers.DatagramHandler
level=WARN
formatter=form04
args=('localhost', handlers.DEFAULT_UDP_LOGGING_PORT)

[handler_hand05]
class=handlers.SysLogHandler
level=ERROR
formatter=form05
args=((('localhost', handlers.SYSLOG_UDP_PORT), handlers.SysLogHandler.LOG_USER)

[handler_hand06]
class=handlers.NTEventLogHandler
level=CRITICAL
formatter=form06
args=('Python Application', '', 'Application')

[handler_hand07]
class=handlers.SMTPHandler
level=WARN
formatter=form07
args=('localhost', 'from@abc', ['user1@abc', 'user2@xyz'], 'Logger Subject')

[handler_hand08]
class=handlers.MemoryHandler
level=NOTSET
formatter=form08
target=
args=(10, ERROR)

[handler_hand09]
class=handlers.HTTPHandler
level=NOTSET
formatter=form09
args=('localhost:9022', '/log', 'GET')
Sections which specify formatter configuration are typified by the following.

```
[formatter_form01]
format=F1 %(asctime)s %(levelname)s %(message)s
datefmt=
class=logging.Formatter
```

The `format` entry is the overall format string, and the `datefmt` entry is the `strftime()`-compatible date/time format string. If empty, the package substitutes ISO8601 format date/times, which is almost equivalent to specifying the date format string "%Y-%m-%d %H:%M:%S". The ISO8601 format also specifies milliseconds, which are appended to the result of using the above format string, with a comma separator. An example time in ISO8601 format is 2003-01-23 00:29:50,411.

The `class` entry is optional. It indicates the name of the formatter's class (as a dotted module and class name.) This option is useful for instantiating a `Formatter` subclass. Subclasses of `Formatter` can present exception tracebacks in an expanded or condensed format.

### 15.7.21.4. Configuration server example

Here is an example of a module using the logging configuration server:

```python
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig("logging.conf")

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()
```
logger = logging.getLogger("simpleExample")

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug("debug message")
        logger.info("info message")
        logger.warn("warn message")
        logger.error("error message")
        logger.critical("critical message")
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
t.join()

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```python
#!/usr/bin/env python
import socket, sys, struct

data_to_send = open(sys.argv[1], "r").read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print "connecting..."
s.connect((HOST, PORT))
print "sending config..."
s.send(struct.pack(">L", len(data_to_send)))
s.send(data_to_send)
s.close()
print "complete"
```
15.7.22. More examples

15.7.22.1. Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```python
import logging
logger = logging.getLogger("simple_example")
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler("spam.log")
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter("%(asctime)s	-	%(name)s	-	%(levelname)s	-	%(message)s")
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# "application" code
logger.debug("debug message")
logger.info("info message")
logger.warn("warn message")
logger.error("error message")
logger.critical("critical message")
```
Notice that the “application” code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named \textit{fh}.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many \texttt{print} statements for debugging, use \texttt{logger.debug}: Unlike the print statements, which you will have to delete or comment out later, the logger.debug statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

15.7.22.2. Using logging in multiple modules

It was mentioned above that multiple calls to \texttt{logging.getLogger('someLogger')} return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```python
import logging
import auxiliary_module

# create logger with "spam_application"
logger = logging.getLogger("spam_application")
logger.setLevel(logging.DEBUG)

# create file handler which logs even debug messages
fh = logging.FileHandler("spam.log")
fh.setLevel(logging.DEBUG)

# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
```
Here is the auxiliary module:

```python
import logging

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger("spam_application.auxiliary")
        self.logger.info("creating an instance of Auxiliary")
    def do_something(self):
        self.logger.info("doing something")
        a = 1 + 1
        self.logger.info("done doing something")

    def some_function():
        module_logger.info("received a call to \"some_function\"")
```

The output looks like this:

```
```
2005-03-23 23:47:11,671 - spam_application - INFO - calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary - INFO - received a call to "some_function"
2005-03-23 23:47:11,673 - spam_application - INFO - done with auxiliary_module.some_function()
The `getpass` module provides two functions:

`getpass.getpass([prompt[, stream]])`

Prompt the user for a password without echoing. The user is prompted using the string `prompt`, which defaults to `'Password:'`. On Unix, the prompt is written to the file-like object `stream`. `stream` defaults to the controlling terminal (`/dev/tty`) or if that is unavailable to `sys.stderr` (this argument is ignored on Windows).

If echo free input is unavailable `getpass()` falls back to printing a warning message to `stream` and reading from `sys.stdin` and issuing a `GetPassWarning`.

Availability: Macintosh, Unix, Windows.

*Changed in version 2.5:* The `stream` parameter was added.

*Changed in version 2.6:* On Unix it defaults to using `/dev/tty` before falling back to `sys.stdin` and `sys.stderr`.

**Note:** If you call `getpass` from within IDLE, the input may be done in the terminal you launched IDLE from rather than the idle window itself.

`exception getpass.GetPassWarning`

A `UserWarning` subclass issued when password input may be echoed.

`getpass.getuser()`
Return the “login name” of the user. Availability: Unix, Windows.

This function checks the environment variables LOGNAME, USER, LNAME and USERNAME, in order, and returns the value of the first one which is set to a non-empty string. If none are set, the login name from the password database is returned on systems which support the pwd module, otherwise, an exception is raised.
15.9. curses — Terminal handling for character-cell displays

Platforms: Unix

Changed in version 1.6: Added support for the ncurses library and converted to a package.

The curses module provides an interface to the curses library, the de-facto standard for portable advanced terminal handling.

While curses is most widely used in the Unix environment, versions are available for DOS, OS/2, and possibly other systems as well. This extension module is designed to match the API of ncurses, an open-source curses library hosted on Linux and the BSD variants of Unix.

Note: Since version 5.4, the ncurses library decides how to interpret non-ASCII data using the nl_langinfo function. That means that you have to call locale.setlocale() in the application and encode Unicode strings using one of the system’s available encodings. This example uses the system’s default encoding:

```python
import locale
locale.setlocale(locale.LC_ALL, '')
code = locale.getpreferredencoding()
```

Then use code as the encoding for str.encode() calls.

See also:

Module curses.ascii

Utilities for working with ASCII characters, regardless of your
locale settings.

**Module curses.panel**
A panel stack extension that adds depth to curses windows.

**Module curses.textpad**
Editable text widget for curses supporting Emacs-like bindings.

**Module curses.wrapper**
Convenience function to ensure proper terminal setup and resetting on application entry and exit.

**Curses Programming with Python**
Tutorial material on using curses with Python, by Andrew Kuchling and Eric Raymond.

The Demo/curses/ directory in the Python source distribution contains some example programs using the curses bindings provided by this module.
15.9.1. Functions

The module `curses` defines the following exception:

```python
exception curses.error
    Exception raised when a curses library function returns an error.
```

**Note:** Whenever `x` or `y` arguments to a function or a method are optional, they default to the current cursor location. Whenever `attr` is optional, it defaults to `A_NORMAL`.

The module `curses` defines the following functions:

**`curses.baudrate()`**

Returns the output speed of the terminal in bits per second. On software terminal emulators it will have a fixed high value. Included for historical reasons; in former times, it was used to write output loops for time delays and occasionally to change interfaces depending on the line speed.

**`curses.beep()`**

Emit a short attention sound.

**`curses.can_change_color()`**

Returns true or false, depending on whether the programmer can change the colors displayed by the terminal.

**`curses.cbreak()`**

Enter cbreak mode. In cbreak mode (sometimes called “rare” mode) normal tty line buffering is turned off and characters are available to be read one by one. However, unlike raw mode, special characters (interrupt, quit, suspend, and flow control) retain their effects on the tty driver and calling program. Calling
first raw() then cbreak() leaves the terminal in cbreak mode.

curses.color_content(color_number)
Returns the intensity of the red, green, and blue (RGB) components in the color color_number, which must be between 0 and COLORS. A 3-tuple is returned, containing the R,G,B values for the given color, which will be between 0 (no component) and 1000 (maximum amount of component).

curses.color_pair(color_number)
Returns the attribute value for displaying text in the specified color. This attribute value can be combined with A_STANDOUT, A_REVERSE, and the other A_* attributes. pair_number() is the counterpart to this function.

curses.curs_set(visibility)
Sets the cursor state. visibility can be set to 0, 1, or 2, for invisible, normal, or very visible. If the terminal supports the visibility requested, the previous cursor state is returned; otherwise, an exception is raised. On many terminals, the “visible” mode is an underline cursor and the “very visible” mode is a block cursor.

curses.def_prog_mode()
Saves the current terminal mode as the “program” mode, the mode when the running program is using curses. (Its counterpart is the “shell” mode, for when the program is not in curses.) Subsequent calls to reset_prog_mode() will restore this mode.

curses.def_shell_mode()
Saves the current terminal mode as the “shell” mode, the mode when the running program is not using curses. (Its counterpart is the “program” mode, when the program is using curses
capabilities.) Subsequent calls to \texttt{reset\_shell\_mode()} will restore this mode.

\texttt{curses.\texttt{delay\_output}(ms)}

Inserts an \textit{ms} millisecond pause in output.

\texttt{curses.\texttt{doupdate}()}

Update the physical screen. The \texttt{curses} library keeps two data structures, one representing the current physical screen contents and a virtual screen representing the desired next state. The \texttt{doupdate()} ground updates the physical screen to match the virtual screen.

The virtual screen may be updated by a \texttt{noutrefresh()} call after write operations such as \texttt{addstr()} have been performed on a window. The normal \texttt{refresh()} call is simply \texttt{noutrefresh()} followed by \texttt{doupdate()}; if you have to update multiple windows, you can speed performance and perhaps reduce screen flicker by issuing \texttt{noutrefresh()} calls on all windows, followed by a single \texttt{doupdate()}.

\texttt{curses.\texttt{echo}()}

Enter echo mode. In echo mode, each character input is echoed to the screen as it is entered.

\texttt{curses.\texttt{endwin}()}

De-initialize the library, and return terminal to normal status.

\texttt{curses.\texttt{erasechar}()}

Returns the user’s current erase character. Under Unix operating systems this is a property of the controlling tty of the \texttt{curses} program, and is not set by the \texttt{curses} library itself.

\texttt{curses.\texttt{filter}()}
The `filter()` routine, if used, must be called before `initscr()` is called. The effect is that, during those calls, LINES is set to 1; the capabilities clear, cup, cud, cud1, cuu1, cuu, vpa are disabled; and the home string is set to the value of cr. The effect is that the cursor is confined to the current line, and so are screen updates. This may be used for enabling character-at-a-time line editing without touching the rest of the screen.

**curses.**`flash()`

Flash the screen. That is, change it to reverse-video and then change it back in a short interval. Some people prefer such as 'visible bell' to the audible attention signal produced by `beep()`.

**curses.**`flushinp()`

Flush all input buffers. This throws away any typeahead that has been typed by the user and has not yet been processed by the program.

**curses.**`getmouse()`

After `getch()` returns `KEY_MOUSE` to signal a mouse event, this method should be call to retrieve the queued mouse event, represented as a 5-tuple `(id, x, y, z, bstate)`. `id` is an ID value used to distinguish multiple devices, and `x, y, z` are the event's coordinates. (z is currently unused.). `bstate` is an integer value whose bits will be set to indicate the type of event, and will be the bitwise OR of one or more of the following constants, where `n` is the button number from 1 to 4: `BUTTONn_PRESSED`, `BUTTONn_RELEASED`, `BUTTONn_CLICKED`, `BUTTONn_DOUBLE_CLICKED`, `BUTTONn_TRIPLE_CLICKED`, `BUTTON_SHIFT`, `BUTTON_CTRL`, `BUTTON_ALT`.

**curses.**`getsyx()`

Returns the current coordinates of the virtual screen cursor in `y` and `x`. If `leaveok` is currently true, then `-1,-1` is returned.
curses.\texttt{getwin(file)}

Reads window related data stored in the file by an earlier \texttt{putwin()} call. The routine then creates and initializes a new window using that data, returning the new window object.

curses.\texttt{has_colors()}

Returns true if the terminal can display colors; otherwise, it returns false.

curses.\texttt{has_ic()}

Returns true if the terminal has insert- and delete-character capabilities. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.\texttt{has_il()}

Returns true if the terminal has insert- and delete-line capabilities, or can simulate them using scrolling regions. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.\texttt{has_key(ch)}

Takes a key value \textit{ch}, and returns true if the current terminal type recognizes a key with that value.

curses.\texttt{halfdelay(tenths)}

Used for half-delay mode, which is similar to cbreak mode in that characters typed by the user are immediately available to the program. However, after blocking for \textit{tenths} tenths of seconds, an exception is raised if nothing has been typed. The value of \textit{tenths} must be a number between 1 and 255. Use \texttt{nocbreak()} to leave half-delay mode.

curses.\texttt{init_color(color_number, r, g, b)}

Changes the definition of a color, taking the number of the color
to be changed followed by three RGB values (for the amounts of red, green, and blue components). The value of color_number must be between 0 and COLORS. Each of r, g, b, must be a value between 0 and 1000. When init_color() is used, all occurrences of that color on the screen immediately change to the new definition. This function is a no-op on most terminals; it is active only if can_change_color() returns 1.

curses.init_pair(pair_number, fg, bg)
Changes the definition of a color-pair. It takes three arguments: the number of the color-pair to be changed, the foreground color number, and the background color number. The value of pair_number must be between 1 and COLOR_PAIRS - 1 (the 0 color pair is wired to white on black and cannot be changed). The value of fg and bg arguments must be between 0 and COLORS. If the color-pair was previously initialized, the screen is refreshed and all occurrences of that color-pair are changed to the new definition.

curses.initscr()
Initialize the library. Returns a WindowObject which represents the whole screen.

**Note:** If there is an error opening the terminal, the underlying curses library may cause the interpreter to exit.

curses.isendwin()
Returns true if endwin() has been called (that is, the curses library has been deinitialized).

curses.keyname(k)
Return the name of the key numbered k. The name of a key generating printable ASCII character is the key's character. The
name of a control-key combination is a two-character string consisting of a caret followed by the corresponding printable ASCII character. The name of an alt-key combination (128-255) is a string consisting of the prefix ‘M-‘ followed by the name of the corresponding ASCII character.

curses.**killchar**()

Returns the user’s current line kill character. Under Unix operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

curses.**longname**()

Returns a string containing the terminfo long name field describing the current terminal. The maximum length of a verbose description is 128 characters. It is defined only after the call to **initscr()**.

curses.**meta**(yes)

If yes is 1, allow 8-bit characters to be input. If yes is 0, allow only 7-bit chars.

curses.**mouseinterval**(interval)

Sets the maximum time in milliseconds that can elapse between press and release events in order for them to be recognized as a click, and returns the previous interval value. The default value is 200 msec, or one fifth of a second.

curses.**mousemask**(mousemask)

Sets the mouse events to be reported, and returns a tuple *(availmask, oldmask)*. *availmask* indicates which of the specified mouse events can be reported; on complete failure it returns 0. *oldmask* is the previous value of the given window’s mouse event mask. If this function is never called, no mouse events are ever reported.
curses.**napms**(*ms*)

Sleep for *ms* milliseconds.

curses.**newpad**(*nlines*, *ncols*)

Creates and returns a pointer to a new pad data structure with the given number of lines and columns. A pad is returned as a window object.

A pad is like a window, except that it is not restricted by the screen size, and is not necessarily associated with a particular part of the screen. Pads can be used when a large window is needed, and only a part of the window will be on the screen at one time. Automatic refreshes of pads (such as from scrolling or echoing of input) do not occur. The `refresh()` and `noutrefresh()` methods of a pad require 6 arguments to specify the part of the pad to be displayed and the location on the screen to be used for the display. The arguments are `pminrow`, `pmincol`, `sminrow`, `smincol`, `smaxrow`, `smaxcol`; the `p` arguments refer to the upper left corner of the pad region to be displayed and the `s` arguments define a clipping box on the screen within which the pad region is to be displayed.

curses.**newwin**([*nlines*, *ncols*], *begin_y*, *begin_x*)

Return a new window, whose left-upper corner is at (*begin_y*, *begin_x*), and whose height/width is *nlines*/*ncols*.

By default, the window will extend from the specified position to the lower right corner of the screen.

curses.**nl**()

Enter newline mode. This mode translates the return key into newline on input, and translates newline into return and line-feed on output. Newline mode is initially on.
curses.nocbreak()
Leave cbreak mode. Return to normal “cooked” mode with line buffering.

curses.noecho()
Leave echo mode. Echoing of input characters is turned off.

curses.nonl()
Leave newline mode. Disable translation of return into newline on input, and disable low-level translation of newline into newline/return on output (but this does not change the behavior of addch(‘\n’), which always does the equivalent of return and line feed on the virtual screen). With translation off, curses can sometimes speed up vertical motion a little; also, it will be able to detect the return key on input.

curses.noqiflush()
When the noqiflush routine is used, normal flush of input and output queues associated with the INTR, QUIT and SUSP characters will not be done. You may want to call noqiflush() in a signal handler if you want output to continue as though the interrupt had not occurred, after the handler exits.

curses.noraw()
Leave raw mode. Return to normal “cooked” mode with line buffering.

curses.pair_content(pair_number)
Returns a tuple (fg, bg) containing the colors for the requested color pair. The value of pair_number must be between 1 and COLOR_PAIRS - 1.

curses.pair_number(attr)
Returns the number of the color-pair set by the attribute value
**attr. color_pair()** is the counterpart to this function.

**curses. putp(string)**

Equivalent to `tputs(str, 1, putchar)`; emits the value of a specified terminfo capability for the current terminal. Note that the output of putp always goes to standard output.

**curses. qiflush([flag])**

If flag is false, the effect is the same as calling `noqiflush()`. If flag is true, or no argument is provided, the queues will be flushed when these control characters are read.

**curses. raw()**

Enter raw mode. In raw mode, normal line buffering and processing of interrupt, quit, suspend, and flow control keys are turned off; characters are presented to curses input functions one by one.

**curses. reset_prog_mode()**

Restores the terminal to “program” mode, as previously saved by `def_prog_mode()`.

**curses. reset_shell_mode()**

Restores the terminal to “shell” mode, as previously saved by `def_shell_mode()`.

**curses. setsyx(y, x)**

Sets the virtual screen cursor to y, x. If y and x are both -1, then leaveok is set.

**curses. setupterm([termstr, fd])**

Initializes the terminal. termstr is a string giving the terminal name; if omitted, the value of the TERM environment variable will be used. fd is the file descriptor to which any initialization
sequences will be sent; if not supplied, the file descriptor for sys.stdout will be used.

curses.start_color()
Must be called if the programmer wants to use colors, and before any other color manipulation routine is called. It is good practice to call this routine right after initscr().

start_color() initializes eight basic colors (black, red, green, yellow, blue, magenta, cyan, and white), and two global variables in the curses module, COLORS and COLOR_PAIRS, containing the maximum number of colors and color-pairs the terminal can support. It also restores the colors on the terminal to the values they had when the terminal was just turned on.

curses.termattrs()
Returns a logical OR of all video attributes supported by the terminal. This information is useful when a curses program needs complete control over the appearance of the screen.

curses.termname()
Returns the value of the environment variable TERM, truncated to 14 characters.

curses.tigetflag(capname)
Returns the value of the Boolean capability corresponding to the terminfo capability name capname. The value -1 is returned if capname is not a Boolean capability, or 0 if it is canceled or absent from the terminal description.

curses.tigetnum(capname)
Returns the value of the numeric capability corresponding to the terminfo capability name capname. The value -2 is returned if capname is not a numeric capability, or -1 if it is canceled or
absent from the terminal description.

curses.tigetstr(capname)
Returns the value of the string capability corresponding to the terminfo capability name capname. None is returned if capname is not a string capability, or is canceled or absent from the terminal description.

curses.tparm(str[, ...])
Instantiates the string str with the supplied parameters, where str should be a parameterized string obtained from the terminfo database. E.g. tparm(tigetstr("cup"), 5, 3) could result in \033[6;4H, the exact result depending on terminal type.

curses.typeahead(fd)
Specifies that the file descriptor fd be used for typeahead checking. If fd is -1, then no typeahead checking is done.

The curses library does “line-breakout optimization” by looking for typeahead periodically while updating the screen. If input is found, and it is coming from a tty, the current update is postponed until refresh or douupdate is called again, allowing faster response to commands typed in advance. This function allows specifying a different file descriptor for typeahead checking.

curses.unctrl(ch)
Returns a string which is a printable representation of the character ch. Control characters are displayed as a caret followed by the character, for example as ^C. Printing characters are left as they are.

curses.ungetch(ch)
Push ch so the next getch() will return it.
Note: Only one `ch` can be pushed before `getch()` is called.

curses. `ungetmouse(id, x, y, z, bstate)`
Push a `KEY_MOUSE` event onto the input queue, associating the given state data with it.

curses. `use_env(flag)`
If used, this function should be called before `initscr()` or `newterm` are called. When `flag` is false, the values of lines and columns specified in the terminfo database will be used, even if environment variables `LINES` and `COLUMNS` (used by default) are set, or if curses is running in a window (in which case default behavior would be to use the window size if `LINES` and `COLUMNS` are not set).

curses. `use_default_colors()`
Allow use of default values for colors on terminals supporting this feature. Use this to support transparency in your application. The default color is assigned to the color number -1. After calling this function, `init_pair(x, curses.COLOR_RED, -1)` initializes, for instance, color pair `x` to a red foreground color on the default background.
15.9.2. Window Objects

Window objects, as returned by `initscr()` and `newwin()` above, have the following methods:

```python
window.addch([y, x], ch[, attr])
```

**Note:** A character means a C character (an ASCII code), rather than a Python character (a string of length 1). (This note is true whenever the documentation mentions a character.) The built-in `ord()` is handy for conveying strings to codes.

Paint character `ch` at `(y, x)` with attributes `attr`, overwriting any character previously painter at that location. By default, the character position and attributes are the current settings for the window object.

```python
window.addnstr([y, x], str, n[, attr])
```

Paint at most `n` characters of the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```python
window.addstr([y, x], str[, attr])
```

Paint the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```python
window.attroff(attr)
```

Remove attribute `attr` from the “background” set applied to all writes to the current window.

```python
window.attron(attr)
```

Add attribute `attr` from the “background” set applied to all writes to the current window.
window. **attrset**(attr)

Set the “background” set of attributes to attr. This set is initially 0 (no attributes).

window. **bgd**([ch[, attr]])

Sets the background property of the window to the character ch, with attributes attr. The change is then applied to every character position in that window:

- The attribute of every character in the window is changed to the new background attribute.
- Wherever the former background character appears, it is changed to the new background character.

window. **bgdset**(ch[, attr])

Sets the window’s background. A window’s background consists of a character and any combination of attributes. The attribute part of the background is combined (OR’ed) with all non-blank characters that are written into the window. Both the character and attribute parts of the background are combined with the blank characters. The background becomes a property of the character and moves with the character through any scrolling and insert/delete line/character operations.

window. **border**(ls[, rs[, ts[, bs[, tl[, tr[, bl[, br]]]]]]])

Draw a border around the edges of the window. Each parameter specifies the character to use for a specific part of the border; see the table below for more details. The characters can be specified as integers or as one-character strings.

**Note:** A 0 value for any parameter will cause the default character to be used for that parameter. Keyword parameters can not be used. The defaults are listed in this table:
<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>ls</td>
<td>Left side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td>rs</td>
<td>Right side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td>ts</td>
<td>Top</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td>bs</td>
<td>Bottom</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td>tl</td>
<td>Upper-left corner</td>
<td>ACS_ULCORNER</td>
</tr>
<tr>
<td>tr</td>
<td>Upper-right corner</td>
<td>ACS_URCORNER</td>
</tr>
<tr>
<td>bl</td>
<td>Bottom-left corner</td>
<td>ACS_LLCORNER</td>
</tr>
<tr>
<td>br</td>
<td>Bottom-right corner</td>
<td>ACS_LRCORNER</td>
</tr>
</tbody>
</table>

`window.box([vertch, horch])`

Similar to `border()`, but both `ls` and `rs` are `vertch` and both `ts` and `bs` are `horch`. The default corner characters are always used by this function.

`window.chgat([y, x][, num], attr)`

Sets the attributes of `num` characters at the current cursor position, or at position `(y, x)` if supplied. If no value of `num` is given or `num = -1`, the attribute will be set on all the characters to the end of the line. This function does not move the cursor. The changed line will be touched using the `touchline()` method so that the contents will be redisplayed by the next window refresh.

`window.clear()`

Like `erase()`, but also causes the whole window to be repainted upon next call to `refresh()`.

`window.clearok(1)`

If `yes` is `1`, the next call to `refresh()` will clear the window completely.

`window.clrtohot()`

Erase from cursor to the end of the window: all lines below the
cursor are deleted, and then the equivalent of `clrtoeol()` is performed.

```c
window.clrtoeol()
Erase from cursor to the end of the line.
```

```c
window.cursyncup()
Updates the current cursor position of all the ancestors of the window to reflect the current cursor position of the window.
```

```c
window.delch([y, x])
Delete any character at (y, x).
```

```c
window.delete1n()
Delete the line under the cursor. All following lines are moved up by 1 line.
```

```c
window.derwin([nlines, ncols], begin_y, begin_x)
An abbreviation for “derive window”, `derwin()` is the same as calling `subwin()`, except that `begin_y` and `begin_x` are relative to the origin of the window, rather than relative to the entire screen. Returns a window object for the derived window.
```

```c
window.echochar(ch[, attr])
Add character `ch` with attribute `attr`, and immediately call `refresh()` on the window.
```

```c
window.enclose(y, x)
Tests whether the given pair of screen-relative character-cell coordinates are enclosed by the given window, returning true or false. It is useful for determining what subset of the screen windows enclose the location of a mouse event.
```

```c
window.erase()
```
Clear the window.

`window.getbegyx()`  
Return a tuple `(y, x)` of co-ordinates of upper-left corner.

`window.getch([y, x])`  
Get a character. Note that the integer returned does not have to be in ASCII range: function keys, keypad keys and so on return numbers higher than 256. In no-delay mode, -1 is returned if there is no input, else `getch()` waits until a key is pressed.

`window.getkey([y, x])`  
Get a character, returning a string instead of an integer, as `getch()` does. Function keys, keypad keys and so on return a multibyte string containing the key name. In no-delay mode, an exception is raised if there is no input.

`window.getmaxyx()`  
Return a tuple `(y, x)` of the height and width of the window.

`window.getparyx()`  
Returns the beginning coordinates of this window relative to its parent window into two integer variables y and x. Returns -1,-1 if this window has no parent.

`window.getstr([y, x])`  
Read a string from the user, with primitive line editing capacity.

`window.getyx()`  
Return a tuple `(y, x)` of current cursor position relative to the window’s upper-left corner.

`window.hline([y, x], ch, n)`
Display a horizontal line starting at \((y, x)\) with length \(n\) consisting of the character \(ch\).

**window. idcok(flag)**

If \(flag\) is false, curses no longer considers using the hardware insert/delete character feature of the terminal; if \(flag\) is true, use of character insertion and deletion is enabled. When curses is first initialized, use of character insert/delete is enabled by default.

**window. idlok(yes)**

If called with \(yes\) equal to 1, \(curses\) will try and use hardware line editing facilities. Otherwise, line insertion/deletion are disabled.

**window. immedok(flag)**

If \(flag\) is true, any change in the window image automatically causes the window to be refreshed; you no longer have to call \(refresh()\) yourself. However, it may degrade performance considerably, due to repeated calls to \(wrefresh\). This option is disabled by default.

**window. inch([y, x])**

Return the character at the given position in the window. The bottom 8 bits are the character proper, and upper bits are the attributes.

**window. insch([y, x], ch[, attr])**

Paint character \(ch\) at \((y, x)\) with attributes \(attr\), moving the line from position \(x\) right by one character.

**window. insdelln(nlines)**

Inserts \(nlines\) lines into the specified window above the current line. The \(nlines\) bottom lines are lost. For negative \(nlines\), delete \(nlines\) lines starting with the one under the cursor, and move the
remaining lines up. The bottom \textit{nlines} lines are cleared. The
current cursor position remains the same.

\texttt{window.insertln()}

Insert a blank line under the cursor. All following lines are moved
down by 1 line.

\texttt{window.insnstr([y, x], str, n[, attr])}

Insert a character string (as many characters as will fit on the
line) before the character under the cursor, up to \( n \) characters. If
\( n \) is zero or negative, the entire string is inserted. All characters to
the right of the cursor are shifted right, with the rightmost
characters on the line being lost. The cursor position does not
change (after moving to \( y, x \), if specified).

\texttt{window.insstr([y, x], str[, attr])}

Insert a character string (as many characters as will fit on the
line) before the character under the cursor. All characters to the
right of the cursor are shifted right, with the rightmost characters
on the line being lost. The cursor position does not change (after
moving to \( y, x \), if specified).

\texttt{window.instr([y, x][, n])}

Returns a string of characters, extracted from the window starting
at the current cursor position, or at \( y, x \) if specified. Attributes are
stripped from the characters. If \( n \) is specified, \texttt{instr()} returns
return a string at most \( n \) characters long (exclusive of the trailing
NUL).

\texttt{window.is_linetouched(line)}

Returns true if the specified line was modified since the last call
to \texttt{refresh()}; otherwise returns false. Raises a \texttt{curses.error}
exception if \texttt{line} is not valid for the given window.
window. **is_wintouched()**

Returns true if the specified window was modified since the last call to `refresh()`; otherwise returns false.

window. **keypad(yes)**

If yes is 1, escape sequences generated by some keys (keypad, function keys) will be interpreted by `curses`. If yes is 0, escape sequences will be left as is in the input stream.

window. **leaveok(yes)**

If yes is 1, cursor is left where it is on update, instead of being at “cursor position.” This reduces cursor movement where possible. If possible the cursor will be made invisible.

If yes is 0, cursor will always be at “cursor position” after an update.

window. **move(new_y, new_x)**

Move cursor to `(new_y, new_x)`.

window. **mvderwin(y, x)**

Moves the window inside its parent window. The screen-relative parameters of the window are not changed. This routine is used to display different parts of the parent window at the same physical position on the screen.

window. **mvwin(new_y, new_x)**

Move the window so its upper-left corner is at `(new_y, new_x)`.

window. **nodelay(yes)**

If yes is 1, `getch()` will be non-blocking.

window. **notimeout(yes)**

If yes is 1, escape sequences will not be timed out.
If yes is 0, after a few milliseconds, an escape sequence will not be interpreted, and will be left in the input stream as is.

`window.noutrefresh()`
Mark for refresh but wait. This function updates the data structure representing the desired state of the window, but does not force an update of the physical screen. To accomplish that, call `doupdate()`.

`window.overlay(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])`
Overlay the window on top of `destwin`. The windows need not be the same size, only the overlapping region is copied. This copy is non-destructive, which means that the current background character does not overwrite the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overlay()` can be used. `sminrow` and `smincol` are the upper-left coordinates of the source window, and the other variables mark a rectangle in the destination window.

`window.overwrite(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])`
Overwrite the window on top of `destwin`. The windows need not be the same size, in which case only the overlapping region is copied. This copy is destructive, which means that the current background character overwrites the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overwrite()` can be used. `sminrow` and `smincol` are the upper-left coordinates of the source window, the other variables mark a rectangle in the destination window.

`window.putwin(file)`
Writes all data associated with the window into the provided file object. This information can be later retrieved using the `getwin()` function.

`window.redrawln(beg, num)`
Indicates that the `num` screen lines, starting at line `beg`, are corrupted and should be completely redrawn on the next `refresh()` call.

`window.redrawwin()`
Touches the entire window, causing it to be completely redrawn on the next `refresh()` call.

`window.refresh([pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol])`
Update the display immediately (sync actual screen with previous drawing/deleting methods).

The 6 optional arguments can only be specified when the window is a pad created with `newpad()`. The additional parameters are needed to indicate what part of the pad and screen are involved. `pminrow` and `pmincol` specify the upper left-hand corner of the rectangle to be displayed in the pad. `sminrow, smincol, smaxrow,` and `smaxcol` specify the edges of the rectangle to be displayed on the screen. The lower right-hand corner of the rectangle to be displayed in the pad is calculated from the screen coordinates, since the rectangles must be the same size. Both rectangles must be entirely contained within their respective structures. Negative values of `pminrow, pmincol, sminrow,` or `smincol` are treated as if they were zero.

`window.scroll([lines=1])`
Scroll the screen or scrolling region upward by `lines` lines.
window. **scrollok**(flag)

Controls what happens when the cursor of a window is moved off the edge of the window or scrolling region, either as a result of a newline action on the bottom line, or typing the last character of the last line. If `flag` is false, the cursor is left on the bottom line. If `flag` is true, the window is scrolled up one line. Note that in order to get the physical scrolling effect on the terminal, it is also necessary to call `idlok()`.

window. **setscrreg**(top, bottom)

Set the scrolling region from line `top` to line `bottom`. All scrolling actions will take place in this region.

window. **standend**()

Turn off the standout attribute. On some terminals this has the side effect of turning off all attributes.

window. **standout**()

Turn on attribute `A_STANDOUT`.

window. **subpad**([nlines, ncols], begin_y, begin_x)

Return a sub-window, whose upper-left corner is at `(begin_y, begin_x)`, and whose width/height is `ncols/nlines`.

window. **subwin**([nlines, ncols], begin_y, begin_x)

Return a sub-window, whose upper-left corner is at `(begin_y, begin_x)`, and whose width/height is `ncols/nlines`.

By default, the sub-window will extend from the specified position to the lower right corner of the window.

window. **syncdown**()

Touches each location in the window that has been touched in any of its ancestor windows. This routine is called by `refresh()`,
so it should almost never be necessary to call it manually.

`window.syncok(flag)`

If called with `flag` set to true, then `syncup()` is called automatically whenever there is a change in the window.

`window.syncup()`

Touches all locations in ancestors of the window that have been changed in the window.

`window.timeout(delay)`

Sets blocking or non-blocking read behavior for the window. If `delay` is negative, blocking read is used (which will wait indefinitely for input). If `delay` is zero, then non-blocking read is used, and -1 will be returned by `getch()` if no input is waiting. If `delay` is positive, then `getch()` will block for `delay` milliseconds, and return -1 if there is still no input at the end of that time.

`window.touchline(start, count[, changed])`

Pretend `count` lines have been changed, starting with line `start`. If `changed` is supplied, it specifies whether the affected lines are marked as having been changed (`changed=1`) or unchanged (`changed=0`).

`window.touchwin()`

Pretend the whole window has been changed, for purposes of drawing optimizations.

`window.untouchwin()`

Marks all lines in the window as unchanged since the last call to `refresh()`.

`window.vline([y, x], ch, n)`

Display a vertical line starting at `(y, x)` with length `n` consisting
of the character $ch$. 
15.9.3. Constants

The **curses** module defines the following data members:

**curses.ERR**
- Some curses routines that return an integer, such as `getch()`, return **ERR** upon failure.

**curses.OK**
- Some curses routines that return an integer, such as `napsms()`, return **OK** upon success.

**curses.version**
- A string representing the current version of the module. Also available as **__version__**.

Several constants are available to specify character cell attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_ALTCCHARSET</td>
<td>Alternate character set mode.</td>
</tr>
<tr>
<td>A_BLINK</td>
<td>Blink mode.</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Bold mode.</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Dim mode.</td>
</tr>
<tr>
<td>A_NORMAL</td>
<td>Normal attribute.</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>Standout mode.</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underline mode.</td>
</tr>
</tbody>
</table>

Keys are referred to by integer constants with names starting with **KEY_**. The exact keycaps available are system dependent.

</tbody>
</table>

On VT100s and their software emulations, such as X terminal
emulators, there are normally at least four function keys (KEY_F1, KEY_F2, KEY_F3, KEY_F4) available, and the arrow keys mapped to KEY_UP, KEY_DOWN, KEY_LEFT and KEY_RIGHT in the obvious way. If your machine has a PC keyboard, it is safe to expect arrow keys and twelve function keys (older PC keyboards may have only ten function keys); also, the following keypad mappings are standard:

<table>
<thead>
<tr>
<th>Keycap</th>
<th>Constant</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert</td>
<td>KEY_IC</td>
</tr>
<tr>
<td>Delete</td>
<td>KEY_DC</td>
</tr>
<tr>
<td>Home</td>
<td>KEY_HOME</td>
</tr>
<tr>
<td>End</td>
<td>KEY_END</td>
</tr>
<tr>
<td>Page Up</td>
<td>KEY_NPAGE</td>
</tr>
<tr>
<td>Page Down</td>
<td>KEY_PPAGE</td>
</tr>
</tbody>
</table>

The following table lists characters from the alternate character set. These are inherited from the VT100 terminal, and will generally be available on software emulations such as X terminals. When there is no graphic available, curses falls back on a crude printable ASCII approximation.

**Note:** These are available only after `initscr()` has been called.

</tbody>
</table>
15.10. `curses.textpad` — Text input widget for curses programs

New in version 1.6.

The `curses.textpad` module provides a `Textbox` class that handles elementary text editing in a curses window, supporting a set of keybindings resembling those of Emacs (thus, also of Netscape Navigator, BBedit 6.x, FrameMaker, and many other programs). The module also provides a rectangle-drawing function useful for framing text boxes or for other purposes.

The module `curses.textpad` defines the following function:

```python
curses.textpad.rectangle(win, uly, ulx, lry, lrx)
```

Draw a rectangle. The first argument must be a window object; the remaining arguments are coordinates relative to that window. The second and third arguments are the y and x coordinates of the upper left hand corner of the rectangle to be drawn; the fourth and fifth arguments are the y and x coordinates of the lower right hand corner. The rectangle will be drawn using VT100/IBM PC forms characters on terminals that make this possible (including xterm and most other software terminal emulators). Otherwise it will be drawn with ASCII dashes, vertical bars, and plus signs.
15.10.1. Textbox objects

You can instantiate a `Textbox` object as follows:

```python
class curses.textpad.Textbox(win)
```

Return a textbox widget object. The `win` argument should be a `curses.WindowObject` in which the textbox is to be contained. The edit cursor of the textbox is initially located at the upper left hand corner of the containing window, with coordinates \((0, 0)\). The instance's `stripspaces` flag is initially on.

`Textbox` objects have the following methods:

`edit([validator])`

This is the entry point you will normally use. It accepts editing keystrokes until one of the termination keystrokes is entered. If `validator` is supplied, it must be a function. It will be called for each keystroke entered with the keystroke as a parameter; command dispatch is done on the result. This method returns the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` member.

`do_command(ch)`

Process a single command keystroke. Here are the supported special keystrokes:

<table>
<thead>
<tr>
<th>Keystroke</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control-A</td>
<td>Go to left edge of window.</td>
</tr>
<tr>
<td>Control-B</td>
<td>Cursor left, wrapping to previous line if appropriate.</td>
</tr>
<tr>
<td>Control-D</td>
<td>Delete character under cursor.</td>
</tr>
<tr>
<td>Control-E</td>
<td>Go to right edge (stripspaces off) or end of line (stripspaces on).</td>
</tr>
</tbody>
</table>
Control-F | Cursor right, wrapping to next line when appropriate.
Control-G | Terminate, returning the window contents.
Control-H | Delete character backward.
Control-J | Terminate if the window is 1 line, otherwise insert newline.
Control-K | If line is blank, delete it, otherwise clear to end of line.
Control-L | Refresh screen.
Control-N | Cursor down; move down one line.
Control-O | Insert a blank line at cursor location.
Control-P | Cursor up; move up one line.

Move operations do nothing if the cursor is at an edge where the movement is not possible. The following synonyms are supported where possible:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Keystroke</th>
</tr>
</thead>
<tbody>
<tr>
<td>KEY_LEFT</td>
<td>Control-B</td>
</tr>
<tr>
<td>KEY_RIGHT</td>
<td>Control-F</td>
</tr>
<tr>
<td>KEY_UP</td>
<td>Control-P</td>
</tr>
<tr>
<td>KEY_DOWN</td>
<td>Control-N</td>
</tr>
<tr>
<td>KEY_BACKSPACE</td>
<td>Control-h</td>
</tr>
</tbody>
</table>

All other keystrokes are treated as a command to insert the given character and move right (with line wrapping).

`gather()`

This method returns the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` member.

`stripspaces`

This data member is a flag which controls the interpretation of blanks in the window. When it is on, trailing blanks on each line are ignored; any cursor motion that would land the cursor
on a trailing blank goes to the end of that line instead, and trailing blanks are stripped when the window contents are gathered.
15.11. `curses.wrapper` — Terminal handler for curses programs

*New in version 1.6.*

This module supplies one function, `wrapper()`, which runs another function which should be the rest of your curses-using application. If the application raises an exception, `wrapper()` will restore the terminal to a sane state before re-raising the exception and generating a traceback.

```python
    curses.wrapper(func, ...)
```

Wrapper function that initializes curses and calls another function, `func`, restoring normal keyboard/screen behavior on error. The callable object `func` is then passed the main window ‘stdscr’ as its first argument, followed by any other arguments passed to `wrapper()`.

Before calling the hook function, `wrapper()` turns on cbreak mode, turns off echo, enables the terminal keypad, and initializes colors if the terminal has color support. On exit (whether normally or by exception) it restores cooked mode, turns on echo, and disables the terminal keypad.
15.12. `curses.ascii` — Utilities for ASCII characters

*New in version 1.6.*

The `curses.ascii` module supplies name constants for ASCII characters and functions to test membership in various ASCII character classes. The constants supplied are names for control characters as follows:

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>NUL</td>
<td>Start of heading, console interrupt</td>
</tr>
<tr>
<td>SOH</td>
<td>Start of text</td>
</tr>
<tr>
<td>STX</td>
<td>End of text</td>
</tr>
<tr>
<td>ETX</td>
<td>End of transmission</td>
</tr>
<tr>

</tr>
<tr>
<td>VT</td>
<td>Vertical tab</td>
</tr>
<tr>
<td>FF</td>
<td>Form feed</td>
</tr>
<tr>
<td>CR</td>
<td>Carriage return</td>
</tr>
<tr>
<td>SO</td>
<td>Shift-out, begin alternate character set</td>
</tr>
<tr>
<td>SI</td>
<td>Shift-in, resume default character set</td>
</tr>
<tr>
<td>DLE</td>
<td>Data-link escape</td>
</tr>
<tr>
<td>DC1</td>
<td>XON, for flow control</td>
</tr>
<tr>
<td>Code</td>
<td>Description</td>
</tr>
<tr>
<td>------</td>
<td>-------------</td>
</tr>
<tr>
<td>DC2</td>
<td>Device control 2, block-mode flow control</td>
</tr>
<tr>
<td>DC3</td>
<td>XOFF, for flow control</td>
</tr>
<tr>
<td>DC4</td>
<td>Device control 4</td>
</tr>
<tr>
<td>NAK</td>
<td>Negative acknowledgement</td>
</tr>
<tr>
<td>SYN</td>
<td>Synchronous idle</td>
</tr>
<tr>
<td>ETB</td>
<td>End transmission block</td>
</tr>
<tr>
<td>CAN</td>
<td>Cancel</td>
</tr>
<tr>
<td>EM</td>
<td>End of medium</td>
</tr>
<tr>
<td>SUB</td>
<td>Substitute</td>
</tr>
<tr>
<td>ESC</td>
<td>Escape</td>
</tr>
<tr>
<td>FS</td>
<td>File separator</td>
</tr>
<tr>
<td>GS</td>
<td>Group separator</td>
</tr>
<tr>
<td>RS</td>
<td>Record separator, block-mode terminator</td>
</tr>
<tr>
<td>US</td>
<td>Unit separator</td>
</tr>
<tr>
<td>SP</td>
<td>Space</td>
</tr>
<tr>
<td>DEL</td>
<td>Delete</td>
</tr>
</tbody>
</table>

Note that many of these have little practical significance in modern usage. The mnemonics derive from teleprinter conventions that predate digital computers.

The module supplies the following functions, patterned on those in the standard C library:

```c
#include <curses.ascii>

// Checks for an ASCII alphanumeric character; it is equivalent to
// isalpha(c) or isdigit(c).

int isalnum(int c) {
    return isalpha(c) || isdigit(c);
}

// Checks for an ASCII alphabetic character; it is equivalent to
// isupper(c) or islower(c).

int isalpha(int c) {
    return isupper(c) || islower(c);
}

// Checks if a character is a valid ASCII character.

int isascii(int c) {
    return c >= 0 && c <= 127;
}
```
Checks for a character value that fits in the 7-bit ASCII set.

curses.ascii.isblank(c)
  Checks for an ASCII whitespace character.

curses.ascii.iscntrl(c)
  Checks for an ASCII control character (in the range 0x00 to 0x1f).

curses.ascii.isdigit(c)
  Checks for an ASCII decimal digit, '0' through '9'. This is equivalent to c in string.digits.

curses.ascii.isgraph(c)
  Checks for ASCII any printable character except space.

curses.ascii.islower(c)
  Checks for an ASCII lower-case character.

curses.ascii.isprint(c)
  Checks for any ASCII printable character including space.

curses.ascii.ispunct(c)
  Checks for any printable ASCII character which is not a space or an alphanumeric character.

curses.ascii.isspace(c)
  Checks for ASCII white-space characters; space, line feed, carriage return, form feed, horizontal tab, vertical tab.

curses.ascii.isupper(c)
  Checks for an ASCII uppercase letter.

curses.ascii.isxdigit(c)
  Checks for an ASCII hexadecimal digit. This is equivalent to c in
The following two functions take either a single-character string or integer byte value; they return a value of the same type.

**curses.ascii.ascii(c)**
Return the ASCII value corresponding to the low 7 bits of c.

**curses.ascii.ctrl(c)**
Return the control character corresponding to the given character (the character bit value is bitwise-anded with 0x1f).

**curses.ascii.alt(c)**
Return the 8-bit character corresponding to the given ASCII character (the character bit value is bitwise-ored with 0x80).

The following function takes either a single-character string or integer value; it returns a string.
curses.ascii.unctrl(c)

Return a string representation of the ASCII character c. If c is printable, this string is the character itself. If the character is a control character (0x00-0x1f) the string consists of a caret (^) followed by the corresponding uppercase letter. If the character is an ASCII delete (0x7f) the string is '^?'. If the character has its meta bit (0x80) set, the meta bit is stripped, the preceding rules applied, and '!' prepended to the result.

curses.ascii.controlnames

A 33-element string array that contains the ASCII mnemonics for the thirty-two ASCII control characters from 0 (NUL) to 0x1f (US), in order, plus the mnemonic sp for the space character.
Standard Library » 15. Generic Operating System Services »
Panels are windows with the added feature of depth, so they can be stacked on top of each other, and only the visible portions of each window will be displayed. Panels can be added, moved up or down in the stack, and removed.
15.13.1. Functions

The module `curses.panel` defines the following functions:

`curses.panel.bottom_panel()`

Returns the bottom panel in the panel stack.

`curses.panel.new_panel(win)`

Returns a panel object, associating it with the given window `win`. Be aware that you need to keep the returned panel object referenced explicitly. If you don’t, the panel object is garbage collected and removed from the panel stack.

`curses.panel.top_panel()`

Returns the top panel in the panel stack.

`curses.panel.update_panels()`

Updates the virtual screen after changes in the panel stack. This does not call `curses.doupdate()`, so you’ll have to do this yourself.
15.13.2. Panel Objects

Panel objects, as returned by `new_panel()` above, are windows with a stacking order. There's always a window associated with a panel which determines the content, while the panel methods are responsible for the window's depth in the panel stack.

Panel objects have the following methods:

Panel. `above()`
- Returns the panel above the current panel.

Panel. `below()`
- Returns the panel below the current panel.

Panel. `bottom()`
- Push the panel to the bottom of the stack.

Panel. `hidden()`
- Returns true if the panel is hidden (not visible), false otherwise.

Panel. `hide()`
- Hide the panel. This does not delete the object, it just makes the window on screen invisible.

Panel. `move(y, x)`
- Move the panel to the screen coordinates \((y, x)\).

Panel. `replace(win)`
- Change the window associated with the panel to the window \(win\).

Panel. `set_userptr(obj)`
- Set the panel's user pointer to \(obj\). This is used to associate an
arbitrary piece of data with the panel, and can be any Python object.

```python
Panel.show()
```

Display the panel (which might have been hidden).

```python
Panel.top()
```

Push panel to the top of the stack.

```python
Panel.userptr()
```

Returns the user pointer for the panel. This might be any Python object.

```python
Panel.window()
```

Returns the window object associated with the panel.
15.14. platform — Access to underlying platform’s identifying data

New in version 2.3.

Note: Specific platforms listed alphabetically, with Linux included in the Unix section.

platform.architecture(executable=sys.executable, bits='', linkage='')

Queries the given executable (defaults to the Python interpreter binary) for various architecture information.

Returns a tuple (bits, linkage) which contain information about the bit architecture and the linkage format used for the executable. Both values are returned as strings.

Values that cannot be determined are returned as given by the parameter presets. If bits is given as '', the sizeof(pointer)() (or sizeof(long)() on Python version < 1.5.2) is used as indicator for the supported pointer size.

The function relies on the system’s `file` command to do the actual work. This is available on most if not all Unix platforms and some non-Unix platforms and then only if the executable points to the Python interpreter. Reasonable defaults are used when the above needs are not met.

platform.machine()

Returns the machine type, e.g. 'i386'. An empty string is returned if the value cannot be determined.

platform.node()

Returns the computer’s network name (may not be fully qualified!). An empty string is returned if the value cannot be determined.

platform.platform(aliased=0, terse=0)

Returns a single string identifying the underlying platform with as
much useful information as possible.

The output is intended to be *human readable* rather than machine parseable. It may look different on different platforms and this is intended.

If `aliased` is true, the function will use aliases for various platforms that report system names which differ from their common names, for example SunOS will be reported as Solaris. The `system_alias()` function is used to implement this.

Setting `terse` to true causes the function to return only the absolute minimum information needed to identify the platform.

platform.**processor**()

 Returns the (real) processor name, e.g. `'amdk6'`.

An empty string is returned if the value cannot be determined. Note that many platforms do not provide this information or simply return the same value as for `machine()`. NetBSD does this.

platform.**python_build**()

 Returns a tuple `(buildno, builddate)` stating the Python build number and date as strings.

platform.**python_compiler**()

 Returns a string identifying the compiler used for compiling Python.

platform.**python_branch**()

 Returns a string identifying the Python implementation SCM branch.

*New in version 2.6.*
platform.\texttt{python\_implementation}()

Returns a string identifying the Python implementation. Possible return values are: ‘CPython’, ‘IronPython’, ‘Jython’.

\textit{New in version 2.6.}

platform.\texttt{python\_revision}()

Returns a string identifying the Python implementation SCM revision.

\textit{New in version 2.6.}

platform.\texttt{python\_version}()

Returns the Python version as string \texttt{'major.minor.patchlevel'}

Note that unlike the Python \texttt{sys.version}, the returned value will always include the patchlevel (it defaults to 0).

platform.\texttt{python\_version\_tuple}()

Returns the Python version as tuple (major, minor, patchlevel) of strings.

Note that unlike the Python \texttt{sys.version}, the returned value will always include the patchlevel (it defaults to '0').

platform.\texttt{release}()

Returns the system's release, e.g. \texttt{'2.2.0'} or \texttt{'NT'} An empty string is returned if the value cannot be determined.

platform.\texttt{system}()

Returns the system/OS name, e.g. \texttt{'Linux'}, \texttt{'Windows'}, or \texttt{'Java'}. An empty string is returned if the value cannot be determined.

platform.\texttt{system\_alias}(\texttt{system, release, version})
Returns (system, release, version) aliased to common marketing names used for some systems. It also does some reordering of the information in some cases where it would otherwise cause confusion.

platform.version()
Returns the system's release version, e.g. '#3 on degas'. An empty string is returned if the value cannot be determined.

platform.uname()
Fairly portable uname interface. Returns a tuple of strings (system, node, release, version, machine, processor) identifying the underlying platform.

Note that unlike the os.uname() function this also returns possible processor information as additional tuple entry.

Entries which cannot be determined are set to ''. 
15.14.2. Java Platform

platform.java_ver(*release*, *vendor*, *vminfo*, *osinfo*)

Version interface for Jython.

Returns a tuple (*release*, *vendor*, *vminfo*, *osinfo*) with *vminfo* being a tuple (*vm_name*, *vm_release*, *vm_vendor*) and *osinfo* being a tuple (*os_name*, *os_version*, *os_arch*). Values which cannot be determined are set to the defaults given as parameters (which all default to '').
15.14.3. Windows Platform

platform.win32_ver(release='', version='', csd='', ptype='')

Get additional version information from the Windows Registry and return a tuple (version, csd, ptype) referring to version number, CSD level and OS type (multi/single processor).

As a hint: *ptype* is 'Uniprocessor Free' on single processor NT machines and 'Multiprocessor Free' on multi processor machines. The 'Free' refers to the OS version being free of debugging code. It could also state 'Checked' which means the OS version uses debugging code, i.e. code that checks arguments, ranges, etc.

**Note:** Note: this function works best with Mark Hammond's *win32all* package installed, but also on Python 2.3 and later (support for this was added in Python 2.6). It obviously only runs on Win32 compatible platforms.

15.14.3.1. Win95/98 specific

platform.popen(cmd, mode='r', bufsize=None)

Portable *popen()* interface. Find a working popen implementation preferring *win32pipe.popen()* . On Windows NT, *win32pipe.popen()* should work; on Windows 9x it hangs due to bugs in the MS C library.
15.14.4. Mac OS Platform

platform.mac_ver(*release*, *versioninfo*, *machine*)

Get Mac OS version information and return it as tuple (*release*, *versioninfo*, *machine*) with *versioninfo* being a tuple (*version*, *dev_stage*, *non_release_version*).

Entries which cannot be determined are set to ''. All tuple entries are strings.

Documentation for the underlying gestalt() API is available online at http://www.rgaros.nl/gestalt/.
15.14.5. Unix Platforms

```python
platform.dist(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...))
```

This is an old version of the functionality now provided by `linux_distribution()`. For new code, please use the `linux_distribution()`.

The only difference between the two is that `dist()` always returns the short name of the distribution taken from the `supported_dists` parameter.

```
Deprecated since version 2.6.
```

```python
platform.linux_distribution(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...), full_distribution_name=1)
```

Tries to determine the name of the Linux OS distribution name.

`supported_dists` may be given to define the set of Linux distributions to look for. It defaults to a list of currently supported Linux distributions identified by their release file name.

If `full_distribution_name` is true (default), the full distribution read from the OS is returned. Otherwise the short name taken from `supported_dists` is used.

Returns a tuple `(distname, version, id)` which defaults to the args given as parameters. `id` is the item in parentheses after the version number. It is usually the version codename.

```
New in version 2.6.
```
platform.libc_ver(executable=sys.executable, lib='', version='', chunksize=2048)

Tries to determine the libc version against which the file executable (defaults to the Python interpreter) is linked. Returns a tuple of strings (lib, version) which default to the given parameters in case the lookup fails.

Note that this function has intimate knowledge of how different libc versions add symbols to the executable is probably only usable for executables compiled using gcc.

The file is read and scanned in chunks of chunksize bytes.
15.15. **errno** — Standard errno system symbols

This module makes available standard `errno` system symbols. The value of each symbol is the corresponding integer value. The names and descriptions are borrowed from `linux/include/errno.h`, which should be pretty all-inclusive.

**errno.errorcode**

Dictionary providing a mapping from the errno value to the string name in the underlying system. For instance, `errno.errorcode[errno.EPERM]` maps to 'EPERM'.

To translate a numeric error code to an error message, use `os.strerror()`.

Of the following list, symbols that are not used on the current platform are not defined by the module. The specific list of defined symbols is available as `errno.errorcode.keys()`. Symbols available can include:

- **errno.EPERM**
  
  Operation not permitted

- **errno.ENOENT**
  
  No such file or directory

- **errno.ESRCH**
  
  No such process

- **errno.EINTR**
  
  Interrupted system call

- **errno.EIO**
I/O error

errno. **ENXIO**
   No such device or address

errno. **E2BIG**
   Arg list too long

errno. **ENOEXEC**
   Exec format error

errno. **EBADF**
   Bad file number

errno. **ECHILD**
   No child processes

errno. **EAGAIN**
   Try again

errno. **ENOMEM**
   Out of memory

errno. **EACCES**
   Permission denied

errno. **EFAULT**
   Bad address

errno. **ENOTBLK**
   Block device required

errno. **EBUSY**
   Device or resource busy

errno. **EEXIST**
   File exists
errno. **EXDEV**  
Cross-device link

errno. **ENODEV**  
No such device

errno. **ENOTDIR**  
Not a directory

errno. **EISDIR**  
Is a directory

errno. **EINVAL**  
Invalid argument

errno. **ENFILE**  
File table overflow

errno. **EMFILE**  
Too many open files

errno. **ENOTTY**  
Not a typewriter

errno. **ETXTBSY**  
Text file busy

errno. **EFBIG**  
File too large

errno. **ENOSPC**  
No space left on device

errno. **ESPIPE**  
Illegal seek

errno. **EROFS**  
Read-only file system
errno. **EMLINK**
    Too many links

errno. **EPIPE**
    Broken pipe

errno. **EDOM**
    Math argument out of domain of func

errno. **ERANGE**
    Math result not representable

errno. **EDEADLK**
    Resource deadlock would occur

errno. **ENAMETOOLONG**
    File name too long

errno. **ENOLCK**
    No record locks available

errno. **ENOSYS**
    Function not implemented

errno. **ENOTEMPTY**
    Directory not empty

errno. **ELOOP**
    Too many symbolic links encountered

errno. **EWOULDBLOCK**
    Operation would block

errno. **ENOMSG**
    No message of desired type

errno. **EIDRM**
    Identifier removed
errno. **ECHRG**
   Channel number out of range

errno. **EL2NSYNC**
   Level 2 not synchronized

errno. **EL3HLT**
   Level 3 halted

errno. **EL3RST**
   Level 3 reset

errno. **ELNRNG**
   Link number out of range

errno. **EUNATCH**
   Protocol driver not attached

errno. **ENOCSI**
   No CSI structure available

errno. **EL2HLT**
   Level 2 halted

errno. **EBADE**
   Invalid exchange

errno. **EBADR**
   Invalid request descriptor

errno. **EXFULL**
   Exchange full

errno. **ENOANO**
   No anode

errno. **EBADRQC**
   Invalid request code
**errno. EBADSLT**
Invalid slot

**errno. EDEADLOCK**
File locking deadlock error

**errno. EBFONT**
Bad font file format

**errno. ENOSTR**
Device not a stream

**errno. ENODATA**
No data available

**errno. ETIME**
Timer expired

**errno. ENOSR**
Out of streams resources

**errno. ENONET**
Machine is not on the network

**errno. ENOPKG**
Package not installed

**errno. EREMOTE**
Object is remote

**errno. ENOLINK**
Link has been severed

**errno. EADV**
Advertise error

**errno. ESRMNT**
Srmount error
errno. ECOMM
    Communication error on send

errno. EPROTO
    Protocol error

errno. EMULTIHOP
    Multihop attempted

errno. EDOTDOT
    RFS specific error

errno. EBADMSG
    Not a data message

errno. EOVERFLOW
    Value too large for defined data type

errno. ENOTUNIQ
    Name not unique on network

errno. EBADFD
    File descriptor in bad state

errno. EREMCHG
    Remote address changed

errno. ELIBACC
    Can not access a needed shared library

errno. ELIBBAD
    Accessing a corrupted shared library

errno. ELIBSCN
    .lib section in a.out corrupted

errno. ELIBMAX
    Attempting to link in too many shared libraries
errno. **ELIBEXEC**  
Cannot exec a shared library directly

errno. **EILSEQ**  
Illegal byte sequence

errno. **ERESTART**  
Interrupted system call should be restarted

errno. **ESTRPIPE**  
Streams pipe error

errno. **EUSERS**  
Too many users

errno. **ENOTSOCK**  
Socket operation on non-socket

errno. **EDESTADDRREQ**  
Destination address required

errno. **EMSGSIZE**  
Message too long

errno. **EPROTOTYPE**  
Protocol wrong type for socket

errno. **ENOPROTOOPT**  
Protocol not available

errno. **EPROTONOSUPPORT**  
Protocol not supported

errno. **ESOCKTNOSUPPORT**  
Socket type not supported

errno. **EOPNOTSUPP**  
Operation not supported on transport endpoint
errno. **EPFNOSUPPORT**
   Protocol family not supported

errno. **EAFNOSUPPORT**
   Address family not supported by protocol

errno. **EADDRINUSE**
   Address already in use

errno. **EADDRNOTAVAIL**
   Cannot assign requested address

errno. **ENETDOWN**
   Network is down

errno. **ENETUNREACH**
   Network is unreachable

errno. **ENETRESET**
   Network dropped connection because of reset

errno. **ECONNABORTED**
   Software caused connection abort

errno. **ECONNRESET**
   Connection reset by peer

errno. **ENOBUFS**
   No buffer space available

errno. **EISCONN**
   Transport endpoint is already connected

errno. **ENOTCONN**
   Transport endpoint is not connected

errno. **ESHUTDOWN**
   Cannot send after transport endpoint shutdown
errno. **ETOOMANYREFS**
   Too many references: cannot splice

errno. **ETIMEDOUT**
   Connection timed out

errno. **ECONNREFUSED**
   Connection refused

errno. **EHOSTDOWN**
   Host is down

errno. **EHOSTUNREACH**
   No route to host

errno. **EALREADY**
   Operation already in progress

errno. **EINPROGRESS**
   Operation now in progress

errno. **ESTALE**
   Stale NFS file handle

errno. **EUCLEAN**
   Structure needs cleaning

errno. **ENOTNAM**
   Not a XENIX named type file

errno. **ENAVAIL**
   No XENIX semaphores available

errno. **EISNAM**
   Is a named type file

errno. **EREMOTEIO**
   Remote I/O error
**errno.EDQUOT**

Quota exceeded
15.16. **ctypes** — A foreign function library for Python

*New in version 2.5.*

**ctypes** is a foreign function library for Python. It provides C compatible data types, and allows calling functions in DLLs or shared libraries. It can be used to wrap these libraries in pure Python.
15.16.1. ctypes tutorial

Note: The code samples in this tutorial use doctest to make sure that they actually work. Since some code samples behave differently under Linux, Windows, or Mac OS X, they contain doctest directives in comments.

Note: Some code samples reference the ctypes c_int type. This type is an alias for the c_long type on 32-bit systems. So, you should not be confused if c_long is printed if you would expect c_int — they are actually the same type.

15.16.1.1. Loading dynamic link libraries

ctypes exports the cdll, and on Windows windll and oledll objects, for loading dynamic link libraries.

You load libraries by accessing them as attributes of these objects. cdll loads libraries which export functions using the standard cdecl calling convention, while windll libraries call functions using the stdcall calling convention. oledll also uses the stdcall calling convention, and assumes the functions return a Windows HRESULT error code. The error code is used to automatically raise a WindowsError exception when the function call fails.

Here are some examples for Windows. Note that msvcrt is the MS standard C library containing most standard C functions, and uses the cdecl calling convention:

```python
>>> from ctypes import *
>>> print windll.kernel32 # doctest: +WINDOWS
<WinDLL 'kernel32', handle ... at ...>
>>> print cdll.msvcrt # doctest: +WINDOWS
<CDLL 'msvcrt', handle ... at ...>
```
Windows appends the usual .dll file suffix automatically.

On Linux, it is required to specify the filename including the extension to load a library, so attribute access can not be used to load libraries. Either the LoadLibrary() method of the dll loaders should be used, or you should load the library by creating an instance of CDLL by calling the constructor:

```python
>>> cdll.LoadLibrary("libc.so.6") # doctest: +LINUX
<CDLL 'libc.so.6', handle ... at ...>
>>> libc = CDLL("libc.so.6")       # doctest: +LINUX
>>> libc                           # doctest: +LINUX
<CDLL 'libc.so.6', handle ... at ...>
```

### 15.16.1.2. Accessing functions from loaded dlls

Functions are accessed as attributes of dll objects:

```python
>>> from ctypes import *
>>> libc.printf
<_FuncPtr object at 0x...>
>>> print windll.kernel32.GetModuleHandleA # doctest: +WINDOWS
<_FuncPtr object at 0x...>
>>> print windll.kernel32.MyOwnFunction # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "ctypes.py", line 239, in __getattr__
    func = _StdcallFuncPtr(name, self)
AttributeError: function 'MyOwnFunction' not found
```

Note that win32 system dlls like kernel32 and user32 often export ANSI as well as UNICODE versions of a function. The UNICODE version is exported with an w appended to the name, while the ANSI version is exported with an A appended to the name. The win32
GetModuleHandle function, which returns a *module handle* for a given module name, has the following C prototype, and a macro is used to expose one of them as GetModuleHandle depending on whether UNICODE is defined or not:

```c
/* ANSI version */
HMODULE GetModuleHandleA(LPCSTR lpModuleName);
/* UNICODE version */
HMODULE GetModuleHandleW(LPCWSTR lpModuleName);
```

`windll` does not try to select one of them by magic, you must access the version you need by specifying `GetModuleHandleA` or `GetModuleHandleW` explicitly, and then call it with strings or unicode strings respectively.

Sometimes, dlls export functions with names which aren’t valid Python identifiers, like `"??2@YAPAXI@Z"`. In this case you have to use `getattr()` to retrieve the function:

```python
>>> getattr(cdll.msvcrt, "??2@YAPAXI@Z")  # doctest: +WINDOWS
<_FuncPtr object at 0x...>
```

On Windows, some dlls export functions not by name but by ordinal. These functions can be accessed by indexing the dll object with the ordinal number:

```python
>>> cdll.kernel32[1]  # doctest: +WINDOWS
<_FuncPtr object at 0x...>
```

15.16.1.3. Calling functions
You can call these functions like any other Python callable. This example uses the `time()` function, which returns system time in seconds since the Unix epoch, and the `GetModuleHandleA()` function, which returns a win32 module handle.

This example calls both functions with a NULL pointer (None should be used as the NULL pointer):

```python
>>> print libc.time(None) # doctest: +SKIP
1150640792
>>> print hex(windll.kernel32.GetModuleHandleA(None)) # doctest: +WINDOWS
0x1d000000
>>> 
```

`ctypes` tries to protect you from calling functions with the wrong number of arguments or the wrong calling convention. Unfortunately this only works on Windows. It does this by examining the stack after the function returns, so although an error is raised the function has been called:

```python
>>> windll.kernel32.GetModuleHandleA() # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments
>>> windll.kernel32.GetModuleHandleA(0, 0) # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with too many arguments
``` 

The same exception is raised when you call an `stdcall` function with the `cdecl` calling convention, or vice versa:

```python
>>> cdll.kernel32.GetModuleHandleA(None) # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
```
To find out the correct calling convention you have to look into the C header file or the documentation for the function you want to call.

On Windows, `ctypes` uses win32 structured exception handling to prevent crashes from general protection faults when functions are called with invalid argument values:

```python
>>> windll.kernel32.GetModuleHandleA(32) # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
WindowsError: exception: access violation reading 0x00000020
```

There are, however, enough ways to crash Python with `ctypes`, so you should be careful anyway.

`None`, integers, longs, byte strings and unicode strings are the only native Python objects that can directly be used as parameters in these function calls. `None` is passed as a C `NULL` pointer, byte strings and unicode strings are passed as pointer to the memory block that contains their data (`char *` or `wchar_t *`). Python integers and Python longs are passed as the platforms default C `int` type, their value is masked to fit into the C type.

Before we move on calling functions with other parameter types, we have to learn more about `ctypes` data types.

**15.16.1.4. Fundamental data types**
**ctypes** defines a number of primitive C compatible data types:

<table>
<thead>
<tr>
<th>ctypes type</th>
<th>C type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_char</td>
<td>char</td>
<td>1-character string</td>
</tr>
<tr>
<td>c_wchar</td>
<td>wchar_t</td>
<td>1-character unicode string</td>
</tr>
<tr>
<td>c_byte</td>
<td>char</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ubyte</td>
<td>unsigned char</td>
<td>int/long</td>
</tr>
<tr>
<td>c_short</td>
<td>short</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ushort</td>
<td>unsigned short</td>
<td>int/long</td>
</tr>
<tr>
<td>c_int</td>
<td>int</td>
<td>int/long</td>
</tr>
<tr>
<td>c_uint</td>
<td>unsigned int</td>
<td>int/long</td>
</tr>
<tr>
<td>c_long</td>
<td>long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ulong</td>
<td>unsigned long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_longlong</td>
<td>__int64 Or long long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ulonglong</td>
<td>unsigned __int64 Or unsigned long long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_float</td>
<td>float</td>
<td>float</td>
</tr>
<tr>
<td>c_double</td>
<td>double</td>
<td>float</td>
</tr>
<tr>
<td>c_longdouble</td>
<td>long double</td>
<td>float</td>
</tr>
<tr>
<td>c_char_p</td>
<td>char * (NUL terminated)</td>
<td>string or None</td>
</tr>
<tr>
<td>c_wchar_p</td>
<td>wchar_t * (NUL terminated)</td>
<td>unicode or None</td>
</tr>
<tr>
<td>c_void_p</td>
<td>void *</td>
<td>int/long Or None</td>
</tr>
</tbody>
</table>

All these types can be created by calling them with an optional initializer of the correct type and value:

```python
g>>> c_int()
c_int(0)
g>>> c_char_p("Hello, World")
c_char_p('Hello, World')
g>>> c_ushort(-3)
c_ushort(-3)
g>>> c_ulong(65533)
>>>```
Since these types are mutable, their value can also be changed afterwards:

```python
>>> i = c_int(42)
>>> print i
18
>>> print i.value
42
>>> i.value = -99
>>> print i.value
-99
```  

Assigning a new value to instances of the pointer types `c_char_p`, `c_wchar_p`, and `c_void_p` changes the memory location they point to, not the contents of the memory block (of course not, because Python strings are immutable):

```python
>>> s = "Hello, World"
>>> c_s = c_char_p(s)
>>> print c_s
c_char_p('Hello, World')
>>> c_s.value = "Hi, there"
>>> print c_s
c_char_p('Hi, there')
>>> print s # first string is unchanged
Hello, World
```  

You should be careful, however, not to pass them to functions expecting pointers to mutable memory. If you need mutable memory blocks, ctypes has a `create_string_buffer()` function which creates these in various ways. The current memory block contents can be accessed (or changed) with the `raw` property; if you want to access it as NUL terminated string, use the `value` property:

```python
>>> from ctypes import *
>>> p = create_string_buffer(3) # create a 3 byte buffer,
>>> print sizeof(p), repr(p.raw)
3 ''\x00\x00\x00''
```
The `create_string_buffer()` function replaces the `c_buffer()` function (which is still available as an alias), as well as the `c_string()` function from earlier ctypes releases. To create a mutable memory block containing unicode characters of the C type `wchar_t` use the `create_unicode_buffer()` function.

15.16.1.5. Calling functions, continued

Note that printf prints to the real standard output channel, not to `sys.stdout`, so these examples will only work at the console prompt, not from within IDLE or PythonWin:
As has been mentioned before, all Python types except integers, strings, and unicode strings have to be wrapped in their corresponding ctypes type, so that they can be converted to the required C data type:

```python
>>> printf("An int %d, a double %f\n", 1234, c_double(3.14))
An int 1234, a double 3.140000
31
```  

15.16.1.6. Calling functions with your own custom data types

You can also customize ctypes argument conversion to allow instances of your own classes be used as function arguments. ctypes looks for an _as_parameter_ attribute and uses this as the function argument. Of course, it must be one of integer, string, or unicode:

```python
>>> class Bottles(object):
...     def __init__(self, number):
...         self._as_parameter_ = number
... >>> bottles = Bottles(42)
>>> printf("%d bottles of beer\n", bottles)
42 bottles of beer
19
```  

If you don't want to store the instance's data in the _as_parameter_ instance variable, you could define a property() which makes the data available.

15.16.1.7. Specifying the required argument types (function prototypes)
It is possible to specify the required argument types of functions exported from DLLs by setting the argtypes attribute.

argtypes must be a sequence of C data types (the printf function is probably not a good example here, because it takes a variable number and different types of parameters depending on the format string, on the other hand this is quite handy to experiment with this feature):

>>> printf.argtypes = [c_char_p, c_char_p, c_int, c_double]
>>> printf("String '%%s', Int %%d, Double %%f\\n", "Hi", 10, 2.2)
String 'Hi', Int 10, Double 2.200000
37

Specifying a format protects against incompatible argument types (just as a prototype for a C function), and tries to convert the arguments to valid types:

>>> printf("%%d %%d %%d", 1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: wrong type
>>> printf("%%s %%d %%f\\n", "X", 2, 3)
X 2 3.000000
13

If you have defined your own classes which you pass to function calls, you have to implement a from_param() class method for them to be able to use them in the argtypes sequence. The from_param() class method receives the Python object passed to the function call, it should do a typecheck or whatever is needed to make sure this object is acceptable, and then return the object itself, its _as_parameter_ attribute, or whatever you want to pass as the C function argument in this case. Again, the result should be an integer, string, unicode, a ctypes instance, or an object with an
By default functions are assumed to return the C `int` type. Other return types can be specified by setting the `restype` attribute of the function object.

Here is a more advanced example, it uses the `strchr` function, which expects a string pointer and a char, and returns a pointer to a string:

```python
>>> strchr = libc.strchr
>>> strchr("abcdef", ord("d")) # doctest: +SKIP
8059983
>>> strchr.restype = c_char_p # c_char_p is a pointer to a string
>>> strchr("abcdef", ord("d"))
'def'
>>> print strchr("abcdef", ord("x"))
None

If you want to avoid the `ord("x")` calls above, you can set the `argtypes` attribute, and the second argument will be converted from a single character Python string into a C char:

```python
>>> strchr.restype = c_char_p
>>> strchr.argtypes = [c_char_p, c_char]
>>> strchr("abcdef", "d")
'def'
>>> strchr("abcdef", "def")
Traceback (most recent call last):
  File "stdin", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: one character
>>> print strchr("abcdef", "x")
None
>>> strchr("abcdef", "d")
'def'
>>>
You can also use a callable Python object (a function or a class for example) as the `restype` attribute, if the foreign function returns an integer. The callable will be called with the `integer` the C function returns, and the result of this call will be used as the result of your function call. This is useful to check for error return values and automatically raise an exception:

```python
>>> GetModuleHandle = windll.kernel32.GetModuleHandleA # doctest: +WINDOWS
>>> def ValidHandle(value):
...    if value == 0:
...        raise WinError()
...    return value
...>>> GetModuleHandle.restype = ValidHandle # doctest: +WINDOWS
>>> GetModuleHandle(None) # doctest: +WINDOWS
486539264
>>> GetModuleHandle("something silly") # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 3, in ValidHandle
WindowsError: [Errno 126] The specified module could not be found.
```

`WinError` is a function which will call Windows `FormatMessage()` api to get the string representation of an error code, and `returns` an exception. `WinError` takes an optional error code parameter, if no one is used, it calls `GetLastError()` to retrieve it.

Please note that a much more powerful error checking mechanism is available through the `errcheck` attribute; see the reference manual for details.

### 15.16.1.9. Passing pointers (or: passing parameters by reference)

Sometimes a C api function expects a `pointer` to a data type as
parameter, probably to write into the corresponding location, or if the data is too large to be passed by value. This is also known as passing parameters by reference.

*ctypes* exports the `byref()` function which is used to pass parameters by reference. The same effect can be achieved with the `pointer()` function, although `pointer()` does a lot more work since it constructs a real pointer object, so it is faster to use `byref()` if you don’t need the pointer object in Python itself:

```python
g>>> i = c_int()
g>>> f = c_float()
g>>> s = create_string_buffer('\000' * 32)
g>>> print i.value, f.value, repr(s.value)
0 0.0 ''
g>>> libc.sscanf("1 3.14 Hello", "%d %f %s",
g... byref(i), byref(f), s)
g3
g>>> print i.value, f.value, repr(s.value)
1 3.1400001049 'Hello'
```

15.16.1.10. Structures and unions

Structures and unions must derive from the *Structure* and *Union* base classes which are defined in the *ctypes* module. Each subclass must define a `_fields_` attribute. `_fields_` must be a list of 2-tuples, containing a *field name* and a *field type*.

The field type must be a *ctypes* type like `c_int`, or any other derived *ctypes* type: structure, union, array, pointer.

Here is a simple example of a POINT structure, which contains two integers named `x` and `y`, and also shows how to initialize a structure in the constructor:

```python
g>>> from ctypes import *
```
You can, however, build much more complicated structures. Structures can itself contain other structures by using a structure as a field type.

Here is a `RECT` structure which contains two `POINTs` named `upperleft` and `lowerright`:

```python
>> class RECT(Structure):
...     _fields_ = ["upperleft", POINT),
...                 "lowerright", POINT]
... 
>> rc = RECT(point)
>> print rc.upperleft.x, rc.upperleft.y
0 5
>> print rc.lowerright.x, rc.lowerright.y
0 0
>>
```

Nested structures can also be initialized in the constructor in several ways:

```python
>>> r = RECT(POINT(1, 2), POINT(3, 4))
>>> r = RECT((1, 2), (3, 4))
```

Field descriptors can be retrieved from the class, they are useful for debugging because they can provide useful information:
15.16.1.11. Structure/union alignment and byte order

By default, Structure and Union fields are aligned in the same way the C compiler does it. It is possible to override this behavior by specifying a _pack_ class attribute in the subclass definition. This must be set to a positive integer and specifies the maximum alignment for the fields. This is what #pragma pack(n) also does in MSVC.

ctypes uses the native byte order for Structures and Unions. To build structures with non-native byte order, you can use one of the BigEndianStructure, LittleEndianStructure, BigEndianUnion, and LittleEndianUnion base classes. These classes cannot contain pointer fields.

15.16.1.12. Bit fields in structures and unions

It is possible to create structures and unions containing bit fields. Bit fields are only possible for integer fields, the bit width is specified as the third item in the _fields_ tuples:

```python
>>> class Int(Structure):
    ...
    _fields_ = [(
        "first_16", c_int,
        16),
    ...
        ("second_16", c_int,
        16)]
    ...
    >>> print Int.first_16
    <Field type=c_long, ofs=0:0, bits=16>
    >>> print Int.second_16
    <Field type=c_long, ofs=0:16, bits=16>
    >>>
```
Arrays are sequences, containing a fixed number of instances of the same type.

The recommended way to create array types is by multiplying a data type with a positive integer:

TenPointsArrayType = POINT * 10

Here is an example of an somewhat artificial data type, a structure containing 4 POINTs among other stuff:

>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = ("x", c_int), ("y", c_int)
... >>>
>>> class MyStruct(Structure):
...     _fields_ = ["a", c_int],
...   ("b", c_float),
...   ("point_array", POINT * 4)]
>>>
>>> print len(MyStruct().point_array)
4

Instances are created in the usual way, by calling the class:

arr = TenPointsArrayType()
for pt in arr:
    print pt.x, pt.y

The above code print a series of 0 0 lines, because the array contents is initialized to zeros.

Initializers of the correct type can also be specified:

>>> from ctypes import *
```python
>>> TenIntegers = c_int * 10
>>> ii = TenIntegers(1, 2, 3, 4, 5, 6, 7, 8, 9, 10)
>>> print ii
<c_long_Array_10 object at 0x...>
>>> for i in ii: print i,
1 2 3 4 5 6 7 8 9 10
>>> 
```

### 15.16.1.14. Pointers

Pointer instances are created by calling the `pointer()` function on a `ctypes` type:

```python
>>> from ctypes import *
>>> i = c_int(42)
>>> pi = pointer(i)
>>> 
```

Pointer instances have a `contents` attribute which returns the object to which the pointer points, the `i` object above:

```python
>>> pi.contents
c_long(42)
>>> 
```

Note that `ctypes` does not have OOR (original object return), it constructs a new, equivalent object each time you retrieve an attribute:

```python
>>> pi.contents is i
False
>>> pi.contents is pi.contents
False
>>> 
```

Assigning another `c_int` instance to the pointer’s contents attribute would cause the pointer to point to the memory location where this is stored:
Pointer instances can also be indexed with integers:

```python
>>> pi[0]
99
```

Assigning to an integer index changes the pointed to value:

```python
>>> print i
c_long(99)
>>> pi[0] = 22
>>> print i
c_long(22)
```

It is also possible to use indexes different from 0, but you must know what you're doing, just as in C: You can access or change arbitrary memory locations. Generally you only use this feature if you receive a pointer from a C function, and you know that the pointer actually points to an array instead of a single item.

Behind the scenes, the `pointer()` function does more than simply create pointer instances, it has to create pointer types first. This is done with the `POINTER()` function, which accepts any `ctypes` type, and returns a new type:

```python
>>> PI = POINTER(c_int)
>>> PI
<class 'ctypes.LP_c_long'>
>>> PI(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: expected c_long instead of int
```
Calling the pointer type without an argument creates a NULL pointer. NULL pointers have a False boolean value:

```python
>>> null_ptr = POINTER(c_int)()
>>> print bool(null_ptr)
False

```

ctypes checks for NULL when dereferencing pointers (but dereferencing invalid non-NULL pointers would crash Python):

```python
>>> null_ptr[0]
Traceback (most recent call last):
  ...  
ValueError: NULL pointer access

>>> null_ptr[0] = 1234
Traceback (most recent call last):
  ...  
ValueError: NULL pointer access
```
To set a POINTER type field to NULL, you can assign `None`:

```python
>>> bar.values = None
```

Sometimes you have instances of incompatible types. In C, you can cast one type into another type. `ctypes` provides a `cast()` function which can be used in the same way. The `Bar` structure defined above accepts `POINTER(c_int)` pointers or `c_int` arrays for its `values` field, but not instances of other types:

```python
>>> bar.values = (c_byte * 4)()  
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: incompatible types, c_byte_Array_4 instance instead
```

For these cases, the `cast()` function is handy.

The `cast()` function can be used to cast a ctypes instance into a pointer to a different ctypes data type. `cast()` takes two parameters, a ctypes object that is or can be converted to a pointer of some kind, and a ctypes pointer type. It returns an instance of the second argument, which references the same memory block as the first argument:
So, `cast()` can be used to assign to the `values` field of `Bar` the structure:

```python
>>> bar = Bar()
>>> bar.values = cast((c_byte * 4)(), POINTER(c_int))
>>> print bar.values[0]
0
```
because the new `class cell` is not available in the class statement itself. In `ctypes`, we can define the `cell` class and set the `_fields_` attribute later, after the class statement:

```python
>>> from ctypes import *
>>> class cell(Structure):
...     pass
... >>> cell._fields_ = ["name", c_char_p],
...     ("next", POINTER(cell))]
>>> 
```

Lets try it. We create two instances of `cell`, and let them point to each other, and finally follow the pointer chain a few times:

```python
>>> c1 = cell()
>>> c1.name = "foo"
>>> c2 = cell()
>>> c2.name = "bar"
>>> c1.next = pointer(c2)
>>> c2.next = pointer(c1)
>>> p = c1
>>> for i in range(8):
...     print p.name,
...     p = p.next[0]
... 
foo bar foo bar foo bar foo bar
```
functions using the normal cdecl calling convention, and, on Windows, the WINFUNCTYPE factory function creates types for callback functions using the stdcall calling convention.

Both of these factory functions are called with the result type as first argument, and the callback functions expected argument types as the remaining arguments.

I will present an example here which uses the standard C library's \texttt{qsort()} function, this is used to sort items with the help of a callback function. \texttt{qsort()} will be used to sort an array of integers:

\begin{verbatim}
>>> IntArray5 = c_int * 5
>>> ia = IntArray5(5, 1, 7, 33, 99)
>>> qsort = libc.qsort
>>> qsort.restype = None
>>>
\end{verbatim}

\texttt{qsort()} must be called with a pointer to the data to sort, the number of items in the data array, the size of one item, and a pointer to the comparison function, the callback. The callback will then be called with two pointers to items, and it must return a negative integer if the first item is smaller than the second, a zero if they are equal, and a positive integer else.

So our callback function receives pointers to integers, and must return an integer. First we create the type for the callback function:

\begin{verbatim}
>>> CMPFUNC = CFUNCTYPE(c_int, POINTER(c_int), POINTER(c_int))
>>>
\end{verbatim}

For the first implementation of the callback function, we simply print the arguments we get, and return 0 (incremental development ;-):

\begin{verbatim}
>>> def py_cmp_func(a, b):
...     print "py_cmp_func", a, b
...     return 0
\end{verbatim}
Create the C callable callback:

```python
>>> cmp_func = CMPFUNC(py_cmp_func)
```  
And we're ready to go:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func)  # doctest: +WINDOWS
```

We know how to access the contents of a pointer, so let's redefine our callback:

```python
>>> def py_cmp_func(a, b):
...     print "py_cmp_func", a[0], b[0]
...     return 0
...
>>> cmp_func = CMPFUNC(py_cmp_func)
```

Here is what we get on Windows:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func)  # doctest: +WINDOWS
```
It is funny to see that on Linux the sort function seems to work much more efficiently, it is doing less comparisons:

```
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func)  # doctest: +LINUX
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 5 7
py_cmp_func 1 7
```
and on Linux:

```python
>>> qsort(ia, len(ia), sizeof(c_int), CMPFUNC(py_cmp_func))  # doctest:
py_cmp_func  5  1
py_cmp_func  33  99
py_cmp_func  7  33
py_cmp_func  1  7
py_cmp_func  5  7

>>> It is quite interesting to see that the Windows `qsort()` function needs more comparisons than the linux version!

As we can easily check, our array is sorted now:

```python
>>> for i in ia: print i,
... 1 5 7 33 99

```python

**Important note for callback functions:**

Make sure you keep references to CFUNCTYPE objects as long as they are used from C code. `ctypes` doesn't, and if you don't, they may be garbage collected, crashing your program when a callback is made.

15.16.1.18. **Accessing values exported from dlls**

Some shared libraries not only export functions, they also export variables. An example in the Python library itself is the `Py_OptimizeFlag`, an integer set to 0, 1, or 2, depending on the `-O` or `-OO` flag given on startup.

`ctypes` can access values like this with the `in_dll()` class methods
of the type. *pythonapi* is a predefined symbol giving access to the Python C api:

```python
top_flag = c_int.in_dll(pythonapi, "Py_OptimizeFlag")
print opt_flag
c_long(0)
```

If the interpreter would have been started with `-O`, the sample would have printed `c_long(1)`, or `c_long(2)` if `-OO` would have been specified.

An extended example which also demonstrates the use of pointers accesses the `PyImport_FrozenModules` pointer exported by Python.

Quoting the Python docs: *This pointer is initialized to point to an array of “struct _frozen” records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.*

So manipulating this pointer could even prove useful. To restrict the example size, we show only how this table can be read with *ctypes*:

```python
>>> from ctypes import *

>>> class struct_frozen(Structure):
...     _fields_ = [('name', c_char_p),
...                 ('code', POINTER(c_ubyte)),
...                 ('size', c_int)]
... 
```

We have defined the *struct _frozen* data type, so we can get the pointer to the table:

```python
>>> FrozenTable = POINTER(struct_frozen)
>>> table = FrozenTable.in_dll(pythonapi, "PyImport_FrozenModul"
Since `table` is a pointer to the array of `struct_frozen` records, we can iterate over it, but we just have to make sure that our loop terminates, because pointers have no size. Sooner or later it would probably crash with an access violation or whatever, so it’s better to break out of the loop when we hit the NULL entry:

```python
>>> for item in table:
...     print item.name, item.size
...     if item.name is None:
...         break
...__hello__ 104
__phello__ -104
__phello__.spam 104
None 0
```

The fact that standard Python has a frozen module and a frozen package (indicated by the negative size member) is not well known, it is only used for testing. Try it out with `import __hello__` for example.

### 15.16.1.19. Surprises

There are some edges in `ctypes` where you may be expect something else than what actually happens.

Consider the following example:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = ("x", c_int), ("y", c_int)
...>>> class RECT(Structure):
...     _fields_ = ("a", POINT), ("b", POINT)
...```
Hm. We certainly expected the last statement to print 3 4 1 2. What happened? Here are the steps of the `rc.a, rc.b = rc.b, rc.a` line above:

```python
>>> temp0, temp1 = rc.b, rc.a
>>> rc.a = temp0
>>> rc.b = temp1
``` 

Note that `temp0` and `temp1` are objects still using the internal buffer of the `rc` object above. So executing `rc.a = temp0` copies the buffer contents of `temp0` into `rc`'s buffer. This, in turn, changes the contents of `temp1`. So, the last assignment `rc.b = temp1`, doesn't have the expected effect.

Keep in mind that retrieving sub-objects from Structure, Unions, and Arrays doesn't copy the sub-object, instead it retrieves a wrapper object accessing the root-object's underlying buffer.

Another example that may behave different from what one would expect is this:

```python
>>> s = c_char_p()
>>> s.value = "abc def ghi"
>>> s.value
'abc def ghi'
>>> s.value is s.value
False
>>>
Why is it printing False? ctypes instances are objects containing a memory block plus some descriptors accessing the contents of the memory. Storing a Python object in the memory block does not store the object itself, instead the contents of the object is stored. Accessing the contents again constructs a new Python object each time!

15.16.1.20. Variable-sized data types

c types provides some support for variable-sized arrays and structures.

The resize() function can be used to resize the memory buffer of an existing ctypes object. The function takes the object as first argument, and the requested size in bytes as the second argument. The memory block cannot be made smaller than the natural memory block specified by the objects type, a ValueError is raised if this is tried:

```python
>>> short_array = (c_short * 4)()
>>> print sizeof(short_array)
8
>>> resize(short_array, 4)
Traceback (most recent call last):
  ... 
ValueError: minimum size is 8
>>> resize(short_array, 32)
>>> sizeof(short_array)
32
>>> sizeof(type(short_array))
8
``` 

This is nice and fine, but how would one access the additional elements contained in this array? Since the type still only knows about 4 elements, we get errors accessing other elements:
Another way to use variable-sized data types with `ctypes` is to use the dynamic nature of Python, and (re-)define the data type after the required size is already known, on a case by case basis.
When programming in a compiled language, shared libraries are accessed when compiling/linking a program, and when the program is run.

The purpose of the `find_library()` function is to locate a library in a way similar to what the compiler does (on platforms with several versions of a shared library the most recent should be loaded), while the ctypes library loaders act like when a program is run, and call the runtime loader directly.

The `ctypes.util` module provides a function which can help to determine the library to load.

```python
ctypes.util.find_library(name)
```

Try to find a library and return a pathname. `name` is the library name without any prefix like `lib`, suffix like `.so`, `.dylib` or version number (this is the form used for the posix linker option `-l`). If no library can be found, returns `None`.

The exact functionality is system dependent.

On Linux, `find_library()` tries to run external programs (`/sbin/ldconfig`, `gcc`, and `objdump`) to find the library file. It returns the filename of the library file. Here are some examples:

```python
>>> from ctypes.util import find_library
>>> find_library("m")
'libm.so.6'
>>> find_library("c")
'libc.so.6'
```
On OS X, `find_library()` tries several predefined naming schemes and paths to locate the library, and returns a full pathname if successful:

```python
>>> from ctypes.util import find_library
>>> find_library("c")
'/usr/lib/libc.dylib'
>>> find_library("m")
'/usr/lib/libm.dylib'
>>> find_library("bz2")
'/usr/lib/libbz2.dylib'
>>> find_library("AGL")
'/System/Library/Frameworks/AGL.framework/AGL'
```

On Windows, `find_library()` searches along the system search path, and returns the full pathname, but since there is no predefined naming scheme a call like `find_library("c")` will fail and return `None`.

If wrapping a shared library with `ctypes`, it may be better to determine the shared library name at development type, and hardcode that into the wrapper module instead of using `find_library()` to locate the library at runtime.

### 15.16.2.2. Loading shared libraries

There are several ways to loaded shared libraries into the Python process. One way is to instantiate one of the following classes:

```python
class ctypes.CDLL(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)
```

Instances of this class represent loaded shared libraries.
Functions in these libraries use the standard C calling convention, and are assumed to return \texttt{int}.

\begin{verbatim}
class ctypes.\texttt{OleDLL}(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the \texttt{stdcall} calling convention, and are assumed to return the windows specific \texttt{HRESULT} code. \texttt{HRESULT} values contain information specifying whether the function call failed or succeeded, together with additional error code. If the return value signals a failure, an \texttt{WindowsError} is automatically raised.

\end{verbatim}

\begin{verbatim}
class ctypes.\texttt{WinDLL}(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the \texttt{stdcall} calling convention, and are assumed to return \texttt{int} by default.

On Windows CE only the standard calling convention is used, for convenience the \texttt{WinDLL} and \texttt{OleDLL} use the standard calling convention on this platform.

The Python \textit{global interpreter lock} is released before calling any function exported by these libraries, and reacquired afterwards.

All these classes can be instantiated by calling them with at least one argument, the pathname of the shared library. If you have an existing handle to an already loaded shared library, it can be passed as the \texttt{handle} named parameter, otherwise the underlying platforms \texttt{dlopen} or \texttt{LoadLibrary} function is used to load the library into the process, and to get a handle to it.

The \texttt{mode} parameter can be used to specify how the library is
loaded. For details, consult the dlopen(3) manpage, on Windows, mode is ignored.

The use_errno parameter, when set to True, enables a ctypes mechanism that allows to access the system errno error number in a safe way. ctypes maintains a thread-local copy of the systems errno variable; if you call foreign functions created with use_errno=True then the errno value before the function call is swapped with the ctypes private copy, the same happens immediately after the function call.

The function ctypes.get_errno() returns the value of the ctypes private copy, and the function ctypes.set_errno() changes the ctypes private copy to a new value and returns the former value.

The use_last_error parameter, when set to True, enables the same mechanism for the Windows error code which is managed by the GetLastError() and SetLastError() Windows API functions; ctypes.get_last_error() and ctypes.set_last_error() are used to request and change the ctypes private copy of the windows error code.

New in version 2.6: The use_last_error and use_errno optional parameters were added.

ctypes. RTLD_GLOBAL
Flag to use as mode parameter. On platforms where this flag is not available, it is defined as the integer zero.

ctypes. RTLD_LOCAL
Flag to use as mode parameter. On platforms where this is not available, it is the same as RTLD_GLOBAL.

ctypes. DEFAULT_MODE
The default mode which is used to load shared libraries. On OSX
10.3, this is `RTLD_GLOBAL`, otherwise it is the same as `RTLD_LOCAL`.

Instances of these classes have no public methods, however `__getattr__()` and `__getitem__()` have special behavior: functions exported by the shared library can be accessed as attributes of by index. Please note that both `__getattr__()` and `__getitem__()` cache their result, so calling them repeatedly returns the same object each time.

The following public attributes are available, their name starts with an underscore to not clash with exported function names:

**PyDLL.** `__handle`

The system handle used to access the library.

**PyDLL.** `__name`

The name of the library passed in the constructor.

Shared libraries can also be loaded by using one of the prefabricated objects, which are instances of the `LibraryLoader` class, either by calling the `LoadLibrary()` method, or by retrieving the library as attribute of the loader instance.

```python
class ctypes.LibraryLoader(dlltype):
    Class which loads shared libraries. `dlltype` should be one of the `CDLL`, `PyDLL`, `WinDLL`, or `OleDLL` types.

    `__getattr__()` has special behavior: It allows to load a shared library by accessing it as attribute of a library loader instance. The result is cached, so repeated attribute accesses return the same library each time.

    `LoadLibrary(name)`
    Load a shared library into the process and return it. This
```
method always returns a new instance of the library.

These prefabricated library loaders are available:

ctypes.\texttt{cdll}

Creates \texttt{CDLL} instances.

ctypes.\texttt{windll}

Windows only: Creates \texttt{WinDLL} instances.

ctypes.\texttt{oledll}

Windows only: Creates \texttt{OleDLL} instances.

ctypes.\texttt{pydll}

Creates \texttt{PyDLL} instances.

For accessing the C Python api directly, a ready-to-use Python shared library object is available:

15.16.2.3. Foreign functions

As explained in the previous section, foreign functions can be accessed as attributes of loaded shared libraries. The function objects created in this way by default accept any number of arguments, accept any ctypes data instances as arguments, and return the default result type specified by the library loader. They are instances of a private class:

\texttt{class ctypes._FuncPtr}

Base class for C callable foreign functions.

Instances of foreign functions are also C compatible data types; they represent C function pointers.

This behavior can be customized by assigning to special attributes of the foreign function object.
restype
Assign a ctypes type to specify the result type of the foreign function. Use None for void, a function not returning anything.

It is possible to assign a callable Python object that is not a ctypes type, in this case the function is assumed to return a C int, and the callable will be called with this integer, allowing to do further processing or error checking. Using this is deprecated, for more flexible post processing or error checking use a ctypes data type as restype and assign a callable to the errcheck attribute.

argtypes
Assign a tuple of ctypes types to specify the argument types that the function accepts. Functions using thestdcall calling convention can only be called with the same number of arguments as the length of this tuple; functions using the C calling convention accept additional, unspecified arguments as well.

When a foreign function is called, each actual argument is passed to the from_param() class method of the items in the argtypes tuple, this method allows to adapt the actual argument to an object that the foreign function accepts. For example, a c_char_p item in the argtypes tuple will convert a unicode string passed as argument into an byte string using ctypes conversion rules.

New: It is now possible to put items in argtypes which are not ctypes types, but each item must have a from_param() method which returns a value usable as argument (integer, string, ctypes instance). This allows to define adapters that can adapt custom objects as function parameters.

errcheck
Assign a Python function or another callable to this attribute. The callable will be called with three or more arguments:

```python
callable(result, func, arguments)
```

`result` is what the foreign function returns, as specified by the `restype` attribute.

`func` is the foreign function object itself, this allows to reuse the same callable object to check or post process the results of several functions.

`arguments` is a tuple containing the parameters originally passed to the function call, this allows to specialize the behavior on the arguments used.

The object that this function returns will be returned from the foreign function call, but it can also check the result value and raise an exception if the foreign function call failed.

```python
exception ctypes.ArgumentError
```

This exception is raised when a foreign function call cannot convert one of the passed arguments.

### 15.16.2.4. Function prototypes

Foreign functions can also be created by instantiating function prototypes. Function prototypes are similar to function prototypes in C; they describe a function (return type, argument types, calling convention) without defining an implementation. The factory functions must be called with the desired result type and the argument types of the function.

```python
ctypes.CFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
```

The returned function prototype creates functions that use the
standard C calling convention. The function will release the GIL during the call. If use_errno is set to True, the ctypes private copy of the system errno variable is exchanged with the real errno value before and after the call; use_last_error does the same for the Windows error code.

*Changed in version 2.6:* The optional use_errno and use_last_error parameters were added.

```python
cTypes.WINFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
```

Windows only: The returned function prototype creates functions that use the **stdcall** calling convention, except on Windows CE where **WINFUNCTYPE()** is the same as **CFUNCTYPE()**. The function will release the GIL during the call. use_errno and use_last_error have the same meaning as above.

```python
cTypes.PYFUNCTYPE(restype, *argtypes)
```

The returned function prototype creates functions that use the Python calling convention. The function will *not* release the GIL during the call.

Function prototypes created by these factory functions can be instantiated in different ways, depending on the type and number of the parameters in the call:

```python
prototype(address)
```

Returns a foreign function at the specified address which must be an integer.

```python
prototype(callable)
```

Create a C callable function (a callback function) from a Python callable.
**prototype**(*func_spec[, paramflags]*)

Returns a foreign function exported by a shared library.  *func_spec* must be a 2-tuple (*name_or_ordinal*, *library*).  The first item is the name of the exported function as string, or the ordinal of the exported function as small integer.  The second item is the shared library instance.

**prototype**(*vtbl_index, name[, paramflags[, iid]]*)

Returns a foreign function that will call a COM method.  *vtbl_index* is the index into the virtual function table, a small non-negative integer.  *name* is name of the COM method.  *iid* is an optional pointer to the interface identifier which is used in extended error reporting.

COM methods use a special calling convention: They require a pointer to the COM interface as first argument, in addition to those parameters that are specified in the *argtypes* tuple.

The optional *paramflags* parameter creates foreign function wrappers with much more functionality than the features described above.

*paramflags* must be a tuple of the same length as *argtypes*.

Each item in this tuple contains further information about a parameter, it must be a tuple containing one, two, or three items.

The first item is an integer containing a combination of direction flags for the parameter:

1

   Specifies an input parameter to the function.

2

   Output parameter.  The foreign function fills in a value.
Input parameter which defaults to the integer zero.

The optional second item is the parameter name as string. If this is specified, the foreign function can be called with named parameters.

The optional third item is the default value for this parameter.

This example demonstrates how to wrap the Windows `MessageBoxA` function so that it supports default parameters and named arguments. The C declaration from the windows header file is this:

```c
WINUSERAPI int WINAPI MessageBoxA(
    HWND hWnd ,
    LPCSTR lpText ,
    LPCSTR lpCaption ,
    UINT uType);
```

Here is the wrapping with `ctypes`:

```python
>>> from ctypes import c_int, WINFUNCTYPE, windll
>>> from ctypes.wintypes import HWND, LPCSTR, UINT
>>> prototype = WINFUNCTYPE(c_int, HWND, LPCSTR, LPCSTR, UINT)
>>> paramflags = (1, "hwnd", 0), (1, "text", "Hi"), (1, "caption", None), (1, "flags", 0)
>>> MessageBox = prototype(("MessageBoxA", windll.user32), paramflags)

The MessageBox foreign function can now be called in these ways:

```python
>>> MessageBox()
>>> MessageBox(text="Spam, spam, spam")
>>> MessageBox(flags=2, text="foo bar")
```

A second example demonstrates output parameters. The `win32` `GetWindowRect` function retrieves the dimensions of a specified
window by copying them into `RECT` structure that the caller has to supply. Here is the C declaration:

```c
WINUSERAPI BOOL WINAPI GetWindowRect(
    HWND hWnd,
    LPRECT lpRect);
```

Here is the wrapping with `ctypes`:

```python
>>> from ctypes import POINTER, WINFUNCTYPE, windll, WinError
>>> from ctypes.wintypes import BOOL, HWND, RECT
>>> prototype = WINFUNCTYPE(BOOL, HWND, POINTER(RECT))
>>> paramflags = (1, "hwnd"), (2, "lprect")
>>> GetWindowRect = prototype(("GetWindowRect", windll.user32),
...
```

Functions with output parameters will automatically return the output parameter value if there is a single one, or a tuple containing the output parameter values when there are more than one, so the `GetWindowRect` function now returns a `RECT` instance, when called.

Output parameters can be combined with the `errcheck` protocol to do further output processing and error checking. The `win32` `GetWindowRect` api function returns a `BOOL` to signal success or failure, so this function could do the error checking, and raises an exception when the api call failed:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     return args
...
>>> GetWindowRect.errcheck = errcheck
```  

If the `errcheck` function returns the argument tuple it receives unchanged, `ctypes` continues the normal processing it does on the
output parameters. If you want to return a tuple of window coordinates instead of a \texttt{RECT} instance, you can retrieve the fields in the function and return them instead, the normal processing will no longer take place:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     rc = args[1]
...     return rc.left, rc.top, rc.bottom, rc.right
... >>> GetWindowRect.errcheck = errcheck
```  

### 15.16.2.5. Utility functions

** ctypes.\texttt{addressof}(obj) **

Returns the address of the memory buffer as integer. \texttt{obj} must be an instance of a ctypes type.

** ctypes.\texttt{alignment}(obj\_or\_type) **

Returns the alignment requirements of a ctypes type. \texttt{obj\_or\_type} must be a ctypes type or instance.

** ctypes.\texttt{byref}(obj[, offset]) **

Returns a light-weight pointer to \texttt{obj}, which must be an instance of a ctypes type. \texttt{offset} defaults to zero, and must be an integer that will be added to the internal pointer value.

\texttt{byref(obj, offset)} corresponds to this C code:

```c
dlca = ((char *)&obj) + offset
```

The returned object can only be used as a foreign function call parameter. It behaves similar to \texttt{pointer(obj)}, but the construction is a lot faster.
New in version 2.6: The offset optional argument was added.

**ctypes.cast**(obj, type)
This function is similar to the cast operator in C. It returns a new instance of type which points to the same memory block as obj. type must be a pointer type, and obj must be an object that can be interpreted as a pointer.

**ctypes.create_string_buffer**(init_or_size[, size])
This function creates a mutable character buffer. The returned object is a ctypes array of c_char.

init_or_size must be an integer which specifies the size of the array, or a string which will be used to initialize the array items.

If a string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.

If the first parameter is a unicode string, it is converted into an 8-bit string according to ctypes conversion rules.

**ctypes.create_unicode_buffer**(init_or_size[, size])
This function creates a mutable unicode character buffer. The returned object is a ctypes array of c_wchar.

init_or_size must be an integer which specifies the size of the array, or a unicode string which will be used to initialize the array items.

If a unicode string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer
can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.

If the first parameter is a 8-bit string, it is converted into an unicode string according to ctypes conversion rules.

**ctypes.** **DllCanUnloadNow()**

Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllCanUnloadNow function that the _ctypes extension dll exports.

**ctypes.** **DllGetClassObject()**

Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllGetClassObject function that the _ctypes extension dll exports.

**ctypes.util.** **find_library(name)**

Try to find a library and return a pathname. *name* is the library name without any prefix like `lib`, suffix like `.so`, `.dylib` or version number (this is the form used for the posix linker option `-l`). If no library can be found, returns `None`.

The exact functionality is system dependent.

*Changed in version 2.6:* Windows only: `find_library("m")` or `find_library("c")` return the result of a call to `find_msvcrt()`.

**ctypes.util.** **find_msvcrt()**

Windows only: return the filename of the VC runtype library used by Python, and by the extension modules. If the name of the library cannot be determined, `None` is returned.

If you need to free memory, for example, allocated by an extension module with a call to the `free(void *)`, it is important that you use the function in the same library that allocated the
memory.

New in version 2.6.

```python
ctypes.FormatError([code])
```

Windows only: Returns a textual description of the error code `code`. If no error code is specified, the last error code is used by calling the Windows api function GetLastError.

```python
ctypes.GetLastError()
```

Windows only: Returns the last error code set by Windows in the calling thread. This function calls the Windows `GetLastError()` function directly, it does not return the ctypes-private copy of the error code.

```python
ctypes.get_errno()
```

Returns the current value of the ctypes-private copy of the system `errno` variable in the calling thread.

New in version 2.6.

```python
ctypes.get_last_error()
```

Windows only: returns the current value of the ctypes-private copy of the system `LastError` variable in the calling thread.

New in version 2.6.

```python
ctypes.memmove(dst, src, count)
```

Same as the standard C memmove library function: copies `count` bytes from `src` to `dst`. `dst` and `src` must be integers or ctypes instances that can be converted to pointers.

```python
ctypes.memset(dst, c, count)
```

Same as the standard C memset library function: fills the memory block at address `dst` with `count` bytes of value `c`. `dst` must be an
integer specifying an address, or a ctypes instance.

cypes.POINTER(type)
This factory function creates and returns a new ctypes pointer type. Pointer types are cached and reused internally, so calling this function repeatedly is cheap. type must be a ctypes type.

cypes.pointer(obj)
This function creates a new pointer instance, pointing to obj. The returned object is of the type POINTER(type(obj)).

Note: If you just want to pass a pointer to an object to a foreign function call, you should use byref(obj) which is much faster.

cypes.resize(obj, size)
This function resizes the internal memory buffer of obj, which must be an instance of a ctypes type. It is not possible to make the buffer smaller than the native size of the objects type, as given by sizeof(type(obj)), but it is possible to enlarge the buffer.

cypes.set_conversion_mode(encoding, errors)
This function sets the rules that ctypes objects use when converting between 8-bit strings and unicode strings. encoding must be a string specifying an encoding, like 'utf-8' or 'mbcs', errors must be a string specifying the error handling on encoding/decoding errors. Examples of possible values are "strict", "replace", Or "ignore".

set_conversion_mode() returns a 2-tuple containing the previous conversion rules. On windows, the initial conversion rules are ('mbcs', 'ignore'), on other systems ('ascii', 'strict').

cypes.set_errno(value)
Set the current value of the ctypes-private copy of the system *errno* variable in the calling thread to *value* and return the previous value.

*New in version 2.6.*

**ctypes.** *set_last_error*(*value*)

Windows only: set the current value of the ctypes-private copy of the system *LastError* variable in the calling thread to *value* and return the previous value.

*New in version 2.6.*

**ctypes.** *sizeof*(*obj_or_type*)

Returns the size in bytes of a ctypes type or instance memory buffer. Does the same as the C *sizeof()* function.

**ctypes.** *string_at*(*address*, *size*)

This function returns the string starting at memory address *address*. If *size* is specified, it is used as size, otherwise the string is assumed to be zero-terminated.

**ctypes.** *WinError*(*code=None, descr=None*)

Windows only: this function is probably the worst-named thing in ctypes. It creates an instance of WindowsError. If *code* is not specified, *GetLastError* is called to determine the error code. If *descr* is not specified, *FormatError()* is called to get a textual description of the error.

**ctypes.** *wstring_at*(*address*, *size*)

This function returns the wide character string starting at memory address *address* as unicode string. If *size* is specified, it is used as the number of characters of the string, otherwise the string is assumed to be zero-terminated.
15.16.2.6. Data types

```
class ctypes._CData
    This non-public class is the common base class of all ctypes data types. Among other things, all ctypes type instances contain a memory block that hold C compatible data; the address of the memory block is returned by the `addressof()` helper function. Another instance variable is exposed as `_objects`; this contains other Python objects that need to be kept alive in case the memory block contains pointers.

Common methods of ctypes data types, these are all class methods (to be exact, they are methods of the `metaclass`):

    `from_buffer(source[, offset])`
    This method returns a ctypes instance that shares the buffer of the `source` object. The `source` object must support the writeable buffer interface. The optional `offset` parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a `ValueError` is raised.

    `New in version 2.6.`

    `from_buffer_copy(source[, offset])`
    This method creates a ctypes instance, copying the buffer from the `source` object buffer which must be readable. The optional `offset` parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a `ValueError` is raised.

    `New in version 2.6.`

    `from_address(address)`
```
This method returns a ctypes type instance using the memory specified by \textit{address} which must be an integer.

\textbf{from\_param}(\textit{obj})

This method adapts \textit{obj} to a ctypes type. It is called with the actual object used in a foreign function call when the type is present in the foreign function’s \textit{argtypes} tuple; it must return an object that can be used as a function call parameter.

All ctypes data types have a default implementation of this classmethod that normally returns \textit{obj} if that is an instance of the type. Some types accept other objects as well.

\textbf{in\_dll}(\textit{library, name})

This method returns a ctypes type instance exported by a shared library. \textit{name} is the name of the symbol that exports the data, \textit{library} is the loaded shared library.

Common instance variables of ctypes data types:

\texttt{\_b\_base\_}

Sometimes ctypes data instances do not own the memory block they contain, instead they share part of the memory block of a base object. The \texttt{\_b\_base\_} read-only member is the root ctypes object that owns the memory block.

\texttt{\_b\_needsfree\_}

This read-only variable is true when the ctypes data instance has allocated the memory block itself, false otherwise.

\texttt{\_objects}

This member is either \texttt{None} or a dictionary containing Python objects that need to be kept alive so that the memory block contents is kept valid. This object is only exposed for debugging; never modify the contents of this dictionary.
15.16.2.7. Fundamental data types

class ctypes._SimpleCData

This non-public class is the base class of all fundamental ctypes data types. It is mentioned here because it contains the common attributes of the fundamental ctypes data types. _SimpleCData is a subclass of _CData, so it inherits their methods and attributes.

Changed in version 2.6: ctypes data types that are not and do not contain pointers can now be pickled.

Instances have a single attribute:

value

This attribute contains the actual value of the instance. For integer and pointer types, it is an integer, for character types, it is a single character string, for character pointer types it is a Python string or unicode string.

When the value attribute is retrieved from a ctypes instance, usually a new object is returned each time. ctypes does not implement original object return, always a new object is constructed. The same is true for all other ctypes object instances.

Fundamental data types, when returned as foreign function call results, or, for example, by retrieving structure field members or array items, are transparently converted to native Python types. In other words, if a foreign function has a restype of c_char_p, you will always receive a Python string, not a c_char_p instance.

Subclasses of fundamental data types do not inherit this behavior. So, if a foreign functions restype is a subclass of c_void_p, you will receive an instance of this subclass from the function call. Of course,
you can get the value of the pointer by accessing the `value` attribute.

These are the fundamental ctypes data types:

```python
class ctypes.c_byte
    Represents the C `signed char` datatype, and interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_char
    Represents the C `char` datatype, and interprets the value as a single character. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

class ctypes.c_char_p
    Represents the C `char *` datatype when it points to a zero-terminated string. For a general character pointer that may also point to binary data, `POINTER(c_char)` must be used. The constructor accepts an integer address, or a string.

class ctypes.c_double
    Represents the C `double` datatype. The constructor accepts an optional float initializer.

class ctypes.c_longdouble
    Represents the C `long double` datatype. The constructor accepts an optional float initializer. On platforms where `sizeof(long double) == sizeof(double)` it is an alias to `c_double`.

    New in version 2.6.

class ctypes.c_float
    Represents the C `float` datatype. The constructor accepts an optional float initializer.
class ctypes.c_int

Represents the C signed int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where sizeof(int) == sizeof(long) it is an alias to c_long.

class ctypes.c_int8

Represents the C 8-bit signed int datatype. Usually an alias for c_byte.

class ctypes.c_int16

Represents the C 16-bit signed int datatype. Usually an alias for c_short.

class ctypes.c_int32

Represents the C 32-bit signed int datatype. Usually an alias for c_int.

class ctypes.c_int64

Represents the C 64-bit signed int datatype. Usually an alias for c_longlong.

class ctypes.c_long

Represents the C signed long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_longlong

Represents the C signed long long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_short

Represents the C signed short datatype. The constructor accepts an optional integer initializer; no overflow checking is

done.

```python
class ctypes.c_size_t
    Represents the C size_t datatype.
```

```python
class ctypes.c_ssize_t
    Represents the C ssize_t datatype.
    
    New in version 2.7.
```

```python
class ctypes.c_ubyte
    Represents the C unsigned char datatype, it interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.
```

```python
class ctypes.c_uint
    Represents the C unsigned int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where sizeof(int) == sizeof(long) it is an alias for c_ulong.
```

```python
class ctypes.c_uint8
    Represents the C 8-bit unsigned int datatype. Usually an alias for c_ubyte.
```

```python
class ctypes.c_uint16
    Represents the C 16-bit unsigned int datatype. Usually an alias for c_ushort.
```

```python
class ctypes.c_uint32
    Represents the C 32-bit unsigned int datatype. Usually an alias for c_uint.
```

```python
class ctypes.c_uint64
```
Represents the C 64-bit unsigned int datatype. Usually an alias for\n\texttt{c\_ullonglong}.

\texttt{class ctypes.c\_ulong}

Represents the C unsigned long datatype. The constructor accepts an\noptional integer initializer; no overflow checking is done.

\texttt{class ctypes.c\_ulonglong}

Represents the C unsigned long long datatype. The constructor accepts\nan optional integer initializer; no overflow checking is done.

\texttt{class ctypes.c\_ushort}

Represents the C unsigned short datatype. The constructor accepts an\noptional integer initializer; no overflow checking is done.

\texttt{class ctypes.c\_void\_p}

Represents the C void * type. The value is represented as integer. The\nconstructor accepts an optional integer initializer.

\texttt{class ctypes.c\_wchar}

Represents the C wchar_t datatype, and interprets the value as a\nsingle character unicode string. The constructor accepts an\noptional string initializer, the length of the string must be exactly\none character.

\texttt{class ctypes.c\_wchar\_p}

Represents the C wchar_t * datatype, which must be a pointer to a\nzero-terminated wide character string. The constructor accepts an\ninteger address, or a string.

\texttt{class ctypes.c\_bool}
Represent the C bool datatype (more accurately, _Bool from C99). Its value can be True or False, and the constructor accepts any object that has a truth value.

*New in version 2.6.*

class ctypes.HRESULT
    Windows only: Represents a HRESULT value, which contains success or error information for a function or method call.

class ctypes.py_object
    Represents the C PyObject * datatype. Calling this without an argument creates a NULL PyObject * pointer.

The ctypes.wintypes module provides quite some other Windows specific data types, for example HWND, WPARAM, or DWORD. Some useful structures like MSG or RECT are also defined.

### 15.16.2.8. Structured data types

class ctypes.Union(*args, **kw)
    Abstract base class for unions in native byte order.

class ctypes.BigEndianStructure(*args, **kw)
    Abstract base class for structures in big endian byte order.

class ctypes.LittleEndianStructure(*args, **kw)
    Abstract base class for structures in little endian byte order.

Structures with non-native byte order cannot contain pointer type fields, or any other data types containing pointer type fields.

class ctypes.Structure(*args, **kw)
    Abstract base class for structures in native byte order.
Concrete structure and union types must be created by subclassing one of these types, and at least define a `_fields_` class variable. `ctypes` will create descriptors which allow reading and writing the fields by direct attribute accesses. These are the `_fields_`:

A sequence defining the structure fields. The items must be 2-tuples or 3-tuples. The first item is the name of the field, the second item specifies the type of the field; it can be any `ctypes` data type.

For integer type fields like `c_int`, a third optional item can be given. It must be a small positive integer defining the bit width of the field.

Field names must be unique within one structure or union. This is not checked, only one field can be accessed when names are repeated.

It is possible to define the `_fields_` class variable after the class statement that defines the Structure subclass, this allows to create data types that directly or indirectly reference themselves:

```python
class List(Structure):
    pass
List._fields_ = [("pnext", POINTER(List)),
                 ...]
```

The `_fields_` class variable must, however, be defined before the type is first used (an instance is created, `sizeof()` is called on it, and so on). Later assignments to the `_fields_` class variable will raise an `AttributeError`.

Structure and union subclass constructors accept both
positional and named arguments. Positional arguments are used to initialize the fields in the same order as they appear in the `_fields_` definition, named arguments are used to initialize the fields with the corresponding name.

It is possible to defined sub-subclasses of structure types, they inherit the fields of the base class plus the `_fields_` defined in the sub-subclass, if any.

__pack__
An optional small integer that allows to override the alignment of structure fields in the instance. `_pack_` must already be defined when `_fields_` is assigned, otherwise it will have no effect.

__anonymous__
An optional sequence that lists the names of unnamed (anonymous) fields. `_anonymous_` must be already defined when `_fields_` is assigned, otherwise it will have no effect.

The fields listed in this variable must be structure or union type fields. `ctypes` will create descriptors in the structure type that allows to access the nested fields directly, without the need to create the structure or union field.

Here is an example type (Windows):

```python
class _U(Union):
    _fields_ = ["lptdesc", POINTER(TYPEDESC)),
               ("lpdesc", POINTER(ARRAYDESC)),
               ("hreftype", HREFTYPE)]

class TYPEDESC(Structure):
    _anonymous_ = ("u",)
    _fields_ = [("u", _U),
                ("vt", VARTYPE)]
```
The **TYPEDESC** structure describes a COM data type, the **vt** field specifies which one of the union fields is valid. Since the **u** field is defined as anonymous field, it is now possible to access the members directly off the TYPEDESC instance. **td.lptdesc** and **td.u.lptdesc** are equivalent, but the former is faster since it does not need to create a temporary union instance:

```python
td = TYPEDESC()
td.vt = VT_PTR
td.lptdesc = POINTER(some_type)
td.u.lptdesc = POINTER(some_type)
```

It is possible to defined sub-subclasses of structures, they inherit the fields of the base class. If the subclass definition has a separate **_fields_** variable, the fields specified in this are appended to the fields of the base class.

Structure and union constructors accept both positional and keyword arguments. Positional arguments are used to initialize member fields in the same order as they are appear in **_fields_**. Keyword arguments in the constructor are interpreted as attribute assignments, so they will initialize **_fields_** with the same name, or create new attributes for names not present in **_fields_**.

### 15.16.2.9. Arrays and pointers

Not yet written - please see the sections *Pointers* and section *Arrays* in the tutorial.
16. Optional Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on selected operating systems only. The interfaces are generally modeled after the Unix or C interfaces but they are available on some other systems as well (e.g. Windows or NT). Here’s an overview:

- **16.1. select** — Waiting for I/O completion
  - 16.1.1. Edge and Level Trigger Polling (epoll) Objects
  - 16.1.2. Polling Objects
  - 16.1.3. Kqueue Objects
  - 16.1.4. Kevent Objects
- **16.2. threading** — Higher-level threading interface
  - 16.2.1. Thread Objects
  - 16.2.2. Lock Objects
  - 16.2.3. RLock Objects
  - 16.2.4. Condition Objects
  - 16.2.5. Semaphore Objects
    - 16.2.5.1. Semaphore Example
  - 16.2.6. Event Objects
  - 16.2.7. Timer Objects
  - 16.2.8. Using locks, conditions, and semaphores in the with statement
  - 16.2.9. Importing in threaded code
- **16.3. thread** — Multiple threads of control
- **16.4. dummy_threading** — Drop-in replacement for the threading module
- **16.5. dummy_thread** — Drop-in replacement for the thread module
- **16.6. multiprocessing** — Process-based “threading” interface
16.6.1. Introduction

16.6.4. Examples

16.7. rlcompleter — Completion function for GNU readline

- 16.7.1. Completer Objects
Standard Library » 16. Optional Operating System Services »
16.1. select — Waiting for I/O completion

This module provides access to the `select()` and `poll()` functions available in most operating systems, `epoll()` available on Linux 2.5+ and `kqueue()` available on most BSD. Note that on Windows, it only works for sockets; on other operating systems, it also works for other file types (in particular, on Unix, it works on pipes). It cannot be used on regular files to determine whether a file has grown since it was last read.

The module defines the following:

**exception select.error**

The exception raised when an error occurs. The accompanying value is a pair containing the numeric error code from `errno` and the corresponding string, as would be printed by the C function `perror()`.

`select.epoll([sizehint=-1])`

(Only supported on Linux 2.5.44 and newer.) Returns an edge polling object, which can be used as Edge or Level Triggered interface for I/O events; see section *Edge and Level Trigger Polling (epoll) Objects* below for the methods supported by epoll objects.

*New in version 2.6.*

`select.poll()`

(Not supported by all operating systems.) Returns a polling object, which supports registering and unregistering file descriptors, and then polling them for I/O events; see section
Polling Objects below for the methods supported by polling objects.

select. **kqueue()**
(Only supported on BSD.) Returns a kernel queue object object; see section **Kqueue Objects** below for the methods supported by kqueue objects.

*New in version 2.6.*

select. **kevent(**ident, filter=KQ_FILTER_READ,**
flags=KQ_EV_ADD, fflags=0, data=0, udata=0)**
(Only supported on BSD.) Returns a kernel event object object; see section **Kevent Objects** below for the methods supported by kqueue objects.

*New in version 2.6.*

select. **select(rlist, wlist, xlist[, timeout])**
This is a straightforward interface to the Unix select() system call. The first three arguments are sequences of ‘waitable objects’: either integers representing file descriptors or objects with a parameterless method named fileno() returning such an integer:

- **rlist**: wait until ready for reading
- **wlist**: wait until ready for writing
- **xlist**: wait for an “exceptional condition” (see the manual page for what your system considers such a condition)

Empty sequences are allowed, but acceptance of three empty sequences is platform-dependent. (It is known to work on Unix but not on Windows.) The optional **timeout** argument specifies a time-out as a floating point number in seconds. When the **timeout** argument is omitted the function blocks until at least one file
A file descriptor is ready. A time-out value of zero specifies a poll and never blocks.

The return value is a triple of lists of objects that are ready: subsets of the first three arguments. When the time-out is reached without a file descriptor becoming ready, three empty lists are returned.

Among the acceptable object types in the sequences are Python file objects (e.g. `sys.stdin`, or objects returned by `open()` or `os.popen()`), socket objects returned by `socket.socket()`. You may also define a wrapper class yourself, as long as it has an appropriate `fileno()` method (that really returns a file descriptor, not just a random integer).

**Note:** File objects on Windows are not acceptable, but sockets are. On Windows, the underlying `select()` function is provided by the WinSock library, and does not handle file descriptors that don’t originate from WinSock.

`select.PIPE_BUF`

Files reported as ready for writing by `select()`, `poll()` or similar interfaces in this module are guaranteed to not block on a write of up to `PIPE_BUF` bytes. This value is guaranteed by POSIX to be at least 512. Availability: Unix.

*New in version 2.7.*
16.1.1. Edge and Level Trigger Polling (epoll) Objects

http://linux.die.net/man/4/epoll

**eventmask**

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>EPOLLIN</td>
<td>Available for read</td>
</tr>
<tr>
<td>EPOLLOUT</td>
<td>Available for write</td>
</tr>
<tr>
<td>EPOLLPRI</td>
<td>Urgent data for read</td>
</tr>
<tr>
<td>EPOLLERR</td>
<td>Error condition happened on the assoc. fd</td>
</tr>
<tr>
<td>EPOLLHUP</td>
<td>Hang up happened on the assoc. fd</td>
</tr>
<tr>
<td>EPOLLET</td>
<td>Set Edge Trigger behavior, the default is Level Trigger behavior</td>
</tr>
<tr>
<td>EPOLLONESHOT</td>
<td>Set one-shot behavior. After one event is pulled out, the fd is internally disabled</td>
</tr>
<tr>
<td>EPOLLRDNORM</td>

</tr>
<tr>
<td>EPLLWRNORM</td>
<td>???</td>
</tr>
<tr>
<td>EPLLWRBAND</td>
<td>???</td>
</tr>
<tr>
<td>EPOLLMSG</td>
<td>???</td>
</tr>
</tbody>
</table>

**epoll.close()**

Close the control file descriptor of the epoll object.

**epoll.fileno()**

Return the file descriptor number of the control fd.

**epoll.fromfd(fd)**

Create an epoll object from a given file descriptor.
epoll.register(fd[, eventmask])
    Register a fd descriptor with the epoll object.

    **Note:** Registering a file descriptor that’s already registered raises an IOError – contrary to *Polling Objects’s* register.

epoll.modify(fd, eventmask)
    Modify a register file descriptor.

epoll.unregister(fd)
    Remove a registered file descriptor from the epoll object.

epoll.poll([timeout=-1[, maxevents=-1]])
    Wait for events. timeout in seconds (float)
16.1.2. Polling Objects

The `poll()` system call, supported on most Unix systems, provides better scalability for network servers that service many, many clients at the same time. `poll()` scales better because the system call only requires listing the file descriptors of interest, while `select()` builds a bitmap, turns on bits for the fds of interest, and then afterward the whole bitmap has to be linearly scanned again. `select()` is \(O(\text{highest file descriptor})\), while `poll()` is \(O(\text{number of file descriptors})\).

\[\text{poll. register}(fd[, eventmask])\]

Register a file descriptor with the polling object. Future calls to the `poll()` method will then check whether the file descriptor has any pending I/O events. \(fd\) can be either an integer, or an object with a `fileno()` method that returns an integer. File objects implement `fileno()`, so they can also be used as the argument.

eventmask is an optional bitmask describing the type of events you want to check for, and can be a combination of the constants `POLLIN`, `POLLPRI`, and `POLLOUT`, described in the table below. If not specified, the default value used will check for all 3 types of events.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLIN</td>
<td>There is data to read</td>
</tr>
<tr>
<td>POLLPRI</td>
<td>There is urgent data to read</td>
</tr>
<tr>
<td>POLLOUT</td>
<td>Ready for output: writing will not block</td>
</tr>
<tr>
<td>POLLERR</td>
<td>Error condition of some sort</td>
</tr>
<tr>
<td>POLLHUP</td>
<td>Hung up</td>
</tr>
<tr>
<td>POLLNVAL</td>
<td>Invalid request: descriptor not open</td>
</tr>
</tbody>
</table>
Registering a file descriptor that’s already registered is not an error, and has the same effect as registering the descriptor exactly once.

```python
poll.modify(fd, eventmask)
```
Modifies an already registered fd. This has the same effect as `register(fd, eventmask)()`. Attempting to modify a file descriptor that was never registered causes an `IOError` exception with `errno ENOENT` to be raised.

*New in version 2.6.*

```python
poll.unregister(fd)
```
Remove a file descriptor being tracked by a polling object. Just like the `register()` method, `fd` can be an integer or an object with a `fileno()` method that returns an integer.

 Attempting to remove a file descriptor that was never registered causes a `KeyError` exception to be raised.

```python
poll([timeout])
```
Polls the set of registered file descriptors, and returns a possibly-empty list containing `(fd, event)` 2-tuples for the descriptors that have events or errors to report. `fd` is the file descriptor, and `event` is a bitmask with bits set for the reported events for that descriptor — `POLLIN` for waiting input, `POLLOUT` to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If `timeout` is given, it specifies the length of time in milliseconds which the system will wait for events before returning. If `timeout` is omitted, negative, or `None`, the call will block until there is an event for this poll object.
16.1.3. Kqueue Objects

kqueue. `close()`
Close the control file descriptor of the kqueue object.

kqueue. `fileno()`
Return the file descriptor number of the control fd.

kqueue. `fromfd(fd)`
Create a kqueue object from a given file descriptor.

kqueue. `control(changelist, max_events[, timeout=None])` → `eventlist`
Low level interface to kevent

- changelist must be an iterable of kevent object or None
- max_events must be 0 or a positive integer
- timeout in seconds (floats possible)
16.1.4. Kevent Objects

http://www.freebsd.org/cgi/man.cgi?query=kqueue&sektion=2

**kevent. ident**
Value used to identify the event. The interpretation depends on the filter but it's usually the file descriptor. In the constructor ident can either be an int or an object with a fileno() function. kevent stores the integer internally.

**kevent. filter**
Name of the kernel filter.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>KQ_FILTER_READ</td>
<td>Takes a descriptor and returns whenever there is data available to read</td>

<tr>
<td>KQ_FILTER_TIMER</td>
<td>Establishes an arbitrary timer</td>
</tr>
</tbody>
</table>

**kevent. flags**
Filter action.
### Constant | Meaning
---|---
KQ_EV_ADD | Adds or modifies an event
KQ_EV_DELETE | Removes an event from the queue
KQ_EV_ENABLE | Permits control() to return the event
KQ_EV_DISABLE | Disable event
KQ_EV_ONESHOT | Removes event after first occurrence
KQ_EV_CLEAR | Reset the state after an event is retrieved
KQ_EV_SYSFLAGS | Internal event
KQ_EV_FLAG1 | Internal event
KQ_EV_EOF | Filter specific EOF condition
KQ_EV_ERROR | See return values

**kevent.fflags**
Filter specific flags.

<td>link state is invalid</td>
</tr>
</tbody>
</table>

`kevent.data`
Filter specific data.

`kevent.udata`
User defined value.
16.2. threading — Higher-level threading interface

This module constructs higher-level threading interfaces on top of the lower level `thread` module. See also the `mutex` and `Queue` modules.

The `dummy_threading` module is provided for situations where `threading` cannot be used because `thread` is missing.

**Note:** Starting with Python 2.6, this module provides PEP 8 compliant aliases and properties to replace the camelCase names that were inspired by Java's threading API. This updated API is compatible with that of the `multiprocessing` module. However, no schedule has been set for the deprecation of the camelCase names and they remain fully supported in both Python 2.x and 3.x.

**Note:** Starting with Python 2.5, several Thread methods raise `RuntimeError` instead of `AssertionError` if called erroneously.

This module defines the following functions and objects:

```python
threading.active_count()
threading.activeCount()
    Return the number of `Thread` objects currently alive. The returned count is equal to the length of the list returned by `enumerate()`.

threading.Condition()
    A factory function that returns a new condition variable object. A condition variable allows one or more threads to wait until they are notified by another thread.
```
threading. `current_thread()`

Return the current Thread object, corresponding to the caller’s thread of control. If the caller’s thread of control was not created through the `threading` module, a dummy thread object with limited functionality is returned.

threading. `currentThread()`

Return the current Thread object, corresponding to the caller's thread of control. If the caller's thread of control was not created through the `threading` module, a dummy thread object with limited functionality is returned.

threading. `enumerate()`

Return a list of all Thread objects currently alive. The list includes daemonic threads, dummy thread objects created by `current_thread()`, and the main thread. It excludes terminated threads and threads that have not yet been started.

threading. `Event()`

A factory function that returns a new event object. An event manages a flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true.

class threading. `local`

A class that represents thread-local data. Thread-local data are data whose values are thread specific. To manage thread-local data, just create an instance of `local` (or a subclass) and store attributes on it:

```python
mydata = threading.local()
mydata.x = 1
```

The instance's values will be different for separate threads.

For more details and extensive examples, see the documentation string of the `_threading_local` module.

*New in version 2.4.*
threading. **Lock()**

A factory function that returns a new primitive lock object. Once a thread has acquired it, subsequent attempts to acquire it block, until it is released; any thread may release it.

threading. **RLock()**

A factory function that returns a new reentrant lock object. A reentrant lock must be released by the thread that acquired it. Once a thread has acquired a reentrant lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

threading. **Semaphore([value])**

A factory function that returns a new semaphore object. A semaphore manages a counter representing the number of `release()` calls minus the number of `acquire()` calls, plus an initial value. The `acquire()` method blocks if necessary until it can return without making the counter negative. If not given, `value` defaults to 1.

threading. **BoundedSemaphore([value])**

A factory function that returns a new bounded semaphore object. A bounded semaphore checks to make sure its current value doesn't exceed its initial value. If it does, `ValueError` is raised. In most situations semaphores are used to guard resources with limited capacity. If the semaphore is released too many times it's a sign of a bug. If not given, `value` defaults to 1.

**class** threading. **Thread**

A class that represents a thread of control. This class can be safely subclassed in a limited fashion.

**class** threading. **Timer**

A thread that executes a function after a specified interval has
threading.settrace(func)
Set a trace function for all threads started from the `threading` module. The `func` will be passed to `sys.settrace()` for each thread, before its `run()` method is called.

New in version 2.3.

threading.setprofile(func)
Set a profile function for all threads started from the `threading` module. The `func` will be passed to `sys.setprofile()` for each thread, before its `run()` method is called.

New in version 2.3.

threading.stack_size([size])
Return the thread stack size used when creating new threads. The optional `size` argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32kB). If changing the thread stack size is unsupported, a `ThreadError` is raised. If the specified stack size is invalid, a `ValueError` is raised and the stack size is unmodified. 32kB is currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32kB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4kB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.
New in version 2.5.

Detailed interfaces for the objects are documented below.

The design of this module is loosely based on Java’s threading model. However, where Java makes locks and condition variables basic behavior of every object, they are separate objects in Python. Python’s Thread class supports a subset of the behavior of Java’s Thread class; currently, there are no priorities, no thread groups, and threads cannot be destroyed, stopped, suspended, resumed, or interrupted. The static methods of Java’s Thread class, when implemented, are mapped to module-level functions.

All of the methods described below are executed atomically.
16.2.1. Thread Objects

This class represents an activity that is run in a separate thread of control. There are two ways to specify the activity: by passing a callable object to the constructor, or by overriding the `run()` method in a subclass. No other methods (except for the constructor) should be overridden in a subclass. In other words, *only* override the `__init__()` and `run()` methods of this class.

Once a thread object is created, its activity must be started by calling the thread’s `start()` method. This invokes the `run()` method in a separate thread of control.

Once the thread’s activity is started, the thread is considered ‘alive’. It stops being alive when its `run()` method terminates — either normally, or by raising an unhandled exception. The `is_alive()` method tests whether the thread is alive.

Other threads can call a thread’s `join()` method. This blocks the calling thread until the thread whose `join()` method is called is terminated.

A thread has a name. The name can be passed to the constructor, and read or changed through the `name` attribute.

A thread can be flagged as a “daemon thread”. The significance of this flag is that the entire Python program exits when only daemon threads are left. The initial value is inherited from the creating thread. The flag can be set through the `daemon` property.

There is a “main thread” object; this corresponds to the initial thread of control in the Python program. It is not a daemon thread.
There is the possibility that “dummy thread objects” are created. These are thread objects corresponding to “alien threads”, which are threads of control started outside the threading module, such as directly from C code. Dummy thread objects have limited functionality; they are always considered alive and daemonic, and cannot be join()ed. They are never deleted, since it is impossible to detect the termination of alien threads.

```python
class threading.Thread(
    group=None, target=None, name=None,
    args=(), kwargs={})
```

This constructor should always be called with keyword arguments. Arguments are:

- **group** should be **None**; reserved for future extension when a `ThreadGroup` class is implemented.

- **target** is the callable object to be invoked by the `run()` method. Defaults to **None**, meaning nothing is called.

- **name** is the thread name. By default, a unique name is constructed of the form “Thread-N” where N is a small decimal number.

- **args** is the argument tuple for the target invocation. Defaults to `()`.

- **kwargs** is a dictionary of keyword arguments for the target invocation. Defaults to `{}`.

If the subclass overrides the constructor, it must make sure to invoke the base class constructor (`Thread.__init__()`) before doing anything else to the thread.

```python
start()
```

Start the thread's activity.
It must be called at most once per thread object. It arranges for the object’s `run()` method to be invoked in a separate thread of control.

This method will raise a `Runtime Exception` if called more than once on the same thread object.

**run()**

Method representing the thread's activity.

You may override this method in a subclass. The standard `run()` method invokes the callable object passed to the object’s constructor as the `target` argument, if any, with sequential and keyword arguments taken from the `args` and `kwargs` arguments, respectively.

**join([timeout])**

Wait until the thread terminates. This blocks the calling thread until the thread whose `join()` method is called terminates – either normally or through an unhandled exception – or until the optional timeout occurs.

When the `timeout` argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof). As `join()` always returns `None`, you must call `isAlive()` after `join()` to decide whether a timeout happened – if the thread is still alive, the `join()` call timed out.

When the `timeout` argument is not present or `None`, the operation will block until the thread terminates.

A thread can be `join()`ed many times.
join() raises a **RuntimeError** if an attempt is made to join the current thread as that would cause a deadlock. It is also an error to join() a thread before it has been started and attempts to do so raises the same exception.

getName()
setName()
Old API for name.

name
A string used for identification purposes only. It has no semantics. Multiple threads may be given the same name. The initial name is set by the constructor.

ident
The ‘thread identifier’ of this thread or None if the thread has not been started. This is a nonzero integer. See the thread.get_ident() function. Thread identifiers may be recycled when a thread exits and another thread is created. The identifier is available even after the thread has exited.

    New in version 2.6.

is_alive()
isAlive()
Return whether the thread is alive.

    Roughly, a thread is alive from the moment the start() method returns until its run() method terminates. The module function enumerate() returns a list of all alive threads.

isDaemon()
setDaemon()
Old API for daemon.
daemon

A boolean value indicating whether this thread is a daemon thread (True) or not (False). This must be set before start() is called, otherwise RuntimeError is raised. Its initial value is inherited from the creating thread; the main thread is not a daemon thread and therefore all threads created in the main thread default to daemon = False.

The entire Python program exits when no alive non-daemon threads are left.
16.2.2. Lock Objects

A primitive lock is a synchronization primitive that is not owned by a particular thread when locked. In Python, it is currently the lowest level synchronization primitive available, implemented directly by the thread extension module.

A primitive lock is in one of two states, “locked” or “unlocked”. It is created in the unlocked state. It has two basic methods, acquire() and release(). When the state is unlocked, acquire() changes the state to locked and returns immediately. When the state is locked, acquire() blocks until a call to release() in another thread changes it to unlocked, then the acquire() call resets it to locked and returns. The release() method should only be called in the locked state; it changes the state to unlocked and returns immediately. If an attempt is made to release an unlocked lock, a RuntimeError will be raised.

When more than one thread is blocked in acquire() waiting for the state to turn to unlocked, only one thread proceeds when a release() call resets the state to unlocked; which one of the waiting threads proceeds is not defined, and may vary across implementations.

All methods are executed atomically.

Lock. `acquire([blocking=1])`

Acquire a lock, blocking or non-blocking.

When invoked without arguments, block until the lock is unlocked, then set it to locked, and return true.

When invoked with the blocking argument set to true, do the same thing as when called without arguments, and return true.
When invoked with the \textit{blocking} argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

\texttt{Lock} . \texttt{release()}

Release a lock.

When the lock is locked, reset it to unlocked, and return. If any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

Do not call this method when the lock is unlocked.

There is no return value.
16.2.3. RLock Objects

A reentrant lock is a synchronization primitive that may be acquired multiple times by the same thread. Internally, it uses the concepts of “owning thread” and “recursion level” in addition to the locked/unlocked state used by primitive locks. In the locked state, some thread owns the lock; in the unlocked state, no thread owns it.

To lock the lock, a thread calls its acquire() method; this returns once the thread owns the lock. To unlock the lock, a thread calls its release() method. acquire()/release() call pairs may be nested; only the final release() (the release() of the outermost pair) resets the lock to unlocked and allows another thread blocked in acquire() to proceed.

RLock.acquire([blocking=1])

Acquire a lock, blocking or non-blocking.

When invoked without arguments: if this thread already owns the lock, increment the recursion level by one, and return immediately. Otherwise, if another thread owns the lock, block until the lock is unlocked. Once the lock is unlocked (not owned by any thread), then grab ownership, set the recursion level to one, and return. If more than one thread is blocked waiting until the lock is unlocked, only one at a time will be able to grab ownership of the lock. There is no return value in this case.

When invoked with the blocking argument set to true, do the same thing as when called without arguments, and return true.

When invoked with the blocking argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without
arguments, and return true.

```python
RLock.release()
```

Release a lock, decrementing the recursion level. If after the decrement it is zero, reset the lock to unlocked (not owned by any thread), and if any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed. If after the decrement the recursion level is still nonzero, the lock remains locked and owned by the calling thread.

Only call this method when the calling thread owns the lock. A `RuntimeError` is raised if this method is called when the lock is unlocked.

There is no return value.
16.2.4. Condition Objects

A condition variable is always associated with some kind of lock; this can be passed in or one will be created by default. (Passing one in is useful when several condition variables must share the same lock.)

A condition variable has acquire() and release() methods that call the corresponding methods of the associated lock. It also has a wait() method, and notify() and notifyAll() methods. These three must only be called when the calling thread has acquired the lock, otherwise a RuntimeError is raised.

The wait() method releases the lock, and then blocks until it is awakened by a notify() or notifyAll() call for the same condition variable in another thread. Once awakened, it re-acquires the lock and returns. It is also possible to specify a timeout.

The notify() method wakes up one of the threads waiting for the condition variable, if any are waiting. The notifyAll() method wakes up all threads waiting for the condition variable.

Note: the notify() and notifyAll() methods don't release the lock; this means that the thread or threads awakened will not return from their wait() call immediately, but only when the thread that called notify() or notifyAll() finally relinquishes ownership of the lock.

Tip: the typical programming style using condition variables uses the lock to synchronize access to some shared state; threads that are interested in a particular change of state call wait() repeatedly until they see the desired state, while threads that modify the state call notify() or notifyAll() when they change the state in such a way that it could possibly be a desired state for one of the waiters. For example, the following code is a generic producer-consumer
situation with unlimited buffer capacity:

```python
# Consume one item
cv.acquire()
while not an_item_is_available():
    cv.wait()
get_an_available_item()
cv.release()

# Produce one item
cv.acquire()
make_an_item_available()
cv.notify()
cv.release()
```

To choose between `notify()` and `notifyAll()`, consider whether one state change can be interesting for only one or several waiting threads. E.g. in a typical producer-consumer situation, adding one item to the buffer only needs to wake up one consumer thread.

```python
class threading.Condition([lock])
    If the lock argument is given and not None, it must be a Lock or RLock object, and it is used as the underlying lock. Otherwise, a new RLock object is created and used as the underlying lock.

    acquire(*args)
    Acquire the underlying lock. This method calls the corresponding method on the underlying lock; the return value is whatever that method returns.

    release()
    Release the underlying lock. This method calls the corresponding method on the underlying lock; there is no return value.

    wait([timeout])
    Wait until notified or until a timeout occurs. If the calling thread
```
has not acquired the lock when this method is called, a `RuntimeError` is raised.

This method releases the underlying lock, and then blocks until it is awakened by a `notify()` or `notifyAll()` call for the same condition variable in another thread, or until the optional timeout occurs. Once awakened or timed out, it re-acquires the lock and returns.

When the `timeout` argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

When the underlying lock is an `RLock`, it is not released using its `release()` method, since this may not actually unlock the lock when it was acquired multiple times recursively. Instead, an internal interface of the `RLock` class is used, which really unlocks it even when it has been recursively acquired several times. Another internal interface is then used to restore the recursion level when the lock is reacquired.

### notify()

Wake up a thread waiting on this condition, if any. If the calling thread has not acquired the lock when this method is called, a `RuntimeError` is raised.

This method wakes up one of the threads waiting for the condition variable, if any are waiting; it is a no-op if no threads are waiting.

The current implementation wakes up exactly one thread, if any are waiting. However, it’s not safe to rely on this behavior. A future, optimized implementation may occasionally wake up more than one thread.
Note: the awakened thread does not actually return from its \texttt{wait()} call until it can reacquire the lock. Since \texttt{notify()} does not release the lock, its caller should.

\texttt{notify\_all()}

\texttt{notifyAll()}

Wake up all threads waiting on this condition. This method acts like \texttt{notify()}, but wakes up all waiting threads instead of one. If the calling thread has not acquired the lock when this method is called, a \texttt{RuntimeError} is raised.
16.2.5. Semaphore Objects

This is one of the oldest synchronization primitives in the history of computer science, invented by the early Dutch computer scientist Edsger W. Dijkstra (he used \( P() \) and \( V() \) instead of \( \text{acquire}() \) and \( \text{release}() \)).

A semaphore manages an internal counter which is decremented by each \( \text{acquire}() \) call and incremented by each \( \text{release}() \) call. The counter can never go below zero; when \( \text{acquire}() \) finds that it is zero, it blocks, waiting until some other thread calls \( \text{release}() \).

```
class threading.Semaphore([value])
```

The optional argument gives the initial value for the internal counter; it defaults to 1. If the value given is less than 0, \( \text{ValueError} \) is raised.

```
acquire([blocking])
```

Acquire a semaphore.

When invoked without arguments: if the internal counter is larger than zero on entry, decrement it by one and return immediately. If it is zero on entry, block, waiting until some other thread has called \( \text{release}() \) to make it larger than zero. This is done with proper interlocking so that if multiple \( \text{acquire}() \) calls are blocked, \( \text{release}() \) will wake exactly one of them up. The implementation may pick one at random, so the order in which blocked threads are awakened should not be relied on. There is no return value in this case.

When invoked with \( \text{blocking} \) set to true, do the same thing as when called without arguments, and return true.
When invoked with $blocking$ set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

release()
Release a semaphore, incrementing the internal counter by one. When it was zero on entry and another thread is waiting for it to become larger than zero again, wake up that thread.

16.2.5.1. Semaphore Example

Semaphores are often used to guard resources with limited capacity, for example, a database server. In any situation where the size of the resource size is fixed, you should use a bounded semaphore. Before spawning any worker threads, your main thread would initialize the semaphore:

```python
maxconnections = 5
... pool_sema = BoundedSemaphore(value=maxconnections)
```

Once spawned, worker threads call the semaphore's acquire and release methods when they need to connect to the server:

```python
pool_sema.acquire()
conn = connectdb()
... use connection ...
conn.close()
pool_sema.release()
```

The use of a bounded semaphore reduces the chance that a programming error which causes the semaphore to be released more than it's acquired will go undetected.
16.2.6. Event Objects

This is one of the simplest mechanisms for communication between threads: one thread signals an event and other threads wait for it.

An event object manages an internal flag that can be set to true with the \texttt{set()} method and reset to false with the \texttt{clear()} method. The \texttt{wait()} method blocks until the flag is true.

\texttt{class \: threading.Event}

The internal flag is initially false.

\begin{itemize}
  \item \texttt{is\_set()}
  \texttt{isSet()}
  \begin{itemize}
    \item Return true if and only if the internal flag is true.
  \end{itemize}

  \textit{Changed in version 2.6:} The \texttt{is\_set()} syntax is new.

  \item \texttt{set()}
  \begin{itemize}
    \item Set the internal flag to true. All threads waiting for it to become true are awakened. Threads that call \texttt{wait()} once the flag is true will not block at all.
  \end{itemize}

  \item \texttt{clear()}
  \begin{itemize}
    \item Reset the internal flag to false. Subsequently, threads calling \texttt{wait()} will block until \texttt{set()} is called to set the internal flag to true again.
  \end{itemize}

  \item \texttt{wait([timeout])}
  \begin{itemize}
    \item Block until the internal flag is true. If the internal flag is true on entry, return immediately. Otherwise, block until another thread calls \texttt{set()} to set the flag to true, or until the optional \texttt{timeout} occurs.
  \end{itemize}
\end{itemize}
When the timeout argument is present and not \texttt{None}, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

This method returns the internal flag on exit, so it will always return \texttt{True} except if a timeout is given and the operation times out.

\textit{Changed in version 2.7:} Previously, the method always returned \texttt{None}. 
16.2.7. Timer Objects

This class represents an action that should be run only after a certain amount of time has passed — a timer. Timer is a subclass of Thread and as such also functions as an example of creating custom threads.

Timers are started, as with threads, by calling their start() method. The timer can be stopped (before its action has begun) by calling the cancel() method. The interval the timer will wait before executing its action may not be exactly the same as the interval specified by the user.

For example:

```python
def hello():
    print "hello, world"
t = Timer(30.0, hello)
t.start()  # after 30 seconds, "hello, world" will be printed
```

```python
class threading.Timer(interval, function, args=[], kwargs={})
    Create a timer that will run function with arguments args and keyword arguments kwargs, after interval seconds have passed.
```

```python
cancel()
    Stop the timer, and cancel the execution of the timer's action.
    This will only work if the timer is still in its waiting stage.
```
16.2.8. Using locks, conditions, and semaphores in the `with` statement

All of the objects provided by this module that have `acquire()` and `release()` methods can be used as context managers for a `with` statement. The `acquire()` method will be called when the block is entered, and `release()` will be called when the block is exited.

Currently, `Lock`, `RLock`, `Condition`, `Semaphore`, and `BoundedSemaphore` objects may be used as `with` statement context managers. For example:

```python
import threading

some_rlock = threading.RLock()

with some_rlock:
    print "some_rlock is locked while this executes"
```
16.2.9. Importing in threaded code

While the import machinery is thread safe, there are two key restrictions on threaded imports due to inherent limitations in the way that thread safety is provided:

- Firstly, other than in the main module, an import should not have the side effect of spawning a new thread and then waiting for that thread in any way. Failing to abide by this restriction can lead to a deadlock if the spawned thread directly or indirectly attempts to import a module.
- Secondly, all import attempts must be completed before the interpreter starts shutting itself down. This can be most easily achieved by only performing imports from non-daemon threads created through the threading module. Daemon threads and threads created directly with the thread module will require some other form of synchronization to ensure they do not attempt imports after system shutdown has commenced. Failure to abide by this restriction will lead to intermittent exceptions and crashes during interpreter shutdown (as the late imports attempt to access machinery which is no longer in a valid state).
16.3. thread — Multiple threads of control

**Note:** The `thread` module has been renamed to `_thread` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0; however, you should consider using the high-level `threading` module instead.

This module provides low-level primitives for working with multiple threads (also called *light-weight processes* or *tasks*) — multiple threads of control sharing their global data space. For synchronization, simple locks (also called *mutexes* or *binary semaphores*) are provided. The `threading` module provides an easier to use and higher-level threading API built on top of this module.

The module is optional. It is supported on Windows, Linux, SGI IRIX, Solaris 2.x, as well as on systems that have a POSIX thread (a.k.a. “pthread”) implementation. For systems lacking the `thread` module, the `dummy_thread` module is available. It duplicates this module’s interface and can be used as a drop-in replacement.

It defines the following constant and functions:

* `exception thread.error`
  
  Raised on thread-specific errors.

* `thread.LockType`
  
  This is the type of lock objects.

* `thread.start_new_thread(function, args[, kwargs])`
  
  Start a new thread and return its identifier. The thread executes the function `function` with the argument list `args` (which must be a
tuple). The optional *kwargs argument specifies a dictionary of keyword arguments. When the function returns, the thread silently exits. When the function terminates with an unhandled exception, a stack trace is printed and then the thread exits (but other threads continue to run).

**thread.interrupt_main()**

Raise a *KeyboardInterrupt* exception in the main thread. A subthread can use this function to interrupt the main thread.

*New in version 2.3.*

**thread.exit()**

Raise the *SystemExit* exception. When not caught, this will cause the thread to exit silently.

**thread.allocate_lock()**

Return a new lock object. Methods of locks are described below. The lock is initially unlocked.

**thread.get_ident()**

Return the ‘thread identifier’ of the current thread. This is a nonzero integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

**thread.stack_size([size])**

Return the thread stack size used when creating new threads. The optional size argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32kB). If changing the thread stack size is unsupported, the *error* exception is raised. If the specified stack size is invalid, a
ValueError is raised and the stack size is unmodified. 32kB is currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32kB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4kB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.

New in version 2.5.

Lock objects have the following methods:

lock.**acquire**(\[[waitflag]\])
Without the optional argument, this method acquires the lock unconditionally, if necessary waiting until it is released by another thread (only one thread at a time can acquire a lock — that's their reason for existence). If the integer *waitflag* argument is present, the action depends on its value: if it is zero, the lock is only acquired if it can be acquired immediately without waiting, while if it is nonzero, the lock is acquired unconditionally as before. The return value is True if the lock is acquired successfully, False if not.

lock.**release**()
Releases the lock. The lock must have been acquired earlier, but not necessarily by the same thread.

lock.**locked**()
Return the status of the lock: True if it has been acquired by some thread, False if not.
In addition to these methods, lock objects can also be used via the `with` statement, e.g.:

```python
import thread
a_lock = thread.allocate_lock()
with a_lock:
    print "a_lock is locked while this executes"
```

**Caveats:**

- Threads interact strangely with interrupts: the `KeyboardInterrupt` exception will be received by an arbitrary thread. (When the `signal` module is available, interrupts always go to the main thread.)

- Calling `sys.exit()` or raising the `SystemExit` exception is equivalent to calling `thread.exit()`.

- Not all built-in functions that may block waiting for I/O allow other threads to run. (The most popular ones (`time.sleep()`, `file.read()`, `select.select()`) work as expected.)

- It is not possible to interrupt the `acquire()` method on a lock — the `KeyboardInterrupt` exception will happen after the lock has been acquired.

- When the main thread exits, it is system defined whether the other threads survive. On SGI IRIX using the native thread implementation, they survive. On most other systems, they are killed without executing `try ... finally` clauses or executing object destructors.

- When the main thread exits, it does not do any of its usual cleanup (except that `try ... finally` clauses are honored), and
the standard I/O files are not flushed.
16.4. dummy_threading — Drop-in replacement for the threading module

This module provides a duplicate interface to the `threading` module. It is meant to be imported when the `thread` module is not provided on a platform.

Suggested usage is:

```python
try:
    import threading as _threading
except ImportError:
    import dummy_threading as _threading
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
16.5. **dummy_thread** — Drop-in replacement for the `thread` module

**Note:** The `dummy_thread` module has been renamed to `_dummy_thread` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0; however, you should consider using the high-lever `dummy_threading` module instead.

This module provides a duplicate interface to the `thread` module. It is meant to be imported when the `thread` module is not provided on a platform.

Suggested usage is:

```python
try:
    import thread as _thread
except ImportError:
    import dummy_thread as _thread
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
16.6. multiprocessing — Process-based “threading” interface

New in version 2.6.
16.6.1. Introduction

`multiprocessing` is a package that supports spawning processes using an API similar to the `threading` module. The `multiprocessing` package offers both local and remote concurrency, effectively side-stepping the *Global Interpreter Lock* by using subprocesses instead of threads. Due to this, the `multiprocessing` module allows the programmer to fully leverage multiple processors on a given machine. It runs on both Unix and Windows.

**Warning:** Some of this package's functionality requires a functioning shared semaphore implementation on the host operating system. Without one, the `multiprocessing.synchronize` module will be disabled, and attempts to import it will result in an `ImportError`. See issue 3770 for additional information.

**Note:** Functionality within this package requires that the `__main__` method be importable by the children. This is covered in *Programming guidelines* however it is worth pointing out here. This means that some examples, such as the `multiprocessing.Pool` examples will not work in the interactive interpreter. For example:

```python
>>> from multiprocessing import Pool
>>> p = Pool(5)
>>> def f(x):
...     return x*x
... >>> p.map(f, [1,2,3])
Process PoolWorker-1:
Process PoolWorker-2:
Process PoolWorker-3:
Traceback (most recent call last):
  [snip]
AttributeError: 'module' object has no attribute 'f'
```

16.6.1.1. The Process class

In multiprocessing, processes are spawned by creating a Process object and then calling its start() method. Process follows the API of threading.Thread. A trivial example of a multiprocess program is

```python
from multiprocessing import Process

def f(name):
    print 'hello', name

if __name__ == '__main__':
    p = Process(target=f, args=('bob',))
    p.start()
    p.join()
```

To show the individual process IDs involved, here is an expanded example:

```python
from multiprocessing import Process
import os

def info(title):
    print title
    print 'module name:', __name__
    print 'parent process:', os.getppid()
    print 'process id:', os.getpid()

def f(name):
    info('function f')
    print 'hello', name

if __name__ == '__main__':
```
For an explanation of why (on Windows) the `if __name__ == '__main__'` part is necessary, see *Programming guidelines*.

## 16.6.1.2. Exchanging objects between processes

`multiprocessing` supports two types of communication channel between processes:

### Queues

The `Queue` class is a near clone of `Queue.Queue`. For example:

```python
from multiprocessing import Process, Queue

def f(q):
    q.put([42, None, 'hello'])

if __name__ == '__main__':
    q = Queue()
    p = Process(target=f, args=(q,))
    p.start()
    print q.get()  # prints '[42, None, 'hello']'
    p.join()
```

Queues are thread and process safe.

### Pipes

The `Pipe()` function returns a pair of connection objects connected by a pipe which by default is duplex (two-way). For example:

```python
from multiprocessing import Process, Pipe
```
The two connection objects returned by `Pipe()` represent the two ends of the pipe. Each connection object has `send()` and `recv()` methods (among others). Note that data in a pipe may become corrupted if two processes (or threads) try to read from or write to the same end of the pipe at the same time. Of course there is no risk of corruption from processes using different ends of the pipe at the same time.

### 16.6.1.3. Synchronization between processes

`multiprocessing` contains equivalents of all the synchronization primitives from `threading`. For instance one can use a lock to ensure that only one process prints to standard output at a time:

```python
def f(l, i):
    l.acquire()
    print 'hello world', i
    l.release()

if __name__ == '__main__':
    lock = Lock()

    for num in range(10):
        Process(target=f, args=(lock, num)).start()
```

Without using the lock output from the different processes is liable to
get all mixed up.

16.6.1.4. Sharing state between processes

As mentioned above, when doing concurrent programming it is usually best to avoid using shared state as far as possible. This is particularly true when using multiple processes.

However, if you really do need to use some shared data then multiprocessing provides a couple of ways of doing so.

Shared memory

Data can be stored in a shared memory map using Value or Array. For example, the following code

```python
from multiprocessing import Process, Value, Array

def f(n, a):
    n.value = 3.1415927
    for i in range(len(a)):
        a[i] = -a[i]

if __name__ == '__main__':
    num = Value('d', 0.0)
    arr = Array('i', range(10))

    p = Process(target=f, args=(num, arr))
    p.start()
    p.join()

    print num.value
    print arr[:]
```

will print

```plaintext
3.1415927
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
```
The 'd' and 'i' arguments used when creating `num` and `arr` are typecodes of the kind used by the `array` module: 'd' indicates a double precision float and 'i' indicates a signed integer. These shared objects will be process and thread safe.

For more flexibility in using shared memory one can use the `multiprocessing.sharedctypes` module which supports the creation of arbitrary `ctypes` objects allocated from shared memory.

Server process

A manager object returned by `Manager()` controls a server process which holds Python objects and allows other processes to manipulate them using proxies.

A manager returned by `Manager()` will support types `list`, `dict`, `Namespace`, `Lock`, `RLock`, `Semaphore`, `BoundedSemaphore`, `Condition`, `Event`, `Queue`, `Value` and `Array`. For example,

```python
from multiprocessing import Process, Manager

def f(d, l):
    d[1] = '1'
    d['2'] = 2
    d[0.25] = None
    l.reverse()

if __name__ == '__main__':
    manager = Manager()
    
    d = manager.dict()
    l = manager.list(range(10))
    
    p = Process(target=f, args=(d, l))
    p.start()
    p.join()
    
    print d
    print l
```
will print

```
{0.25: None, 1: '1', '2': 2}
[9, 8, 7, 6, 5, 4, 3, 2, 1, 0]
```

Server process managers are more flexible than using shared memory objects because they can be made to support arbitrary object types. Also, a single manager can be shared by processes on different computers over a network. They are, however, slower than using shared memory.

### 16.6.1.5. Using a pool of workers

The **Pool** class represents a pool of worker processes. It has methods which allows tasks to be offloaded to the worker processes in a few different ways.

For example:

```python
from multiprocessing import Pool

def f(x):
    return x*x

if __name__ == '__main__':
    pool = Pool(processes=4)  # start 4 worker proc
    result = pool.apply_async(f, [10])  # evaluate "f(10)" a
    print result.get(timeout=1)  # prints "100" unless
    print pool.map(f, range(10))  # prints "[0, 1, 4,..
```
16.6.2. Reference

The multiprocessing package mostly replicates the API of the threading module.

16.6.2.1. Process and exceptions

```python
class multiprocessing.Process([group[, target[, name[, args[, kwargs]]]]])
```

Process objects represent activity that is run in a separate process. The `Process` class has equivalents of all the methods of `threading.Thread`.

The constructor should always be called with keyword arguments. `group` should always be `None`; it exists solely for compatibility with `threading.Thread`. `target` is the callable object to be invoked by the `run()` method. It defaults to `None`, meaning nothing is called. `name` is the process name. By default, a unique name is constructed of the form `Process-N_1:N_2:...:N_k` where `N_1,N_2,...,N_k` is a sequence of integers whose length is determined by the `generation` of the process. `args` is the argument tuple for the target invocation. `kwargs` is a dictionary of keyword arguments for the target invocation. By default, no arguments are passed to `target`.

If a subclass overrides the constructor, it must make sure it invokes the base class constructor (`Process.__init__()`)) before doing anything else to the process.

```python
run()
```

Method representing the process’s activity.
You may override this method in a subclass. The standard `run()` method invokes the callable object passed to the object’s constructor as the target argument, if any, with sequential and keyword arguments taken from the `args` and `kwargs` arguments, respectively.

`start()`

Start the process’s activity.

This must be called at most once per process object. It arranges for the object’s `run()` method to be invoked in a separate process.

`join([timeout])`

Block the calling thread until the process whose `join()` method is called terminates or until the optional timeout occurs.

If `timeout` is `None` then there is no timeout.

A process can be joined many times.

A process cannot join itself because this would cause a deadlock. It is an error to attempt to join a process before it has been started.

`name`

The process’s name.

The name is a string used for identification purposes only. It has no semantics. Multiple processes may be given the same name. The initial name is set by the constructor.

`is_alive()`

Return whether the process is alive.
Roughly, a process object is alive from the moment the `start()` method returns until the child process terminates.

**daemon**

The process's daemon flag, a Boolean value. This must be set before `start()` is called.

The initial value is inherited from the creating process.

When a process exits, it attempts to terminate all of its daemonic child processes.

Note that a daemonic process is not allowed to create child processes. Otherwise a daemonic process would leave its children orphaned if it gets terminated when its parent process exits. Additionally, these are **not** Unix daemons or services, they are normal processes that will be terminated (and not joined) if non-dameonic processes have exited.

In addition to the `Threading.Thread` API, `Process` objects also support the following attributes and methods:

**pid**

Return the process ID. Before the process is spawned, this will be `None`.

**exitcode**

The child's exit code. This will be `None` if the process has not yet terminated. A negative value `-N` indicates that the child was terminated by signal `N`.

**authkey**

The process's authentication key (a byte string).

When `multiprocessing` is initialized the main process is assigned a random string using `os.random()`.
When a `Process` object is created, it will inherit the authentication key of its parent process, although this may be changed by setting `authkey` to another byte string.

See `Authentication keys`.

**terminate()**

Terminate the process. On Unix this is done using the `SIGTERM` signal; on Windows `TerminateProcess()` is used. Note that exit handlers and finally clauses, etc., will not be executed.

Note that descendant processes of the process will *not* be terminated – they will simply become orphaned.

**Warning:** If this method is used when the associated process is using a pipe or queue then the pipe or queue is liable to become corrupted and may become unusable by other process. Similarly, if the process has acquired a lock or semaphore etc. then terminating it is liable to cause other processes to deadlock.

Note that the `start()`, `join()`, `is_alive()` and `exit_code` methods should only be called by the process that created the process object.

Example usage of some of the methods of `Process`:

```python
>>> import multiprocessing, time, signal
>>> p = multiprocessing.Process(target=time.sleep, args=(100,
>>> print p, p.is_alive())  # <Process(Process-1, initial)> False
>>> p.start()
>>> print p, p.is_alive()  # <Process(Process-1, started)> True
>>> p.terminate()
>>> time.sleep(0.1)
>>> print p, p.is_alive()  # False
```
```python
<Process(Process-1, stopped[SIGTERM])> False
>>> p.exitcode == -signal.SIGTERM
True
```

**exception** multiprocessing.``BufferTooShort``

Exception raised by `Connection.recv_bytes_into()` when the supplied buffer object is too small for the message read.

If `e` is an instance of `BufferTooShort` then `e.args[0]` will give the message as a byte string.

### 16.6.2.2. Pipes and Queues

When using multiple processes, one generally uses message passing for communication between processes and avoids having to use any synchronization primitives like locks.

For passing messages one can use `Pipe()` (for a connection between two processes) or a queue (which allows multiple producers and consumers).

The `Queue` and `JoinableQueue` types are multi-producer, multi-consumer FIFO queues modelled on the `Queue.Queue` class in the standard library. They differ in that `Queue` lacks the `task_done()` and `join()` methods introduced into Python 2.5’s `Queue.Queue` class.

If you use `JoinableQueue` then you must call `JoinableQueue.task_done()` for each task removed from the queue or else the semaphore used to count the number of unfinished tasks may eventually overflow raising an exception.

Note that one can also create a shared queue by using a manager object – see `Managers`. 
Note: multiprocessing uses the usual Queue.Empty and Queue.Full exceptions to signal a timeout. They are not available in the multiprocessing namespace so you need to import them from Queue.

Warning: If a process is killed using Process.terminate() or os.kill() while it is trying to use a Queue, then the data in the queue is likely to become corrupted. This may cause any other processes to get an exception when it tries to use the queue later on.

Warning: As mentioned above, if a child process has put items on a queue (and it has not used JoinableQueue.cancel_join_thread()), then that process will not terminate until all buffered items have been flushed to the pipe.

This means that if you try joining that process you may get a deadlock unless you are sure that all items which have been put on the queue have been consumed. Similarly, if the child process is non-daemonic then the parent process may hang on exit when it tries to join all its non-daemonic children.

Note that a queue created using a manager does not have this issue. See Programming guidelines.

For an example of the usage of queues for interprocess communication see Examples.

multiprocessing.Pipe([duplex])

Returns a pair (conn1, conn2) of Connection objects representing the ends of a pipe.
If `duplex` is `True` (the default) then the pipe is bidirectional. If `duplex` is `False` then the pipe is unidirectional: `conn1` can only be used for receiving messages and `conn2` can only be used for sending messages.

```
class multiprocessing.Queue([maxsize])
```

Returns a process shared queue implemented using a pipe and a few locks/semaphores. When a process first puts an item on the queue a feeder thread is started which transfers objects from a buffer into the pipe.

The usual `Queue.Empty` and `Queue.Full` exceptions from the standard library’s `Queue` module are raised to signal timeouts.

`Queue` implements all the methods of `Queue.Queue` except for `task_done()` and `join()`.

`qsize()`
Return the approximate size of the queue. Because of multithreading/multiprocessing semantics, this number is not reliable.

Note that this may raise `NotImplementedError` on Unix platforms like Mac OS X where `sem_getvalue()` is not implemented.

`empty()`
Return `True` if the queue is empty, `False` otherwise. Because of multithreading/multiprocessing semantics, this is not reliable.

`full()`
Return `True` if the queue is full, `False` otherwise. Because of multithreading/multiprocessing semantics, this is not reliable.
put\((item[, \ block[, \ timeout]])\)
Put item into the queue. If the optional argument \(block\) is True (the default) and \(timeout\) is None (the default), block if necessary until a free slot is available. If \(timeout\) is a positive number, it blocks at most \(timeout\) seconds and raises the \Queue.Full\ exception if no free slot was available within that time. Otherwise (\(block\) is False), put an item on the queue if a free slot is immediately available, else raise the \Queue.Full\ exception (\(timeout\) is ignored in that case).

put_nowait\(\)(item)
Equivalent to put\((item, False)\).

get\([\ block[, \ timeout]]\)
Remove and return an item from the queue. If optional args \(block\) is True (the default) and \(timeout\) is None (the default), block if necessary until an item is available. If \(timeout\) is a positive number, it blocks at most \(timeout\) seconds and raises the \Queue.Empty\ exception if no item was available within that time. Otherwise (\(block\) is False), return an item if one is immediately available, else raise the \Queue.Empty\ exception (\(timeout\) is ignored in that case).

get_nowait\()
get_no_wait\()
Equivalent to get\((False)\).

\textbf{multiprocessing.Queue} has a few additional methods not found in \Queue.Queue\. These methods are usually unnecessary for most code:

close()
Indicate that no more data will be put on this queue by the
current process. The background thread will quit once it has flushed all buffered data to the pipe. This is called automatically when the queue is garbage collected.

**join_thread()**

Join the background thread. This can only be used after `close()` has been called. It blocks until the background thread exits, ensuring that all data in the buffer has been flushed to the pipe.

By default if a process is not the creator of the queue then on exit it will attempt to join the queue’s background thread. The process can call `cancel_join_thread()` to make `join_thread()` do nothing.

**cancel_join_thread()**

Prevent `join_thread()` from blocking. In particular, this prevents the background thread from being joined automatically when the process exits – see `join_thread()`.

```python
class multiprocessing.JoinableQueue([maxsize])
```

`JoinableQueue`, a `Queue` subclass, is a queue which additionally has `task_done()` and `join()` methods.

**task_done()**

Indicate that a formerly enqueued task is complete. Used by queue consumer threads. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).
Raises a `ValueError` if called more times than there were items placed in the queue.

`join()`
Block until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

### 16.6.2.3. Miscellaneous

**`multiprocessing.active_children()`**
Return list of all live children of the current process.

Calling this has the side affect of “joining” any processes which have already finished.

**`multiprocessing.cpu_count()`**
Return the number of CPUs in the system. May raise `NotImplementedError`.

**`multiprocessing.current_process()`**
Return the `Process` object corresponding to the current process.

An analogue of `threading.current_thread()`.

**`multiprocessing.freeze_support()`**
Add support for when a program which uses `multiprocessing` has been frozen to produce a Windows executable. (Has been tested with `py2exe`, `PyInstaller` and `cx_Freeze`.)
One needs to call this function straight after the `if __name__ == '__main__'` line of the main module. For example:

```python
from multiprocessing import Process, freeze_support

def f():
    print 'hello world!

if __name__ == '__main__':
    freeze_support()
    Process(target=f).start()
```

If the `freeze_support()` line is omitted then trying to run the frozen executable will raise `RuntimeError`.

If the module is being run normally by the Python interpreter then `freeze_support()` has no effect.

`multiprocessing.set_executable()`
Sets the path of the Python interpreter to use when starting a child process. (By default `sys.executable` is used). Embedders will probably need to do some thing like

```python
setExecutable(os.path.join(sys.exec_prefix, 'pythonw.exe'))
```

before they can create child processes. (Windows only)

**Note:** `multiprocessing` contains no analogues of `threading.active_count()`, `threading.enumerate()`, `threading.settrace()`, `threading.setprofile()`, `threading.Timer`, or `threading.local`.

### 16.6.2.4. Connection Objects

Connection objects allow the sending and receiving of picklable objects or strings. They can be thought of as message oriented
connected sockets.

Connection objects usually created using `Pipe()` – see also *Listeners and Clients*.

```python
class multiprocessing.Connection
    send(obj)
        Send an object to the other end of the connection which should be read using `recv()`.

        The object must be picklable. Very large pickles (approximately 32 MB+, though it depends on the OS) may raise a ValueError exception.

    recv()
        Return an object sent from the other end of the connection using `send()`. Raises EOFError if there is nothing left to receive and the other end was closed.

    fileno()
        Returns the file descriptor or handle used by the connection.

    close()
        Close the connection.

        This is called automatically when the connection is garbage collected.

    poll([timeout])
        Return whether there is any data available to be read.

        If `timeout` is not specified then it will return immediately. If `timeout` is a number then this specifies the maximum time in seconds to block. If `timeout` is `None` then an infinite timeout is used.
```
send_bytes(buffer[, offset[, size]])
Send byte data from an object supporting the buffer interface as a complete message.

If offset is given then data is read from that position in buffer. If size is given then that many bytes will be read from buffer. Very large buffers (approximately 32 MB+, though it depends on the OS) may raise a ValueError exception.

recv_bytes([maxlength])
Return a complete message of byte data sent from the other end of the connection as a string. Raises EOFError if there is nothing left to receive and the other end has closed.

If maxlen is specified and the message is longer than maxlen then IOError is raised and the connection will no longer be readable.

recv_bytes_into(buffer[, offset])
Read into buffer a complete message of byte data sent from the other end of the connection and return the number of bytes in the message. Raises EOFError if there is nothing left to receive and the other end was closed.

buffer must be an object satisfying the writable buffer interface. If offset is given then the message will be written into the buffer from that position. Offset must be a non-negative integer less than the length of buffer (in bytes).

If the buffer is too short then a BufferTooShort exception is raised and the complete message is available as e.args[0] where e is the exception instance.

For example:
>>> from multiprocessing import Pipe
>>> a, b = Pipe()
>>> a.send([1, 'hello', None])
>>> b.recv()
[1, 'hello', None]
>>> b.send_bytes('thank you')
>>> a.recv_bytes()
'thank you'
>>> import array
>>> arr1 = array.array('i', range(5))
>>> arr2 = array.array('i', [0] * 10)
>>> a.send_bytes(arr1)
>>> count = b.recv_bytes_into(arr2)
>>> assert count == len(arr1) * arr1.itemsize
>>> arr2
array('i', [0, 1, 2, 3, 4, 0, 0, 0, 0, 0])

**Warning:** The `Connection.recv()` method automatically unpickles the data it receives, which can be a security risk unless you can trust the process which sent the message.

Therefore, unless the connection object was produced using `Pipe()` you should only use the `recv()` and `send()` methods after performing some sort of authentication. See *Authentication keys*.

**Warning:** If a process is killed while it is trying to read or write to a pipe then the data in the pipe is likely to become corrupted, because it may become impossible to be sure where the message boundaries lie.

### 16.6.2.5. Synchronization primitives

Generally synchronization primitives are not as necessary in a multiprocess program as they are in a multithreaded program. See the documentation for *threading* module.

Note that one can also create synchronization primitives by using a
manager object – see *Managers*.

`class multiprocessing.BoundedSemaphore([value])`

(On *Mac OS X*, this is indistinguishable from `Semaphore` because `sem_getvalue()` is not implemented on that platform).

`class multiprocessing.Condition([lock])`

If `lock` is specified then it should be a `Lock` or `RLock` object from `multiprocessing`.

`class multiprocessing.Event`

A clone of `threading.Event`. This method returns the state of the internal semaphore on exit, so it will always return `True` except if a timeout is given and the operation times out.

*Changed in version 2.7:* Previously, the method always returned `None`.

`class multiprocessing.Lock`

A non-recursive lock object: a clone of `threading.Lock`.

`class multiprocessing.RLock`

A recursive lock object: a clone of `threading.RLock`.

`class multiprocessing.Semaphore([value])`

A bounded semaphore object: a clone of `threading.Semaphore`.

**Note:** The `acquire()` method of `BoundedSemaphore`, `Lock`, `RLock`
and **Semaphore** has a timeout parameter not supported by the equivalents in **threading**. The signature is `acquire(block=True, timeout=None)` with keyword parameters being acceptable. If `block` is `True` and `timeout` is not `None` then it specifies a timeout in seconds. If `block` is `False` then `timeout` is ignored.

On Mac OS X, `sem_timedwait` is unsupported, so calling `acquire()` with a timeout will emulate that function’s behavior using a sleeping loop.

**Note:** If the SIGINT signal generated by Ctrl-C arrives while the main thread is blocked by a call to `BoundedSemaphore.acquire()`, `Lock.acquire()`, `RLock.acquire()`, `Semaphore.acquire()`, `Condition.acquire()` or `Condition.wait()` then the call will be immediately interrupted and `KeyboardInterrupt` will be raised.

This differs from the behaviour of **threading** where SIGINT will be ignored while the equivalent blocking calls are in progress.

### 16.6.2.6. Shared `ctypes` Objects

It is possible to create shared objects using shared memory which can be inherited by child processes.

```python
multiprocessing.Value(typecode_or_type, *args[, lock])
```

Return a `ctypes` object allocated from shared memory. By default the return value is actually a synchronized wrapper for the object.

`typecode_or_type` determines the type of the returned object: it is either a ctypes type or a one character typecode of the kind used by the `array` module. `*args` is passed on to the constructor for the
If `lock` is `True` (the default) then a new lock object is created to synchronize access to the value. If `lock` is a `Lock` or `RLock` object then that will be used to synchronize access to the value. If `lock` is `False` then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that `lock` is a keyword-only argument.

```
multiprocessing.Array(typecode_or_type, size_or_initializer, *,
lock=True)
```

Return a ctypes array allocated from shared memory. By default the return value is actually a synchronized wrapper for the array.

`typecode_or_type` determines the type of the elements of the returned array: it is either a ctypes type or a one character typecode of the kind used by the `array` module. If `size_or_initializer` is an integer, then it determines the length of the array, and the array will be initially zeroed. Otherwise, `size_or_initializer` is a sequence which is used to initialize the array and whose length determines the length of the array.

If `lock` is `True` (the default) then a new lock object is created to synchronize access to the value. If `lock` is a `Lock` or `RLock` object then that will be used to synchronize access to the value. If `lock` is `False` then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that `lock` is a keyword only argument.

Note that an array of `ctypes.c_char` has value and raw attributes which allow one to use it to store and retrieve strings.
16.6.2.6.1. The multiprocessing.sharedctypes module

The multiprocessing.sharedctypes module provides functions for allocating ctypes objects from shared memory which can be inherited by child processes.

**Note:** Although it is possible to store a pointer in shared memory remember that this will refer to a location in the address space of a specific process. However, the pointer is quite likely to be invalid in the context of a second process and trying to dereference the pointer from the second process may cause a crash.

```python
multiprocessing.sharedctypes.RawArray(typecode_or_type, size_or_initializer)
```

Return a ctypes array allocated from shared memory.

`typecode_or_type` determines the type of the elements of the returned array: it is either a ctypes type or a one character typecode of the kind used by the array module. If `size_or_initializer` is an integer then it determines the length of the array, and the array will be initially zeroed. Otherwise `size_or_initializer` is a sequence which is used to initialize the array and whose length determines the length of the array.

Note that setting and getting an element is potentially non-atomic – use `Array()` instead to make sure that access is automatically synchronized using a lock.

```python
multiprocessing.sharedctypes.RawValue(typecode_or_type, *args)
```

Return a ctypes object allocated from shared memory.

`typecode_or_type` determines the type of the returned object: it is either a ctypes type or a one character typecode of the kind used by the array module. `*args` is passed on to the constructor for the
type.

Note that setting and getting the value is potentially non-atomic – use `Value()` instead to make sure that access is automatically synchronized using a lock.

Note that an array of `ctypes.c_char` has `value` and `raw` attributes which allow one to use it to store and retrieve strings – see documentation for `ctypes`.

```
multiprocessing.sharedctypes.Array(typecode_or_type, size_or_initializer, *args[, lock])
```

The same as `RawArray()` except that depending on the value of `lock` a process-safe synchronization wrapper may be returned instead of a raw ctypes array.

If `lock` is `True` (the default) then a new lock object is created to synchronize access to the value. If `lock` is a `Lock` or `RLock` object then that will be used to synchronize access to the value. If `lock` is `False` then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that `lock` is a keyword-only argument.

```
multiprocessing.sharedctypes.Value(typecode_or_type, *args[, lock])
```

The same as `RawValue()` except that depending on the value of `lock` a process-safe synchronization wrapper may be returned instead of a raw ctypes object.

If `lock` is `True` (the default) then a new lock object is created to synchronize access to the value. If `lock` is a `Lock` or `RLock` object then that will be used to synchronize access to the value. If `lock`
is `False` then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that `lock` is a keyword-only argument.

```python
multiprocessing.sharedctypes.copy(obj)
```

Return a ctypes object allocated from shared memory which is a copy of the ctypes object `obj`.

```python
multiprocessing.sharedctypes.synchronized(obj[, lock])
```

Return a process-safe wrapper object for a ctypes object which uses `lock` to synchronize access. If `lock` is `None` (the default) then a `multiprocessing.RLock` object is created automatically.

A synchronized wrapper will have two methods in addition to those of the object it wraps: `get_obj()` returns the wrapped object and `get_lock()` returns the lock object used for synchronization.

Note that accessing the ctypes object through the wrapper can be a lot slower than accessing the raw ctypes object.

The table below compares the syntax for creating shared ctypes objects from shared memory with the normal ctypes syntax. (In the table `MyStruct` is some subclass of `ctypes.Structure`.)

<table>
<thead>
<tr>
<th>ctypes</th>
<th>sharedctypes using type</th>
<th>sharedctypes using typecode</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_double(2.4)</td>
<td>RawValue(c_double, 2.4)</td>
<td>RawValue('d', 2.4)</td>
</tr>
<tr>
<td>MyStruct(4, 6)</td>
<td>RawValue(MyStruct, 4, 6)</td>
<td></td>
</tr>
<tr>
<td>(c_short * 7)()</td>
<td>RawArray(c_short, 7)</td>
<td>RawArray('h', 7)</td>
</tr>
<tr>
<td>(c_int * 3)(9, 2, 8)</td>
<td>RawArray(c_int, (9, 2, 8))</td>
<td>RawArray('i', (9, 2, 8))</td>
</tr>
</tbody>
</table>
Below is an example where a number of ctypes objects are modified by a child process:

```python
from multiprocessing import Process, Lock
from multiprocessing.sharedctypes import Value, Array
from ctypes import Structure, c_double

class Point(Structure):
    _fields_ = [('x', c_double), ('y', c_double)]

def modify(n, x, s, A):
    n.value **= 2
    x.value **= 2
    s.value = s.value.upper()
    for a in A:
        a.x **= 2
        a.y **= 2

if __name__ == '__main__':
    lock = Lock()

    n = Value('i', 7)
    x = Value(c_double, 1.0/3.0, lock=False)
    s = Array('c', 'hello world', lock=lock)
    A = Array(Point, [(1.875,-6.25), (-5.75,2.0), (2.375,9.5)], lock=lock)

    p = Process(target=modify, args=(n, x, s, A))
    p.start()
    p.join()

    print n.value
    print x.value
    print s.value
    print [(a.x, a.y) for a in A]
```

The results printed are

```
49
0.1111111111111111
HELLO WORLD
[(3.515625, 39.0625), (33.0625, 4.0), (5.640625, 90.25)]
```

16.6.2.7. Managers
Managers provide a way to create data which can be shared between different processes. A manager object controls a server process which manages *shared objects*. Other processes can access the shared objects by using proxies.

```python
multiprocessing.Manager()
```

Returns a started `SyncManager` object which can be used for sharing objects between processes. The returned manager object corresponds to a spawned child process and has methods which will create shared objects and return corresponding proxies.

Manager processes will be shutdown as soon as they are garbage collected or their parent process exits. The manager classes are defined in the `multiprocessing.managers` module:

```python
class multiprocessing.managers.BaseManager([address[, authkey]])
```

Create a BaseManager object.

Once created one should call `start()` or `get_server().serve_forever()` to ensure that the manager object refers to a started manager process.

`address` is the address on which the manager process listens for new connections. If `address` is `None` then an arbitrary one is chosen.

`authkey` is the authentication key which will be used to check the validity of incoming connections to the server process. If `authkey` is `None` then `current_process().authkey`. Otherwise `authkey` is used and it must be a string.
**start**([`initializer`, `initargs`])

Start a subprocess to start the manager. If `initializer` is not `None` then the subprocess will call `initializer(*initargs)` when it starts.

**get_server()**

Returns a `Server` object which represents the actual server under the control of the Manager. The `Server` object supports the `serve_forever()` method:

```python
>>> from multiprocessing.managers import BaseManager
>>> manager = BaseManager(address=('', 50000), authkey='abc')
>>> server = manager.get_server()
>>> server.serve_forever()
```

`Server` additionally has an `address` attribute.

**connect()**

Connect a local manager object to a remote manager process:

```python
>>> from multiprocessing.managers import BaseManager
>>> m = BaseManager(address=('127.0.0.1', 5000), authkey='abc')
>>> m.connect()
```

**shutdown()**

Stop the process used by the manager. This is only available if `start()` has been used to start the server process.

This can be called multiple times.

**register**( `typeid`[,  `callable`[,  `proxytype`[,  `exposed`[,  `method_to_typeid`[,  `create_method`]]]])

A classmethod which can be used for registering a type or
callable with the manager class.

`typeid` is a “type identifier” which is used to identify a particular type of shared object. This must be a string.

`callable` is a callable used for creating objects for this type identifier. If a manager instance will be created using the `from_address()` classmethod or if the `create_method` argument is `False` then this can be left as `None`.

`proxytype` is a subclass of `BaseProxy` which is used to create proxies for shared objects with this `typeid`. If `None` then a proxy class is created automatically.

`exposed` is used to specify a sequence of method names which proxies for this typeid should be allowed to access using `BaseProxy._callMethod()`. (If `exposed` is `None` then `proxytype._exposed_` is used instead if it exists.) In the case where no exposed list is specified, all “public methods” of the shared object will be accessible. (Here a “public method” means any attribute which has a `__call__()` method and whose name does not begin with `_`.)

`method_to_typeid` is a mapping used to specify the return type of those exposed methods which should return a proxy. It maps method names to typeid strings. (If `method_to_typeid` is `None` then `proxytype._method_to_typeid_` is used instead if it exists.) If a method’s name is not a key of this mapping or if the mapping is `None` then the object returned by the method will be copied by value.

`create_method` determines whether a method should be created with name `typeid` which can be used to tell the server process to create a new shared object and return a proxy for
it. By default it is **True**.

**BaseManager** instances also have one read-only property:

**address**

The address used by the manager.

```python
class multiprocessing.managers. SyncManager

A subclass of **BaseManager** which can be used for the synchronization of processes. Objects of this type are returned by multiprocessing.Manager().
```

It also supports creation of shared lists and dictionaries.

**BoundedSemaphore([value])**

Create a shared `threading.BoundedSemaphore` object and return a proxy for it.

**Condition([lock])**

Create a shared `threading.Condition` object and return a proxy for it.

If `lock` is supplied then it should be a proxy for a `threading.Lock` or `threading.RLock` object.

**Event()**

Create a shared `threading.Event` object and return a proxy for it.

**Lock()**

Create a shared `threading.Lock` object and return a proxy for it.

**Namespace()**

Create a shared `Namespace` object and return a proxy for it.
Queue\([\{maxsize\}]\)
Create a shared \texttt{queue.Queue} object and return a proxy for it.

\texttt{RLock}()
Create a shared \texttt{threading.RLock} object and return a proxy for it.

\texttt{Semaphore}[\{value\}]
Create a shared \texttt{threading.Semaphore} object and return a proxy for it.

\texttt{Array}(\texttt{typecode}, \texttt{sequence})
Create an array and return a proxy for it.

\texttt{Value}(\texttt{typecode}, \texttt{value})
Create an object with a writable \texttt{value} attribute and return a proxy for it.

\texttt{dict}()
\texttt{dict}(\texttt{mapping})
\texttt{dict}(\texttt{sequence})
Create a shared \texttt{dict} object and return a proxy for it.

\texttt{list}()
\texttt{list}(\texttt{sequence})
Create a shared \texttt{list} object and return a proxy for it.

\textbf{16.6.2.7.1. Namespace objects}

A namespace object has no public methods, but does have writable attributes. Its representation shows the values of its attributes.

However, when using a proxy for a namespace object, an attribute beginning with \texttt{\_} will be an attribute of the proxy and not an attribute of the referent:
>>> manager = multiprocessing.Manager()
>>> Global = manager.Namespace()
>>> Global.x = 10
>>> Global.y = 'hello'
>>> Global._z = 12.3  # this is an attribute of the proxy
>>> print Global
Namespace(x=10, y='hello')

### 16.6.2.7.2. Customized managers

To create one's own manager, one creates a subclass of `BaseManager` and use the `register()` classmethod to register new types or callables with the manager class. For example:

```python
from multiprocessing.managers import BaseManager

class MathsClass(object):
    def add(self, x, y):
        return x + y
    def mul(self, x, y):
        return x * y

class MyManager(BaseManager):
    pass

MyManager.register('Maths', MathsClass)

if __name__ == '__main__':
    manager = MyManager()
    manager.start()
    maths = manager.Maths()
    print maths.add(4, 3)  # prints 7
    print maths.mul(7, 8)  # prints 56
```

### 16.6.2.7.3. Using a remote manager

It is possible to run a manager server on one machine and have clients use it from other machines (assuming that the firewalls involved allow it).

Running the following commands creates a server for a single
shared queue which remote clients can access:

```python
>>> from multiprocessing.managers import BaseManager
>>> import Queue
>>> queue = Queue.Queue()
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue', callable=lambda:queue)
>>> m = QueueManager(address=('', 50000), authkey='abracadabra')
>>> s = m.get_server()
>>> s.serve_forever()
```

One client can access the server as follows:

```python
>>> from multiprocessing.managers import BaseManager
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue')
>>> m = QueueManager(address=('foo.bar.org', 50000), authkey='abracadabra')
>>> m.connect()
>>> queue = m.get_queue()
>>> queue.put('hello')
```

Another client can also use it:

```python
>>> from multiprocessing.managers import BaseManager
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue')
>>> m = QueueManager(address=('foo.bar.org', 50000), authkey='abracadabra')
>>> m.connect()
>>> queue = m.get_queue()
>>> queue.get()
'hello'
```

Local processes can also access that queue, using the code from above on the client to access it remotely:

```python
>>> from multiprocessing import Process, Queue
>>> from multiprocessing.managers import BaseManager
>>> class Worker(Process):
...     def __init__(self, q):
...         self.q = q
```
A proxy is an object which refers to a shared object which lives (presumably) in a different process. The shared object is said to be the referent of the proxy. Multiple proxy objects may have the same referent.

A proxy object has methods which invoke corresponding methods of its referent (although not every method of the referent will necessarily be available through the proxy). A proxy can usually be used in most of the same ways that its referent can:

```python
>>> from multiprocessing import Manager
>>> manager = Manager()
>>> l = manager.list([i**2 for i in range(10)])
>>> print l
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]
>>> print repr(l)
<ListProxy object, typeid 'list' at 0x...>
>>> l[4]
16
>>> l[2:5]
[4, 9, 16]
```

Notice that applying `str()` to a proxy will return the representation of the referent, whereas applying `repr()` will return the representation.
of the proxy.

An important feature of proxy objects is that they are picklable so they can be passed between processes. Note, however, that if a proxy is sent to the corresponding manager’s process then unpickling it will produce the referent itself. This means, for example, that one shared object can contain a second:

```python
>>> a = manager.list()
>>> b = manager.list()
>>> a.append(b)         # referent of a now contains referent of b
>>> print a, b
[[], []]
>>> b.append('hello')
>>> print a, b
[['hello'], ['hello']]
```

**Note:** The proxy types in `multiprocessing` do nothing to support comparisons by value. So, for instance, we have:

```python
>>> manager.list([1,2,3]) == [1,2,3]
False
```

One should just use a copy of the referent instead when making comparisons.

```python
class multiprocessing.managers.BaseProxy

Proxy objects are instances of subclasses of `BaseProxy`.

 `_callmethod(methodname[, args[, kwds]])`

Call and return the result of a method of the proxy’s referent.

If `proxy` is a proxy whose referent is `obj` then the expression

`proxy._callmethod(methodname, args, kwds)`
will evaluate the expression

```
getattr(obj, methodname)(*args, **kwds)
```

in the manager’s process.

The returned value will be a copy of the result of the call or a proxy to a new shared object – see documentation for the `method_to_typeid` argument of `BaseManager.register()`.

If an exception is raised by the call, then then is re-raised by `_callmethod()`. If some other exception is raised in the manager’s process then this is converted into a `RemoteError` exception and is raised by `_callmethod()`.

Note in particular that an exception will be raised if `methodname` has not been exposed

An example of the usage of `_callmethod()`:

```
>>> l = manager.list(range(10))
>>> l._callmethod('__len__')
10
>>> l._callmethod('__getslice__', (2, 7))  # equiv to `l[2, 3, 4, 5, 6]
>>> l._callmethod('__getitem__', (20,))  # equiv to `l[20]
Traceback (most recent call last):
...  
IndexError: list index out of range
```

__getvalue__()

Return a copy of the referent.

If the referent is unpicklable then this will raise an exception.

__repr__()

Return a representation of the proxy object.
16.6.2.8.1. Cleanup

A proxy object uses a weakref callback so that when it gets garbage collected it deregisters itself from the manager which owns its referent.

A shared object gets deleted from the manager process when there are no longer any proxies referring to it.

16.6.2.9. Process Pools

One can create a pool of processes which will carry out tasks submitted to it with the `Pool` class.

```python
class multiprocessing.Pool([processes[, initializer[, initargs[, maxtasksperchild]]]])
```

A process pool object which controls a pool of worker processes to which jobs can be submitted. It supports asynchronous results with timeouts and callbacks and has a parallel map implementation.

- `processes` is the number of worker processes to use. If `processes` is `None` then the number returned by `cpu_count()` is used. If `initializer` is not `None` then each worker process will call `initializer(*initargs)` when it starts.

- `maxtasksperchild` is the number of tasks a worker process can complete before it will exit and be replaced with a fresh worker process, to enable unused resources to be freed. The default `maxtasksperchild` is `None`, which means worker processes will live as long as the pool.
Note: Worker processes within a Pool typically live for the complete duration of the Pool's work queue. A frequent pattern found in other systems (such as Apache, mod_wsgi, etc) to free resources held by workers is to allow a worker within a pool to complete only a set amount of work before being exiting, being cleaned up and a new process spawned to replace the old one. The `maxtasksperchild` argument to the Pool exposes this ability to the end user.

```python
apply(func, args, kwds])
```
Equivalent of the `apply()` built-in function. It blocks till the result is ready. Given this blocks, `apply_async()` is better suited for performing work in parallel. Additionally, the passed in function is only executed in one of the workers of the pool.

```python
apply_async(func, args, kwds, callback])
```
A variant of the `apply()` method which returns a result object.

If `callback` is specified then it should be a callable which accepts a single argument. When the result becomes ready `callback` is applied to it (unless the call failed). `callback` should complete immediately since otherwise the thread which handles the results will get blocked.

```python
map(func, iterable, chunksize])
```
A parallel equivalent of the `map()` built-in function (it supports only one `iterable` argument though). It blocks till the result is ready.

This method chops the iterable into a number of chunks which it submits to the process pool as separate tasks. The (approximate) size of these chunks can be specified by setting `chunksize` to a positive integer.
map_async(func, iterable[, chunksize[, callback]])
A variant of the map() method which returns a result object.

If callback is specified then it should be a callable which accepts a single argument. When the result becomes ready callback is applied to it (unless the call failed). callback should complete immediately since otherwise the thread which handles the results will get blocked.

imap(func, iterable[, chunksize])
An equivalent of itertools.imap().

The chunksize argument is the same as the one used by the map() method. For very long iterables using a large value for chunksize can make make the job complete much faster than using the default value of 1.

Also if chunksize is 1 then the next() method of the iterator returned by the imap() method has an optional timeout parameter: next(timeout) will raise multiprocessing.TimeoutError if the result cannot be returned within timeout seconds.

imap_unordered(func, iterable[, chunksize])
The same as imap() except that the ordering of the results from the returned iterator should be considered arbitrary. (Only when there is only one worker process is the order guaranteed to be “correct”.)

close()
Prevents any more tasks from being submitted to the pool. Once all the tasks have been completed the worker processes will exit.
terminate()
   Stops the worker processes immediately without completing outstanding work. When the pool object is garbage collected terminate() will be called immediately.

join()
   Wait for the worker processes to exit. One must call close() or terminate() before using join().

class multiprocessing.poolAsyncResult
   The class of the result returned by Pool.apply_async() and Pool.map_async().

get([timeout])
   Return the result when it arrives. If timeout is not None and the result does not arrive within timeout seconds then multiprocessing.TimeoutError is raised. If the remote call raised an exception then that exception will be reraised by get().

wait([timeout])
   Wait until the result is available or until timeout seconds pass.

ready()
   Return whether the call has completed.

successful()
   Return whether the call completed without raising an exception. Will raise AssertionError if the result is not ready.

The following example demonstrates the use of a pool:

```python
from multiprocessing import Pool

def f(x):
```
return x**x

if __name__ == '__main__':
    pool = Pool(processes=4)  # start 4 worker proc
    result = pool.apply_async(f, (10,))  # evaluate "f(10)" a
    print result.get(timeout=1)  # prints "100" unless
    print pool.map(f, range(10))  # prints "[0, 1, 4, ..
    it = pool.imap(f, range(10))
    print it.next()  # prints "0"
    print it.next()  # prints "1"
    print it.next(timeout=1)  # prints "4" unless y

import time
result = pool.apply_async(time.sleep, (10,))
print result.get(timeout=1)  # raises TimeoutError

16.6.2.10. Listeners and Clients

Usually message passing between processes is done using queues or by using Connection objects returned by Pipe().

However, the multiprocessing.connection module allows some extra flexibility. It basically gives a high level message oriented API for dealing with sockets or Windows named pipes, and also has support for digest authentication using the hmac module.

multiprocessing.connection.deliver_challenge(connection, authkey)

Send a randomly generated message to the other end of the connection and wait for a reply.

If the reply matches the digest of the message using authkey as the key then a welcome message is sent to the other end of the connection. Otherwise AuthenticationError is raised.
multiprocessing.connection.\texttt{answerChallenge}(connection, authkey)

Receive a message, calculate the digest of the message using \texttt{authkey} as the key, and then send the digest back.

If a welcome message is not received, then \texttt{AuthenticationError} is raised.

multiprocessing.connection.\texttt{Client}(address[, family[, authenticate[, authkey]]])

Attempt to set up a connection to the listener which is using address \texttt{address}, returning a \texttt{Connection}.

The type of the connection is determined by \texttt{family} argument, but this can generally be omitted since it can usually be inferred from the format of \texttt{address}. (See \textit{Address Formats})

If \texttt{authenticate} is True or \texttt{authkey} is a string then digest authentication is used. The key used for authentication will be either \texttt{authkey} or \texttt{current_process().authkey} if \texttt{authkey} is None. If authentication fails then \texttt{AuthenticationError} is raised. See \textit{Authentication keys}.

class multiprocessing.connection.\texttt{Listener}([address[, family[, backlog[, authenticate[, authkey]]]]])

A wrapper for a bound socket or Windows named pipe which is ‘listening’ for connections.

\texttt{address} is the address to be used by the bound socket or named pipe of the listener object.

\begin{note} If an address of ‘0.0.0.0’ is used, the address will not be a connectable end point on Windows. If you require a
connectable end-point, you should use ‘127.0.0.1’.

family is the type of socket (or named pipe) to use. This can be one of the strings ‘AF_INET’ (for a TCP socket), ‘AF_UNIX’ (for a Unix domain socket) or ‘AF_PIPE’ (for a Windows named pipe). Of these only the first is guaranteed to be available. If family is None then the family is inferred from the format of address. If address is also None then a default is chosen. This default is the family which is assumed to be the fastest available. See Address Formats. Note that if family is ‘AF_UNIX’ and address is None then the socket will be created in a private temporary directory created using tempfile.mkstemp().

If the listener object uses a socket then backlog (1 by default) is passed to the listen() method of the socket once it has been bound.

If authenticate is True (False by default) or authkey is not None then digest authentication is used.

If authkey is a string then it will be used as the authentication key; otherwise it must be None.

If authkey is None and authenticate is True then current_process().authkey is used as the authentication key. If authkey is None and authenticate is False then no authentication is done. If authentication fails then AuthenticationError is raised. See Authentication keys.

accept()

Accept a connection on the bound socket or named pipe of the listener object and return a Connection object. If authentication is attempted and fails, then AuthenticationError is raised.
close()

Close the bound socket or named pipe of the listener object. This is called automatically when the listener is garbage collected. However it is advisable to call it explicitly.

Listener objects have the following read-only properties:

address

The address which is being used by the Listener object.

last_accepted

The address from which the last accepted connection came. If this is unavailable then it is None.

The module defines two exceptions:

exception multiprocessing.connection.AuthenticationError

Exception raised when there is an authentication error.

Examples

The following server code creates a listener which uses 'secret password' as an authentication key. It then waits for a connection and sends some data to the client:

```python
from multiprocessing.connection import Listener
from array import array

address = ('localhost', 6000)  # family is deduced to be 'AF'
listener = Listener(address, authkey='secret password')

conn = listener.accept()
print 'connection accepted from', listener.last_accepted

conn.send([2.25, None, 'junk', float])
conn.send_bytes('hello')
conn.send_bytes(array('i', [42, 1729]))
```
The following code connects to the server and receives some data from the server:

```python
from multiprocessing.connection import Client
from array import array

data = ('localhost', 6000)
conn = Client(data, authkey='secret password')
print(conn.recv())  # => [2.25, None, 'junk', float]
print(conn.recv_bytes())  # => 'hello'
arr = array('i', [0, 0, 0, 0, 0])
print(conn.recv_bytes_into(arr))  # => 8
print(arr)  # => array('i', [42, 1729, 0, 0, 0])
conn.close()
```

**16.6.2.10.1. Address Formats**

- An `'AF_INET'` address is a tuple of the form `(hostname, port)` where *hostname* is a string and *port* is an integer.

- An `'AF_UNIX'` address is a string representing a filename on the filesystem.

- An `'AF_PIPE'` address is a string of the form `r'\pipe\PipeName'`. To use `Client()` to connect to a named pipe on a remote computer called *ServerName* one should use an address of the form `r'\ServerName\pipe\PipeName'` instead.

Note that any string beginning with two backslashes is assumed by
default to be an 'AF_PIPE' address rather than an 'AF_UNIX' address.

### 16.6.2.11. Authentication keys

When one uses `Connection.recv()`, the data received is automatically unpickled. Unfortunately unpickling data from an untrusted source is a security risk. Therefore `Listener` and `Client()` use the `hmac` module to provide digest authentication.

An authentication key is a string which can be thought of as a password: once a connection is established both ends will demand proof that the other knows the authentication key. (Demonstrating that both ends are using the same key does **not** involve sending the key over the connection.)

If authentication is requested but do authentication key is specified then the return value of `current_process().authkey` is used (see `Process`). This value will automatically inherited by any `Process` object that the current process creates. This means that (by default) all processes of a multi-process program will share a single authentication key which can be used when setting up connections between themselves.

Suitable authentication keys can also be generated by using `os.urandom()`.

### 16.6.2.12. Logging

Some support for logging is available. Note, however, that the `logging` package does not use process shared locks so it is possible (depending on the handler type) for messages from different processes to get mixed up.
multiprocessing. `get_logger()`

Returns the logger used by multiprocessing. If necessary, a new one will be created.

When first created the logger has level `logging.NOTSET` and no default handler. Messages sent to this logger will not by default propagate to the root logger.

Note that on Windows child processes will only inherit the level of the parent process's logger – any other customization of the logger will not be inherited.

multiprocessing. `log_to_stderr()`

This function performs a call to `get_logger()` but in addition to returning the logger created by `get_logger`, it adds a handler which sends output to `sys.stderr` using format `'[%(levelname)s/%(processName)s] %(message)s'`.

Below is an example session with logging turned on:

```python
>>> import multiprocessing, logging
>>> logger = multiprocessing.log_to_stderr()
>>> logger.setLevel(logging.INFO)
>>> logger.warning('doomed')
[WARNING/MainProcess] doomed
>>> m = multiprocessing.Manager()
[INFO/SyncManager-...] child process calling self.run()
[INFO/SyncManager-...] created temp directory /.../pymp-...
[INFO/SyncManager-...] manager serving at '/.../listener-...'
>>> del m
[INFO/MainProcess] sending shutdown message to manager
[INFO/SyncManager-...] manager exiting with exitcode 0
```

In addition to having these two logging functions, the multiprocessing also exposes two additional logging level attributes. These are `SUBWARNING` and `SUBDEBUG`. The table below illustrates where theses fit in the normal level hierarchy.
<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>SUBWARNING</td>
<td>25</td>
</tr>
<tr>
<td>SUBDEBUG</td>
<td>5</td>
</tr>
</tbody>
</table>

For a full table of logging levels, see the `logging` module.

These additional logging levels are used primarily for certain debug messages within the multiprocessing module. Below is the same example as above, except with `SUBDEBUG` enabled:

```python
>>> import multiprocessing, logging
>>> logger = multiprocessing.log_to_stderr()
>>> logger.setLevel(multiprocessing.SUBDEBUG)
>>> logger.warning('doomed')
[WARNING/MainProcess] doomed
>>> m = multiprocessing.Manager()
[INFO/SyncManager-....] child process calling self.run()
[INFO/SyncManager-....] created temp directory /.../pymp-...
[INFO/SyncManager-....] manager serving at '/.../pymp-djGBXN/lis
>>> del m
[SUBDEBUG/MainProcess] finalizer calling ...
[INFO/MainProcess] sending shutdown message to manager
[DEBUG/SyncManager-....] manager received shutdown message
[SUBDEBUG/SyncManager-....] calling <Finalize object, callback=u
[SUBDEBUG/SyncManager-....] finalizer calling <built-in function
[SUBDEBUG/SyncManager-....] calling <Finalize object, dead>
[SUBDEBUG/SyncManager-....] finalizer calling <function rmtree a
[INFO/SyncManager-....] manager exiting with exitcode 0
```

### 16.6.2.13. The `multiprocessing.dummy` module

`multiprocessing.dummy` replicates the API of `multiprocessing` but is no more than a wrapper around the `threading` module.
16.6.3. Programming guidelines

There are certain guidelines and idioms which should be adhered to when using `multiprocessing`.

16.6.3.1. All platforms

Avoid shared state

As far as possible one should try to avoid shifting large amounts of data between processes.

It is probably best to stick to using queues or pipes for communication between processes rather than using the lower level synchronization primitives from the `threading` module.

Picklability

Ensure that the arguments to the methods of proxies are pickleable.

Thread safety of proxies

Do not use a proxy object from more than one thread unless you protect it with a lock.

(There is never a problem with different processes using the same proxy.)

Joining zombie processes

On Unix when a process finishes but has not been joined it becomes a zombie. There should never be very many because each time a new process starts (or `active_children()` is called) all completed processes which have not yet been joined will be
joined. Also calling a finished process's `Process.is_alive()` will join the process. Even so it is probably good practice to explicitly join all the processes that you start.

Better to inherit than pickle/unpickle

On Windows many types from `multiprocessing` need to be picklable so that child processes can use them. However, one should generally avoid sending shared objects to other processes using pipes or queues. Instead you should arrange the program so that a process which need access to a shared resource created elsewhere can inherit it from an ancestor process.

Avoid terminating processes

Using the `Process.terminate()` method to stop a process is liable to cause any shared resources (such as locks, semaphores, pipes and queues) currently being used by the process to become broken or unavailable to other processes.

Therefore it is probably best to only consider using `Process.terminate()` on processes which never use any shared resources.

Joining processes that use queues

Bear in mind that a process that has put items in a queue will wait before terminating until all the buffered items are fed by the “feeder” thread to the underlying pipe. (The child process can call the `Queue.cancel_join_thread()` method of the queue to avoid this behaviour.)

This means that whenever you use a queue you need to make sure that all items which have been put on the queue will eventually be removed before the process is joined. Otherwise you cannot be sure that processes which have put items on the
queue will terminate. Remember also that non-daemonic processes will be automatically be joined.

An example which will deadlock is the following:

```python
from multiprocessing import Process, Queue

def f(q):
    q.put('X' * 1000000)

if __name__ == '__main__':
    queue = Queue()
    p = Process(target=f, args=(queue,))
    p.start()
    p.join()                # this deadlocks
    obj = queue.get()
```

A fix here would be to swap the last two lines round (or simply remove the `p.join()` line).

Explicitly pass resources to child processes

On Unix a child process can make use of a shared resource created in a parent process using a global resource. However, it is better to pass the object as an argument to the constructor for the child process.

Apart from making the code (potentially) compatible with Windows this also ensures that as long as the child process is still alive the object will not be garbage collected in the parent process. This might be important if some resource is freed when the object is garbage collected in the parent process.

So for instance

```python
from multiprocessing import Process, Lock

def f():
    ... do something using "lock" ...
```
```python
if __name__ == '__main__':
    lock = Lock()
    for i in range(10):
        Process(target=f).start()
```

should be rewritten as

```python
from multiprocessing import Process, Lock

def f(l):
    ... do something using "l" ...

if __name__ == '__main__':
    lock = Lock()
    for i in range(10):
        Process(target=f, args=(lock,)).start()
```

Beware replacing `sys.stdin` with a “file like object”

```python
multiprocessing` originally unconditionally called:

goose.close(sys.stdin.fileno())
```

in the `multiprocessing.Process._bootstrap()` method — this resulted in issues with processes-in-processes. This has been changed to:

```python
sys.stdin.close()
sys.stdin = open(os.devnull)
```

Which solves the fundamental issue of processes colliding with each other resulting in a bad file descriptor error, but introduces a potential danger to applications which replace `sys.stdin()` with a “file-like object” with output buffering. This danger is that if multiple processes call `close()` on this file-like object, it could result in the same data being flushed to the object multiple times, resulting in corruption.
If you write a file-like object and implement your own caching, you can make it fork-safe by storing the pid whenever you append to the cache, and discarding the cache when the pid changes. For example:

```python
@property
def cache(self):
    pid = os.getpid()
    if pid != self._pid:
        self._pid = pid
        self._cache = []
    return self._cache
```

For more information, see issue 5155, issue 5313 and issue 5331

### 16.6.3.2. Windows

Since Windows lacks `os.fork()` it has a few extra restrictions:

**More picklability**

Ensure that all arguments to `Process.__init__()` are picklable. This means, in particular, that bound or unbound methods cannot be used directly as the `target` argument on Windows — just define a function and use that instead.

Also, if you subclass `Process` then make sure that instances will be picklable when the `Process.start()` method is called.

**Global variables**

Bear in mind that if code run in a child process tries to access a global variable, then the value it sees (if any) may not be the same as the value in the parent process at the time that `Process.start()` was called.
However, global variables which are just module level constants cause no problems.

Safe importing of main module

Make sure that the main module can be safely imported by a new Python interpreter without causing unintended side effects (such a starting a new process).

For example, under Windows running the following module would fail with a `RuntimeError`:

```python
from multiprocessing import Process
def foo():
    print 'hello'
p = Process(target=foo)
p.start()
```

Instead one should protect the “entry point” of the program by using `if __name__ == '__main__':` as follows:

```python
from multiprocessing import Process, freeze_support
def foo():
    print 'hello'
if __name__ == '__main__':
    freeze_support()
p = Process(target=foo)
p.start()
```

(The `freeze_support()` line can be omitted if the program will be run normally instead of frozen.)

This allows the newly spawned Python interpreter to safely import the module and then run the module's `foo()` function.
Similar restrictions apply if a pool or manager is created in the main module.
Demonstration of how to create and use customized managers and proxies:

```python
# This module shows how to use arbitrary callables with a subclass `BaseManager`.  
# Copyright (c) 2006-2008, R Oudkerk  
# All rights reserved.  

from multiprocessing import freeze_support  
from multiprocessing.managers import BaseManager, BaseProxy  
import operator

##

class Foo(object):
    def f(self):
        print 'you called Foo.f()'
    def g(self):
        print 'you called Foo.g()'
    def _h(self):
        print 'you called Foo._h()'

    # A simple generator function
    def baz():
        for i in xrange(10):
            yield i*i

    # Proxy type for generator objects
    class GeneratorProxy(BaseProxy):
        _exposed_ = ('next', '__next__')
        def __iter__(self):
            return self
        def next(self):
            return self._callmethod('next')
        def __next__(self):
            return self._callmethod('__next__')

    # Function to return the operator module
```python
def get_operator_module():
    return operator

##

class MyManager(BaseManager):
    pass

# register the Foo class; make `f()` and `g()` accessible via proxy
MyManager.register('Foo1', Foo)

# register the Foo class; make `g()` and `_h()` accessible via proxy
MyManager.register('Foo2', Foo, exposed=('g', '_h'))

# register the generator function baz; use `GeneratorProxy` to make proxies
MyManager.register('baz', baz, proxytype=GeneratorProxy)

# register get_operator_module(); make public functions accessible via proxy
MyManager.register('operator', get_operator_module)

##

def test():
    manager = MyManager()
    manager.start()

    print '-' * 20

    f1 = manager.Foo1()
    f1.f()
    f1.g()
    assert not hasattr(f1, '_h')
    assert sorted(f1._exposed_) == sorted(['f', 'g'])

    print '-' * 20

    f2 = manager.Foo2()
    f2.g()
    f2._h()
    assert not hasattr(f2, 'f')
    assert sorted(f2._exposed_) == sorted(['g', '_h'])

    print '-' * 20

    it = manager.baz()
    for i in it:
        print '<%d>' % i,
```
print

print '-' * 20

op = manager.operator()
print 'op.add(23, 45) =', op.add(23, 45)
print 'op.pow(2, 94) =', op.pow(2, 94)
print 'op.getslice(range(10), 2, 6) =', op.getslice(range(10), 2, 6)
print 'op.repeaterange(5), 3) =', op.repeat(range(5), 3)
print 'op._exposed_ =', op._exposed_

##

if __name__ == '__main__':
    freeze_support()
    test()

An showing how to use queues to feed tasks to a collection of
worker process and collect the results:

```python
# Simple example which uses a pool of workers to carry out some
# Notice that the results will probably not come out of the out
# queue in the same in the same order as the corresponding task
# put on the input queue. If it is important to get the result
# in the original order then consider using `Pool.map()` or
# `Pool.imap()` (which will save on the amount of code needed a

16. Optional Operating System Services

The Python Standard Library

IronPython v2.7.4a1 documentation » The Python Standard Library » 16. Optional Operating System Services »
16.7. rlcompleter — Completion function for GNU readline

The `rlcompleter` module defines a completion function suitable for the `readline` module by completing valid Python identifiers and keywords.

When this module is imported on a Unix platform with the `readline` module available, an instance of the `Completer` class is automatically created and its `complete()` method is set as the `readline` completer.

Example:

```python
>>> import rlcompleter
>>> import readline
>>> readline.parse_and_bind("tab: complete")
>>> readline.<TAB PRESSED>
readline.__doc__     readline.get_line_buffer(    readline.r
readline.__file__    readline.insert_text(    readline.s
readline.__name__    readline.parse_and_bind(  
>>> readline.
```

The `rlcompleter` module is designed for use with Python's interactive mode. A user can add the following lines to his or her initialization file (identified by the `PYTHONSTARTUP` environment variable) to get automatic Tab completion:

```python
try:
    import readline
except ImportError:
    print "Module readline not available."
else:
    import rlcompleter
    readline.parse_and_bind("tab: complete")
```
On platforms without `readline`, the `Completer` class defined by this module can still be used for custom purposes.
Completer objects have the following method:

```python
Completer.complete(text, state)
```

Return the state\text{th} completion for `text`.

If called for `text` that doesn't include a period character (`.\text{'}`), it will complete from names currently defined in `__main__`, `__builtin__` and keywords (as defined by the `keyword` module).

If called for a dotted name, it will try to evaluate anything without obvious side-effects (functions will not be evaluated, but it can generate calls to `__getattr__()` up to the last part, and find matches for the rest via the `dir()` function. Any exception raised during the evaluation of the expression is caught, silenced and `None` is returned.
17. Interprocess Communication and Networking

The modules described in this chapter provide mechanisms for different processes to communicate.

Some modules only work for two processes that are on the same machine, e.g. `signal` and `subprocess`. Other modules support networking protocols that two or more processes can used to communicate across machines.

The list of modules described in this chapter is:

- **17.1. subprocess** — Subprocess management
  - 17.1.1. Using the subprocess Module
    - 17.1.1.1. Convenience Functions
    - 17.1.1.2. Exceptions
    - 17.1.1.3. Security
  - 17.1.2. Popen Objects
  - 17.1.3. Replacing Older Functions with the subprocess Module
    - 17.1.3.1. Replacing /bin/sh shell backquote
    - 17.1.3.2. Replacing shell pipeline
    - 17.1.3.3. Replacing `os.system()`
    - 17.1.3.4. Replacing the `os.spawn` family
    - 17.1.3.5. Replacing `os.popen()`, `os.popen2()`, `os.popen3()`
    - 17.1.3.6. Replacing functions from the `popen2` module
- **17.2. socket** — Low-level networking interface
  - 17.2.1. Socket Objects
  - 17.2.2. Example
- **17.3. ssl** — SSL wrapper for socket objects
- 17.3.1. Functions, Constants, and Exceptions
- 17.3.2. SSLSocket Objects
- 17.3.3. Certificates
- 17.3.4. Examples
  - 17.3.4.1. Testing for SSL support
  - 17.3.4.2. Client-side operation
  - 17.3.4.3. Server-side operation
- 17.4. `signal` — Set handlers for asynchronous events
  - 17.4.1. Example
- 17.5. `popen2` — Subprocesses with accessible I/O streams
  - 17.5.1. Popen3 and Popen4 Objects
  - 17.5.2. Flow Control Issues
- 17.6. `asyncore` — Asynchronous socket handler
  - 17.6.1. asyncore Example basic HTTP client
- 17.7. `asynchat` — Asynchronous socket command/response handler
  - 17.7.1. asynchat - Auxiliary Classes
  - 17.7.2. asynchat Example
17.1. subprocess — Subprocess management

New in version 2.4.

The subprocess module allows you to spawn new processes, connect to their input/output/error pipes, and obtain their return codes. This module intends to replace several other, older modules and functions, such as:

```python
os.system
os.spawn*
os.popen*
popen2.*
commands.*
```

Information about how the subprocess module can be used to replace these modules and functions can be found in the following sections.

See also: PEP 324 – PEP proposing the subprocess module
17.1.1. Using the subprocess Module

This module defines one class called `Popen`:

```python
class subprocess.Popen(args, bufsize=0, executable=None,
                        stdin=None, stdout=None, stderr=None,
                        preexec_fn=None,
                        close_fds=False, shell=False, cwd=None, env=None,
                        universal_newlines=False, startupinfo=None, creationflags=0)
```

Arguments are:

`args` should be a string, or a sequence of program arguments. The program to execute is normally the first item in the args sequence or the string if a string is given, but can be explicitly set by using the `executable` argument. When `executable` is given, the first item in the args sequence is still treated by most programs as the command name, which can then be different from the actual executable name. On Unix, it becomes the display name for the executing program in utilities such as `ps`.

On Unix, with `shell=False` (default): In this case, the Popen class uses `os.execvp()` to execute the child program. `args` should normally be a sequence. If a string is specified for `args`, it will be used as the name or path of the program to execute; this will only work if the program is being given no arguments.

**Note:** `shlex.split()` can be useful when determining the correct tokenization for `args`, especially in complex cases:

```python
>>> import shlex, subprocess
>>> command_line = raw_input()
/bin/vikings -input eggs.txt -output "spam spam.txt" -cmd 'echo $MONEY'
>>> args = shlex.split(command_line)
>>> print args
['/bin/vikings', '-input', 'eggs.txt', '-output', 'spam spam.txt', '-cmd', 'echo $MONEY']
>>> p = subprocess.Popen(args) # Success!
```
Note in particular that options (such as \texttt{-input}) and arguments (such as \texttt{eggs.txt}) that are separated by whitespace in the shell go in separate list elements, while arguments that need quoting or backslash escaping when used in the shell (such as filenames containing spaces or the \texttt{echo} command shown above) are single list elements.

On Unix, with \texttt{shell=True}: If \texttt{args} is a string, it specifies the command string to execute through the shell. This means that the string must be formatted exactly as it would be when typed at the shell prompt. This includes, for example, quoting or backslash escaping filenames with spaces in them. If \texttt{args} is a sequence, the first item specifies the command string, and any additional items will be treated as additional arguments to the shell itself. That is to say, \texttt{Popen} does the equivalent of:

\begin{verbatim}
Popen(['/bin/sh', '-c', args[0], args[1], ...])
\end{verbatim}

On Windows: the \texttt{Popen} class uses \texttt{CreateProcess()} to execute the child program, which operates on strings. If \texttt{args} is a sequence, it will be converted to a string using the \texttt{list2cmdline()} method. Please note that not all MS Windows applications interpret the command line the same way: \texttt{list2cmdline()} is designed for applications using the same rules as the MS C runtime.

\texttt{bufsize}, if given, has the same meaning as the corresponding argument to the built-in \texttt{open()} function: 0 means unbuffered, 1 means line buffered, any other positive value means use a buffer of (approximately) that size. A negative \texttt{bufsize} means to use the system default, which usually means fully buffered. The default value for \texttt{bufsize} is 0 (unbuffered).
Note: If you experience performance issues, it is recommended that you try to enable buffering by setting bufsize to either -1 or a large enough positive value (such as 4096).

The executable argument specifies the program to execute. It is very seldom needed: Usually, the program to execute is defined by the args argument. If shell=True, the executable argument specifies which shell to use. On Unix, the default shell is /bin/sh. On Windows, the default shell is specified by the COMSPEC environment variable. The only reason you would need to specify shell=True on Windows is where the command you wish to execute is actually built in to the shell, eg dir, copy. You don't need shell=True to run a batch file, nor to run a console-based executable.

stdin, stdout and stderr specify the executed programs' standard input, standard output and standard error file handles, respectively. Valid values are PIPE, an existing file descriptor (a positive integer), an existing file object, and None. PIPE indicates that a new pipe to the child should be created. With None, no redirection will occur; the child's file handles will be inherited from the parent. Additionally, stderr can be STDOUT, which indicates that the stderr data from the applications should be captured into the same file handle as for stdout.

If preexec_fn is set to a callable object, this object will be called in the child process just before the child is executed. (Unix only)

If close_fds is true, all file descriptors except 0, 1 and 2 will be closed before the child process is executed. (Unix only). Or, on Windows, if close_fds is true then no handles will be inherited by the child process. Note that on Windows, you cannot set close_fds to true and also redirect the standard handles by setting stdin, stdout or stderr.
If `shell` is `True`, the specified command will be executed through the shell.

If `cwd` is not `None`, the child’s current directory will be changed to `cwd` before it is executed. Note that this directory is not considered when searching the executable, so you can’t specify the program’s path relative to `cwd`.

If `env` is not `None`, it must be a mapping that defines the environment variables for the new process; these are used instead of inheriting the current process’ environment, which is the default behavior.

**Note:** If specified, `env` must provide any variables required for the program to execute. On Windows, in order to run a side-by-side assembly the specified `env` must include a valid `SystemRoot`.

If `universal_newlines` is `True`, the file objects `stdout` and `stderr` are opened as text files, but lines may be terminated by any of `'\n'`, the Unix end-of-line convention, `'\r'`, the old Macintosh convention or `'\r\n'`, the Windows convention. All of these external representations are seen as `'\n'` by the Python program.

**Note:** This feature is only available if Python is built with universal newline support (the default). Also, the newlines attribute of the file objects `stdout`, `stdin` and `stderr` are not updated by the communicate() method.

The `startupinfo` and `creationflags`, if given, will be passed to the underlying CreateProcess() function. They can specify things such as appearance of the main window and priority for the new process. (Windows only)
subprocess.PIPE

Special value that can be used as the stdin, stdout or stderr argument to Popen and indicates that a pipe to the standard stream should be opened.

subprocess.STDOUT

Special value that can be used as the stderr argument to Popen and indicates that standard error should go into the same handle as standard output.

17.1.1.1. Convenience Functions

This module also defines two shortcut functions:

subprocess.call(*popenargs, **kwargs)

Run command with arguments. Wait for command to complete, then return the returncode attribute.

The arguments are the same as for the Popen constructor. Example:

```python
>>> retcode = subprocess.call(['ls', '-l'])
```

**Warning:** Like Popen.wait(), this will deadlock when using stdout=PIPE and/or stderr=PIPE and the child process generates enough output to a pipe such that it blocks waiting for the OS pipe buffer to accept more data.

subprocess.check_call(*popenargs, **kwargs)

Run command with arguments. Wait for command to complete. If the exit code was zero then return, otherwise raise CalledProcessError. The CalledProcessError object will have the return code in the returncode attribute.
The arguments are the same as for the `Popen` constructor. Example:

```python
>>> subprocess.check_call(['ls', '-l'])
0
```

*New in version 2.5.*

**Warning:** See the warning for `call()`.

```python
subprocess.check_output(*popenargs, **kwargs)
```

Run command with arguments and return its output as a byte string.

If the exit code was non-zero it raises a `CalledProcessError`. The `CalledProcessError` object will have the return code in the `returncode` attribute and output in the `output` attribute.

The arguments are the same as for the `Popen` constructor. Example:

```python
>>> subprocess.check_output(['ls', '-l', '/dev/null'])
'crw-rw-rw- 1 root root 1, 3 Oct 18 2007 /dev/null
'
```

The stdout argument is not allowed as it is used internally. To capture standard error in the result, use `stderr=subprocess.STDOUT`:

```python
>>> subprocess.check_output(
...     ['/bin/sh', '-c', 'ls non_existent_file; exit 0'],
...     stderr=subprocess.STDOUT)
'ls: non_existent_file: No such file or directory
'
```

*New in version 2.7.*

### 17.1.1.2. Exceptions
Exceptions raised in the child process, before the new program has started to execute, will be re-raised in the parent. Additionally, the exception object will have one extra attribute called `child_traceback`, which is a string containing traceback information from the child's point of view.

The most common exception raised is `OSError`. This occurs, for example, when trying to execute a non-existent file. Applications should prepare for `OSError` exceptions.

A `ValueError` will be raised if `Popen` is called with invalid arguments.

`check_call()` will raise `CalledProcessError`, if the called process returns a non-zero return code.

### 17.1.1.3. Security

Unlike some other popen functions, this implementation will never call `/bin/sh` implicitly. This means that all characters, including shell metacharacters, can safely be passed to child processes.
17.1.2. Popen Objects

Instances of the `Popen` class have the following methods:

**Popen. `poll()`**
Check if child process has terminated. Set and return `returncode` attribute.

**Popen. `wait()`**
Wait for child process to terminate. Set and return `returncode` attribute.

**Warning:** This will deadlock when using `stdout=PIPE` and/or `stderr=PIPE` and the child process generates enough output to a pipe such that it blocks waiting for the OS pipe buffer to accept more data. Use `communicate()` to avoid that.

**Popen. `communicate(input=None)`**
Interact with process: Send data to stdin. Read data from stdout and stderr, until end-of-file is reached. Wait for process to terminate. The optional `input` argument should be a string to be sent to the child process, or `None`, if no data should be sent to the child.

`communicate()` returns a tuple `(stdoutdata, stderrdata)`.

Note that if you want to send data to the process’s stdin, you need to create the Popen object with `stdin=PIPE`. Similarly, to get anything other than `None` in the result tuple, you need to give `stdout=PIPE` and/or `stderr=PIPE` too.

**Note:** The data read is buffered in memory, so do not use this
method if the data size is large or unlimited.

Popen. \texttt{send\_signal}\texttt{(signal)}

Sends the signal \texttt{signal} to the child.

\begin{quote}
\textbf{Note:} On Windows, SIGTERM is an alias for \texttt{terminate()}. \\
CTRL\_C\_EVENT and CTRL\_BREAK\_EVENT can be sent to processes started with a \texttt{creationflags} parameter which includes \texttt{CREATE\_NEW\_PROCESS\_GROUP}.
\end{quote}

\textit{New in version 2.6.}

Popen. \texttt{terminate()}

Stop the child. On Posix OSs the method sends SIGTERM to the child. On Windows the Win32 API function \texttt{TerminateProcess()} is called to stop the child.

\textit{New in version 2.6.}

Popen. \texttt{kill()}

Kills the child. On Posix OSs the function sends SIGKILL to the child. On Windows \texttt{kill()} is an alias for \texttt{terminate()}.

\textit{New in version 2.6.}

The following attributes are also available:

\begin{quote}
\textbf{Warning:} Use \texttt{communicate()} rather than \texttt{.stdin.write}, \texttt{.stdout.read} or \texttt{.stderr.read} to avoid deadlocks due to any of the other OS pipe buffers filling up and blocking the child process.
\end{quote}

Popen. \texttt{stdin}

If the \texttt{stdin} argument was \texttt{PIPE}, this attribute is a file object that provides input to the child process. Otherwise, it is \texttt{None}. 
Popen. **stdout**
If the `stdout` argument was **PIPE**, this attribute is a file object that provides output from the child process. Otherwise, it is **None**.

Popen. **stderr**
If the `stderr` argument was **PIPE**, this attribute is a file object that provides error output from the child process. Otherwise, it is **None**.

Popen. **pid**
The process ID of the child process.

Note that if you set the `shell` argument to **True**, this is the process ID of the spawned shell.

Popen. **returncode**
The child return code, set by `poll()` and `wait()` (and indirectly by `communicate()`). A **None** value indicates that the process hasn’t terminated yet.

A negative value `-N` indicates that the child was terminated by signal `N` (Unix only).
17.1.3. Replacing Older Functions with the subprocess Module

In this section, “a == b” means that b can be used as a replacement for a.

**Note:** All functions in this section fail (more or less) silently if the executed program cannot be found; this module raises an OSError exception.

In the following examples, we assume that the subprocess module is imported with “from subprocess import *”.

### 17.1.3.1. Replacing /bin/sh shell backquote

```python
output=`mycmd myarg`
==> output = Popen(['mycmd', 'myarg'], stdout=PIPE).communicate()[0]
```

### 17.1.3.2. Replacing shell pipeline

```python
output=`dmesg | grep hda`
==> p1 = Popen(['dmesg'], stdout=PIPE)
p2 = Popen(['grep', 'hda'], stdin=p1.stdout, stdout=PIPE)
output = p2.communicate()[0]
```

### 17.1.3.3. Replacing os.system()

```python
sts = os.system('mycmd " myarg")
==> p = Popen('mycmd " myarg", shell=True)
sts = os.waitpid(p.pid, 0)[1]
```
Notes:

- Calling the program through the shell is usually not required.
- It’s easier to look at the returncode attribute than the exit status.

A more realistic example would look like this:

```python
try:
    retcode = call("mycmd" + " myarg", shell=True)
    if retcode < 0:
        print >>sys.stderr, "Child was terminated by signal", -
    else:
        print >>sys.stderr, "Child returned", retcode
except OSError, e:
    print >>sys.stderr, "Execution failed:", e
```

### 17.1.3.4. Replacing the `os.spawn` family

**P_NOWAIT example:**

```python
pid = os.spawnlp(os.P_NOWAIT, "/bin/mycmd", "mycmd", "myarg")
==> pid = Popen(["/bin/mycmd", "myarg"]).pid
```

**P_WAIT example:**

```python
retcode = os.spawnlp(os.P_WAIT, "/bin/mycmd", "mycmd", "myarg")
==> retcode = call(["/bin/mycmd", "myarg"])
```

**Vector example:**

```python
os.spawnvp(os.P_NOWAIT, path, args)
==> Popen([path] + args[1:])
```

**Environment example:**
17.1.3.5. Replacing `os.popen()`, `os.popen2()`, `os.popen3()`

```python
pipe = os.popen("cmd", 'r', bufsize)
=>
pipe = Popen("cmd", shell=True, bufsize=bufsize, stdout=PIPE).stdout
```

```python
pipe = os.popen("cmd", 'w', bufsize)
=>
pipe = Popen("cmd", shell=True, bufsize=bufsize, stdin=PIPE).stdin
```

```python
(child_stdin, child_stdout) = os.popen2("cmd", mode, bufsize)
=>
p = Popen("cmd", shell=True, bufsize=bufsize,
    stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdin, child_stdout) = (p.stdin, p.stdout)
```

```python
(child_stdin, child_stdout, child_stderr) = os.popen3("cmd", mode, bufsize)
=>
p = Popen("cmd", shell=True, bufsize=bufsize,
    stdin=PIPE, stdout=PIPE, stderr=PIPE, close_fds=True)
(child_stdin, child_stdout, child_stderr) = (p.stdin, p.stdout, p.stderr)
```

```python
(child_stdin, child_stdout_and_stderr) = os.popen4("cmd", mode, bufsize)
=>
p = Popen("cmd", shell=True, bufsize=bufsize,
    stdin=PIPE, stdout=PIPE, stderr=STDOUT, close_fds=True)
(child_stdin, child_stdout_and_stderr) = (p.stdin, p.stdout)
```

On Unix, `os.popen2`, `os.popen3` and `os.popen4` also accept a
sequence as the command to execute, in which case arguments will be passed directly to the program without shell intervention. This usage can be replaced as follows:

```python
(child_stdin, child_stdout) = os.popen2( ["/bin/ls", "-l"], mode = bufsize )
p = Popen( ["/bin/ls", "-l"], bufsize = bufsize, stdin = PIPE, stdout = PIPE )
(child_stdin, child_stdout) = (p.stdin, p.stdout)
```

Return code handling translates as follows:

```python
pipe = os.popen("cmd", 'w')
...
rc = pipe.close()
if rc is not None and rc % 256:
    print "There were some errors"
=>
process = Popen("cmd", 'w', shell=True, stdin=PIPE)
...
process.stdin.close()
if process.wait() != 0:
    print "There were some errors"
```

**17.1.3.6. Replacing functions from the popen2 module**

```python
(child_stdout, child_stdin) = popen2.popen2("somestring", bufsize)
=>
p = Popen( ["somestring"], shell=True, bufsize=bufsize, stdin=PIPE, stdout=PIPE, close_fds=True )
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

On Unix, popen2 also accepts a sequence as the command to execute, in which case arguments will be passed directly to the program without shell intervention. This usage can be replaced as follows:
(child_stdout, child_stdin) = popen2.popen2(\['mycmd', 'myarg'\], mode)

p = Popen(['mycmd', 'myarg'], bufsize=bufsize,
           stdin=PIPE, stdout=PIPE, close_fds=True)

(child_stdout, child_stdin) = (p.stdout, p.stdin)

popen2.Popen3 and popen2.Popen4 basically work as subprocess.Popen, except that:

- **Popen** raises an exception if the execution fails.
- the **capturestderr** argument is replaced with the **stderr** argument.
- **stdin=PIPE** and **stdout=PIPE** must be specified.
- popen2 closes all file descriptors by default, but you have to specify close_fds=True with **Popen**.
17.2. socket — Low-level networking interface

This module provides access to the BSD socket interface. It is available on all modern Unix systems, Windows, Mac OS X, BeOS, OS/2, and probably additional platforms.

**Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs.

For an introduction to socket programming (in C), see the following papers: An Introductory 4.3BSD Interprocess Communication Tutorial, by Stuart Sechrest and An Advanced 4.3BSD Interprocess Communication Tutorial, by Samuel J. Leffler et al, both in the UNIX Programmer's Manual, Supplementary Documents 1 (sections PS1:7 and PS1:8). The platform-specific reference material for the various socket-related system calls are also a valuable source of information on the details of socket semantics. For Unix, refer to the manual pages; for Windows, see the WinSock (or Winsock 2) specification. For IPv6-ready APIs, readers may want to refer to RFC 3493 titled Basic Socket Interface Extensions for IPv6.

The Python interface is a straightforward transliteration of the Unix system call and library interface for sockets to Python's object-oriented style: the `socket()` function returns a `socket object` whose methods implement the various socket system calls. Parameter types are somewhat higher-level than in the C interface: as with `read()` and `write()` operations on Python files, buffer allocation on receive operations is automatic, and buffer length is implicit on send operations.

Socket addresses are represented as follows: A single string is used
for the `AF_UNIX` address family. A pair `(host, port)` is used for the 
`AF_INET` address family, where `host` is a string representing either a 
hostname in Internet domain notation like `'daring.cwi.nl'` or an 
IPv4 address like `'100.50.200.5'`, and `port` is an integral port 
number. For `AF_INET6` address family, a four-tuple `(host, port, 
flowinfo, scopeid)` is used, where `flowinfo` and `scopeid` represents 
`sin6_flowinfo` and `sin6_scope_id` member in `struct sockaddr_in6` in 
C. For `socket` module methods, `flowinfo` and `scopeid` can be omitted 
just for backward compatibility. Note, however, omission of `scopeid` 
can cause problems in manipulating scoped IPv6 addresses. Other 
address families are currently not supported. The address format 
required by a particular socket object is automatically selected based 
on the address family specified when the socket object was created.

For IPv4 addresses, two special forms are accepted instead of a 
host address: the empty string represents `INADDR_ANY`, and the string 
`'<broadcast>'` represents `INADDR_BROADCAST`. The behavior is not 
available for IPv6 for backward compatibility, therefore, you may 
want to avoid these if you intend to support IPv6 with your Python 
programs.

If you use a hostname in the `host` portion of IPv4/v6 socket address, 
the program may show a nondeterministic behavior, as Python uses 
the first address returned from the DNS resolution. The socket 
address will be resolved differently into an actual IPv4/v6 address, 
depending on the results from DNS resolution and/or the host 
configuration. For deterministic behavior use a numeric address in 
`host` portion.

*New in version 2.5:* AF_NETLINK sockets are represented as pairs 
pid, groups.

*New in version 2.6:* Linux-only support for TIPC is also available 
using the `AF_TIPC` address family. TIPC is an open, non-IP based
networked protocol designed for use in clustered computer environments. Addresses are represented by a tuple, and the fields depend on the address type. The general tuple form is \((\text{addr
type}, \, \text{v1}, \, \text{v2}, \, \text{v3} \, [\, \text{scope}])\), where:

- \textit{addr
type} is one of TIPC_ADDR_NAMESEQ, TIPC_ADDR_NAME, or TIPC_ADDR_ID.

- \textit{scope} is one of TIPC_ZONE_SCOPE, TIPC_CLUSTER_SCOPE, and TIPC_NODE_SCOPE.

- If \textit{addr
type} is TIPC_ADDR_NAME, then \textit{v1} is the server type, \textit{v2} is the port identifier, and \textit{v3} should be 0.

  If \textit{addr
type} is TIPC_ADDR_NAMESEQ, then \textit{v1} is the server type, \textit{v2} is the lower port number, and \textit{v3} is the upper port number.

  If \textit{addr
type} is TIPC_ADDR_ID, then \textit{v1} is the node, \textit{v2} is the reference, and \textit{v3} should be set to 0.

All errors raise exceptions. The normal exceptions for invalid argument types and out-of-memory conditions can be raised; errors related to socket or address semantics raise the error \texttt{socket.error}.

Non-blocking mode is supported through \texttt{setblocking()}. A generalization of this based on timeouts is supported through \texttt{settimeout()}.

The module \texttt{socket} exports the following constants and functions:

\texttt{exception socket.error}

This exception is raised for socket-related errors. The accompanying value is either a string telling what went wrong or a pair \((\text{errno, string})\) representing an error returned by a
system call, similar to the value accompanying \texttt{os.error}. See the module \texttt{errno}, which contains names for the error codes defined by the underlying operating system.

\textit{Changed in version 2.6:} \texttt{socket.error} is now a child class of \texttt{IOError}.

\texttt{exception} \texttt{socket.herror}

This exception is raised for address-related errors, i.e. for functions that use \texttt{h_errno} in the C API, including \texttt{gethostbyname_ex()} and \texttt{gethostbyaddr()}.

The accompanying value is a pair \((h\_errno, \text{string})\) representing an error returned by a library call. \texttt{string} represents the description of \texttt{h_errno}, as returned by the \texttt{hstrerror()} C function.

\texttt{exception} \texttt{socket.gaierror}

This exception is raised for address-related errors, for \texttt{getaddrinfo()} and \texttt{getnameinfo()}. The accompanying value is a pair \((\text{error, string})\) representing an error returned by a library call. \texttt{string} represents the description of \texttt{error}, as returned by the \texttt{gai_strerror()} C function. The \texttt{error} value will match one of the \texttt{EAI_*} constants defined in this module.

\texttt{exception} \texttt{socket.timeout}

This exception is raised when a timeout occurs on a socket which has had timeouts enabled via a prior call to \texttt{settimeout()}. The accompanying value is a string whose value is currently always “timed out”.

\textit{New in version 2.3.}

\texttt{socket.AF_UNIX}

\texttt{socket.AF_INET}
socket.AF_INET6

These constants represent the address (and protocol) families, used for the first argument to socket(). If the AF_UNIX constant is not defined then this protocol is unsupported.

socket.SOCK_STREAM
socket.SOCK_DGRAM
socket.SOCK_RAW
socket.SOCK_RDM
socket.SOCK_SEQPACKET

These constants represent the socket types, used for the second argument to socket(). (Only SOCK_STREAM and SOCK_DGRAM appear to be generally useful.)

SO_*
socket.SOMAXCONN
MSG_*
SO_*
IPPROTO_*
IPPORT_*
INADDR_*
IP_*
IPV6_*
EAI_*
AI_*
NI_*
TCP_*

Many constants of these forms, documented in the Unix documentation on sockets and/or the IP protocol, are also defined in the socket module. They are generally used in arguments to the setsockopt() and getsockopt() methods of socket objects. In most cases, only those symbols that are defined in the Unix header files are defined; for a few symbols, default values are provided.

SIO_*
RCVALL_*

Constants for Windows' WSAIoctl(). The constants are used as
arguments to the `ioctl()` method of socket objects.

*New in version 2.6.*

**TIPC_***

TIPC related constants, matching the ones exported by the C socket API. See the TIPC documentation for more information.

*New in version 2.6.*

socket. **has_ipv6**

This constant contains a boolean value which indicates if IPv6 is supported on this platform.

*New in version 2.3.*

socket. **create_connection**(*address*, *timeout*, *source_address*)

Convenience function. Connect to `address` (a 2-tuple `(host, port)`), and return the socket object. Passing the optional `timeout` parameter will set the timeout on the socket instance before attempting to connect. If no `timeout` is supplied, the global default timeout setting returned by `getdefaulttimeout()` is used.

If supplied, `source_address` must be a 2-tuple `(host, port)` for the socket to bind to as its source address before connecting. If host or port are " or 0 respectively the OS default behavior will be used.

*New in version 2.6.*

*Changed in version 2.7: source_address was added.*

socket. **getaddrinfo**(host, port, family=0, socktype=0, proto=0, flags=0)

Translate the `host/port` argument into a sequence of 5-tuples that
contain all the necessary arguments for creating a socket connected to that service. host is a domain name, a string representation of an IPv4/v6 address or None. port is a string service name such as 'http', a numeric port number or None. By passing None as the value of host and port, you can pass NULL to the underlying C API.

The family, socktype and proto arguments can be optionally specified in order to narrow the list of addresses returned. Passing zero as a value for each of these arguments selects the full range of results. The flags argument can be one or several of the AI_* constants, and will influence how results are computed and returned. For example, AI_NUMERICHOST will disable domain name resolution and will raise an error if host is a domain name.

The function returns a list of 5-tuples with the following structure:

(family, socktype, proto, canonname, sockaddr)

In these tuples, family, socktype, proto are all integers and are meant to be passed to the socket() function. canonname will be a string representing the canonical name of the host if AI_CANONNAME is part of the flags argument; else canonname will be empty. sockaddr is a tuple describing a socket address, whose format depends on the returned family (a (address, port) 2-tuple for AF_INET, a (address, port, flow info, scope id) 4-tuple for AF_INET6), and is meant to be passed to the socket.connect() method.

The following example fetches address information for a hypothetical TCP connection to www.python.org on port 80 (results may differ on your system if IPv6 isn’t enabled):

```python
>>> socket.getaddrinfo("www.python.org", 80, 0, 0, socket.S0
```
New in version 2.2.

socket. `getfqdn([name])`

Return a fully qualified domain name for `name`. If `name` is omitted or empty, it is interpreted as the local host. To find the fully qualified name, the hostname returned by `gethostbyaddr()` is checked, followed by aliases for the host, if available. The first name which includes a period is selected. In case no fully qualified domain name is available, the hostname as returned by `gethostname()` is returned.

New in version 2.0.

socket. `gethostbyname(hostname)`

Translate a host name to IPv4 address format. The IPv4 address is returned as a string, such as `'100.50.200.5'`. If the host name is an IPv4 address itself it is returned unchanged. See `gethostbyname_ex()` for a more complete interface. `gethostbyname()` does not support IPv6 name resolution, and `getaddrinfo()` should be used instead for IPv4/v6 dual stack support.

socket. `gethostbyname_ex(hostname)`

Translate a host name to IPv4 address format, extended interface. Return a triple `(hostname, aliaslist, ipaddrlist)` where `hostname` is the primary host name responding to the given `ip_address`, `aliaslist` is a (possibly empty) list of alternative host names for the same address, and `ipaddrlist` is a list of IPv4 addresses for the same interface on the same host (often but not always a single address). `gethostbyname_ex()` does not support...
IPv6 name resolution, and \texttt{getaddrinfo()} should be used instead for IPv4/v6 dual stack support.

\texttt{socket.gethostname()}

Return a string containing the hostname of the machine where the Python interpreter is currently executing.

If you want to know the current machine's IP address, you may want to use \texttt{gethostbyname(gethostname())}. This operation assumes that there is a valid address-to-host mapping for the host, and the assumption does not always hold.

Note: \texttt{gethostname()} doesn't always return the fully qualified domain name; use \texttt{getfqdn()} (see above).

\texttt{socket.gethostbyaddr(ip_address)}

Return a triple \texttt{(hostname, aliaslist, ipaddrlist)} where \texttt{hostname} is the primary host name responding to the given \texttt{ip_address}, \texttt{aliaslist} is a (possibly empty) list of alternative host names for the same address, and \texttt{ipaddrlist} is a list of IPv4/v6 addresses for the same interface on the same host (most likely containing only a single address). To find the fully qualified domain name, use the function \texttt{getfqdn()}. \texttt{gethostbyaddr()} supports both IPv4 and IPv6.

\texttt{socket.getnameinfo(sockaddr, flags)}

Translate a socket address \texttt{sockaddr} into a 2-tuple \texttt{(host, port)}. Depending on the settings of \texttt{flags}, the result can contain a fully-qualified domain name or numeric address representation in \texttt{host}. Similarly, \texttt{port} can contain a string port name or a numeric port number.

\textit{New in version 2.2.}
socket. **getprotobynamel**(protocolname)
Translate an Internet protocol name (for example, 'icmp') to a constant suitable for passing as the (optional) third argument to the socket() function. This is usually only needed for sockets opened in “raw” mode (SOCK_RAW); for the normal socket modes, the correct protocol is chosen automatically if the protocol is omitted or zero.

socket. **getservbyname**(servicename[, protocolname])
Translate an Internet service name and protocol name to a port number for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

socket. **getservbyport**(port[, protocolname])
Translate an Internet port number and protocol name to a service name for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

socket. **socket**(family[, type[, proto]])
Create a new socket using the given address family, socket type and protocol number. The address family should be AF_INET (the default), AF_INET6 or AF_UNIX. The socket type should be SOCK_STREAM (the default), SOCK_DGRAM or perhaps one of the other sock_ constants. The protocol number is usually zero and may be omitted in that case.

socket. **socketpair**(family[, type[, proto]])
Build a pair of connected socket objects using the given address family, socket type, and protocol number. Address family, socket type, and protocol number are as for the socket() function above. The default family is AF_UNIX if defined on the platform; otherwise, the default is AF_INET. Availability: Unix.
New in version 2.4.

socket.\texttt{fromfd}(fd, family, type[, proto])
Duplicate the file descriptor \texttt{fd} (an integer as returned by a file object’s \texttt{fileno()} method) and build a socket object from the result. Address family, socket type and protocol number are as for the \texttt{socket()} function above. The file descriptor should refer to a socket, but this is not checked — subsequent operations on the object may fail if the file descriptor is invalid. This function is rarely needed, but can be used to get or set socket options on a socket passed to a program as standard input or output (such as a server started by the Unix inet daemon). The socket is assumed to be in blocking mode. Availability: Unix.

socket.\texttt{n�폴}(x)
Convert 32-bit positive integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

socket.\texttt{n�폴s}(x)
Convert 16-bit positive integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

socket.\texttt{h똑n}(x)
Convert 32-bit positive integers from host to network byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

socket.\texttt{h똑s}(x)
Convert 16-bit positive integers from host to network byte order.
On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

socket.inet_aton(ip_string)
Convert an IPv4 address from dotted-quad string format (for example, ‘123.45.67.89’) to 32-bit packed binary format, as a string four characters in length. This is useful when conversing with a program that uses the standard C library and needs objects of type struct in_addr, which is the C type for the 32-bit packed binary this function returns.

inet_aton() also accepts strings with less than three dots; see the Unix manual page inet(3) for details.

If the IPv4 address string passed to this function is invalid, socket.error will be raised. Note that exactly what is valid depends on the underlying C implementation of inet_aton().

inet_aton() does not support IPv6, and inet_pton() should be used instead for IPv4/v6 dual stack support.

socket.inet_ntoa(packed_ip)
Convert a 32-bit packed IPv4 address (a string four characters in length) to its standard dotted-quad string representation (for example, ‘123.45.67.89’). This is useful when conversing with a program that uses the standard C library and needs objects of type struct in_addr, which is the C type for the 32-bit packed binary data this function takes as an argument.

If the string passed to this function is not exactly 4 bytes in length, socket.error will be raised. inet_ntoa() does not support IPv6, and inet_ntop() should be used instead for IPv4/v6 dual stack support.
socket.**inet_pton**(address_family, ip_string)

Convert an IP address from its family-specific string format to a packed, binary format. **inet_pton()** is useful when a library or network protocol calls for an object of type `struct in_addr` (similar to `inet_aton()`) or `struct in6_addr`.

Supported values for `address_family` are currently **AF_INET** and **AF_INET6**. If the IP address string `ip_string` is invalid, `socket.error` will be raised. Note that exactly what is valid depends on both the value of `address_family` and the underlying implementation of `inet_pton()`.

Availability: Unix (maybe not all platforms).

*New in version 2.3.*

socket.**inet_ntop**(address_family, packed_ip)

Convert a packed IP address (a string of some number of characters) to its standard, family-specific string representation (for example, '7.10.0.5' or '5aef:2b::8') **inet_ntop()** is useful when a library or network protocol returns an object of type `struct in_addr` (similar to `inet_ntoa()`) or `struct in6_addr`.

Supported values for `address_family` are currently **AF_INET** and **AF_INET6**. If the string `packed_ip` is not the correct length for the specified address family, **ValueError** will be raised. A `socket.error` is raised for errors from the call to **inet_ntop()**.

Availability: Unix (maybe not all platforms).

*New in version 2.3.*

socket.**getdefaulttimeout()**

Return the default timeout in floating seconds for new socket
objects. A value of \texttt{None} indicates that new socket objects have no timeout. When the socket module is first imported, the default is \texttt{None}.

\textit{New in version 2.3.}

\texttt{socket.setdefaulttimeout(\textit{timeout})}

Set the default timeout in floating seconds for new socket objects. A value of \texttt{None} indicates that new socket objects have no timeout. When the socket module is first imported, the default is \texttt{None}.

\textit{New in version 2.3.}

\texttt{socket.SocketType}

This is a Python type object that represents the socket object type. It is the same as \texttt{type(socket(...))}.

\textbf{See also:}

\textbf{Module \texttt{SocketServer}}

Classes that simplify writing network servers.
17.2.1. Socket Objects

Socket objects have the following methods. Except for `makefile()` these correspond to Unix system calls applicable to sockets.

```python
socket.accept()
```
Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair `(conn, address)` where `conn` is a new socket object usable to send and receive data on the connection, and `address` is the address bound to the socket on the other end of the connection.

```python
socket.bind(address)
```
Bind the socket to `address`. The socket must not already be bound. (The format of `address` depends on the address family — see above.)

**Note:** This method has historically accepted a pair of parameters for `AF_INET` addresses instead of only a tuple. This was never intentional and is no longer available in Python 2.0 and later.

```python
socket.close()
```
Close the socket. All future operations on the socket object will fail. The remote end will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

```python
socket.connect(address)
```
Connect to a remote socket at `address`. (The format of `address` depends on the address family — see above.)
socket.connect_ex(address)
Like connect(address), but return an error indicator instead of raising an exception for errors returned by the C-level connect() call (other problems, such as “host not found,” can still raise exceptions). The error indicator is 0 if the operation succeeded, otherwise the value of the errno variable. This is useful to support, for example, asynchronous connects.

socket.fileno()
Return the socket's file descriptor (a small integer). This is useful with select.select().

Under Windows the small integer returned by this method cannot be used where a file descriptor can be used (such as os.fdopen()). Unix does not have this limitation.

socket.getpeername()
Return the remote address to which the socket is connected. This is useful to find out the port number of a remote IPv4/v6 socket, for instance. (The format of the address returned depends on the address family — see above.) On some systems this function is not supported.
socket. **getsockname()**

Return the socket's own address. This is useful to find out the port number of an IPv4/v6 socket, for instance. (The format of the address returned depends on the address family — see above.)

socket. **getsockopt(level, optname[, buflen])**

Return the value of the given socket option (see the Unix man page `getsockopt(2)`). The needed symbolic constants (so_* etc.) are defined in this module. If buflen is absent, an integer option is assumed and its integer value is returned by the function. If buflen is present, it specifies the maximum length of the buffer used to receive the option in, and this buffer is returned as a string. It is up to the caller to decode the contents of the buffer (see the optional built-in module `struct` for a way to decode C structures encoded as strings).

socket. **ioctl(control, option)**

**Platform:** Windows

The ioctl() method is a limited interface to the WSAIoctl system interface. Please refer to the Win32 documentation for more information.

On other platforms, the generic `fcntl.fcntl()` and `fcntl.ioctl()` functions may be used; they accept a socket object as their first argument.

*New in version 2.6.*

socket. **listen(backlog)**

Listen for connections made to the socket. The backlog argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).
socket.makefile(\([mode[, bufsize]]\))

Return a file object associated with the socket. (File objects are described in File Objects.) The file object references a dup() ped version of the socket file descriptor, so the file object and socket object may be closed or garbage-collected independently. The socket must be in blocking mode (it can not have a timeout). The optional mode and bufsize arguments are interpreted the same way as by the built-in file() function.

socket.recv(bufsize[, flags])

Receive data from the socket. The return value is a string representing the data received. The maximum amount of data to be received at once is specified by bufsize. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero.

Note: For best match with hardware and network realities, the value of bufsize should be a relatively small power of 2, for example, 4096.

socket.recvfrom(bufsize[, flags])

Receive data from the socket. The return value is a pair (string, address) where string is a string representing the data received and address is the address of the socket sending the data. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero. (The format of address depends on the address family — see above.)

socket.recvfrom_into(buffer[, nbytes[, flags]])

Receive data from the socket, writing it into buffer instead of creating a new string. The return value is a pair (nbytes, address) where nbytes is the number of bytes received and
address is the address of the socket sending the data. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero. (The format of address depends on the address family — see above.)

*New in version 2.5.*

socket. **recv_into**(buffer[, nbytes[, flags]])
Receive up to nbytes bytes from the socket, storing the data into a buffer rather than creating a new string. If nbytes is not specified (or 0), receive up to the size available in the given buffer. Returns the number of bytes received. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero.

*New in version 2.5.*

socket. **send**(string[, flags])
Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for recv() above. Returns the number of bytes sent. Applications are responsible for checking that all data has been sent; if only some of the data was transmitted, the application needs to attempt delivery of the remaining data.

socket. **sendall**(string[, flags])
Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for recv() above. Unlike send(), this method continues to send data from string until either all data has been sent or an error occurs. **None** is returned on success. On error, an exception is raised, and there is no way to determine how much data, if any, was successfully sent.
socket. **sendto**(string[, flags], address)

Send data to the socket. The socket should not be connected to a remote socket, since the destination socket is specified by `address`. The optional `flags` argument has the same meaning as for `recv()` above. Return the number of bytes sent. (The format of `address` depends on the address family — see above.)

socket. **setblocking**(flag)

Set blocking or non-blocking mode of the socket: if `flag` is 0, the socket is set to non-blocking, else to blocking mode. Initially all sockets are in blocking mode. In non-blocking mode, if a `recv()` call doesn’t find any data, or if a `send()` call can’t immediately dispose of the data, a `error` exception is raised; in blocking mode, the calls block until they can proceed. `s.setblocking(0)` is equivalent to `s.settimeout(0.0);` `s.setblocking(1)` is equivalent to `s.settimeout(None).`

socket. **settimeout**(value)

Set a timeout on blocking socket operations. The `value` argument can be a nonnegative float expressing seconds, or `None`. If a float is given, subsequent socket operations will raise a `timeout` exception if the timeout period `value` has elapsed before the operation has completed. Setting a timeout of `None` disables timeouts on socket operations. `s.settimeout(0.0)` is equivalent to `s.setblocking(0);` `s.settimeout(None)` is equivalent to `s.setblocking(1).

*New in version 2.3.*

socket. **gettimeout**()

Return the timeout in floating seconds associated with socket operations, or `None` if no timeout is set. This reflects the last call
to \texttt{setblocking()} or \texttt{settimeout()}.

\textit{New in version 2.3.}

Some notes on socket blocking and timeouts: A socket object can be in one of three modes: blocking, non-blocking, or timeout. Sockets are always created in blocking mode. In blocking mode, operations block until complete or the system returns an error (such as connection timed out). In non-blocking mode, operations fail (with an error that is unfortunately system-dependent) if they cannot be completed immediately. In timeout mode, operations fail if they cannot be completed within the timeout specified for the socket or if the system returns an error. The \texttt{setblocking()} method is simply a shorthand for certain \texttt{settimeout()} calls.

Timeout mode internally sets the socket in non-blocking mode. The blocking and timeout modes are shared between file descriptors and socket objects that refer to the same network endpoint. A consequence of this is that file objects returned by the \texttt{makefile()} method must only be used when the socket is in blocking mode; in timeout or non-blocking mode file operations that cannot be completed immediately will fail.

Note that the \texttt{connect()} operation is subject to the timeout setting, and in general it is recommended to call \texttt{settimeout()} before calling \texttt{connect()} or pass a timeout parameter to \texttt{create_connection()}. The system network stack may return a connection timeout error of its own regardless of any Python socket timeout setting.

\texttt{socket.setsockopt(level, optname, value)}

Set the value of the given socket option (see the Unix manual page \texttt{setsockopt(2)}). The needed symbolic constants are defined in the \texttt{socket} module (\texttt{SO_*} etc.). The value can be an integer or a string representing a buffer. In the latter case it is up to the
caller to ensure that the string contains the proper bits (see the optional built-in module `struct` for a way to encode C structures as strings).

socket. `shutdown` *(how)*

Shut down one or both halves of the connection. If `how` is `SHUT_RD`, further receives are disallowed. If `how` is `SHUT_WR`, further sends are disallowed. If `how` is `SHUT_RDWR`, further sends and receives are disallowed.

Note that there are no methods `read()` or `write()`; use `recv()` and `send()` without `flags` argument instead.

Socket objects also have these (read-only) attributes that correspond to the values given to the `socket` constructor.

socket. `family`

The socket family.

*New in version 2.5.*

socket. `type`

The socket type.

*New in version 2.5.*

socket. `proto`

The socket protocol.

*New in version 2.5.*
17.2.2. Example

Here are four minimal example programs using the TCP/IP protocol: a server that echoes all data that it receives back (servicing only one client), and a client using it. Note that a server must perform the sequence `socket()`, `bind()`, `listen()`, `accept()` (possibly repeating the `accept()` to service more than one client), while a client only needs the sequence `socket()`, `connect()`. Also note that the server does not `send()`/`recv()` on the socket it is listening on but on the new socket returned by `accept()`.

The first two examples support IPv4 only.

```
# Echo server program
import socket

HOST = ''  # Symbolic name meaning all available addresses
PORT = 50007  # Arbitrary non-privileged port
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.bind((HOST, PORT))
s.listen(1)
conn, addr = s.accept()
print 'Connected by', addr
while 1:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()
```

```
# Echo client program
import socket

HOST = 'daring.cwi.nl'  # The remote host
PORT = 50007  # The same port as used by the server
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.connect((HOST, PORT))
s.send('Hello, world')
data = s.recv(1024)
s.close()
```
The next two examples are identical to the above two, but support both IPv4 and IPv6. The server side will listen to the first address family available (it should listen to both instead). On most of IPv6-ready systems, IPv6 will take precedence and the server may not accept IPv4 traffic. The client side will try to connect to the all addresses returned as a result of the name resolution, and sends traffic to the first one connected successfully.

```python
# Echo server program
import socket
import sys

HOST = None  # Symbolic name meaning all available
PORT = 50007  # Arbitrary non-privileged port
s = None
for res in socket.getaddrinfo(HOST, PORT, socket.AF_UNSPEC, socket.SOCK_STREAM, 0, socket.AI_PASSIVE):
    af, socktype, proto, canonname, sa = res
    try:
        s = socket.socket(af, socktype, proto)
    except socket.error, msg:
        s = None
        continue
    try:
        s.bind(sa)
        s.listen(1)
    except socket.error, msg:
        s.close()
        s = None
        continue
    break
if s is None:
    print 'could not open socket'
    sys.exit(1)
conn, addr = s.accept()
print 'Connected by', addr
while 1:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()
```
The last example shows how to write a very simple network sniffer with raw sockets on Windows. The example requires administrator privileges to modify the interface:

```python
import socket

# the public network interface
HOST = socket.gethostbyname(socket.gethostname())

# create a raw socket and bind it to the public interface
s = socket.socket(socket.AF_INET, socket.SOCK_RAW, socket.IPPROTO_IP)
s.bind((HOST, 0))
```
# Include IP headers
s.setsockopt(socket.IPPROTO_IP, socket.IP_HDRINCL, 1)

# receive all packages
s.ioctl(socket.SIO_RCVALL, socket.RCVALL_ON)

# receive a package
print s.recvfrom(65565)

# disabled promiscuous mode
s.ioctl(socket.SIO_RCVALL, socket.RCVALL_OFF)
17.3. ssl — SSL wrapper for socket objects

New in version 2.6.

This module provides access to Transport Layer Security (often known as “Secure Sockets Layer”) encryption and peer authentication facilities for network sockets, both client-side and server-side. This module uses the OpenSSL library. It is available on all modern Unix systems, Windows, Mac OS X, and probably additional platforms, as long as OpenSSL is installed on that platform.

**Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs. The installed version of OpenSSL may also cause variations in behavior.

This section documents the objects and functions in the `ssl` module; for more general information about TLS, SSL, and certificates, the reader is referred to the documents in the “See Also” section at the bottom.

This module provides a class, `ssl.SSLSocket`, which is derived from the `socket.socket` type, and provides a socket-like wrapper that also encrypts and decrypts the data going over the socket with SSL. It supports additional `read()` and `write()` methods, along with a method, `getpeercert()`, to retrieve the certificate of the other side of the connection, and a method, `cipher()`, to retrieve the cipher being used for the secure connection.
17.3.1. Functions, Constants, and Exceptions

exception ssl.SSLError

Raised to signal an error from the underlying SSL implementation. This signifies some problem in the higher-level encryption and authentication layer that’s superimposed on the underlying network connection. This error is a subtype of socket.error, which in turn is a subtype of IOError.

ssl.wrap_socket(sock, keyfile=None, certfile=None, server_side=False, cert_reqs=CERT_NONE, ssl_version={see docs}, ca_certs=None, do_handshake_on_connect=True, suppress_ragged_eofs=True, ciphers=None)

Takes an instance of socket.socket, and returns an instance of ssl.SSLSocket, a subtype of socket.socket, which wraps the underlying socket in an SSL context. For client-side sockets, the context construction is lazy; if the underlying socket isn’t connected yet, the context construction will be performed after connect() is called on the socket. For server-side sockets, if the socket has no remote peer, it is assumed to be a listening socket, and the server-side SSL wrapping is automatically performed on client connections accepted via the accept() method. wrap_socket() may raise SSLError.

The keyfile and certfile parameters specify optional files which contain a certificate to be used to identify the local side of the connection. See the discussion of Certificates for more information on how the certificate is stored in the certfile.

Often the private key is stored in the same file as the certificate; in this case, only the certfile parameter need be passed. If the
private key is stored in a separate file, both parameters must be used. If the private key is stored in the `certfile`, it should come before the first certificate in the certificate chain:

```
-----BEGIN RSA PRIVATE KEY-----
...
-----END RSA PRIVATE KEY-----
-----BEGIN CERTIFICATE-----
...
-----END CERTIFICATE-----
```

The parameter `server_side` is a boolean which identifies whether server-side or client-side behavior is desired from this socket.

The parameter `cert_reqs` specifies whether a certificate is required from the other side of the connection, and whether it will be validated if provided. It must be one of the three values `CERT_NONE` (certificates ignored), `CERT_OPTIONAL` (not required, but validated if provided), or `CERT_REQUIRED` (required and validated). If the value of this parameter is not `CERT_NONE`, then the `ca_certs` parameter must point to a file of CA certificates.

The `ca_certs` file contains a set of concatenated “certification authority” certificates, which are used to validate certificates passed from the other end of the connection. See the discussion of Certificates for more information about how to arrange the certificates in this file.

The parameter `ssl_version` specifies which version of the SSL protocol to use. Typically, the server chooses a particular protocol version, and the client must adapt to the server’s choice. Most of the versions are not interoperable with the other versions. If not specified, for client-side operation, the default SSL version is SSLv3; for server-side operation, SSLv23. These version selections provide the most compatibility with other versions.
Here's a table showing which versions in a client (down the side) can connect to which versions in a server (along the top):

<table>
<thead>
<tr>
<th>client / server</th>
<th>SSLv2</th>
<th>SSLv3</th>
<th>SSLv23</th>
<th>TLSv1</th>
</tr>
</thead>
<tbody>
<tr>
<td>SSLv2</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>SSLv3</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>SSLv23</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>TLSv1</td>
<td>no</td>
<td>no</td>
<td>yes</td>
<td>yes</td>
</tr>
</tbody>
</table>

**Note:** Which connections succeed will vary depending on the version of OpenSSL. For instance, in some older versions of OpenSSL (such as 0.9.7I on OS X 10.4), an SSLv2 client could not connect to an SSLv23 server. Another example: beginning with OpenSSL 1.0.0, an SSLv23 client will not actually attempt SSLv2 connections unless you explicitly enable SSLv2 ciphers; for example, you might specify "ALL" or "SSLv2" as the ciphers parameter to enable them.

The `ciphers` parameter sets the available ciphers for this SSL object. It should be a string in the OpenSSL cipher list format.

The parameter `do_handshake_on_connect` specifies whether to do the SSL handshake automatically after doing a `socket.connect()`, or whether the application program will call it explicitly, by invoking the `SSLSocket.do_handshake()` method. Calling `SSLSocket.do_handshake()` explicitly gives the program control over the blocking behavior of the socket I/O involved in the handshake.

The parameter `suppress_ragged_eofs` specifies how the `SSLSocket.read()` method should signal unexpected EOF from the other end of the connection. If specified as `True` (the default), it returns a normal EOF in response to unexpected EOF errors raised from the underlying socket; if `False`, it will raise the
exceptions back to the caller.

_Changed in version 2.7:_ New optional argument _ciphers_.

**ssl.**\texttt{RAND\_status()}\hspace{1cm}

Returns True if the SSL pseudo-random number generator has been seeded with ‘enough’ randomness, and False otherwise. You can use \texttt{ssl.RAND\_egd()} and \texttt{ssl.RAND\_add()} to increase the randomness of the pseudo-random number generator.

**ssl.**\texttt{RAND\_egd(path)}\hspace{1cm}

If you are running an entropy-gathering daemon (EGD) somewhere, and \texttt{path} is the pathname of a socket connection open to it, this will read 256 bytes of randomness from the socket, and add it to the SSL pseudo-random number generator to increase the security of generated secret keys. This is typically only necessary on systems without better sources of randomness.

See \url{http://egd.sourceforge.net/} or \url{http://prngd.sourceforge.net/} for sources of entropy-gathering daemons.

**ssl.**\texttt{RAND\_add(bytes, entropy)}\hspace{1cm}

Mixes the given \texttt{bytes} into the SSL pseudo-random number generator. The parameter \texttt{entropy} (a float) is a lower bound on the entropy contained in string (so you can always use \texttt{0.0}). See \texttt{RFC 1750} for more information on sources of entropy.

**ssl.**\texttt{cert\_time\_to\_seconds(timestring)}\hspace{1cm}

Returns a floating-point value containing a normal seconds-after-the-epoch time value, given the time-string representing the “notBefore” or “notAfter” date from a certificate.

Here’s an example:
ssl.get_server_certificate(addr, ssl_version=PROTOCOL_SSLv3, ca_certs=None)
    Given the address addr of an SSL-protected server, as a (hostname, port-number) pair, fetches the server’s certificate, and returns it as a PEM-encoded string. If ssl_version is specified, uses that version of the SSL protocol to attempt to connect to the server. If ca_certs is specified, it should be a file containing a list of root certificates, the same format as used for the same parameter in wrap_socket(). The call will attempt to validate the server certificate against that set of root certificates, and will fail if the validation attempt fails.

ssl.DER_cert_to_PEM_cert(DER_cert_bytes)
    Given a certificate as a DER-encoded blob of bytes, returns a PEM-encoded string version of the same certificate.

ssl.PEM_cert_to_DER_cert(PEM_cert_string)
    Given a certificate as an ASCII PEM string, returns a DER-encoded sequence of bytes for that same certificate.

ssl.CERT_NONE
    Value to pass to the cert_reqs parameter to sslobject() when no certificates will be required or validated from the other side of the socket connection.

ssl.CERT_OPTIONAL
    Value to pass to the cert_reqs parameter to sslobject() when
no certificates will be required from the other side of the socket connection, but if they are provided, will be validated. Note that use of this setting requires a valid certificate validation file also be passed as a value of the `ca_certs` parameter.

**ssl.CERT_REQUIRED**

Value to pass to the `cert_reqs` parameter to `sslobject()` when certificates will be required from the other side of the socket connection. Note that use of this setting requires a valid certificate validation file also be passed as a value of the `ca_certs` parameter.

**ssl.PROTOCOL_SSLv2**

Selects SSL version 2 as the channel encryption protocol.

**Warning:** SSL version 2 is insecure. Its use is highly discouraged.

**ssl.PROTOCOL_SSLv23**

Selects SSL version 2 or 3 as the channel encryption protocol. This is a setting to use with servers for maximum compatibility with the other end of an SSL connection, but it may cause the specific ciphers chosen for the encryption to be of fairly low quality.

**ssl.PROTOCOL_SSLv3**

Selects SSL version 3 as the channel encryption protocol. For clients, this is the maximally compatible SSL variant.

**ssl.PROTOCOL_TLSv1**

Selects TLS version 1 as the channel encryption protocol. This is the most modern version, and probably the best choice for maximum protection, if both sides can speak it.

**ssl.OPENSSL_VERSION**
The version string of the OpenSSL library loaded by the interpreter:

```python
>>> ssl.OPENSSL_VERSION
'OpenSSL 0.9.8k 25 Mar 2009'
```

*New in version 2.7.*

**ssl. OPENSSL_VERSION_INFO**

A tuple of five integers representing version information about the OpenSSL library:

```python
>>> ssl.OPENSSL_VERSION_INFO
(0, 9, 8, 11, 15)
```

*New in version 2.7.*

**ssl. OPENSSL_VERSION_NUMBER**

The raw version number of the OpenSSL library, as a single integer:

```python
>>> ssl.OPENSSL_VERSION_NUMBER
9470143L
>>> hex(ssl.OPENSSL_VERSION_NUMBER)
'0x9080bfL'
```

*New in version 2.7.*
17.3.2. SSLSocket Objects

SSLSocket. **read**([*nbytes=1024*])

Reads up to *nbytes* bytes from the SSL-encrypted channel and returns them.

SSLSocket. **write**(data)

Writes the data to the other side of the connection, using the SSL channel to encrypt. Returns the number of bytes written.

SSLSocket. **getpeercert**(binary_form=False)

If there is no certificate for the peer on the other end of the connection, returns None.

If the parameter *binary_form* is False, and a certificate was received from the peer, this method returns a dict instance. If the certificate was not validated, the dict is empty. If the certificate was validated, it returns a dict with the keys *subject* (the principal for which the certificate was issued), and *notAfter* (the time after which the certificate should not be trusted). The certificate was already validated, so the *notBefore* and *issuer* fields are not returned. If a certificate contains an instance of the Subject Alternative Name extension (see RFC 3280), there will also be a *subjectAltName* key in the dictionary.

The “subject” field is a tuple containing the sequence of relative distinguished names (RDNs) given in the certificate’s data structure for the principal, and each RDN is a sequence of name-value pairs:

```py
{'notAfter': 'Feb 16 16:54:50 2013 GMT',
 'subject': (((('countryName', u'US'),),
             (('stateOrProvinceName', u'Delaware'),)),
```
If the `binary_form` parameter is `True`, and a certificate was provided, this method returns the DER-encoded form of the entire certificate as a sequence of bytes, or `None` if the peer did not provide a certificate. This return value is independent of validation; if validation was required (CERT OPTIONAL or CERT_REQUIRED), it will have been validated, but if CERT_NONE was used to establish the connection, the certificate, if present, will not have been validated.

`SSLSocket.cipher()`

Returns a three-value tuple containing the name of the cipher being used, the version of the SSL protocol that defines its use, and the number of secret bits being used. If no connection has been established, returns `None`.

`SSLSocket.do_handshake()`

Perform a TLS/SSL handshake. If this is used with a non-blocking socket, it may raise `SSLError` with an `arg[0]` of `SSL_ERROR_WANT_READ` or `SSL_ERROR_WANT_WRITE`, in which case it must be called again until it completes successfully. For example, to simulate the behavior of a blocking socket, one might write:

```python
while True:
    try:
        s.do_handshake()
        break
    except ssl.SSLError, err:
        if err.args[0] == ssl.SSL_ERROR_WANT_READ:
            select.select([s], [], [])
        elif err.args[0] == ssl.SSL_ERROR_WANT_WRITE:
            select.select([], [s], [])
        else:
            pass
```
SSLSocket. **unwrap()**
Performs the SSL shutdown handshake, which removes the TLS layer from the underlying socket, and returns the underlying socket object. This can be used to go from encrypted operation over a connection to unencrypted. The socket instance returned should always be used for further communication with the other side of the connection, rather than the original socket instance (which may not function properly after the unwrap).
17.3.3. Certificates

Certificates in general are part of a public-key / private-key system. In this system, each principal, (which may be a machine, or a person, or an organization) is assigned a unique two-part encryption key. One part of the key is public, and is called the public key; the other part is kept secret, and is called the private key. The two parts are related, in that if you encrypt a message with one of the parts, you can decrypt it with the other part, and only with the other part.

A certificate contains information about two principals. It contains the name of a subject, and the subject's public key. It also contains a statement by a second principal, the issuer, that the subject is who he claims to be, and that this is indeed the subject's public key. The issuer's statement is signed with the issuer's private key, which only the issuer knows. However, anyone can verify the issuer's statement by finding the issuer's public key, decrypting the statement with it, and comparing it to the other information in the certificate. The certificate also contains information about the time period over which it is valid. This is expressed as two fields, called “notBefore” and “notAfter”.

In the Python use of certificates, a client or server can use a certificate to prove who they are. The other side of a network connection can also be required to produce a certificate, and that certificate can be validated to the satisfaction of the client or server that requires such validation. The connection attempt can be set to raise an exception if the validation fails. Validation is done automatically, by the underlying OpenSSL framework; the application need not concern itself with its mechanics. But the application does usually need to provide sets of certificates to allow this process to take place.

Python uses files to contain certificates. They should be formatted as
“PEM” (see RFC 1422), which is a base-64 encoded form wrapped with a header line and a footer line:

```
-----BEGIN CERTIFICATE-----
... (certificate in base64 PEM encoding) ...
-----END CERTIFICATE-----
```

The Python files which contain certificates can contain a sequence of certificates, sometimes called a certificate chain. This chain should start with the specific certificate for the principal who “is” the client or server, and then the certificate for the issuer of that certificate, and then the certificate for the issuer of that certificate, and so on up the chain till you get to a certificate which is self-signed, that is, a certificate which has the same subject and issuer, sometimes called a root certificate. The certificates should just be concatenated together in the certificate file. For example, suppose we had a three certificate chain, from our server certificate to the certificate of the certification authority that signed our server certificate, to the root certificate of the agency which issued the certification authority’s certificate:

```
-----BEGIN CERTIFICATE-----
... (certificate for your server)...
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
... (the certificate for the CA)...
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
... (the root certificate for the CA's issuer)...
-----END CERTIFICATE-----
```

If you are going to require validation of the other side of the connection’s certificate, you need to provide a “CA certs” file, filled with the certificate chains for each issuer you are willing to trust. Again, this file just contains these chains concatenated together. For validation, Python will use the first chain it finds in the file which matches.
Some “standard” root certificates are available from various certification authorities: CACert.org, Thawte, Verisign, Positive SSL (used by python.org), Equifax and GeoTrust.

In general, if you are using SSL3 or TLS1, you don’t need to put the full chain in your “CA certs” file; you only need the root certificates, and the remote peer is supposed to furnish the other certificates necessary to chain from its certificate to a root certificate. See RFC 4158 for more discussion of the way in which certification chains can be built.

If you are going to create a server that provides SSL-encrypted connection services, you will need to acquire a certificate for that service. There are many ways of acquiring appropriate certificates, such as buying one from a certification authority. Another common practice is to generate a self-signed certificate. The simplest way to do this is with the OpenSSL package, using something like the following:

```
% openssl req -new -x509 -days 365 -nodes -out cert.pem -keyout cert.pem
Generating a 1024 bit RSA private key
.........+++++
................++++++++
writing new private key to 'cert.pem'
-----
You are about to be asked to enter information that will be incorporated into your certificate request.
What you are about to enter is what is called a Distinguished Name or DN. There are quite a few fields but you can leave some blank.
For some fields there will be a default value, if you enter '.', the field will be left blank.
-----
Country Name (2 letter code) [AU]:US
State or Province Name (full name) [Some-State]:MyState
Locality Name (eg, city) []:Some City
Organization Name (eg, company) [Internet Widgits Pty Ltd]:My Organization
Organizational Unit Name (eg, section) []:My Group
Common Name (eg, YOUR name) []:myserver.mygroup.myorganization.com
Email Address []:ops@myserver.mygroup.myorganization.com
%```
The disadvantage of a self-signed certificate is that it is its own root certificate, and no one else will have it in their cache of known (and trusted) root certificates.
17.3.4. Examples

17.3.4.1. Testing for SSL support

To test for the presence of SSL support in a Python installation, user code should use the following idiom:

```python
try:
    import ssl
except ImportError:
    pass
else:
    [ do something that requires SSL support ]
```

17.3.4.2. Client-side operation

This example connects to an SSL server, prints the server's address and certificate, sends some bytes, and reads part of the response:

```python
import socket, ssl, pprint
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
#	require a certificate from the server
ssl_sock = ssl.wrap_socket(s,
                          ca_certs="/etc/ca_certs_file",
                          cert_reqs=ssl.CERT_REQUIRED)
ssl_sock.connect(('www.verisign.com', 443))
print repr(ssl_sock.getpeername())
print ssl_sock.cipher()
print pprint.pformat(ssl_sock.getpeercert())
#	Set a simple HTTP request -- use httplib in actual code.
ssl_sock.write("GET / HTTP/1.0\r
Host: www.verisign.com\r\n\r\n"")
#	Read a chunk of data. Will not necessarily
```
As of September 6, 2007, the certificate printed by this program looked like this:

```json

{'notAfter': 'May 8 23:59:59 2009 GMT',
'subject': (((('serialNumber', u'2497886'),),
(('1.3.6.1.4.1.311.60.2.1.3', u'US'),),
(('1.3.6.1.4.1.311.60.2.1.2', u'Delaware'),),
(('countryName', u'US'),),
(('postalCode', u'94043'),),
(('stateOrProvinceName', u'California'),),
(('localityName', u'Mountain View'),),
(('streetAddress', u'487 East Middlefield Road'),),
(('organizationName', u'VeriSign, Inc.'),),
(('organizationalUnitName', u'Production Security Services'),),
(('organizationalUnitName', u'Terms of use at www.verisign.com/rpa (c)06'),)
(('commonName', u'www.verisign.com'),))}
```

which is a fairly poorly-formed `subject` field.

### 17.3.4.3. Server-side operation

For server operation, typically you'd need to have a server certificate, and private key, each in a file. You’d open a socket, bind it to a port, call `listen()` on it, then start waiting for clients to connect:

```python

import socket, ssl

bindsocket = socket.socket()
bindsocket.bind(('myaddr.mydomain.com', 10023))
bindsocket.listen(5)
```
When one did, you’d call `accept()` on the socket to get the new socket from the other end, and use `wrap_socket()` to create a server-side SSL context for it:

```python
while True:
    newsocket, fromaddr = bindsocket.accept()
    connstream = ssl.wrap_socket(newsocket,
                                server_side=True,
                                certfile="mycertfile",
                                keyfile="mykeyfile",
                                ssl_version=ssl.PROTOCOL_TLSv1)
    deal_with_client(connstream)
```

Then you’d read data from the `connstream` and do something with it till you are finished with the client (or the client is finished with you):

```python
def deal_with_client(connstream):
    data = connstream.read()
    # null data means the client is finished with us
    while data:
        if not do_something(connstream, data):
            # we'll assume do_something returns False
            # when we're finished with client
            break
        data = connstream.read()
    # finished with client
    connstream.close()
```

And go back to listening for new client connections.

17.4. signal — Set handlers for asynchronous events

This module provides mechanisms to use signal handlers in Python. Some general rules for working with signals and their handlers:

- A handler for a particular signal, once set, remains installed until it is explicitly reset (Python emulates the BSD style interface regardless of the underlying implementation), with the exception of the handler for SIGCHLD, which follows the underlying implementation.
- There is no way to “block” signals temporarily from critical sections (since this is not supported by all Unix flavors).
- Although Python signal handlers are called asynchronously as far as the Python user is concerned, they can only occur between the “atomic” instructions of the Python interpreter. This means that signals arriving during long calculations implemented purely in C (such as regular expression matches on large bodies of text) may be delayed for an arbitrary amount of time.
- When a signal arrives during an I/O operation, it is possible that the I/O operation raises an exception after the signal handler returns. This is dependent on the underlying Unix system’s semantics regarding interrupted system calls.
- Because the C signal handler always returns, it makes little sense to catch synchronous errors like SIGFPE or SIGSEGV.
- Python installs a small number of signal handlers by default: SIGPIPE is ignored (so write errors on pipes and sockets can be reported as ordinary Python exceptions) and SIGINT is translated into a KeyboardInterrupt exception. All of these can be overridden.
- Some care must be taken if both signals and threads are used...
in the same program. The fundamental thing to remember in using signals and threads simultaneously is: always perform \texttt{signal()} operations in the main thread of execution. Any thread can perform an \texttt{alarm()}, \texttt{getsignal()}, \texttt{pause()}, \texttt{setitimer()} or \texttt{getitimer()}; only the main thread can set a new signal handler, and the main thread will be the only one to receive signals (this is enforced by the Python \texttt{signal} module, even if the underlying thread implementation supports sending signals to individual threads). This means that signals can't be used as a means of inter-thread communication. Use locks instead.

The variables defined in the \texttt{signal} module are:

\texttt{signal.SIG_DFL}

This is one of two standard signal handling options; it will simply perform the default function for the signal. For example, on most systems the default action for \texttt{SIGQUIT} is to dump core and exit, while the default action for \texttt{SIGCHLD} is to simply ignore it.

\texttt{signal.SIG_IGN}

This is another standard signal handler, which will simply ignore the given signal.

\texttt{SIG*}

All the signal numbers are defined symbolically. For example, the hangup signal is defined as \texttt{signal.SIGHUP}; the variable names are identical to the names used in C programs, as found in \texttt{<signal.h>}. The Unix man page for \texttt{`signal()`} lists the existing signals (on some systems this is \texttt{signal(2)}, on others the list is in \texttt{signal(7)}). Note that not all systems define the same set of signal names; only those names defined by the system are defined by this module.

\texttt{signalCTRL_C_EVENT}

The signal corresponding to the CTRL+C keystroke event.
Availability: Windows.

*New in version 2.7.*

**signal.** **CTRL_BREAK_EVENT**

The signal corresponding to the CTRL+BREAK keystroke event. 
Availability: Windows.

*New in version 2.7.*

**signal.** **NSIG**

One more than the number of the highest signal number.

**signal.** **ITIMER_REAL**

Decrements interval timer in real time, and delivers **SIGALRM** upon expiration.

**signal.** **ITIMER_VIRTUAL**

Decrements interval timer only when the process is executing, and delivers **SIGVTALRM** upon expiration.

**signal.** **ITIMER_PROF**

Decrements interval timer both when the process executes and when the system is executing on behalf of the process. Coupled with **ITIMER_VIRTUAL**, this timer is usually used to profile the time spent by the application in user and kernel space. **SIGPROF** is delivered upon expiration.

The **signal** module defines one exception:

**exception** **signal.** **ItimerError**

Raised to signal an error from the underlying **setitimer()** or **getitimer()** implementation. Expect this error if an invalid interval timer or a negative time is passed to **setitimer()**. This error is a subtype of **IOError**.
The `signal` module defines the following functions:

**signal.alarm(time)**

If `time` is non-zero, this function requests that a `SIGALRM` signal be sent to the process in `time` seconds. Any previously scheduled alarm is canceled (only one alarm can be scheduled at any time). The returned value is then the number of seconds before any previously set alarm was to have been delivered. If `time` is zero, no alarm is scheduled, and any scheduled alarm is canceled. If the return value is zero, no alarm is currently scheduled. (See the Unix man page `alarm(2)`.) Availability: Unix.

**signal.getsignal(signalnum)**

Return the current signal handler for the signal `signalnum`. The returned value may be a callable Python object, or one of the special values `signal.SIG_IGN`, `signal.SIG_DFL` or `None`. Here, `signal.SIG_IGN` means that the signal was previously ignored, `signal.SIG_DFL` means that the default way of handling the signal was previously in use, and `None` means that the previous signal handler was not installed from Python.

**signal.pause()**

Cause the process to sleep until a signal is received; the appropriate handler will then be called. Returns nothing. Not on Windows. (See the Unix man page `signal(2)`.)

**signal.setitimer(which, seconds[, interval])**

Sets given interval timer (one of `signal.ITIMER_REAL`, `signal.ITIMER_VIRTUAL` or `signal.ITIMER_PROF`) specified by `which` to fire after `seconds` (float is accepted, different from `alarm()`) and after that every `interval` seconds. The interval timer specified by `which` can be cleared by setting `seconds` to zero.
When an interval timer fires, a signal is sent to the process. The signal sent is dependent on the timer being used; `signal.ITIMER_REAL` will deliver `SIGALRM`, `signal.ITIMER_VIRTUAL` sends `SIGVTALRM`, and `signal.ITIMER_PROF` will deliver `SIGPROF`.

The old values are returned as a tuple: (delay, interval).

Attempting to pass an invalid interval timer will cause an `ItimerError`. Availability: Unix.

*New in version 2.6.*

`signal.getitimer(which)`

Returns current value of a given interval timer specified by `which`. Availability: Unix.

*New in version 2.6.*

`signal.set_wakeup_fd(fd)`

Set the wakeup fd to `fd`. When a signal is received, a '\0' byte is written to the fd. This can be used by a library to wakeup a poll or select call, allowing the signal to be fully processed.

The old wakeup fd is returned. `fd` must be non-blocking. It is up to the library to remove any bytes before calling poll or select again.

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a `ValueError` exception to be raised.

`signal.siginterrupt(signalnum, flag)`

Change system call restart behaviour: if `flag` is `False`, system calls will be restarted when interrupted by signal `signalnum`, otherwise system calls will be interrupted. Returns nothing. Availability: Unix (see the man page `siginterrupt(3)` for further
information).

Note that installing a signal handler with \texttt{signal()} will reset the restart behaviour to interruptible by implicitly calling \texttt{siginterrupt()} with a true \texttt{flag} value for the given signal.

\textit{New in version 2.6.}

\texttt{signal.\textbf{signal}(signalnum, handler)}

Set the handler for signal \texttt{signalnum} to the function \texttt{handler}. \texttt{handler} can be a callable Python object taking two arguments (see below), or one of the special values \texttt{signal.SIG_IGN} or \texttt{signal.SIG_DFL}. The previous signal handler will be returned (see the description of \texttt{getsignal()} above). (See the Unix man page \texttt{signal(2)}.)

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a \texttt{ValueError} exception to be raised.

The \texttt{handler} is called with two arguments: the signal number and the current stack frame (\texttt{None} or a frame object; for a description of frame objects, see the \textit{description in the type hierarchy} or see the attribute descriptions in the \texttt{inspect} module).
17.4.1. Example

Here is a minimal example program. It uses the `alarm()` function to limit the time spent waiting to open a file; this is useful if the file is for a serial device that may not be turned on, which would normally cause the `os.open()` to hang indefinitely. The solution is to set a 5-second alarm before opening the file; if the operation takes too long, the alarm signal will be sent, and the handler raises an exception.

```python
import signal, os

def handler(signum, frame):
    print 'Signal handler called with signal', signum
    raise IOError("Couldn't open device!")

# Set the signal handler and a 5-second alarm
signal.signal(signal.SIGALRM, handler)
signal.alarm(5)

# This open() may hang indefinitely
fd = os.open('/dev/ttyS0', os.O_RDWR)

signal.alarm(0)  # Disable the alarm
```
This module allows you to spawn processes and connect to their input/output/error pipes and obtain their return codes under Unix and Windows.

The `subprocess` module provides more powerful facilities for spawning new processes and retrieving their results. Using the `subprocess` module is preferable to using the `popen2` module.

The primary interface offered by this module is a trio of factory functions. For each of these, if `bufsize` is specified, it specifies the buffer size for the I/O pipes. `mode`, if provided, should be the string 'b' or 't'; on Windows this is needed to determine whether the file objects should be opened in binary or text mode. The default value for `mode` is 't'.

On Unix, `cmd` may be a sequence, in which case arguments will be passed directly to the program without shell intervention (as with `os.spawnv()`). If `cmd` is a string it will be passed to the shell (as with `os.system()`).

The only way to retrieve the return codes for the child processes is by using the `poll()` or `wait()` methods on the `Popen3` and `Popen4` classes; these are only available on Unix. This information is not available when using the `popen2()`, `popen3()`, and `popen4()` functions, or the equivalent functions in the `os` module. (Note that the
tuples returned by the os module's functions are in a different order from the ones returned by the popen2 module.)

popen2. popen2(cmd[, bufsize[, mode]])
    Executes cmd as a sub-process. Returns the file objects (child_stdout, child_stdin).

popen2. popen3(cmd[, bufsize[, mode]])
    Executes cmd as a sub-process. Returns the file objects (child_stdout, child_stdin, child_stderr).

popen2. popen4(cmd[, bufsize[, mode]])
    Executes cmd as a sub-process. Returns the file objects (child_stdout_and_stderr, child_stdin).

    New in version 2.0.

On Unix, a class defining the objects returned by the factory functions is also available. These are not used for the Windows implementation, and are not available on that platform.

class popen2. Popen3(cmd[, capturestderr[, bufsize]])
    This class represents a child process. Normally, Popen3 instances are created using the popen2() and popen3() factory functions described above.

    If not using one of the helper functions to create Popen3 objects, the parameter cmd is the shell command to execute in a sub-process. The capturestderr flag, if true, specifies that the object should capture standard error output of the child process. The default is false. If the bufsize parameter is specified, it specifies the size of the I/O buffers to/from the child process.
class popen2. **Popen4**(cmd[, bufsize])

Similar to **Popen3**, but always captures standard error into the same file object as standard output. These are typically created using **popen4()**.

*New in version 2.0.*
17.5.1. Popen3 and Popen4 Objects

Instances of the Popen3 and Popen4 classes have the following methods:

Popen3. poll()

Returns -1 if child process hasn’t completed yet, or its status code (see wait()) otherwise.

Popen3. wait()

Waits for and returns the status code of the child process. The status code encodes both the return code of the process and information about whether it exited using the exit() system call or died due to a signal. Functions to help interpret the status code are defined in the os module; see section Process Management for the W*() family of functions.

The following attributes are also available:

Popen3. fromchild

A file object that provides output from the child process. For Popen4 instances, this will provide both the standard output and standard error streams.

Popen3. tochild

A file object that provides input to the child process.

Popen3. childerr

A file object that provides error output from the child process, if capturestderr was true for the constructor, otherwise None. This will always be None for Popen4 instances.

Popen3. pid
The process ID of the child process.
17.5.2. Flow Control Issues

Any time you are working with any form of inter-process communication, control flow needs to be carefully thought out. This remains the case with the file objects provided by this module (or the os module equivalents).

When reading output from a child process that writes a lot of data to standard error while the parent is reading from the child's standard output, a deadlock can occur. A similar situation can occur with other combinations of reads and writes. The essential factors are that more than _PC_PIPE_BUF bytes are being written by one process in a blocking fashion, while the other process is reading from the first process, also in a blocking fashion.

There are several ways to deal with this situation.

The simplest application change, in many cases, will be to follow this model in the parent process:

```python
import popen2

r, w, e = popen2.popen3('python slave.py')
e.readlines()
r.readlines()
r.close()
e.close()
w.close()
```

with code like this in the child:

```python
import os
import sys

# note that each of these print statements
# writes a single long string
```
print >>sys.stderr, 400 * 'this is a test
'  
print >>sys.stdout, 400 * 'this is another test
'

In particular, note that `sys.stderr` must be closed after writing all data, or `readlines()` won’t return. Also note that `os.close()` must be used, as `sys.stderr.close()` won’t close `stderr` (otherwise assigning to `sys.stderr` will silently close it, so no further errors can be printed).

Applications which need to support a more general approach should integrate I/O over pipes with their `select()` loops, or use separate threads to read each of the individual files provided by whichever `popen*()` function or `Popen*` class was used.

**See also:**

**Module** subprocess

Module for spawning and managing subprocesses.
17.6. asyncore — Asynchronous socket handler

This module provides the basic infrastructure for writing asynchronous socket service clients and servers.

There are only two ways to have a program on a single processor do “more than one thing at a time.” Multi-threaded programming is the simplest and most popular way to do it, but there is another very different technique, that lets you have nearly all the advantages of multi-threading, without actually using multiple threads. It's really only practical if your program is largely I/O bound. If your program is processor bound, then pre-emptive scheduled threads are probably what you really need. Network servers are rarely processor bound, however.

If your operating system supports the \texttt{select()} system call in its I/O library (and nearly all do), then you can use it to juggle multiple communication channels at once; doing other work while your I/O is taking place in the “background.” Although this strategy can seem strange and complex, especially at first, it is in many ways easier to understand and control than multi-threaded programming. The \texttt{asyncore} module solves many of the difficult problems for you, making the task of building sophisticated high-performance network servers and clients a snap. For “conversational” applications and protocols the companion \texttt{asynchat} module is invaluable.

The basic idea behind both modules is to create one or more network \texttt{channels}, instances of class \texttt{asyncore.dispatcher} and \texttt{asynchat.async_chat}. Creating the channels adds them to a global map, used by the \texttt{loop()} function if you do not provide it with your own map.
Once the initial channel(s) is(are) created, calling the `loop()` function activates channel service, which continues until the last channel (including any that have been added to the map during asynchronous service) is closed.

```python
asyncore.loop([timeout[, use_poll[, map[, count]]]])
```

Enter a polling loop that terminates after count passes or all open channels have been closed. All arguments are optional. The `count` parameter defaults to None, resulting in the loop terminating only when all channels have been closed. The `timeout` argument sets the timeout parameter for the appropriate `select()` or `poll()` call, measured in seconds; the default is 30 seconds. The `use_poll` parameter, if true, indicates that `poll()` should be used in preference to `select()` (the default is `False`).

The `map` parameter is a dictionary whose items are the channels to watch. As channels are closed they are deleted from their map. If `map` is omitted, a global map is used. Channels (instances of `asyncore.dispatcher`, `asynchat.async_chat` and subclasses thereof) can freely be mixed in the map.

```python
class asyncore.dispatcher
```

The `dispatcher` class is a thin wrapper around a low-level socket object. To make it more useful, it has a few methods for event-handling which are called from the asynchronous loop. Otherwise, it can be treated as a normal non-blocking socket object.

The firing of low-level events at certain times or in certain connection states tells the asynchronous loop that certain higher-level events have taken place. For example, if we have asked for a socket to connect to another host, we know that the connection has been made when the socket becomes writable for the first time (at this point you know that you may write to it with the
expectation of success). The implied higher-level events are:

<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>handle_connect()</td>
<td>Implied by the first read or write event</td>
</tr>
<tr>
<td>handle_close()</td>
<td>Implied by a read event with no data available</td>
</tr>
<tr>
<td>handle_accept()</td>
<td>Implied by a read event on a listening socket</td>
</tr>
</tbody>
</table>

During asynchronous processing, each mapped channel's `readable()` and `writable()` methods are used to determine whether the channel's socket should be added to the list of channels `select()`ed or `poll()`ed for read and write events.

Thus, the set of channel events is larger than the basic socket events. The full set of methods that can be overridden in your subclass follows:

**handle_read()**

Called when the asynchronous loop detects that a `read()` call on the channel's socket will succeed.

**handle_write()**

Called when the asynchronous loop detects that a writable socket can be written. Often this method will implement the necessary buffering for performance. For example:

```python
def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[sent:]
```

**handle_expt()**

Called when there is out of band (OOB) data for a socket connection. This will almost never happen, as OOB is tenuously supported and rarely used.
**handle_connect()**
Called when the active opener’s socket actually makes a connection. Might send a “welcome” banner, or initiate a protocol negotiation with the remote endpoint, for example.

**handle_close()**
Called when the socket is closed.

**handle_error()**
Called when an exception is raised and not otherwise handled. The default version prints a condensed traceback.

**handle_accept()**
Called on listening channels (passive openers) when a connection can be established with a new remote endpoint that has issued a `connect()` call for the local endpoint.

**readable()**
Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which read events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in read events.

**writable()**
Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which write events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in write events.

In addition, each channel delegates or extends many of the socket methods. Most of these are nearly identical to their socket partners.

**create_socket**(family, type)
This is identical to the creation of a normal socket, and will use the same options for creation. Refer to the socket documentation for information on creating sockets.

**connect(address)**

As with the normal socket object, *address* is a tuple with the first element the host to connect to, and the second the port number.

**send(data)**

Send *data* to the remote end-point of the socket.

**recv(buffer_size)**

Read at most *buffer_size* bytes from the socket’s remote end-point. An empty string implies that the channel has been closed from the other end.

**listen(backlog)**

Listen for connections made to the socket. The *backlog* argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

**bind(address)**

Bind the socket to *address*. The socket must not already be bound. (The format of *address* depends on the address family — refer to the socket documentation for more information.) To mark the socket as re-usable (setting the SO_REUSEADDR option), call the *dispatcher* object’s set_reuse_addr() method.

**accept()**

Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair *(conn, address)* where *conn* is a new socket object
usable to send and receive data on the connection, and
address is the address bound to the socket on the other end
of the connection.

close()
Close the socket. All future operations on the socket object
will fail. The remote end-point will receive no more data (after
queued data is flushed). Sockets are automatically closed
when they are garbage-collected.

class asyncore.file_dispatcher
A file_dispatcher takes a file descriptor or file object along with an
optional map argument and wraps it for use with the poll() or
loop() functions. If provided a file object or anything with a
fileno() method, that method will be called and passed to the
file_wrapper constructor. Availability: UNIX.

class asyncore.file_wrapper
A file_wrapper takes an integer file descriptor and calls os.dup()
to duplicate the handle so that the original handle may be closed
independently of the file_wrapper. This class implements
sufficient methods to emulate a socket for use by the
file_dispatcher class. Availability: UNIX.
Here is a very basic HTTP client that uses the `dispatcher` class to implement its socket handling:

```python
import asyncore, socket

class http_client(asyncore.dispatcher):
    def __init__(self, host, path):
        asyncore.dispatcher.__init__(self)
        self.create_socket(socket.AF_INET, socket.SOCK_STREAM)
        self.connect((host, 80))
        self.buffer = 'GET %s HTTP/1.0\r\n\r\n' % path

    def handle_connect(self):
        pass

    def handle_close(self):
        self.close()

    def handle_read(self):
        print self.recv(8192)

    def writable(self):
        return (len(self.buffer) > 0)

    def handle_write(self):
        sent = self.send(self.buffer)
        self.buffer = self.buffer[sent:]

    c = http_client('www.python.org', '/')
asyncore.loop()
```

Found a bug?

Created using Sphinx 0.6.3.
This module builds on the asyncore infrastructure, simplifying asynchronous clients and servers and making it easier to handle protocols whose elements are terminated by arbitrary strings, or are of variable length. asynchat defines the abstract class async_chat that you subclass, providing implementations of the collect_incoming_data() and found_terminator() methods. It uses the same asynchronous loop as asyncore, and the two types of channel, asyncore.dispatcher and asynchat.async_chat, can freely be mixed in the channel map. Typically an asyncore.dispatcher server channel generates new asynchat.async_chat channel objects as it receives incoming connection requests.

class asynchat.async_chat

This class is an abstract subclass of asyncore.dispatcher. To make practical use of the code you must subclass async_chat, providing meaningful collect_incoming_data() and found_terminator() methods. The asyncore.dispatcher methods can be used, although not all make sense in a message/response context.

Like asyncore.dispatcher, async_chat defines a set of events that are generated by an analysis of socket conditions after a select() call. Once the polling loop has been started the async_chat object’s methods are called by the event-processing framework with no action on the part of the programmer.

Two class attributes can be modified, to improve performance, or possibly even to conserve memory.
**ac_in_buffer_size**

The asynchronous input buffer size (default 4096).

**ac_out_buffer_size**

The asynchronous output buffer size (default 4096).

Unlike `asyncore.dispatcher`, `async_chat` allows you to define a first-in-first-out queue (fifo) of producers. A producer need have only one method, `more()`, which should return data to be transmitted on the channel. The producer indicates exhaustion (i.e. that it contains no more data) by having its `more()` method return the empty string. At this point the `async_chat` object removes the producer from the fifo and starts using the next producer, if any. When the producer fifo is empty the `handle_write()` method does nothing. You use the channel object's `set_terminator()` method to describe how to recognize the end of, or an important breakpoint in, an incoming transmission from the remote endpoint.

To build a functioning `async_chat` subclass your input methods `collect_incoming_data()` and `found_terminator()` must handle the data that the channel receives asynchronously. The methods are described below.

`async_chat.close_when_done()`

Pushes a `None` on to the producer fifo. When this producer is popped off the fifo it causes the channel to be closed.

`async_chat.collect_incoming_data(data)`

Called with `data` holding an arbitrary amount of received data. The default method, which must be overridden, raises a `NotImplementedError` exception.

`async_chat.discard_buffers()`
In emergencies this method will discard any data held in the input and/or output buffers and the producer fifo.

async_chat.found_terminator()
Called when the incoming data stream matches the termination condition set by set_terminator(). The default method, which must be overridden, raises a `NotImplementedError` exception. The buffered input data should be available via an instance attribute.

async_chat.get_terminator()
Returns the current terminator for the channel.

async_chat.push(data)
Pushes data on to the channel's fifo to ensure its transmission. This is all you need to do to have the channel write the data out to the network, although it is possible to use your own producers in more complex schemes to implement encryption and chunking, for example.

async_chat.push_with_producer(producer)
Takes a producer object and adds it to the producer fifo associated with the channel. When all currently-pushed producers have been exhausted the channel will consume this producer's data by calling its `more()` method and send the data to the remote endpoint.

async_chat.set_terminator(term)
Sets the terminating condition to be recognized on the channel. `term` may be any of three types of value, corresponding to three different ways to handle incoming protocol data.

<table>
<thead>
<tr>
<th>term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>string</td>
<td>Will call <code>found_terminator()</code> when the string is found in the input stream</td>
</tr>
<tr>
<td>integer</td>
<td>Will call <code>found_terminator()</code> when the indicated number of characters have been received</td>
</tr>
<tr>
<td>---------</td>
<td>----------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>None</td>
<td>The channel continues to collect data forever</td>
</tr>
</tbody>
</table>

Note that any data following the terminator will be available for reading by the channel after `found_terminator()` is called.
17.7.1. asynchat - Auxiliary Classes

class asynchat.fifo([list=None])

A fifo holding data which has been pushed by the application but not yet popped for writing to the channel. A fifo is a list used to hold data and/or producers until they are required. If the list argument is provided then it should contain producers or data items to be written to the channel.

is_empty()

Returns True if and only if the fifo is empty.

first()

Returns the least-recently pushed item from the fifo.

push(data)

Adds the given data (which may be a string or a producer object) to the producer fifo.

pop()

If the fifo is not empty, returns True, first(), deleting the popped item. Returns False, None for an empty fifo.
17.7.2. asynchat Example

The following partial example shows how HTTP requests can be read with `async_chat`. A web server might create an `http_request_handler` object for each incoming client connection. Notice that initially the channel terminator is set to match the blank line at the end of the HTTP headers, and a flag indicates that the headers are being read.

Once the headers have been read, if the request is of type POST (indicating that further data are present in the input stream) then the `Content-Length:` header is used to set a numeric terminator to read the right amount of data from the channel.

The `handle_request()` method is called once all relevant input has been marshalled, after setting the channel terminator to `None` to ensure that any extraneous data sent by the web client are ignored.

class http_request_handler(asynchat.async_chat):
    def __init__(self, sock, addr, sessions, log):
        asynchat.async_chat.__init__(self, sock=sock)
        self.addr = addr
        self.sessions = sessions
        self.ibuffer = []
        self.obuffer = ""
        self.set_terminator("\r\n\r\n")
        self.reading_headers = True
        self.handling = False
        self.cgi_data = None
        self.log = log

    def collect_incoming_data(self, data):
        """Buffer the data""
        self.ibuffer.append(data)

    def found_terminator(self):
        if self.reading_headers:
self.reading_headers = False
self.parse_headers(''.join(self.ibuffer))
self.ibuffer = []
if self.op.upper() == "POST":
    clen = self.headers.getheader("content-length")
    self.set_terminator(int(clen))
else:
    self.handling = True
    self.set_terminator(None)
    self.handle_request()
elif not self.handling:
    self.set_terminator(None)  # browsers sometimes over
    self.cgi_data = parse(self.headers, ' '.join(self.ibuffer))
    self.handling = True
    self.ibuffer = []
    self.handle_request()
18. Internet Data Handling

This chapter describes modules which support handling data formats commonly used on the Internet.

- **18.1. email** — An email and MIME handling package
  - 18.1.1. email: Representing an email message
  - 18.1.2. email: Parsing email messages
    - 18.1.2.1. FeedParser API
    - 18.1.2.2. Parser class API
    - 18.1.2.3. Additional notes
  - 18.1.3. email: Generating MIME documents
  - 18.1.4. email: Creating email and MIME objects from scratch
  - 18.1.5. email: Internationalized headers
  - 18.1.6. email: Representing character sets
  - 18.1.7. email: Encoders
  - 18.1.8. email: Exception and Defect classes
  - 18.1.9. email: Miscellaneous utilities
  - 18.1.10. email: Iterators
  - 18.1.11. email: Examples
  - 18.1.12. Package History
  - 18.1.13. Differences from mimelib

- **18.2. json** — JSON encoder and decoder
  - 18.2.1. Basic Usage
  - 18.2.2. Encoders and decoders

- **18.3. mailcap** — Mailcap file handling

- **18.4. mailbox** — Manipulate mailboxes in various formats
  - 18.4.1. Mailbox objects
    - 18.4.1.1. Maildir
    - 18.4.1.2. mbox
18.4.1.3. MH
18.4.1.4. Babyl
18.4.1.5. MMDF

18.4.2. Message objects
   18.4.2.1. MaildirMessage
   18.4.2.2. mboxMessage
   18.4.2.3. MHMessage
   18.4.2.4. BabylMessage
   18.4.2.5. MMDFMessage

18.4.3. Exceptions
18.4.4. Deprecated classes and methods
18.4.5. Examples

18.5. mhlib — Access to MH mailboxes
   18.5.1. MH Objects
   18.5.2. Folder Objects
   18.5.3. Message Objects

18.6. mime tools — Tools for parsing MIME messages
   18.6.1. Additional Methods of Message Objects

18.7. mime types — Map filenames to MIME types
   18.7.1. MimeTypes Objects

18.8. MimeWriter — Generic MIME file writer
   18.8.1. MimeWriter Objects

18.9. mimify — MIME processing of mail messages

18.10. multofile — Support for files containing distinct parts
   18.10.1. MultiFile Objects
   18.10.2. MultiFile Example

18.11. rfc822 — Parse RFC 2822 mail headers
   18.11.1. Message Objects
   18.11.2. AddressList Objects

18.12. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings

18.13. binhex — Encode and decode binhex4 files
18.13.1. Notes

- **18.14. binascii** — Convert between binary and ASCII
- **18.15. quopri** — Encode and decode MIME quoted-printable data
- **18.16. uu** — Encode and decode uuencode files
18.1. email — An email and MIME handling package

*New in version 2.2.*

The `email` package is a library for managing email messages, including MIME and other RFC 2822-based message documents. It subsumes most of the functionality in several older standard modules such as `rfc822`, `mimetools`, `multifile`, and other non-standard packages such as `mimecntl`. It is specifically *not* designed to do any sending of email messages to SMTP (RFC 2821), NNTP, or other servers; those are functions of modules such as `smtplib` and `nntplib`. The `email` package attempts to be as RFC-compliant as possible, supporting in addition to RFC 2822, such MIME-related RFCs as RFC 2045, RFC 2046, RFC 2047, and RFC 2231.

The primary distinguishing feature of the `email` package is that it splits the parsing and generating of email messages from the internal *object model* representation of email. Applications using the `email` package deal primarily with objects; you can add sub-objects to messages, remove sub-objects from messages, completely re-arrange the contents, etc. There is a separate parser and a separate generator which handles the transformation from flat text to the object model, and then back to flat text again. There are also handy subclasses for some common MIME object types, and a few miscellaneous utilities that help with such common tasks as extracting and parsing message field values, creating RFC-compliant dates, etc.

The following sections describe the functionality of the `email` package. The ordering follows a progression that should be common in applications: an email message is read as flat text from a file or
other source, the text is parsed to produce the object structure of the email message, this structure is manipulating, and finally, the object tree is rendered back into flat text.

It is perfectly feasible to create the object structure out of whole cloth — i.e. completely from scratch. From there, a similar progression can be taken as above.

Also included are detailed specifications of all the classes and modules that the email package provides, the exception classes you might encounter while using the email package, some auxiliary utilities, and a few examples. For users of the older mimelib package, or previous versions of the email package, a section on differences and porting is provided.

Contents of the email package documentation:

- 18.1.1. email: Representing an email message
- 18.1.2. email: Parsing email messages
  - 18.1.2.1. FeedParser API
  - 18.1.2.2. Parser class API
  - 18.1.2.3. Additional notes
- 18.1.3. email: Generating MIME documents
- 18.1.4. email: Creating email and MIME objects from scratch
- 18.1.5. email: Internationalized headers
- 18.1.6. email: Representing character sets
- 18.1.7. email: Encoders
- 18.1.8. email: Exception and Defect classes
- 18.1.9. email: Miscellaneous utilities
- 18.1.10. email: Iterators
- 18.1.11. email: Examples

18.1.12. Package History

This table describes the release history of the email package, corresponding to the version of Python that the package was released with. For purposes of this document, when you see a note about change or added versions, these refer to the Python version the change was made in, not the email package version. This table also describes the Python compatibility of each version of the package.

<table>
<thead>

</tr>
</tbody>
</table>

Here are the major differences between email version 4 and version 3:

- All modules have been renamed according to PEP 8 standards. For example, the version 3 module `email.Message` was renamed to `email.message` in version 4.

- A new subpackage `email.mime` was added and all the version 3 `email.MIME*` modules were renamed and situated into the `email.mime` subpackage. For example, the version 3 module `email.MIMEText` was renamed to `email.mime.text`.

Note that the version 3 names will continue to work until Python 2.6.
The `email.mime.application` module was added, which contains the `MIMEApplication` class.

Methods that were deprecated in version 3 have been removed. These include `Generator.__call__()`, `Message.get_type()`, `Message.get_main_type()`, and `Message.get_subtype()`.

Fixes have been added for [RFC 2231](https://tools.ietf.org/html/rfc2231) support which can change some of the return types for `Message.get_param()` and friends. Under some circumstances, values which used to return a 3-tuple now return simple strings (specifically, if all extended parameter segments were unencoded, there is no language and charset designation expected, so the return type is now a simple string). Also, %-decoding used to be done for both encoded and unencoded segments; this decoding is now done only for encoded segments.

Here are the major differences between `email` version 3 and version 2:

- The `FeedParser` class was introduced, and the `Parser` class was implemented in terms of the `FeedParser`. All parsing therefore is non-strict, and parsing will make a best effort never to raise an exception. Problems found while parsing messages are stored in the message's `defect` attribute.
- All aspects of the API which raised `DeprecationWarning`s in version 2 have been removed. These include the `__encoder` argument to the `MIMEText` constructor, the `Message.add_payload()` method, the `Utils.dump_address_pair()` function, and the functions `Utils.decode()` and `Utils.encode()`.
- New `DeprecationWarning`s have been added to: `Generator.__call__()`, `Message.get_type()`, `Message.get_main_type()`, and `Message.get_subtype()`, and the `strict`
argument to the `Parser` class. These are expected to be removed in future versions.

- Support for Python versions earlier than 2.3 has been removed.

Here are the differences between `email` version 2 and version 1:

- The `email.Header` and `email.Charset` modules have been added.

- The pickle format for `Message` instances has changed. Since this was never (and still isn't) formally defined, this isn't considered a backward incompatibility. However, if your application pickles and unpickles `Message` instances, be aware that in `email` version 2, `Message` instances now have private variables `_charset` and `_default_type`.

- Several methods in the `Message` class have been deprecated, or their signatures changed. Also, many new methods have been added. See the documentation for the `Message` class for details. The changes should be completely backward compatible.

- The object structure has changed in the face of `message/rfc822` content types. In `email` version 1, such a type would be represented by a scalar payload, i.e. the container message's `is_multipart()` returned false, `get_payload()` was not a list object, but a single `Message` instance.

  This structure was inconsistent with the rest of the package, so the object representation for `message/rfc822` content types was changed. In `email` version 2, the container does return `True` from `is_multipart()`, and `get_payload()` returns a list containing a single `Message` item.

  Note that this is one place that backward compatibility could not
be completely maintained. However, if you’re already testing the return type of `get_payload()`, you should be fine. You just need to make sure your code doesn’t do a `set_payload()` with a `Message` instance on a container with a content type of `message/rfc822`.

- The `Parser` constructor’s `strict` argument was added, and its `parse()` and `parsestr()` methods grew a `headersonly` argument. The `strict` flag was also added to functions `email.message_from_file()` and `email.message_from_string()`.

- `Generator.__call__()` is deprecated; use `Generator.flatten()` instead. The `Generator` class has also grown the `clone()` method.

- The `DecodedGenerator` class in the `email.Generator` module was added.

- The intermediate base classes `MIMENonMultipart` and `MIMEMultipart` have been added, and interposed in the class hierarchy for most of the other MIME-related derived classes.

- The `_encoder` argument to the `MIMEText` constructor has been deprecated. Encoding now happens implicitly based on the `_charset` argument.

- The following functions in the `email.Utils` module have been deprecated: `dump_address_pairs()`, `decode()`, and `encode()`. The following functions have been added to the module: `make_msgid()`, `decode_rfc2231()`, `encode_rfc2231()`, and `decode_params()`.

- The non-public function `email.Iterators._structure()` was added.
18.1.13. Differences from mimelib

The email package was originally prototyped as a separate library called mimelib. Changes have been made so that method names are more consistent, and some methods or modules have either been added or removed. The semantics of some of the methods have also changed. For the most part, any functionality available in mimelib is still available in the email package, albeit often in a different way. Backward compatibility between the mimelib package and the email package was not a priority.

Here is a brief description of the differences between the mimelib and the email packages, along with hints on how to port your applications.

Of course, the most visible difference between the two packages is that the package name has been changed to email. In addition, the top-level package has the following differences:

- `messageFromString()` has been renamed to `message_from_string()`.
- `messageFromFile()` has been renamed to `message_from_file()`.

The Message class has the following differences:

- The method `asString()` was renamed to `as_string()`.
- The method `ismultipart()` was renamed to `is_multipart()`.
- The `get_payload()` method has grown a `decode` optional argument.
- The method `getall()` was renamed to `get_all()`.
- The method `addheader()` was renamed to `add_header()`.
- The method `gettype()` was renamed to `get_type()`.
The method `getmaintype()` was renamed to `get_main_type()`.

The method `getsubtype()` was renamed to `get_subtype()`.

The method `getparams()` was renamed to `get_params()`. Also, whereas `getparams()` returned a list of strings, `get_params()` returns a list of 2-tuples, effectively the key/value pairs of the parameters, split on the `=' sign.

The method `getparam()` was renamed to `get_param()`.

The method `getcharsets()` was renamed to `get_charsets()`.

The method `getfilename()` was renamed to `get_filename()`.

The method `getboundary()` was renamed to `get_boundary()`.

The method `setboundary()` was renamed to `set_boundary()`.

The method `getdecodedpayload()` was removed. To get similar functionality, pass the value 1 to the `decode` flag of the `get_payload()` method.

The method `getpayloadastext()` was removed. Similar functionality is supported by the `DecodedGenerator` class in the `email.generator` module.

The method `getbodyastext()` was removed. You can get similar functionality by creating an iterator with `typed_subpart_iterator()` in the `email.iterators` module.

The `Parser` class has no differences in its public interface. It does have some additional smarts to recognize `message/delivery-status` type messages, which it represents as a `Message` instance containing separate `Message` subparts for each header block in the delivery status notification [1].

The `Generator` class has no differences in its public interface. There is a new class in the `email.generator` module though, called `DecodedGenerator` which provides most of the functionality previously available in the `Message.getpayloadastext()` method.
The following modules and classes have been changed:

- The **MIMEBase** class constructor arguments `_major` and `_minor` have changed to `_maintype` and `_subtype` respectively.

- The **Image** class/module has been renamed to **MIMEImage**. The `_minor` argument has been renamed to `_subtype`.

- The **Text** class/module has been renamed to **MIMEText**. The `_minor` argument has been renamed to `_subtype`.

- The **MessageRFC822** class/module has been renamed to **MIMEMessage**. Note that an earlier version of **mimelib** called this class/module **RFC822**, but that clashed with the Python standard library module **rfc822** on some case-insensitive file systems.

  Also, the **MIMEMessage** class now represents any kind of MIME message with main type *message*. It takes an optional argument `_subtype` which is used to set the MIME subtype. `_subtype` defaults to rfc822.

**mimelib** provided some utility functions in its **address** and **date** modules. All of these functions have been moved to the **email.utils** module.

The **MsgReader** class/module has been removed. Its functionality is most closely supported in the **body_line_iterator()** function in the **email.iterators** module.

**Footnotes**

[1] Delivery Status Notifications (DSN) are defined in **RFC 1894**.
18.1. email — An email and MIME handling package
18.1.1. email: Representing an email message

The central class in the email package is the Message class, imported from the email.message module. It is the base class for the email object model. Message provides the core functionality for setting and querying header fields, and for accessing message bodies.

Conceptually, a Message object consists of headers and payloads. Headers are RFC 2822 style field names and values where the field name and value are separated by a colon. The colon is not part of either the field name or the field value.

Headers are stored and returned in case-preserving form but are matched case-insensitively. There may also be a single envelope header, also known as the Unix-From header or the From_ header. The payload is either a string in the case of simple message objects or a list of Message objects for MIME container documents (e.g. multipart/* and message/rfc822).

Message objects provide a mapping style interface for accessing the message headers, and an explicit interface for accessing both the headers and the payload. It provides convenience methods for generating a flat text representation of the message object tree, for accessing commonly used header parameters, and for recursively walking over the object tree.

Here are the methods of the Message class:

```python
class email.message.Message
    The constructor takes no arguments.

    as_string([unixfrom])```
Return the entire message flattened as a string. When optional `unixfrom` is `True`, the envelope header is included in the returned string. `unixfrom` defaults to `False`. Flattening the message may trigger changes to the `Message` if defaults need to be filled in to complete the transformation to a string (for example, MIME boundaries may be generated or modified).

Note that this method is provided as a convenience and may not always format the message the way you want. For example, by default it mangles lines that begin with `From`. For more flexibility, instantiate a `Generator` instance and use its `flatten()` method directly. For example:

```python
from cStringIO import StringIO
from email.generator import Generator
fp = StringIO()
g = Generator(fp, mangle_from_=False, maxheaderlen=60)
g.flatten(msg)
text = fp.getvalue()
```

`__str__()`  
Equivalent to `as_string(unixfrom=True)`.

`is_multipart()`  
Return `True` if the message’s payload is a list of sub-`Message` objects, otherwise return `False`. When `is_multipart()` returns `False`, the payload should be a string object.

`set_unixfrom(unixfrom)`  
Set the message’s envelope header to `unixfrom`, which should be a string.

`get_unixfrom()`  
Return the message’s envelope header. Defaults to `None` if the envelope header was never set.
**attach**(*payload*)

Add the given *payload* to the current payload, which must be `None` or a list of `Message` objects before the call. After the call, the payload will always be a list of `Message` objects. If you want to set the payload to a scalar object (e.g. a string), use `set_payload()` instead.

**get_payload([i[, *decode*]])**

Return the current payload, which will be a list of `Message` objects when `is_multipart()` is `True`, or a string when `is_multipart()` is `False`. If the payload is a list and you mutate the list object, you modify the message's payload in place.

With optional argument *i*, `get_payload()` will return the *i*-th element of the payload, counting from zero, if `is_multipart()` is `True`. An `IndexError` will be raised if *i* is less than 0 or greater than or equal to the number of items in the payload. If the payload is a string (i.e. `is_multipart()` is `False`) and *i* is given, a `TypeError` is raised.

Optional *decode* is a flag indicating whether the payload should be decoded or not, according to the *Content-Transfer-Encoding* header. When `True` and the message is not a multipart, the payload will be decoded if this header's value is `quoted-printable` or `base64`. If some other encoding is used, or `Content-Transfer-Encoding` header is missing, or if the payload has bogus base64 data, the payload is returned as-is (undecoded). If the message is a multipart and the *decode* flag is `True`, then `None` is returned. The default for *decode* is `False`.

**set_payload**(*payload[, *charset]*)
Set the entire message object’s payload to *payload*. It is the client’s responsibility to ensure the payload invariants. Optional *charset* sets the message’s default character set; see `set_charset()` for details.

*Changed in version 2.2.2: charset argument added.*

**set_charset(charset)**

Set the character set of the payload to *charset*, which can either be a [Charset](https://docs.python.org/3/library/email.charset.html) instance (see `email.charset`), a string naming a character set, or `None`. If it is a string, it will be converted to a [Charset](https://docs.python.org/3/library/email.charset.html) instance. If *charset* is `None`, the *charset* parameter will be removed from the *Content-Type* header. Anything else will generate a `TypeError`.

The message will be assumed to be of type `text/*`, with the payload either in unicode or encoded with *charset.input_charset*. It will be encoded or converted to *charset.output_charset* and transfer encoded properly, if needed, when generating the plain text representation of the message. MIME headers (MIME-Version, Content-Type, Content-Transfer-Encoding) will be added as needed.

*New in version 2.2.2.*

**get_charset()**

Return the [Charset](https://docs.python.org/3/library/email.charset.html) instance associated with the message’s payload.

*New in version 2.2.2.*

The following methods implement a mapping-like interface for accessing the message’s RFC 2822 headers. Note that there are some semantic differences between these methods and a normal mapping (i.e. dictionary) interface. For example, in a dictionary
there are no duplicate keys, but here there may be duplicate message headers. Also, in dictionaries there is no guaranteed order to the keys returned by `keys()`, but in a `Message` object, headers are always returned in the order they appeared in the original message, or were added to the message later. Any header deleted and then re-added are always appended to the end of the header list.

These semantic differences are intentional and are biased toward maximal convenience.

Note that in all cases, any envelope header present in the message is not included in the mapping interface.

```python
__len__()

Return the total number of headers, including duplicates.

__contains__(name)

Return true if the message object has a field named `name`. Matching is done case-insensitively and `name` should not include the trailing colon. Used for the `in` operator, e.g.:

```python
if 'message-id' in myMessage:
    print 'Message-ID:', myMessage['message-id']
```

__getitem__(name)

Return the value of the named header field. `name` should not include the colon field separator. If the header is missing, `None` is returned; a `KeyError` is never raised.

Note that if the named field appears more than once in the message’s headers, exactly which of those field values will be returned is undefined. Use the `get_all()` method to get the values of all the extant named headers.
__setitem__(name, val)

Add a header to the message with field name `name` and value `val`. The field is appended to the end of the message’s existing fields.

Note that this does *not* overwrite or delete any existing header with the same name. If you want to ensure that the new header is the only one present in the message with field name `name`, delete the field first, e.g.:

```python
def msg['subject']
msg['subject'] = 'Python roolz!'
```

__delitem__(name)

Delete all occurrences of the field with name `name` from the message’s headers. No exception is raised if the named field isn’t present in the headers.

has_key(name)

Return true if the message contains a header field named `name`, otherwise return false.

keys()

Return a list of all the message’s header field names.

values()

Return a list of all the message’s field values.

items()

Return a list of 2-tuples containing all the message’s field headers and values.

get(name[, failobj])

Return the value of the named header field. This is identical to __getitem__() except that optional `failobj` is returned if the named header is missing (defaults to `None`).
Here are some additional useful methods:

get_all(name[, failobj])
Return a list of all the values for the field named name. If there are no such named headers in the message, failobj is returned (defaults to None).

add_header(_name, _value, **_params)
Extended header setting. This method is similar to __setitem__() except that additional header parameters can be provided as keyword arguments. _name is the header field to add and _value is the primary value for the header.

For each item in the keyword argument dictionary _params, the key is taken as the parameter name, with underscores converted to dashes (since dashes are illegal in Python identifiers). Normally, the parameter will be added as key="value" unless the value is None, in which case only the key will be added.

Here's an example:

```python
msg.add_header('Content-Disposition', 'attachment', filename='bud.gif')
```

This will add a header that looks like

```
Content-Disposition: attachment; filename="bud.gif"
```

replace_header(_name, _value)
Replace a header. Replace the first header found in the message that matches _name, retaining header order and field name case. If no matching header was found, a KeyError is raised.

New in version 2.2.2.
**get_content_type()**

Return the message's content type. The returned string is coerced to lower case of the form maintype/subtype. If there was no Content-Type header in the message the default type as given by get_default_type() will be returned. Since according to RFC 2045, messages always have a default type, get_content_type() will always return a value.

RFC 2045 defines a message's default type to be text/plain unless it appears inside a multipart/digest container, in which case it would be message/rfc822. If the Content-Type header has an invalid type specification, RFC 2045 mandates that the default type be text/plain.

*New in version 2.2.2.*

**get_content_maintype()**

Return the message's main content type. This is the maintype part of the string returned by get_content_type().

*New in version 2.2.2.*

**get_content_subtype()**

Return the message's sub-content type. This is the subtype part of the string returned by get_content_type().

*New in version 2.2.2.*

**get_default_type()**

Return the default content type. Most messages have a default content type of text/plain, except for messages that are subparts of multipart/digest containers. Such subparts have a default content type of message/rfc822.

*New in version 2.2.2.*
**set_default_type**(*ctype*)

Set the default content type. *ctype* should either be *text/plain* or *message/rfc822*, although this is not enforced. The default content type is not stored in the **Content-Type** header.

New in version 2.2.2.

**get_params**(*[failobj[, header[, unquote]]]*)

Return the message's **Content-Type** parameters, as a list. The elements of the returned list are 2-tuples of key/value pairs, as split on the '=' sign. The left hand side of the '=' is the key, while the right hand side is the value. If there is no '=' sign in the parameter the value is the empty string, otherwise the value is as described in **get_param()** and is unquoted if optional *unquote* is **True** (the default).

Optional *failobj* is the object to return if there is no **Content-Type** header. Optional *header* is the header to search instead of **Content-Type**.

Changed in version 2.2.2: *unquote* argument added.

**get_param**(*param[, failobj[, header[, unquote]]]*)

Return the value of the **Content-Type** header's parameter *param* as a string. If the message has no **Content-Type** header or if there is no such parameter, then *failobj* is returned (defaults to **None**).

Optional *header* if given, specifies the message header to use instead of **Content-Type**.

Parameter keys are always compared case insensitively. The return value can either be a string, or a 3-tuple if the parameter was **RFC 2231** encoded. When it's a 3-tuple, the
elements of the value are of the form (CHARSET, LANGUAGE, VALUE). Note that both CHARSET and LANGUAGE can be None, in which case you should consider VALUE to be encoded in the us-ascii charset. You can usually ignore LANGUAGE.

If your application doesn’t care whether the parameter was encoded as in RFC 2231, you can collapse the parameter value by calling email.utils.collapse_rfc2231_value(), passing in the return value from get_param(). This will return a suitably decoded Unicode string when the value is a tuple, or the original string unquoted if it isn’t. For example:

```python
rawparam = msg.get_param('foo')
param = email.utils.collapse_rfc2231_value(rawparam)
```

In any case, the parameter value (either the returned string, or the VALUE item in the 3-tuple) is always unquoted, unless unquote is set to False.

*Changed in version 2.2.2: unquote argument added, and 3-tuple return value possible.*

```python
set_param(param, value[, header[, requote[, charset[, language]]]]))
```

Set a parameter in the Content-Type header. If the parameter already exists in the header, its value will be replaced with value. If the Content-Type header as not yet been defined for this message, it will be set to text/plain and the new parameter value will be appended as per RFC 2045.

Optional header specifies an alternative header to Content-Type, and all parameters will be quoted as necessary unless optional requote is False (the default is True).
If optional `charset` is specified, the parameter will be encoded according to RFC 2231. Optional `language` specifies the RFC 2231 language, defaulting to the empty string. Both `charset` and `language` should be strings.

*New in version 2.2.2.*

```python
def del_param(param[, header[, requote]])
Remove the given parameter completely from the `Content-Type` header. The header will be re-written in place without the parameter or its value. All values will be quoted as necessary unless `requote` is `False` (the default is `True`). Optional `header` specifies an alternative to `Content-Type`.

*New in version 2.2.2.*
```

```python
def set_type(type[, header][, requote])
Set the main type and subtype for the `Content-Type` header. `type` must be a string in the form `maintype/subtype`, otherwise a `ValueError` is raised.

This method replaces the `Content-Type` header, keeping all the parameters in place. If `requote` is `False`, this leaves the existing header’s quoting as is, otherwise the parameters will be quoted (the default).

An alternative header can be specified in the `header` argument. When the `Content-Type` header is set a `MIME-Version` header is also added.

*New in version 2.2.2.*
```

```python
def get_filename([failobj])
Return the value of the `filename` parameter of the `Content-`
Disposition header of the message. If the header does not have a filename parameter, this method falls back to looking for the name parameter on the Content-Type header. If neither is found, or the header is missing, then failobj is returned. The returned string will always be unquoted as per email.utils.unquote().

get_boundary([failobj])

Return the value of the boundary parameter of the Content-Type header of the message, or failobj if either the header is missing, or has no boundary parameter. The returned string will always be unquoted as per email.utils.unquote().

set_boundary(boundary)

Set the boundary parameter of the Content-Type header to boundary. set_boundary() will always quote boundary if necessary. A HeaderParseError is raised if the message object has no Content-Type header.

Note that using this method is subtly different than deleting the old Content-Type header and adding a new one with the new boundary via add_header(), because set_boundary() preserves the order of the Content-Type header in the list of headers. However, it does not preserve any continuation lines which may have been present in the original Content-Type header.

get_content_charset([failobj])

Return the charset parameter of the Content-Type header, coerced to lower case. If there is no Content-Type header, or if that header has no charset parameter, failobj is returned.

Note that this method differs from get_charset() which
returns the `charset` instance for the default encoding of the message body.

*New in version 2.2.2.*

**get_charsets([failobj])**

Return a list containing the character set names in the message. If the message is a `multipart`, then the list will contain one element for each subpart in the payload, otherwise, it will be a list of length 1.

Each item in the list will be a string which is the value of the `charset` parameter in the `Content-Type` header for the represented subpart. However, if the subpart has no `Content-Type` header, no `charset` parameter, or is not of the `text` main MIME type, then that item in the returned list will be `failobj`.

**walk()**

The `walk()` method is an all-purpose generator which can be used to iterate over all the parts and subparts of a message object tree, in depth-first traversal order. You will typically use `walk()` as the iterator in a `for` loop; each iteration returns the next subpart.

Here’s an example that prints the MIME type of every part of a multipart message structure:

```python
>>> for part in msg.walk():
...     print(part.get_content_type())
multipart/report
text/plain
message/delivery-status
text/plain
text/plain
message/rfc822
```
Changed in version 2.5: The previously deprecated methods `get_type()`, `get_main_type()`, and `get_subtype()` were removed.

Message objects can also optionally contain two instance attributes, which can be used when generating the plain text of a MIME message.

**preamble**

The format of a MIME document allows for some text between the blank line following the headers, and the first multipart boundary string. Normally, this text is never visible in a MIME-aware mail reader because it falls outside the standard MIME armor. However, when viewing the raw text of the message, or when viewing the message in a non-MIME aware reader, this text can become visible.

The `preamble` attribute contains this leading extra-armor text for MIME documents. When the `Parser` discovers some text after the headers but before the first boundary string, it assigns this text to the message’s `preamble` attribute. When the `Generator` is writing out the plain text representation of a MIME message, and it finds the message has a `preamble` attribute, it will write this text in the area between the headers and the first boundary. See `email.parser` and `email.generator` for details.

Note that if the message object has no preamble, the `preamble` attribute will be `None`.

**epilogue**

The `epilogue` attribute acts the same way as the `preamble` attribute, except that it contains text that appears between the last boundary and the end of the message.

Changed in version 2.5: You do not need to set the epilogue
to the empty string in order for the Generator to print a newline at the end of the file.

**defects**

The *defects* attribute contains a list of all the problems found when parsing this message. See `email.errors` for a detailed description of the possible parsing defects.

*New in version 2.4.*
18.1.2. email: Parsing email messages

Message object structures can be created in one of two ways: they can be created from whole cloth by instantiating `Message` objects and stringing them together via `attach()` and `set_payload()` calls, or they can be created by parsing a flat text representation of the email message.

The `email` package provides a standard parser that understands most email document structures, including MIME documents. You can pass the parser a string or a file object, and the parser will return to you the root `Message` instance of the object structure. For simple, non-MIME messages the payload of this root object will likely be a string containing the text of the message. For MIME messages, the root object will return `True` from its `is_multipart()` method, and the subparts can be accessed via the `get_payload()` and `walk()` methods.

There are actually two parser interfaces available for use, the classic `Parser` API and the incremental `FeedParser` API. The classic `Parser` API is fine if you have the entire text of the message in memory as a string, or if the entire message lives in a file on the file system. `FeedParser` is more appropriate for when you’re reading the message from a stream which might block waiting for more input (e.g. reading an email message from a socket). The `FeedParser` can consume and parse the message incrementally, and only returns the root object when you close the parser [1].

Note that the parser can be extended in limited ways, and of course you can implement your own parser completely from scratch. There is no magical connection between the `email` package’s bundled
parser and the `Message` class, so your custom parser can create message object trees any way it finds necessary.
18.1.2.1. FeedParser API

New in version 2.4.

The **FeedParser**, imported from the `email.feedparser` module, provides an API that is conducive to incremental parsing of email messages, such as would be necessary when reading the text of an email message from a source that can block (e.g. a socket). The **FeedParser** can of course be used to parse an email message fully contained in a string or a file, but the classic **Parser** API may be more convenient for such use cases. The semantics and results of the two parser APIs are identical.

The **FeedParser**'s API is simple; you create an instance, feed it a bunch of text until there's no more to feed it, then close the parser to retrieve the root message object. The **FeedParser** is extremely accurate when parsing standards-compliant messages, and it does a very good job of parsing non-compliant messages, providing information about how a message was deemed broken. It will populate a message object's `defects` attribute with a list of any problems it found in a message. See the `email.errors` module for the list of defects that it can find.

Here is the API for the **FeedParser**:

```python
class email.parser.FeedParser([_factory])

Create a **FeedParser** instance. Optional `_factory` is a no-argument callable that will be called whenever a new message object is needed. It defaults to the `email.message.Message` class.

feed(data)

Feed the **FeedParser** some more data. `data` should be a string
```
containing one or more lines. The lines can be partial and the FeedParser will stitch such partial lines together properly. The lines in the string can have any of the common three line endings, carriage return, newline, or carriage return and newline (they can even be mixed).

**close()**

Closing a FeedParser completes the parsing of all previously fed data, and returns the root message object. It is undefined what happens if you feed more data to a closed FeedParser.
The `Parser` class, imported from the `email.parser` module, provides an API that can be used to parse a message when the complete contents of the message are available in a string or file. The `email.parser` module also provides a second class, called `HeaderParser` which can be used if you're only interested in the headers of the message. `HeaderParser` can be much faster in these situations, since it does not attempt to parse the message body, instead setting the payload to the raw body as a string. `HeaderParser` has the same API as the `Parser` class.

```python
class email.parser.Parser(_class)
```

The constructor for the `Parser` class takes an optional argument `_class`. This must be a callable factory (such as a function or a class), and it is used whenever a sub-message object needs to be created. It defaults to `Message` (see `email.message`). The factory will be called without arguments.

The optional `strict` flag is ignored.

`Deprecated since version 2.4:` Because the `Parser` class is a backward compatible API wrapper around the new-in-Python 2.4 `FeedParser`, all parsing is effectively non-strict. You should simply stop passing a `strict` flag to the `Parser` constructor.

`Changed in version 2.2.2:` The `strict` flag was added.

`Changed in version 2.4:` The `strict` flag was deprecated.

The other public `Parser` methods are:
**parse**(*fp[, headersonly]*)

Read all the data from the file-like object *fp*, parse the resulting text, and return the root message object. *fp* must support both the `readline()` and the `read()` methods on file-like objects.

The text contained in *fp* must be formatted as a block of [RFC 2822](https://tools.ietf.org/html/rfc2822) style headers and header continuation lines, optionally preceded by a envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts).

Optional *headersonly* is as with the `parse()` method.

*Changed in version 2.2.2:* The *headersonly* flag was added.

**parsestr**(*text[, headersonly]*)

Similar to the `parse()` method, except it takes a string object instead of a file-like object. Calling this method on a string is exactly equivalent to wrapping *text* in a `StringIO` instance first and calling `parse()`.

Optional *headersonly* is a flag specifying whether to stop parsing after reading the headers or not. The default is `False`, meaning it parses the entire contents of the file.

*Changed in version 2.2.2:* The *headersonly* flag was added.

Since creating a message object structure from a string or a file object is such a common task, two functions are provided as a convenience. They are available in the top-level `email` package namespace.
email.message_from_string(s[, _class[, strict]])
  Return a message object structure from a string. This is exactly equivalent to Parser().parsestr(s). Optional _class and strict are interpreted as with the Parser class constructor.

  Changed in version 2.2.2: The strict flag was added.

email.message_from_file(fp[, _class[, strict]])
  Return a message object structure tree from an open file object. This is exactly equivalent to Parser().parse(fp). Optional _class and strict are interpreted as with the Parser class constructor.

  Changed in version 2.2.2: The strict flag was added.

Here’s an example of how you might use this at an interactive Python prompt:

```python
>>> import email
>>> msg = email.message_from_string(myString)
```
Here are some notes on the parsing semantics:

- Most non-`multipart` type messages are parsed as a single message object with a string payload. These objects will return `False` for `is_multipart()`. Their `get_payload()` method will return a string object.
- All `multipart` type messages will be parsed as a container message object with a list of sub-message objects for their payload. The outer container message will return `True` for `is_multipart()` and their `get_payload()` method will return the list of `Message` subparts.
- Most messages with a content type of `message/*` (e.g. `message/delivery-status` and `message/rfc822`) will also be parsed as container object containing a list payload of length 1. Their `is_multipart()` method will return `True`. The single element in the list payload will be a sub-message object.
- Some non-standards compliant messages may not be internally consistent about their `multipart`-edness. Such messages may have a `Content-Type` header of type `multipart`, but their `is_multipart()` method may return `False`. If such messages were parsed with the `FeedParser`, they will have an instance of the `MultipartInvariantViolationDefect` class in their `defects` attribute list. See `email.errors` for details.

Footnotes

[1] As of email package version 3.0, introduced in Python 2.4, the classic `Parser` was re-implemented in terms of the `FeedParser`, so the semantics and results are identical between the two parsers.
18.1. `email` — An email and MIME handling package
18.1.3. email: Generating MIME documents

One of the most common tasks is to generate the flat text of the email message represented by a message object structure. You will need to do this if you want to send your message via the smtplib module or the nntplib module, or print the message on the console. Taking a message object structure and producing a flat text document is the job of the Generator class.

Again, as with the email.parser module, you aren’t limited to the functionality of the bundled generator; you could write one from scratch yourself. However the bundled generator knows how to generate most email in a standards-compliant way, should handle MIME and non-MIME email messages just fine, and is designed so that the transformation from flat text, to a message structure via the Parser class, and back to flat text, is idempotent (the input is identical to the output). On the other hand, using the Generator on a Message constructed by program may result in changes to the Message object as defaults are filled in.

Here are the public methods of the Generator class, imported from the email.generator module:

```
class email.generator.Generator(outfp[, mangle_from_[, maxheaderlen]])
```

The constructor for the Generator class takes a file-like object called outfp for an argument. outfp must support the write() method and be usable as the output file in a Python extended print statement.
Optional `mangle_from_` is a flag that, when `True`, puts a `>` character in front of any line in the body that starts exactly as `From`, i.e. `From` followed by a space at the beginning of the line. This is the only guaranteed portable way to avoid having such lines be mistaken for a Unix mailbox format envelope header separator (see `WHY THE CONTENT-LENGTH FORMAT IS BAD` for details). `mangle_from_` defaults to `True`, but you might want to set this to `False` if you are not writing Unix mailbox format files.

Optional `maxheaderlen` specifies the longest length for a non-continued header. When a header line is longer than `maxheaderlen` (in characters, with tabs expanded to 8 spaces), the header will be split as defined in the `Header` class. Set to zero to disable header wrapping. The default is 78, as recommended (but not required) by `RFC 2822`.

The other public `Generator` methods are:

`flatten(msg[, unixfrom])`

Print the textual representation of the message object structure rooted at `msg` to the output file specified when the `Generator` instance was created. Subparts are visited depth-first and the resulting text will be properly MIME encoded.

Optional `unixfrom` is a flag that forces the printing of the envelope header delimiter before the first `RFC 2822` header of the root message object. If the root object has no envelope header, a standard one is crafted. By default, this is set to `False` to inhibit the printing of the envelope delimiter.

Note that for subparts, no envelope header is ever printed.

*New in version 2.2.2.*
clone\((fp)\)

Return an independent clone of this Generator instance with the exact same options.

*New in version 2.2.2.*

write\((s)\)

Write the string \(s\) to the underlying file object, i.e. \(outfp\) passed to Generator’s constructor. This provides just enough file-like API for Generator instances to be used in extended print statements.

As a convenience, see the methods `Message.as_string()` and `str(aMessage)`, a.k.a. `Message.__str__()`, which simplify the generation of a formatted string representation of a message object. For more detail, see `email.message`.

The `email.generator` module also provides a derived class, called `DecodedGenerator` which is like the Generator base class, except that non-text parts are substituted with a format string representing the part.

class email.generator.\texttt{DecodedGenerator}(outfp[, \texttt{mangle_from}[, \texttt{maxheaderlen}[. \texttt{fmt}]]])

This class, derived from Generator walks through all the subparts of a message. If the subpart is of main type `text`, then it prints the decoded payload of the subpart. Optional `_mangle_from_` and `maxheaderlen` are as with the Generator base class.

If the subpart is not of main type `text`, optional `fmt` is a format string that is used instead of the message payload. `fmt` is expanded with the following keywords, `%(keyword)s` format:
- **type** – Full MIME type of the non-text part
- **maintype** – Main MIME type of the non-text part
- **subtype** – Sub-MIME type of the non-text part
- **filename** – Filename of the non-text part
- **description** – Description associated with the non-text part
- **encoding** – Content transfer encoding of the non-text part

The default value for `fmt` is `None`, meaning

```
[Non-text (%(type)s) part of message omitted, filename %(filename)s]
```

*New in version 2.2.2.*

*Changed in version 2.5:* The previously deprecated method `__call__()` was removed.
18. Internet Data Handling

18.1. email — An email and MIME handling package
18.1.4. email: Creating email and MIME objects from scratch

Ordinarily, you get a message object structure by passing a file or some text to a parser, which parses the text and returns the root message object. However you can also build a complete message structure from scratch, or even individual `Message` objects by hand. In fact, you can also take an existing structure and add new `Message` objects, move them around, etc. This makes a very convenient interface for slicing-and-dicing MIME messages.

You can create a new object structure by creating `Message` instances, adding attachments and all the appropriate headers manually. For MIME messages though, the `email` package provides some convenient subclasses to make things easier.

Here are the classes:

```python
class email.mime.base.MIMEBase(_maintype, _subtype, **_params)
Module: email.mime.base
```

This is the base class for all the MIME-specific subclasses of `Message`. Ordinarily you won’t create instances specifically of `MIMEBase`, although you could. `MIMEBase` is provided primarily as a convenient base class for more specific MIME-aware subclasses.

`_maintype` is the `Content-Type` major type (e.g. `text` or `image`), and `subtype` is the `Content-Type` minor type (e.g. `plain` or `gif`). `params` is a parameter key/value dictionary and is passed directly to `Message.add_header()`.

The `MIMEBase` class always adds a `Content-Type` header (based on `_maintype`, `_subtype`, and `params`), and a `MIME-Version`
class email.mime.nonmultipart.MIMENonMultipart

A subclass of MIMEBase, this is an intermediate base class for MIME messages that are not multipart. The primary purpose of this class is to prevent the use of the attach() method, which only makes sense for multipart messages. If attach() is called, a MultipartConversionError exception is raised.

New in version 2.2.2.

class email.mime.multipart.MIMEMultipart([_subtype, boundary, _subparts, _params]])

A subclass of MIMEBase, this is an intermediate base class for MIME messages that are multipart. Optional _subtype defaults to mixed, but can be used to specify the subtype of the message. A Content-Type header of multipart/_subtype will be added to the message object. A MIME-Version header will also be added.

Optional boundary is the multipart boundary string. When None (the default), the boundary is calculated when needed (for example, when the message is serialized).

_subparts is a sequence of initial subparts for the payload. It must be possible to convert this sequence to a list. You can always attach new subparts to the message by using the Message.attach() method.

Additional parameters for the Content-Type header are taken from the keyword arguments, or passed into the _params
argument, which is a keyword dictionary.

New in version 2.2.2.

class email.mime.application.MIMEApplication(_data[, _subtype[, _encoder[, **_params]]]])

    Module: email.mime.application

A subclass of MIMENonMultipart, the MIMEApplication class is used to represent MIME message objects of major type application. _data is a string containing the raw byte data. Optional _subtype specifies the MIME subtype and defaults to octet-stream.

Optional _encoder is a callable (i.e. function) which will perform the actual encoding of the data for transport. This callable takes one argument, which is the MIMEApplication instance. It should use get_payload() and set_payload() to change the payload to encoded form. It should also add any Content-Transfer-Encoding or other headers to the message object as necessary. The default encoding is base64. See the email.encoders module for a list of the built-in encoders.

    _params are passed straight through to the base class constructor.

New in version 2.5.

class email.mime.audio.MIMEAudio(_audiodata[, _subtype[, _encoder[, **_params]]]])

    Module: email.mime.audio

A subclass of MIMENonMultipart, the MIMEAudio class is used to create MIME message objects of major type audio. _audiodata is
a string containing the raw audio data. If this data can be decoded by the standard Python module `sndhdr`, then the subtype will be automatically included in the `Content-Type` header. Otherwise you can explicitly specify the audio subtype via the `_subtype` parameter. If the minor type could not be guessed and `_subtype` was not given, then `TypeError` is raised.

Optional `_encoder` is a callable (i.e. function) which will perform the actual encoding of the audio data for transport. This callable takes one argument, which is the `MIMEAudio` instance. It should use `get_payload()` and `set_payload()` to change the payload to encoded form. It should also add any `Content-Transfer-Encoding` or other headers to the message object as necessary. The default encoding is base64. See the `email.encoders` module for a list of the built-in encoders.

`_params` are passed straight through to the base class constructor.

class email.mime.image.MIMEImage(_imagedata[, _subtype[, _encoder[, **_params]]]])

Module: email.mime.image

A subclass of `MIMENonMultipart`, the `MIMEImage` class is used to create MIME message objects of major type `image`. `_imagedata` is a string containing the raw image data. If this data can be decoded by the standard Python module `imghdr`, then the subtype will be automatically included in the `Content-Type` header. Otherwise you can explicitly specify the image subtype via the `_subtype` parameter. If the minor type could not be guessed and `_subtype` was not given, then `TypeError` is raised.

Optional `_encoder` is a callable (i.e. function) which will perform the actual encoding of the image data for transport. This callable
takes one argument, which is the MIMEImage instance. It should use get_payload() and set_payload() to change the payload to encoded form. It should also add any Content-Transfer-Encoding or other headers to the message object as necessary. The default encoding is base64. See the email.encoders module for a list of the built-in encoders.

_params are passed straight through to the MIMEBase constructor.

class email.mime.message.MIMEMessage(_msg[, _subtype])
Module: email.mime.message

A subclass of MIMENonMultipart, the MIMEMessage class is used to create MIME objects of main type message. _msg is used as the payload, and must be an instance of class Message (or a subclass thereof), otherwise a TypeError is raised.

Optional _subtype sets the subtype of the message; it defaults to rfc822.

class email.mime.text.MIMEText(_text[, _subtype[, _charset]])
Module: email.mime.text

A subclass of MIMENonMultipart, the MIMEText class is used to create MIME objects of major type text. _text is the string for the payload. _subtype is the minor type and defaults to plain. _charset is the character set of the text and is passed as a parameter to the MIMENonMultipart constructor; it defaults to ascii. If _text is unicode, it is encoded using the output_charset of _charset, otherwise it is used as-is.

Changed in version 2.4: The previously deprecated _encoding argument has been removed. Content Transfer Encoding now happens implicitly based on the _charset argument.
18. Internet Data Handling

18.1. email — An email and MIME handling package
18.1.5. **email**: Internationalized headers

**RFC 2822** is the base standard that describes the format of email messages. It derives from the older **RFC 822** standard which came into widespread use at a time when most email was composed of ASCII characters only. **RFC 2822** is a specification written assuming email contains only 7-bit ASCII characters.

Of course, as email has been deployed worldwide, it has become internationalized, such that language specific character sets can now be used in email messages. The base standard still requires email messages to be transferred using only 7-bit ASCII characters, so a slew of RFCs have been written describing how to encode email containing non-ASCII characters into **RFC 2822**-compliant format. These RFCs include **RFC 2045**, **RFC 2046**, **RFC 2047**, and **RFC 2231**. The **email** package supports these standards in its **email.header** and **email.charset** modules.

If you want to include non-ASCII characters in your email headers, say in the **Subject** or **To** fields, you should use the **Header** class and assign the field in the **Message** object to an instance of **Header** instead of using a string for the header value. Import the **Header** class from the **email.header** module. For example:

```python
>>> from email.message import Message
>>> from email.header import Header
>>> msg = Message()
>>> h = Header('
\xf6stal', 'iso-8859-1')
>>> msg['Subject'] = h
>>> print msg.as_string()
Subject: =?iso-8859-1?q?p=F6stal?
```

Notice here how we wanted the **Subject** field to contain a non-ASCII
character? We did this by creating a `Header` instance and passing in the character set that the byte string was encoded in. When the subsequent `Message` instance was flattened, the `Subject` field was properly RFC 2047 encoded. MIME-aware mail readers would show this header using the embedded ISO-8859-1 character.

*New in version 2.2.2.*

Here is the `Header` class description:

```python
class email.header.Header([
    s, 
    charset, 
    maxlinelen, 
    header_name, 
    continuation_ws, 
    errors
])
```

Create a MIME-compliant header that can contain strings in different character sets.

Optional `s` is the initial header value. If `None` (the default), the initial header value is not set. You can later append to the header with `append()` method calls. `s` may be a byte string or a Unicode string, but see the `append()` documentation for semantics.

Optional `charset` serves two purposes: it has the same meaning as the `charset` argument to the `append()` method. It also sets the default character set for all subsequent `append()` calls that omit the `charset` argument. If `charset` is not provided in the constructor (the default), the `us-ascii` character set is used both as `s`'s initial charset and as the default for subsequent `append()` calls.

The maximum line length can be specified explicit via `maxlinelen`. For splitting the first line to a shorter value (to account for the field header which isn’t included in `s`, e.g. `Subject`) pass in the name of the field in `header_name`. The default `maxlinelen` is 76, and the default value for `header_name` is `None`, meaning it is not taken into account for the first line of a long, split header.
Optional \texttt{continuation\_ws} must be \textbf{RFC 2822}-compliant folding whitespace, and is usually either a space or a hard tab character. This character will be prepended to continuation lines. \texttt{continuation\_ws} defaults to a single space character (" ").

Optional \texttt{errors} is passed straight through to the \texttt{append()} method.

\begin{verbatim}
\texttt{append(s[, charset[, errors]])}
\end{verbatim}

Append the string \texttt{s} to the MIME header.

Optional \texttt{charset}, if given, should be a \texttt{Charset} instance (see \texttt{email.charset}) or the name of a character set, which will be converted to a \texttt{Charset} instance. A value of \texttt{None} (the default) means that the \texttt{charset} given in the constructor is used.

\texttt{s} may be a byte string or a Unicode string. If it is a byte string (i.e. \texttt{isinstance(s, str) \text{is true}}), then \texttt{charset} is the encoding of that byte string, and a \texttt{UnicodeError} will be raised if the string cannot be decoded with that character set.

If \texttt{s} is a Unicode string, then \texttt{charset} is a hint specifying the character set of the characters in the string. In this case, when producing an \textbf{RFC 2822}-compliant header using \textbf{RFC 2047} rules, the Unicode string will be encoded using the following charsets in order: \texttt{us-ascii}, the \texttt{charset} hint, \texttt{utf-8}. The first character set to not provoke a \texttt{UnicodeError} is used.

Optional \texttt{errors} is passed through to any \texttt{unicode()} or \texttt{ustr.encode()} call, and defaults to “strict”.

\begin{verbatim}
\texttt{encode([splitchars])}
\end{verbatim}

Encode a message header into an RFC-compliant format, possibly wrapping long lines and encapsulating non-ASCII
parts in base64 or quoted-printable encodings. Optional
splitchars is a string containing characters to split long ASCII
lines on, in rough support of RFC 2822's highest level
syntactic breaks. This doesn’t affect RFC 2047 encoded lines.

The Header class also provides a number of methods to support
standard operators and built-in functions.

```python
__str__()
```
A synonym for Header.encode(). Useful for str(aHeader).

```python
__unicode__()
```
A helper for the built-in unicode() function. Returns the
header as a Unicode string.

```python
__eq__(other)
```
This method allows you to compare two Header instances for
equality.

```python
__ne__(other)
```
This method allows you to compare two Header instances for
inequality.

The email.header module also provides the following convenient
functions.

```python
email.header.decode_header(header)
```
Decode a message header value without converting the
character set. The header value is in header.

This function returns a list of (decoded_string, charset) pairs
containing each of the decoded parts of the header. charset is
None for non-encoded parts of the header, otherwise a lower case
string containing the name of the character set specified in the
encoded string.
Here’s an example:
>>> from email.header import decode_header
[('p\xf6stal', 'iso-8859-1')]

[, maxlinelen[,

email.header. make_header (decoded_seq

header_name[, continuation_ws]]])
Create a Header instance from a sequence of pairs as returned
by decode_header() .
takes a header value string and returns a
sequence of pairs of the format (decoded_string, charset)
where charset is the name of the character set.
decode_header()

This function takes one of those sequence of pairs and returns a
Header instance. Optional maxlinelen, header_name, and
continuation_ws are as in the Header constructor.

18.1.6. **email: Representing character sets**

This module provides a class `Charset` for representing character sets and character set conversions in email messages, as well as a character set registry and several convenience methods for manipulating this registry. Instances of `Charset` are used in several other modules within the `email` package.

Import this class from the `email.charset` module.

*New in version 2.2.2.*

```python
class email.charset.Charset([input_charset])
    Map character sets to their email properties.
```

This class provides information about the requirements imposed on email for a specific character set. It also provides convenience routines for converting between character sets, given the availability of the applicable codecs. Given a character set, it will do its best to provide information on how to use that character set in an email message in an RFC-compliant way.

Certain character sets must be encoded with quoted-printable or base64 when used in email headers or bodies. Certain character sets must be converted outright, and are not allowed in email.

Optional `input_charset` is as described below; it is always coerced to lower case. After being alias normalized it is also used as a lookup into the registry of character sets to find out the header encoding, body encoding, and output conversion codec to be used for the character set. For example, if `input_charset` is `iso-8859-1`, then headers and bodies will be encoded using...
quoted-printable and no output conversion codec is necessary. If \texttt{input_charset} is \texttt{euc-jp}, then headers will be encoded with base64, bodies will not be encoded, but output text will be converted from the \texttt{euc-jp} character set to the \texttt{iso-2022-jp} character set.

\textbf{Charset} instances have the following data attributes:

- **input_charset**
  The initial character set specified. Common aliases are converted to their official email names (e.g. \texttt{latin_1} is converted to \texttt{iso-8859-1}). Defaults to 7-bit \texttt{us-ascii}.

- **header_encoding**
  If the character set must be encoded before it can be used in an email header, this attribute will be set to \texttt{Charset.QP} (for quoted-printable), \texttt{Charset.BASE64} (for base64 encoding), or \texttt{Charset.SHORTEST} for the shortest of QP or BASE64 encoding. Otherwise, it will be \texttt{None}.

- **body_encoding**
  Same as \texttt{header_encoding}, but describes the encoding for the mail message's body, which indeed may be different than the header encoding. \texttt{Charset.SHORTEST} is not allowed for \texttt{body_encoding}.

- **output_charset**
  Some character sets must be converted before they can be used in email headers or bodies. If the \texttt{input_charset} is one of them, this attribute will contain the name of the character set output will be converted to. Otherwise, it will be \texttt{None}.

- **input_codec**
  The name of the Python codec used to convert the \texttt{input_charset} to Unicode. If no conversion codec is
necessary, this attribute will be None.

**output_codec**
The name of the Python codec used to convert Unicode to the output_charset. If no conversion codec is necessary, this attribute will have the same value as the input_codec.

Charset instances also have the following methods:

**get_body_encoding()**
Return the content transfer encoding used for body encoding.

This is either the string quoted-printable or base64 depending on the encoding used, or it is a function, in which case you should call the function with a single argument, the Message object being encoded. The function should then set the Content-Transfer-Encoding header itself to whatever is appropriate.

Returns the string quoted-printable if body_encoding is QP, returns the string base64 if body_encoding is BASE64, and returns the string 7bit otherwise.

**convert(s)**
Convert the string s from the input_codec to the output_codec.

**to_splitable(s)**
Convert a possibly multibyte string to a safely splittable format. s is the string to split.

Uses the input_codec to try and convert the string to Unicode, so it can be safely split on character boundaries (even for multibyte characters).

Returns the string as-is if it isn’t known how to convert s to
Unicode with the \textit{input\_charset}.

Characters that could not be converted to Unicode will be replaced with the Unicode replacement character 'U+FFFD'.

\texttt{from\_splittable(ustr[, to\_output])}

Convert a splittable string back into an encoded string. \texttt{ustr} is a Unicode string to “unsplit”.

This method uses the proper codec to try and convert the string from Unicode back into an encoded format. Return the string as-is if it is not Unicode, or if it could not be converted from Unicode.

Characters that could not be converted from Unicode will be replaced with an appropriate character (usually '?').

If \texttt{to\_output} is \texttt{True} (the default), uses \texttt{output\_codec} to convert to an encoded format. If \texttt{to\_output} is \texttt{False}, it uses \texttt{input\_codec}.

\texttt{get\_output\_charset()}

Return the output character set.

This is the \texttt{output\_charset} attribute if that is not \texttt{None}, otherwise it is \texttt{input\_charset}.

\texttt{encoded\_header\_len()}

Return the length of the encoded header string, properly calculating for quoted-printable or base64 encoding.

\texttt{header\_encode(s[, convert])}

Header-encode the string \texttt{s}.

If \texttt{convert} is \texttt{True}, the string will be converted from the input
charset to the output charset automatically. This is not useful for multibyte character sets, which have line length issues (multibyte characters must be split on a character, not a byte boundary); use the higher-level Header class to deal with these issues (see email.header). convert defaults to False.

The type of encoding (base64 or quoted-printable) will be based on the header_encoding attribute.

body_encode(s[, convert])
Body-encode the string s.

If convert is True (the default), the string will be converted from the input charset to output charset automatically. Unlike header_encode(), there are no issues with byte boundaries and multibyte charsets in email bodies, so this is usually pretty safe.

The type of encoding (base64 or quoted-printable) will be based on the body_encoding attribute.

The Charset class also provides a number of methods to support standard operations and built-in functions.

__str__()
Returns input_charset as a string coerced to lower case. __repr__() is an alias for __str__().

__eq__(other)
This method allows you to compare two Charset instances for equality.

__ne__(other)
This method allows you to compare two Charset instances for inequality.
The `email.charset` module also provides the following functions for adding new entries to the global character set, alias, and codec registries:

```python
email.charset.add_charset(charset[, header_enc[, body_enc[, output_charset]]])

Add character properties to the global registry.

`charset` is the input character set, and must be the canonical name of a character set.

Optional `header_enc` and `body_enc` is either `Charset.QP` for quoted-printable, `Charset.BASE64` for base64 encoding, `Charset.SHORTEST` for the shortest of quoted-printable or base64 encoding, or `None` for no encoding. `SHORTEST` is only valid for `header_enc`. The default is `None` for no encoding.

Optional `output_charset` is the character set that the output should be in. Conversions will proceed from input charset, to Unicode, to the output charset when the method `Charset.convert()` is called. The default is to output in the same character set as the input.

Both `input_charset` and `output_charset` must have Unicode codec entries in the module’s character set-to-codec mapping; use `add_codec()` to add codecs the module does not know about. See the `codecs` module’s documentation for more information.

The global character set registry is kept in the module global dictionary `CHARSETS`.

```python
email.charset.add_alias(alias, canonical)

Add a character set alias. `alias` is the alias name, e.g. latin-1. `canonical` is the character set's canonical name, e.g. iso-8859-1.
The global charset alias registry is kept in the module global dictionary `ALIASES`.

```python
e-mail.charset.add_codec(charset, codecname)
```

Add a codec that maps characters in the given character set to and from Unicode.

`charset` is the canonical name of a character set. `codecname` is the name of a Python codec, as appropriate for the second argument to the `unicode()` built-in, or to the `encode()` method of a Unicode string.
18.1.7. email: Encoders

When creating Message objects from scratch, you often need to encode the payloads for transport through compliant mail servers. This is especially true for image/* and text/* type messages containing binary data.

The email package provides some convenient encodings in its encoders module. These encoders are actually used by the MIMEAudio and MIMEImage class constructors to provide default encodings. All encoder functions take exactly one argument, the message object to encode. They usually extract the payload, encode it, and reset the payload to this newly encoded value. They should also set the Content-Transfer-Encoding header as appropriate.

Here are the encoding functions provided:

email.encoders.encode_quopri(msg)
Encodes the payload into quoted-printable form and sets the Content-Transfer-Encoding header to quoted-printable [1]. This is a good encoding to use when most of your payload is normal printable data, but contains a few unprintable characters.

email.encoders.encode_base64(msg)
Encodes the payload into base64 form and sets the Content-Transfer-Encoding header to base64. This is a good encoding to use when most of your payload is unprintable data since it is a more compact form than quoted-printable. The drawback of base64 encoding is that it renders the text non-human readable.

email.encoders.encode_7or8bit(msg)
This doesn’t actually modify the message’s payload, but it does set the Content-Transfer-Encoding header to either 7bit or 8bit.
as appropriate, based on the payload data.

e-mail.encoders.**encode_noop**(*msg*)

This does nothing; it doesn’t even set the **Content-Transfer-Encoding** header.

---

**Footnotes**

[1] Note that encoding with **encode_quopri()** also encodes all tabs and space characters in the data.
18.1.8. email: Exception and Defect classes

The following exception classes are defined in the `email.errors` module:

**exception** `email.errors.MessageError`

This is the base class for all exceptions that the `email` package can raise. It is derived from the standard `Exception` class and defines no additional methods.

**exception** `email.errors.MessageParseError`

This is the base class for exceptions thrown by the `Parser` class. It is derived from `MessageError`.

**exception** `email.errors.HeaderParseError`

Raised under some error conditions when parsing the `RFC 2822` headers of a message, this class is derived from `MessageParseError`. It can be raised from the `Parser.parse()` or `Parser.parsestr()` methods.

Situations where it can be raised include finding an envelope header after the first `RFC 2822` header of the message, finding a continuation line before the first `RFC 2822` header is found, or finding a line in the headers which is neither a header or a continuation line.

**exception** `email.errors.BoundaryError`

Raised under some error conditions when parsing the `RFC 2822` headers of a message, this class is derived from `MessageParseError`. It can be raised from the `Parser.parse()` or `Parser.parsestr()` methods.
Situations where it can be raised include not being able to find the starting or terminating boundary in a `multipart/*` message when strict parsing is used.

**exception** `email.errors.MultipartConversionError`

Raised when a payload is added to a `Message` object using `add_payload()`, but the payload is already a scalar and the message’s `Content-Type` main type is not either `multipart` or missing. `MultipartConversionError` multiply inherits from `MessageError` and the built-in `TypeError`.

Since `Message.add_payload()` is deprecated, this exception is rarely raised in practice. However the exception may also be raised if the `attach()` method is called on an instance of a class derived from `MIMENonMultipart` (e.g. `MIMEImage`).

Here’s the list of the defects that the `FeedParser` can find while parsing messages. Note that the defects are added to the message where the problem was found, so for example, if a message nested inside a `multipart/alternative` had a malformed header, that nested message object would have a defect, but the containing messages would not.

All defect classes are subclassed from `email.errors.MessageDefect`, but this class is *not* an exception!

**New in version 2.4:** All the defect classes were added.

- **NoBoundaryInMultipartDefect** – A message claimed to be a multipart, but had no `boundary` parameter.
- **StartBoundaryNotFoundDefect** – The start boundary claimed in the `Content-Type` header was never found.
- **FirstHeaderLineIsContinuationDefect** – The message had a continuation line as its first header line.
- **MisplacedEnvelopeHeaderDefect** - A “Unix From” header was found in the middle of a header block.
- **MalformedHeaderDefect** – A header was found that was missing a colon, or was otherwise malformed.
- **MultipartInvariantViolationDefect** – A message claimed to be a *multipart*, but no subparts were found. Note that when a message has this defect, its `is_multipart()` method may return false even though its content type claims to be *multipart*.
18. Internet Data Handling

18.1. email — An email and MIME handling package
18.1.9. email: Miscellaneous utilities

There are several useful utilities provided in the `email.utils` module:

`email.utils.quote(str)`

Return a new string with backslashes in `str` replaced by two backslashes, and double quotes replaced by backslash-double quote.

`email.utils.unquote(str)`

Return a new string which is an unquoted version of `str`. If `str` ends and begins with double quotes, they are stripped off. Likewise if `str` ends and begins with angle brackets, they are stripped off.

`email.utils.parseaddr(address)`

Parse address – which should be the value of some address-containing field such as `To` or `Cc` – into its constituent `realname` and `email address` parts. Returns a tuple of that information, unless the parse fails, in which case a 2-tuple of `('', '')` is returned.

`email.utils.formataddr(pair)`

The inverse of `parseaddr()`, this takes a 2-tuple of the form `realname, email_address))` and returns the string value suitable for a `To` or `Cc` header. If the first element of `pair` is false, then the second element is returned unmodified.

`email.utils.getaddresses(fieldvalues)`

This method returns a list of 2-tuples of the form returned by `parseaddr()`. `fieldvalues` is a sequence of header field values as might be returned by `Message.get_all()`. Here's a simple example that gets all the recipients of a message:
from email.utils import getaddresses

tos = msg.get_all('to', [])
ccs = msg.get_all('cc', [])
resent_tos = msg.get_all('resent-to', [])
resent_ccs = msg.get_all('resent-cc', [])
all_recipients = getaddresses(tos + ccs + resent_tos + resent_ccs)

email.utils.parsedate(date)
Attempts to parse a date according to the rules in RFC 2822. However, some mailers don't follow that format as specified, so parsedate() tries to guess correctly in such cases. date is a string containing an RFC 2822 date, such as "Mon, 20 Nov 1995 19:12:08 -0500". If it succeeds in parsing the date, parsedate() returns a 9-tuple that can be passed directly to time.mktime(); otherwise None will be returned. Note that indexes 6, 7, and 8 of the result tuple are not usable.

email.utils.parsedate_tz(date)
Performs the same function as parsedate(), but returns either None or a 10-tuple; the first 9 elements make up a tuple that can be passed directly to time.mktime(), and the tenth is the offset of the date's timezone from UTC (which is the official term for Greenwich Mean Time) [1]. If the input string has no timezone, the last element of the tuple returned is None. Note that indexes 6, 7, and 8 of the result tuple are not usable.

email.utils.mktime_tz(tuple)
Turn a 10-tuple as returned by parsedate_tz() into a UTC timestamp. It the timezone item in the tuple is None, assume local time. Minor deficiency: mktime_tz() interprets the first 8 elements of tuple as a local time and then compensates for the timezone difference. This may yield a slight error around changes in daylight savings time, though not worth worrying about for
common use.

```python
email.utils.formatdate([timeval[, localtime][, usegmt]])
```

Returns a date string as per RFC 2822, e.g.:

```
Fri, 09 Nov 2001 01:08:47 -0000
```

Optional `timeval` if given is a floating point time value as accepted by `time.gmtime()` and `time.localtime()`, otherwise the current time is used.

Optional `localtime` is a flag that when `True`, interprets `timeval`, and returns a date relative to the local timezone instead of UTC, properly taking daylight savings time into account. The default is `False` meaning UTC is used.

Optional `usegmt` is a flag that when `True`, outputs a date string with the timezone as an ascii string `GMT`, rather than a numeric `-0000`. This is needed for some protocols (such as HTTP). This only applies when `localtime` is `False`. The default is `False`.

*New in version 2.4.*

```python
email.utils.make_msgid([idstring])
```

Returns a string suitable for an RFC 2822-compliant `Message-ID` header. Optional `idstring` if given, is a string used to strengthen the uniqueness of the message id.

```python
email.utils.decode_rfc2231(s)
```

Decode the string `s` according to RFC 2231.

```python
email.utils.encode_rfc2231(s[, charset[, language]])
```

Encode the string `s` according to RFC 2231. Optional `charset` and `language`, if given is the character set name and language name
to use. If neither is given, s is returned as-is. If charset is given but language is not, the string is encoded using the empty string for language.

```
email.utils.collapse_rfc2231_value(value[, errors[, fallback_charset]])
```

When a header parameter is encoded in RFC 2231 format, Message.get_param() may return a 3-tuple containing the character set, language, and value. collapse_rfc2231_value() turns this into a unicode string. Optional errors is passed to the errors argument of the built-in unicode() function; it defaults to replace. Optional fallback_charset specifies the character set to use if the one in the RFC 2231 header is not known by Python; it defaults to us-ascii.

For convenience, if the value passed to collapse_rfc2231_value() is not a tuple, it should be a string and it is returned unquoted.

```
email.utils.decode_params(params)
```

Decode parameters list according to RFC 2231. params is a sequence of 2-tuples containing elements of the form (content-type, string-value).

*Changed in version 2.4:* The dump_address_pair() function has been removed; use formataddr() instead.

*Changed in version 2.4:* The decode() function has been removed; use the Header.decode_header() method instead.

*Changed in version 2.4:* The encode() function has been removed; use the Header.encode() method instead.
Footnotes

Note that the sign of the timezone offset is the opposite of the sign of the `time.timezone` variable for the same timezone; the latter variable follows the POSIX standard while this module follows RFC 2822.
Iterating over a message object tree is fairly easy with the `Message.walk()` method. The `email.iterators` module provides some useful higher level iterations over message object trees.

`email.iterators.body_line_iterator(msg[, decode])`

This iterates over all the payloads in all the subparts of `msg`, returning the string payloads line-by-line. It skips over all the subpart headers, and it skips over any subpart with a payload that isn’t a Python string. This is somewhat equivalent to reading the flat text representation of the message from a file using `readline()`, skipping over all the intervening headers.

Optional `decode` is passed through to `Message.get_payload()`.

`email.iterators.typed_subpart_iterator(msg[, maintype[, subtype]])`

This iterates over all the subparts of `msg`, returning only those subparts that match the MIME type specified by `maintype` and `subtype`.

Note that `subtype` is optional; if omitted, then subpart MIME type matching is done only with the main type. `maintype` is optional too; it defaults to `text`.

Thus, by default `typed_subpart_iterator()` returns each subpart that has a MIME type of `text/*`.

The following function has been added as a useful debugging tool. It should not be considered part of the supported public interface for the package.
email.iterators._structure(msg[, fp[, level]])

Prints an indented representation of the content types of the message object structure. For example:

```python
>>> msg = email.message_from_file(somefile)
>>> _structure(msg)
multipart/mixed
text/plain

text/plain

digest
message/rfc822
text/plain

digest
message/rfc822
text/plain

message/rfc822
text/plain

message/rfc822
text/plain

message/rfc822
text/plain

text/plain
```

Optional `fp` is a file-like object to print the output to. It must be suitable for Python’s extended print statement. `level` is used internally.
18.1.11. email: Examples

Here are a few examples of how to use the `email` package to read, write, and send simple email messages, as well as more complex MIME messages.

First, let's see how to create and send a simple text message:

```python
# Import smtplib for the actual sending function
import smtplib

# Import the email modules we'll need
from email.mime.text import MIMEText

# Open a plain text file for reading.  For this example, assume
# the text file contains only ASCII characters.
fp = open('textfile', 'rb')

# Create a text/plain message
msg = MIMEText(fp.read())
fp.close()

# me == the sender's email address
# you == the recipient's email address
msg['Subject'] = 'The contents of %s' % textfile
msg['From'] = me
msg['To'] = you

# Send the message via our own SMTP server, but don't include the
# envelope header.
s = smtplib.SMTP()
s.sendmail(me, [you], msg.as_string())
s.quit()
```

And parsing RFC822 headers can easily be done by the `parse(filename)` or `parsestr(message_as_string)` methods of the `Parser` class:

```python
# Import the email modules we'll need
from email.parser import Parser
```
# If the e-mail headers are in a file, uncomment this line:
#headers = Parser().parse(open(messagefile, 'r'))

# Or for parsing headers in a string, use:
headers = Parser().parsestr('From: <user@example.com>
To: <someone_else@example.com>
Subject: Test message

Body would go here
')

# Now the header items can be accessed as a dictionary:
print 'To: %s' % headers['to']
print 'From: %s' % headers['from']
print 'Subject: %s' % headers['subject']

Here's an example of how to send a MIME message containing a bunch of family pictures that may be residing in a directory:

# Import smtplib for the actual sending function
import smtplib

# Here are the email package modules we'll need
from email.mime.image import MIMEImage
from email.mime.multipart import MIMEMultipart

COMMASPACE = ', '

# Create the container (outer) email message.
msg = MIMEMultipart()
msg['Subject'] = 'Our family reunion'
# me == the sender's email address
# family = the list of all recipients' email addresses
msg['From'] = me
msg['To'] = COMMASPACE.join(family)
msg.preamble = 'Our family reunion'

# Assume we know that the image files are all in PNG format
for file in pngfiles:
    # Open the files in binary mode. Let the MIMEImage class a
guess the specific image type.
    fp = open(file, 'rb')
    img = MIMEImage(fp.read())
    fp.close()
    msg.attach(img)
Here's an example of how to send the entire contents of a directory as an email message: [1]

```python
#!/usr/bin/env python

"""Send the contents of a directory as a MIME message."""

import os
import sys
import smtplib
# For guessing MIME type based on file name extension
import mimetypes

from optparse import OptionParser
from email import encoders
from email.message import Message
from email.mime.audio import MIMEAudio
from email.mime.base import MIMEBase
from email.mime.image import MIMEImage
from email.mime.multipart import MIMEMultipart
from email.mime.text import MIMEText

COMMASPACE = ', '

def main():
    parser = OptionParser(usage="""\nSend the contents of a directory as a MIME message.
Usage: %prog [options]""

Unless the -o option is given, the email is sent by forwarding SMTP server, which then does the normal delivery process. Your machine must be running an SMTP server.
"""
    parser.add_option('-d', '--directory',
        type='string', action='store',
        help="Mail the contents of the specified directory. Only")
```
files in the directory are sent, and we don't recurse to subdirectories.

parser.add_option('-o', '--output',
    type='string', action='store', metavar='FILE',
    help='"Print the composed message to FILE instead of sending the message to the SMTP server."'

parser.add_option('-s', '--sender',
    type='string', action='store', metavar='SENDER',
    help='The value of the From: header (required)'

parser.add_option('-r', '--recipient',
    type='string', action='append', metavar='RECIPIENT',
    default=[], dest='recipients',
    help='A To: header value (at least one required)'

opts, args = parser.parse_args()
if not opts.sender or not opts.recipients:
    parser.print_help()
    sys.exit(1)
directory = opts.directory
if not directory:
    directory = '.'

# Create the enclosing (outer) message
outer = MIME_Multipart()
outer['Subject'] = 'Contents of directory %s' % os.path.abspath(directory)
outer['To'] = COMMASPACE.join(opts.recipients)
outer['From'] = opts.sender
outer.preamble = 'You will not see this in a MIME-aware mail'

for filename in os.listdir(directory):
    path = os.path.join(directory, filename)
    if not os.path.isfile(path):
        continue

    # Guess the content type based on the file's extension. # will be ignored, although we should check for simple # gzip'd or compressed files.
    ctype, encoding = mimetypes.guess_type(path)
    if ctype is None or encoding is not None:
        # No guess could be made, or the file is encoded (c
        # use a generic bag-of-bits type.
        ctype = 'application/octet-stream'
    maintype, subtype = ctype.split('/', 1)
    if maintype == 'text':
        fp = open(path)
        # Note: we should handle calculating the charset
        msg = MIMEText(fp.read(), _subtype=subtype)
        fp.close()
        elif maintype == 'image':
            fp = open(path, 'rb')
Here's an example of how to unpack a MIME message like the one above, into a directory of files:

#!/usr/bin/env python

"""Unpack a MIME message into a directory of files."""

import os
import sys
import email
import errno
import mimetypes

from optparse import OptionParser
def main():
    parser = OptionParser(usage="Unpack a MIME message into a directory of files.
Usage: %prog [options] msgfile 
"")
    parser.add_option('-d', '--directory',
                      type='string',
                      action='store',
                      help="Unpack the MIME message into the named directory, which will be created if it does not already exist.""")
    opts, args = parser.parse_args()
    if not opts.directory:
        parser.print_help()
        sys.exit(1)

    try:
        msgfile = args[0]
    except IndexError:
        parser.print_help()
        sys.exit(1)

    try:
        os.mkdir(opts.directory)
    except OSError, e:
        # Ignore directory exists error
        if e.errno != errno.EEXIST:
            raise

    fp = open(msgfile)
    msg = email.message_from_file(fp)
    fp.close()

    counter = 1
    for part in msg.walk():
        # multipart/* are just containers
        if part.get_content_maintype() == 'multipart':
            continue
        # Applications should really sanitize the given filename
        # email message can't be used to overwrite important files
        filename = part.get_filename()
        if not filename:
            ext = mimetypes.guess_extension(part.get_content_type())
            if not ext:
                # Use a generic bag-of-bits extension
Here's an example of how to create an HTML message with an alternative plain text version: [2]
# Record the MIME types of both parts - text/plain and text/html.
part1 = MIMEText(text, 'plain')
part2 = MIMEText(html, 'html')

# Attach parts into message container.
# According to RFC 2046, the last part of a multipart message, # the HTML message, is best and preferred.
msg.attach(part1)
msg.attach(part2)

# Send the message via local SMTP server.
s = smtplib.SMTP('localhost')
# sendmail function takes 3 arguments: sender's address, recipi # and message to send - here it is sent as one string.
s.sendmail(me, you, msg.as_string())
s.quit()

Footnotes

[1] Thanks to Matthew Dixon Cowles for the original inspiration and examples.
18.2. json — JSON encoder and
decoder
New in version 2.6.
JSON (JavaScript Object Notation) <http://json.org> is a subset of
JavaScript syntax (ECMA-262 3rd edition) used as a lightweight data
interchange format.
exposes an API familiar to users of the standard library
and pickle modules.
json

marshal

Encoding basic Python object hierarchies:
>>> import json
>>> json.dumps(['foo', {'bar': ('baz', None, 1.0, 2)}])
'["foo", {"bar": ["baz", null, 1.0, 2]}]'
>>> print json.dumps("\"foo\bar")
"\"foo\bar"
>>> print json.dumps(u'\u1234')
"\u1234"
>>> print json.dumps('\\')
"\\"
>>> print json.dumps({"c": 0, "b": 0, "a": 0}, sort_keys=True)
{"a": 0, "b": 0, "c": 0}
>>> from StringIO import StringIO
>>> io = StringIO()
>>> json.dump(['streaming API'], io)
>>> io.getvalue()
'["streaming API"]'

Compact encoding:
>>> import json
>>> json.dumps([1,2,3,{'4': 5, '6': 7}], separators=(',',':'))
'[1,2,3,{"4":5,"6":7}]'

Pretty printing:


>>> import json
>>> print json.dumps({'4': 5, '6': 7}, sort_keys=True, indent=4)
{
"4": 5,
"6": 7
}

Decoding JSON:
>>> import json
>>> json.loads('["foo", {"bar":["baz", null, 1.0, 2]}]')
[u'foo', {u'bar': [u'baz', None, 1.0, 2]}]
>>> json.loads('"\\"foo\\bar"')
u'"foo\x08ar'
>>> from StringIO import StringIO
>>> io = StringIO('["streaming API"]')
>>> json.load(io)
[u'streaming API']

Specializing JSON object decoding:
>>> import json
>>> def as_complex(dct):
...
if '__complex__' in dct:
...
return complex(dct['real'], dct['imag'])
...
return dct
...
>>> json.loads('{"__complex__": true, "real": 1, "imag": 2}',
...
object_hook=as_complex)
(1+2j)
>>> import decimal
>>> json.loads('1.1', parse_float=decimal.Decimal)
Decimal('1.1')

Extending

JSONEncoder :

>>> import json
>>> class ComplexEncoder(json.JSONEncoder):
...
def default(self, obj):
...
if isinstance(obj, complex):
...
return [obj.real, obj.imag]
...
return json.JSONEncoder.default(self, obj)


... dumps(2 + 1j, cls=ComplexEncoder)
'\[2.0, 1.0\]'
>>> ComplexEncoder().encode(2 + 1j)
'\[2.0, 1.0\]'
>>> list(ComplexEncoder().iterencode(2 + 1j))
'\[', '2.0', ',', ',', '1.0', ', ]\]'

Using json.tool from the shell to validate and pretty-print:

$ echo '{"json":"obj"}' | python -mjson.tool
{
   "json": "obj"
}
$ echo '{ 1.2:3.4}' | python -mjson.tool
Expecting property name: line 1 column 2 (char 2)

**Note:** The JSON produced by this module's default settings is a subset of YAML, so it may be used as a serializer for that as well.
18.2.1. Basic Usage

```python
json.dump(obj, fp[, skipkeys[, ensure_ascii[, check_circular[, allow_nan[, cls[, indent[, separators[, encoding[, default[, **kw]]]]]]]]]]
```

Serialize `obj` as a JSON formatted stream to `fp` (a `write()`-supporting file-like object).

If `skipkeys` is `True` (default: `False`), then dict keys that are not of a basic type (`str`, `unicode`, `int`, `long`, `float`, `bool`, `None`) will be skipped instead of raising a `TypeError`.

If `ensure_ascii` is `False` (default: `True`), then some chunks written to `fp` may be `unicode` instances, subject to normal Python `str` to `unicode` coercion rules. Unless `fp.write()` explicitly understands `unicode` (as in `codecs.getwriter()`) this is likely to cause an error.

If `check_circular` is `False` (default: `True`), then the circular reference check for container types will be skipped and a circular reference will result in an `OverflowError` (or worse).

If `allow_nan` is `False` (default: `True`), then it will be a `ValueError` to serialize out of range `float` values (`nan`, `inf`, `-inf`) in strict compliance of the JSON specification, instead of using the JavaScript equivalents (`NaN`, `Infinity`, `-Infinity`).

If `indent` is a non-negative integer, then JSON array elements and object members will be pretty-printed with that indent level. An indent level of 0 will only insert newlines. `None` (the default) selects the most compact representation.

If `separators` is an `(item_separator, dict_separator)` tuple, then
it will be used instead of the default (', ', ': ') separators. ('', '', '::') is the most compact JSON representation.

encodings is the character encoding for str instances, default is UTF-8.

default(obj) is a function that should return a serializable version of obj or raise TypeError. The default simply raises TypeError.

To use a custom JSONEncoder subclass (e.g. one that overrides the default() method to serialize additional types), specify it with the cls kwarg.

json.dumps(obj[, skipkeys[, ensure_ascii[, check_circular[, allow_nan[, cls[, indent[, separators[, encoding[, default[, **kw]]]]]]]]]])

Serialize obj to a JSON formatted str.

If ensure_ascii is False, then the return value will be a unicode instance. The other arguments have the same meaning as in dump().

json.loads(fp[, encoding[, cls[, object_hook[, parse_float[, parse_int[, parse_constant[, object_pairs_hook[, **kw]]]]]]]])

Deserialize fp (a .read()-supporting file-like object containing a JSON document) to a Python object.

If the contents of fp are encoded with an ASCII based encoding other than UTF-8 (e.g. latin-1), then an appropriate encoding name must be specified. Encodings that are not ASCII based (such as UCS-2) are not allowed, and should be wrapped with codecs.getreader(encoding)(fp), or simply decoded to a unicode object and passed to loads().
object_hook is an optional function that will be called with the result of any object literal decoded (a dict). The return value of object_hook will be used instead of the dict. This feature can be used to implement custom decoders (e.g. JSON-RPC class hinting).

object_pairs_hook is an optional function that will be called with the result of any object literal decoded with an ordered list of pairs. The return value of object_pairs_hook will be used instead of the dict. This feature can be used to implement custom decoders that rely on the order that the key and value pairs are decoded (for example, collections.OrderedDict() will remember the order of insertion). If object_hook is also defined, the object_pairs_hook takes priority.

Changed in version 2.7: Added support for object_pairs_hook.

parse_float, if specified, will be called with the string of every JSON float to be decoded. By default, this is equivalent to float(num_str). This can be used to use another datatype or parser for JSON floats (e.g. decimal.Decimal).

parse_int, if specified, will be called with the string of every JSON int to be decoded. By default, this is equivalent to int(num_str). This can be used to use another datatype or parser for JSON integers (e.g. float).

parse_constant, if specified, will be called with one of the following strings: '-Infinity', 'Infinity', 'NaN', 'null', 'true', 'false'. This can be used to raise an exception if invalid JSON numbers are encountered.

To use a custom JSONDecoder subclass, specify it with the cls kwarg. Additional keyword arguments will be passed to the
constructor of the class.

```python
json.loads(s[, encoding[, cls[, object_hook[, parse_float[, parse_int[, parse_constant[, object_pairs_hook[, **kw]]]]]]]]
```

Deserialize `s` (a `str` or `unicode` instance containing a JSON document) to a Python object.

If `s` is a `str` instance and is encoded with an ASCII based encoding other than UTF-8 (e.g. latin-1), then an appropriate `encoding` name must be specified. Encodings that are not ASCII based (such as UCS-2) are not allowed and should be decoded to `unicode` first.

The other arguments have the same meaning as in `load()`.
18.2.2. Encoders and decoders

class json.JSONDecoder([encoding[, object_hook[, parse_float[, parse_int[, parse_constant[, strict[, object_pairs_hook]]]]]]])

Simple JSON decoder.

Performs the following translations in decoding by default:

<table>
<thead>
<tr>
<th>JSON</th>
<th>Python</th>
</tr>
</thead>
<tbody>
<tr>
<td>object</td>
<td>dict</td>
</tr>
<tr>
<td>array</td>
<td>list</td>
</tr>
<tr>
<td>string</td>
<td>unicode</td>
</tr>
<tr>
<td>number (int)</td>
<td>int, long</td>
</tr>
<tr>
<td>number (real)</td>
<td>float</td>
</tr>
<tr>
<td>true</td>
<td>True</td>
</tr>
<tr>
<td>false</td>
<td>False</td>
</tr>
<tr>
<td>null</td>
<td>None</td>
</tr>
</tbody>
</table>

It also understands NaN, Infinity, and -Infinity as their corresponding float values, which is outside the JSON spec.

encoding determines the encoding used to interpret any str objects decoded by this instance (UTF-8 by default). It has no effect when decoding unicode objects.

Note that currently only encodings that are a superset of ASCII work, strings of other encodings should be passed in as unicode.

object_hook, if specified, will be called with the result of every JSON object decoded and its return value will be used in place of the given dict. This can be used to provide custom deserializations (e.g. to support JSON-RPC class hinting).
object_pairs_hook, if specified will be called with the result of every JSON object decoded with an ordered list of pairs. The return value of object_pairs_hook will be used instead of the dict. This feature can be used to implement custom decoders that rely on the order that the key and value pairs are decoded (for example, collections.OrderedDict() will remember the order of insertion). If object_hook is also defined, the object_pairs_hook takes priority.

Changed in version 2.7: Added support for object_pairs_hook.

parse_float, if specified, will be called with the string of every JSON float to be decoded. By default, this is equivalent to float(num_str). This can be used to use another datatype or parser for JSON floats (e.g. decimal.Decimal).

parse_int, if specified, will be called with the string of every JSON int to be decoded. By default, this is equivalent to int(num_str). This can be used to use another datatype or parser for JSON integers (e.g. float).

parse_constant, if specified, will be called with one of the following strings: '-Infinity', 'Infinity', 'NaN', 'null', 'true', 'false'. This can be used to raise an exception if invalid JSON numbers are encountered.

decode(s)
Return the Python representation of s (a str or unicode instance containing a JSON document)

raw_decode(s)
Decode a JSON document from s (a str or unicode beginning with a JSON document) and return a 2-tuple of the Python representation and the index in s where the document ended.
This can be used to decode a JSON document from a string that may have extraneous data at the end.

```
class json.JSONEncoder([skipkeys, ensure_ascii, check_circular, allow_nan, sort_keys, indent, separators, encoding, default]))
```

Extensible JSON encoder for Python data structures.

Supports the following objects and types by default:

<table>
<thead>
<tr>
<th>Python</th>
<th>JSON</th>
</tr>
</thead>
<tbody>
<tr>
<td>dict</td>
<td>object</td>
</tr>
<tr>
<td>list, tuple</td>
<td>array</td>
</tr>
<tr>
<td>str, unicode</td>
<td>string</td>
</tr>
<tr>
<td>int, long, float</td>
<td>number</td>
</tr>
<tr>
<td>True</td>
<td>true</td>
</tr>
<tr>
<td>False</td>
<td>false</td>
</tr>
<tr>
<td>None</td>
<td>null</td>
</tr>
</tbody>
</table>

To extend this to recognize other objects, subclass and implement a `default()` method with another method that returns a serializable object for `o` if possible, otherwise it should call the superclass implementation (to raise `TypeError`).

If `skipkeys` is `False` (the default), then it is a `TypeError` to attempt encoding of keys that are not `str`, `int`, `long`, `float` or `None`. If `skipkeys` is `True`, such items are simply skipped.

If `ensure_ascii` is `True` (the default), the output is guaranteed to be `str` objects with all incoming `unicode` characters escaped. If `ensure_ascii` is `False`, the output will be a `unicode` object.

If `check_circular` is `True` (the default), then lists, dicts, and custom encoded objects will be checked for circular references during
encoding to prevent an infinite recursion (which would cause an OverflowError). Otherwise, no such check takes place.

If allow_nan is True (the default), then NaN, Infinity, and -Infinity will be encoded as such. This behavior is not JSON specification compliant, but is consistent with most JavaScript based encoders and decoders. Otherwise, it will be a ValueError to encode such floats.

If sort_keys is True (the default), then the output of dictionaries will be sorted by key; this is useful for regression tests to ensure that JSON serializations can be compared on a day-to-day basis.

If indent is a non-negative integer (it is None by default), then JSON array elements and object members will be pretty-printed with that indent level. An indent level of 0 will only insert newlines. None is the most compact representation.

If specified, separators should be an (item_separator, key_separator) tuple. The default is (',', ' : '). To get the most compact JSON representation, you should specify (',', ':') to eliminate whitespace.

If specified, default is a function that gets called for objects that can’t otherwise be serialized. It should return a JSON encodable version of the object or raise a TypeError.

If encoding is not None, then all input strings will be transformed into unicode using that encoding prior to JSON-encoding. The default is UTF-8.

default(o)
    Implement this method in a subclass such that it returns a serializable object for o, or calls the base implementation (to
raise a `TypeError`.

For example, to support arbitrary iterators, you could implement default like this:

```python
def default(self, o):
    try:
        iterable = iter(o)
    except TypeError:
        pass
    else:
        return list(iterable)
    return JSONEncoder.default(self, o)
```

**`encode(o)`**

Return a JSON string representation of a Python data structure, o. For example:

```python
>>> JSONEncoder().encode({"foo": ["bar", "baz"]})
'{"foo": ["bar", "baz"]}'
```

**`iterencode(o)`**

Encode the given object, o, and yield each string representation as available. For example:

```python
for chunk in JSONEncoder().iterencode(bigobject):
    mysocket.write(chunk)
```
Mailcap files are used to configure how MIME-aware applications such as mail readers and Web browsers react to files with different MIME types. (The name “mailcap” is derived from the phrase “mail capability”.) For example, a mailcap file might contain a line like `video/mpeg; xmpeg %s`. Then, if the user encounters an email message or Web document with the MIME type `video/mpeg`, `%s` will be replaced by a filename (usually one belonging to a temporary file) and the `xmpeg` program can be automatically started to view the file.

The mailcap format is documented in RFC 1524, “A User Agent Configuration Mechanism For Multimedia Mail Format Information,” but is not an Internet standard. However, mailcap files are supported on most Unix systems.

```python
def findmatch(caps, MIMEtype[, key[, filename[, plist]]])
    Return a 2-tuple; the first element is a string containing the command line to be executed (which can be passed to `os.system()`), and the second element is the mailcap entry for a given MIME type. If no matching MIME type can be found, `(None, None)` is returned.
```

`key` is the name of the field desired, which represents the type of activity to be performed; the default value is ‘view’, since in the most common case you simply want to view the body of the MIME-typed data. Other possible values might be ‘compose’ and ‘edit’, if you wanted to create a new body of the given MIME type or alter the existing body data. See RFC 1524 for a complete list of these fields.
*filename* is the filename to be substituted for `%%s` in the command line; the default value is `/dev/null`, which is almost certainly not what you want, so usually you'll override it by specifying a filename.

*plist* can be a list containing named parameters; the default value is simply an empty list. Each entry in the list must be a string containing the parameter name, an equals sign (`=`), and the parameter's value. Mailcap entries can contain named parameters like `%{foo}`, which will be replaced by the value of the parameter named 'foo'. For example, if the command line `showpartial %{id} %{number} %{total}` was in a mailcap file, and *plist* was set to `["id=1", "number=2", "total=3"]`, the resulting command line would be `'showpartial 1 2 3'`.

In a mailcap file, the "test" field can optionally be specified to test some external condition (such as the machine architecture, or the window system in use) to determine whether or not the mailcap line applies. *findmatch()* will automatically check such conditions and skip the entry if the check fails.

```mailcap.getcaps()```

Returns a dictionary mapping MIME types to a list of mailcap file entries. This dictionary must be passed to the *findmatch()* function. An entry is stored as a list of dictionaries, but it shouldn't be necessary to know the details of this representation.

The information is derived from all of the mailcap files found on the system. Settings in the user's mailcap file `$HOME/.mailcap` will override settings in the system mailcap files `/etc/mailcap`, `/usr/etc/mailcap`, and `/usr/local/etc/mailcap`.

An example usage:
>>> import mailcap
>>> d=mailcap.getcaps()
>>> mailcap.findmatch(d, 'video/mpeg', filename='/tmp/tmp1223')
('xmpeg /tmp/tmp1223', {'view': 'xmpeg %s'})
This module defines two classes, `Mailbox` and `Message`, for accessing and manipulating on-disk mailboxes and the messages they contain. `Mailbox` offers a dictionary-like mapping from keys to messages. `Message` extends the `email.Message` module's `Message` class with format-specific state and behavior. Supported mailbox formats are Maildir, mbox, MH, Babyl, and MMDF.

**See also:**

**Module** `email`

Represent and manipulate messages.
18.4.1. Mailbox objects

class mailbox.Mailbox
    A mailbox, which may be inspected and modified.

    The Mailbox class defines an interface and is not intended to be
    instantiated. Instead, format-specific subclasses should inherit
    from Mailbox and your code should instantiate a particular
    subclass.

    The Mailbox interface is dictionary-like, with small keys
    corresponding to messages. Keys are issued by the Mailbox
    instance with which they will be used and are only meaningful to
    that Mailbox instance. A key continues to identify a message
    even if the corresponding message is modified, such as by
    replacing it with another message.

    Messages may be added to a Mailbox instance using the set-like
    method add() and removed using a del statement or the set-like
    methods remove() and discard().

    Mailbox interface semantics differ from dictionary semantics in
    some noteworthy ways. Each time a message is requested, a
    new representation (typically a Message instance) is generated
    based upon the current state of the mailbox. Similarly, when a
    message is added to a Mailbox instance, the provided message
    representation’s contents are copied. In neither case is a
    reference to the message representation kept by the Mailbox
    instance.

    The default Mailbox iterator iterates over message
    representations, not keys as the default dictionary iterator does.
Moreover, modification of a mailbox during iteration is safe and well-defined. Messages added to the mailbox after an iterator is created will not be seen by the iterator. Messages removed from the mailbox before the iterator yields them will be silently skipped, though using a key from an iterator may result in a `KeyError` exception if the corresponding message is subsequently removed.

**Warning:** Be very cautious when modifying mailboxes that might be simultaneously changed by some other process. The safest mailbox format to use for such tasks is Maildir; try to avoid using single-file formats such as mbox for concurrent writing. If you're modifying a mailbox, you must lock it by calling the `lock()` and `unlock()` methods before reading any messages in the file or making any changes by adding or deleting a message. Failing to lock the mailbox runs the risk of losing messages or corrupting the entire mailbox.

Mailbox instances have the following methods:

`add(message)`
Add `message` to the mailbox and return the key that has been assigned to it.

Parameter `message` may be a `Message` instance, an `email.Message.Message` instance, a string, or a file-like object (which should be open in text mode). If `message` is an instance of the appropriate format-specific `Message` subclass (e.g., if it's an `mboxMessage` instance and this is an `mbox` instance), its format-specific information is used. Otherwise, reasonable defaults for format-specific information are used.

`remove(key)`
`__delitem__(key)`
**discard(key)**

Delete the message corresponding to *key* from the mailbox.

If no such message exists, a *KeyError* exception is raised if the method was called as *remove()* or *__delitem__()* but no exception is raised if the method was called as *discard()*.

The behavior of *discard()* may be preferred if the underlying mailbox format supports concurrent modification by other processes.

**__setitem__(key, message)**

Replace the message corresponding to *key* with *message*. Raise a *KeyError* exception if no message already corresponds to *key*.

As with *add()* parameter *message* may be a *Message* instance, an *email.Message.Message* instance, a string, or a file-like object (which should be open in text mode). If *message* is an instance of the appropriate format-specific *Message* subclass (e.g., if it’s an *mboxMessage* instance and this is an *mbox* instance), its format-specific information is used. Otherwise, the format-specific information of the message that currently corresponds to *key* is left unchanged.

**iterkeys()**

**keys()**

Return an iterator over all keys if called as *iterkeys()* or return a list of keys if called as *keys()*.

**itervalues()**

**__iter__()**

**values()**

Return an iterator over representations of all messages if
called as `itervalues()` or `__iter__()`, or return a list of such representations if called as `values()`. The messages are represented as instances of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

**Note:** The behavior of `__iter__()` is unlike that of dictionaries, which iterate over keys.

`iteritems()`  
`items()`  
Return an iterator over `(key, message)` pairs, where `key` is a key and `message` is a message representation, if called as `iteritems()` or return a list of such pairs if called as `items()`. The messages are represented as instances of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

`get(key[, default=None])`  
`__getitem__(key)`  
Return a representation of the message corresponding to `key`. If no such message exists, `default` is returned if the method was called as `get()` and a `KeyError` exception is raised if the method was called as `__getitem__()`. The message is represented as an instance of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

`get_message(key)`  
Return a representation of the message corresponding to `key` as an instance of the appropriate format-specific `Message` subclass, or raise a `KeyError` exception if no such message
exists.

**get_string(key)**
Return a string representation of the message corresponding to *key*, or raise a *KeyError* exception if no such message exists.

**get_file(key)**
Return a file-like representation of the message corresponding to *key*, or raise a *KeyError* exception if no such message exists. The file-like object behaves as if open in binary mode. This file should be closed once it is no longer needed.

---

**Note:** Unlike other representations of messages, file-like representations are not necessarily independent of the *Mailbox* instance that created them or of the underlying mailbox. More specific documentation is provided by each subclass.

**has_key(key)**
**contains__(key)**
Return **True** if *key* corresponds to a message, **False** otherwise.

**len()**
Return a count of messages in the mailbox.

**clear()**
Delete all messages from the mailbox.

**pop(key[, default])**
Return a representation of the message corresponding to *key* and delete the message. If no such message exists, return *default* if it was supplied or else raise a *KeyError* exception.
The message is represented as an instance of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

`popitem()`
Return an arbitrary `(key, message)` pair, where `key` is a key and `message` is a message representation, and delete the corresponding message. If the mailbox is empty, raise a `KeyError` exception. The message is represented as an instance of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

`update(arg)`
Parameter `arg` should be a `key-to-message` mapping or an iterable of `(key, message)` pairs. Updates the mailbox so that, for each given `key` and `message`, the message corresponding to `key` is set to `message` as if by using `__setitem__()`. As with `__setitem__()`, each `key` must already correspond to a message in the mailbox or else a `KeyError` exception will be raised, so in general it is incorrect for `arg` to be a `Mailbox` instance.

**Note:** Unlike with dictionaries, keyword arguments are not supported.

`flush()`
Write any pending changes to the filesystem. For some `Mailbox` subclasses, changes are always written immediately and `flush()` does nothing, but you should still make a habit of calling this method.

`lock()`
Acquire an exclusive advisory lock on the mailbox so that other processes know not to modify it. An `ExternalClashError` is raised if the lock is not available. The particular locking mechanisms used depend upon the mailbox format. You should always lock the mailbox before making any modifications to its contents.

```python
unlock()
```
Release the lock on the mailbox, if any.

```python
close()
```
Flush the mailbox, unlock it if necessary, and close any open files. For some `Mailbox` subclasses, this method does nothing.

### 18.4.1.1. Maildir

```python
class mailbox.Maildir(dirname[, factory=rfc822.Message[, create=True]])
```
A subclass of `Mailbox` for mailboxes in Maildir format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is `None`, `MaildirMessage` is used as the default message representation. If `create` is `True`, the mailbox is created if it does not exist.

It is for historical reasons that `factory` defaults to `rfc822.Message` and that `dirname` is named as such rather than `path`. For a `Maildir` instance that behaves like instances of other `Mailbox` subclasses, set `factory` to `None`.

Maildir is a directory-based mailbox format invented for the qmail mail transfer agent and now widely supported by other programs.
Messages in a Maildir mailbox are stored in separate files within a common directory structure. This design allows Maildir mailboxes to be accessed and modified by multiple unrelated programs without data corruption, so file locking is unnecessary.

Maildir mailboxes contain three subdirectories, namely: `tmp`, `new`, and `cur`. Messages are created momentarily in the `tmp` subdirectory and then moved to the `new` subdirectory to finalize delivery. A mail user agent may subsequently move the message to the `cur` subdirectory and store information about the state of the message in a special “info” section appended to its file name.

Folders of the style introduced by the Courier mail transfer agent are also supported. Any subdirectory of the main mailbox is considered a folder if `.' is the first character in its name. Folder names are represented by Maildir without the leading `.' . Each folder is itself a Maildir mailbox but should not contain other folders. Instead, a logical nesting is indicated using `.' to delimit levels, e.g., “Archived.2005.07”.

**Note:** The Maildir specification requires the use of a colon (`:`) in certain message file names. However, some operating systems do not permit this character in file names. If you wish to use a Maildir-like format on such an operating system, you should specify another character to use instead. The exclamation point (`'!'`) is a popular choice. For example:

```python
import mailbox
mailbox.Maildir.colon = '!'```

The `colon` attribute may also be set on a per-instance basis.

`Maildir` instances have all of the methods of `Mailbox` in addition to the following:
list_folders()
Return a list of the names of all folders.

get_folder(folder)
Return a Maildir instance representing the folder whose name is folder. A NoSuchMailboxError exception is raised if the folder does not exist.

add_folder(folder)
Create a folder whose name is folder and return a Maildir instance representing it.

remove_folder(folder)
Delete the folder whose name is folder. If the folder contains any messages, aNotEmptyError exception will be raised and the folder will not be deleted.

clean()
Delete temporary files from the mailbox that have not been accessed in the last 36 hours. The Maildir specification says that mail-reading programs should do this occasionally.

Some Mailbox methods implemented by Maildir deserve special remarks:

add(message)
__setitem__(key, message)
update(arg)

**Warning:** These methods generate unique file names based upon the current process ID. When using multiple threads, undetected name clashes may occur and cause corruption of the mailbox unless threads are coordinated to avoid using these methods to manipulate the same mailbox simultaneously.
flush()
   All changes to Maildir mailboxes are immediately applied, so this method does nothing.

lock()
unlock()
   Maildir mailboxes do not support (or require) locking, so these methods do nothing.

close()
   Maildir instances do not keep any open files and the underlying mailboxes do not support locking, so this method does nothing.

get_file(key)
   Depending upon the host platform, it may not be possible to modify or remove the underlying message while the returned file remains open.

Using maildir format
   Notes on Maildir by its inventor. Includes an updated name-creation scheme and details on “info” semantics.

maildir man page from Courier
   Another specification of the format. Describes a common extension for supporting folders.

18.4.1.2. mbox

class mailbox.mbox(path[, factory=None[, create=True]])
A subclass of `Mailbox` for mailboxes in mbox format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is `None`, `mboxMessage` is used as the default message representation. If `create` is `True`, the mailbox is created if it does not exist.

The mbox format is the classic format for storing mail on Unix systems. All messages in an mbox mailbox are stored in a single file with the beginning of each message indicated by a line whose first five characters are “From “.

Several variations of the mbox format exist to address perceived shortcomings in the original. In the interest of compatibility, `mbox` implements the original format, which is sometimes referred to as `mboxo`. This means that the `Content-Length` header, if present, is ignored and that any occurrences of “From ” at the beginning of a line in a message body are transformed to “>From ” when storing the message, although occurrences of “>From ” are not transformed to “From ” when reading the message.

Some `Mailbox` methods implemented by `mbox` deserve special remarks:

`get_file(key)`

Using the file after calling `flush()` or `close()` on the `mbox` instance may yield unpredictable results or raise an exception.

`lock()`

`unlock()`

Three locking mechanisms are used—dot locking and, if available, the `flock()` and `lockf()` system calls.

   Another specification of the format, with details on locking.

Configuring Netscape Mail on Unix: Why The Content-Length Format is Bad
   An argument for using the original mbox format rather than a variation.

“mbox” is a family of several mutually incompatible mailbox formats
   A history of mbox variations.

18.4.1.3. MH

class mailbox. MH(path[, factory=None[, create=True]])
   A subclass of Mailbox for mailboxes in MH format. Parameter factory is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If factory is None, MHMessage is used as the default message representation. If create is True, the mailbox is created if it does not exist.

MH is a directory-based mailbox format invented for the MH Message Handling System, a mail user agent. Each message in an MH mailbox resides in its own file. An MH mailbox may contain other MH mailboxes (called folders) in addition to messages. Folders may be nested indefinitely. MH mailboxes also support sequences, which are named lists used to logically group messages without moving them to sub-folders. Sequences are defined in a file called .mh_sequences in each folder.
The **MH** class manipulates MH mailboxes, but it does not attempt to emulate all of **mh**'s behaviors. In particular, it does not modify and is not affected by the **context** or **.mh_profile** files that are used by **mh** to store its state and configuration.

**MH** instances have all of the methods of **Mailbox** in addition to the following:

**list_folders()**
Return a list of the names of all folders.

**get_folder(folder)**
Return an **MH** instance representing the folder whose name is **folder**. A **NoSuchMailboxError** exception is raised if the folder does not exist.

**add_folder(folder)**
Create a folder whose name is **folder** and return an **MH** instance representing it.

**remove_folder(folder)**
Delete the folder whose name is **folder**. If the folder contains any messages, a **NotEmptyError** exception will be raised and the folder will not be deleted.

**get_sequences()**
Return a dictionary of sequence names mapped to key lists. If there are no sequences, the empty dictionary is returned.

**set_sequences(sequences)**
Re-define the sequences that exist in the mailbox based upon **sequences**, a dictionary of names mapped to key lists, like returned by **get_sequences()**.

**pack()**
Rename messages in the mailbox as necessary to eliminate gaps in numbering. Entries in the sequences list are updated correspondingly.

**Note:** Already-issued keys are invalidated by this operation and should not be subsequently used.

Some **Mailbox** methods implemented by **MH** deserve special remarks:

- `remove(key)`
- `__delitem__(key)`
- `discard(key)`

These methods immediately delete the message. The MH convention of marking a message for deletion by prepending a comma to its name is not used.

- `lock()`
- `unlock()`

Three locking mechanisms are used—dot locking and, if available, the `flock()` and `lockf()` system calls. For MH mailboxes, locking the mailbox means locking the `.mh_sequences` file and, only for the duration of any operations that affect them, locking individual message files.

- `get_file(key)`

Depending upon the host platform, it may not be possible to remove the underlying message while the returned file remains open.

- `flush()`

All changes to MH mailboxes are immediately applied, so this method does nothing.

- `close()`
MH instances do not keep any open files, so this method is equivalent to unlock().

A GPL-licensed book on mh and nmh, with some information on the mailbox format.

---

### 18.4.1.4. Babyl

```python
class mailbox.Babyl(path[, factory=None[, create=True]])
```

A subclass of `Mailbox` for mailboxes in Babyl format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is `None`, `BabylMessage` is used as the default message representation. If `create` is `True`, the mailbox is created if it does not exist.

Babyl is a single-file mailbox format used by the Rmail mail user agent included with Emacs. The beginning of a message is indicated by a line containing the two characters Control-Underscore (\037) and Control-L (\014). The end of a message is indicated by the start of the next message or, in the case of the last message, a line containing a Control-Underscore (\037) character.

Messages in a Babyl mailbox have two sets of headers, original headers and so-called visible headers. Visible headers are typically a subset of the original headers that have been reformatted or abridged to be more attractive. Each message in a
Babyl mailbox also has an accompanying list of *labels*, or short strings that record extra information about the message, and a list of all user-defined labels found in the mailbox is kept in the Babyl options section.

**Babyl** instances have all of the methods of Mailbox in addition to the following:

**get_labels()**

Return a list of the names of all user-defined labels used in the mailbox.

**Note:** The actual messages are inspected to determine which labels exist in the mailbox rather than consulting the list of labels in the Babyl options section, but the Babyl section is updated whenever the mailbox is modified.

Some Mailbox methods implemented by Babyl deserve special remarks:

**get_file(key)**

In Babyl mailboxes, the headers of a message are not stored contiguously with the body of the message. To generate a file-like representation, the headers and body are copied together into a StringIO instance (from the StringIO module), which has an API identical to that of a file. As a result, the file-like object is truly independent of the underlying mailbox but does not save memory compared to a string representation.

**lock()**

**unlock()**

Three locking mechanisms are used—dot locking and, if available, the flock() and lockf() system calls.

The Rmail manual, with some information on Babyl semantics.

---

### 18.4.1.5. MMDF

class mailbox.MMDF(path[, factory=None[, create=True]])

A subclass of Mailbox for mailboxes in MMDF format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is `None`, `MMDFMessage` is used as the default message representation. If `create` is `True`, the mailbox is created if it does not exist.

MMDF is a single-file mailbox format invented for the Multichannel Memorandum Distribution Facility, a mail transfer agent. Each message is in the same form as an mbox message but is bracketed before and after by lines containing four Control-A (`\001`) characters. As with the mbox format, the beginning of each message is indicated by a line whose first five characters are “From “, but additional occurrences of “From ” are not transformed to “>From ” when storing messages because the extra message separator lines prevent mistaking such occurrences for the starts of subsequent messages.

Some `Mailbox` methods implemented by `MMDF` deserve special remarks:

def get_file(key)
Using the file after calling `flush()` or `close()` on the MMDF instance may yield unpredictable results or raise an exception.

`lock()`
`unlock()`

Three locking mechanisms are used—dot locking and, if available, the `flock()` and `lockf()` system calls.

A specification of MMDF format from the documentation of tin, a newsreader.

**MMDF**
A Wikipedia article describing the Multichannel Memorandum Distribution Facility.
18.4.2. Message objects

class mailbox.Message([message])

If message is omitted, the new instance is created in a default, empty state. If message is an email.Message.Message instance, its contents are copied; furthermore, any format-specific information is converted insofar as possible if message is a Message instance. If message is a string or a file, it should contain an RFC 2822-compliant message, which is read and parsed.

The format-specific state and behaviors offered by subclasses vary, but in general it is only the properties that are not specific to a particular mailbox that are supported (although presumably the properties are specific to a particular mailbox format). For example, file offsets for single-file mailbox formats and file names for directory-based mailbox formats are not retained, because they are only applicable to the original mailbox. But state such as whether a message has been read by the user or marked as important is retained, because it applies to the message itself.

There is no requirement that Message instances be used to represent messages retrieved using Mailbox instances. In some situations, the time and memory required to generate Message representations might not be acceptable. For such situations, Mailbox instances also offer string and file-like representations, and a custom message factory may be specified when a Mailbox instance is initialized.

18.4.2.1. MaildirMessage
class mailbox.MaildirMessage([message])

A message with Maildir-specific behaviors. Parameter message has the same meaning as with the Message constructor.

Typically, a mail user agent application moves all of the messages in the new subdirectory to the cur subdirectory after the first time the user opens and closes the mailbox, recording that the messages are old whether or not they’ve actually been read. Each message in cur has an “info” section added to its file name to store information about its state. (Some mail readers may also add an “info” section to messages in new.) The “info” section may take one of two forms: it may contain “2,” followed by a list of standardized flags (e.g., “2,FR”) or it may contain “1,” followed by so-called experimental information. Standard flags for Maildir messages are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>D</td>
<td>Draft</td>
<td>Under composition</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>P</td>
<td>Passed</td>
<td>Forwarded, resent, or bounced</td>
</tr>
<tr>
<td>R</td>
<td>Replied</td>
<td>Replied to</td>
</tr>
<tr>
<td>S</td>
<td>Seen</td>
<td>Read</td>
</tr>
<tr>
<td>T</td>
<td>Trashed</td>
<td>Marked for subsequent deletion</td>
</tr>
</tbody>
</table>

MaildirMessage instances offer the following methods:

get_subdir()

Return either “new” (if the message should be stored in the new subdirectory) or “cur” (if the message should be stored in the cur subdirectory).

Note: A message is typically moved from new to cur after its mailbox has been accessed, whether or not the message
is has been read. A message `msg` has been read if "S" in `msg.get_flags()` is True.

**set_subdir(subdir)**
Set the subdirectory the message should be stored in. Parameter `subdir` must be either “new” or “cur”.

**get_flags()**
Return a string specifying the flags that are currently set. If the message complies with the standard Maildir format, the result is the concatenation in alphabetical order of zero or one occurrence of each of 'D', 'F', 'P', 'R', 'S', and 'T'. The empty string is returned if no flags are set or if “info” contains experimental semantics.

**set_flags(flags)**
Set the flags specified by `flags` and unset all others.

**add_flag(flag)**
Set the flag(s) specified by `flag` without changing other flags. To add more than one flag at a time, `flag` may be a string of more than one character. The current “info” is overwritten whether or not it contains experimental information rather than flags.

**remove_flag(flag)**
Unset the flag(s) specified by `flag` without changing other flags. To remove more than one flag at a time, `flag` maybe a string of more than one character. If “info” contains experimental information rather than flags, the current “info” is not modified.

**get_date()**
Return the delivery date of the message as a floating-point number representing seconds since the epoch.
set_date(date)
Set the delivery date of the message to date, a floating-point number representing seconds since the epoch.

get_info()
Return a string containing the “info” for a message. This is useful for accessing and modifying “info” that is experimental (i.e., not a list of flags).

set_info(info)
Set “info” to info, which should be a string.

When a MaildirMessage instance is created based upon an mboxMessage or MMDFMessage instance, the Status and X-Status headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage or MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“cur” subdirectory</td>
<td>O flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>R flag</td>
<td>A flag</td>
</tr>
<tr>
<td>S flag</td>
<td>R flag</td>
</tr>
<tr>
<td>T flag</td>
<td>D flag</td>
</tr>
</tbody>
</table>

When a MaildirMessage instance is created based upon an MHMessage instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“cur” subdirectory</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>“cur” subdirectory and S flag</td>
<td>no “unseen” sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>“flagged” sequence</td>
</tr>
<tr>
<td>R flag</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

When a MaildirMessage instance is created based upon a BabylMessage instance, the following conversions take place:
<table>
<thead>
<tr>
<th>Resulting state</th>
<th>Baby1Message state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“cur” subdirectory</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>“cur” subdirectory and S flag</td>
<td>no “unseen” label</td>
</tr>
<tr>
<td>P flag</td>
<td>“forwarded” or “resent” label</td>
</tr>
<tr>
<td>R flag</td>
<td>“answered” label</td>
</tr>
<tr>
<td>T flag</td>
<td>“deleted” label</td>
</tr>
</tbody>
</table>

### 18.4.2.2. `mboxMessage`

```python
class mailbox.mboxMessage([message])
```

A message with mbox-specific behaviors. Parameter `message` has the same meaning as with the `Message` constructor.

Messages in an mbox mailbox are stored together in a single file. The sender's envelope address and the time of delivery are typically stored in a line beginning with “From ” that is used to indicate the start of a message, though there is considerable variation in the exact format of this data among mbox implementations. Flags that indicate the state of the message, such as whether it has been read or marked as important, are typically stored in `Status` and `X-Status` headers.

Conventional flags for mbox messages are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>Read</td>
<td>Read</td>
</tr>
<tr>
<td>O</td>
<td>Old</td>
<td>Previously detected by MUA</td>
</tr>
<tr>
<td>D</td>
<td>Deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>A</td>
<td>Answered</td>
<td>Replied to</td>
</tr>
</tbody>
</table>

The “R” and “O” flags are stored in the `Status` header, and the “D”, “F”, and “A” flags are stored in the `X-Status` header. The flags and headers typically appear in the order mentioned.
mboxMessage instances offer the following methods:

get_from()
   Return a string representing the “From ” line that marks the start of the message in an mbox mailbox. The leading “From ” and the trailing newline are excluded.

set_from(from_, [time_=None])
   Set the “From ” line to from_, which should be specified without a leading “From ” or trailing newline. For convenience, time_ may be specified and will be formatted appropriately and appended to from_. If time_ is specified, it should be a struct_time instance, a tuple suitable for passing to time.strftime(), or True (to use time.gmtime()).

get_flags()
   Return a string specifying the flags that are currently set. If the message complies with the conventional format, the result is the concatenation in the following order of zero or one occurrence of each of 'R', 'O', 'D', 'F', and 'A'.

set_flags(flags)
   Set the flags specified by flags and unset all others. Parameter flags should be the concatenation in any order of zero or more occurrences of each of 'R', 'O', 'D', 'F', and 'A'.

add_flag(flag)
   Set the flag(s) specified by flag without changing other flags. To add more than one flag at a time, flag may be a string of more than one character.

remove_flag(flag)
   Unset the flag(s) specified by flag without changing other flags. To remove more than one flag at a time, flag maybe a
string of more than one character.

When an `mboxMessage` instance is created based upon a `MaildirMessage` instance, a “From ” line is generated based upon the `MaildirMessage` instance’s delivery date, and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>S flag</td>
</tr>
<tr>
<td>O flag</td>
<td>“cur” subdirectory</td>
</tr>
<tr>
<td>D flag</td>
<td>T flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>R flag</td>
</tr>
</tbody>
</table>

When an `mboxMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” sequence</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>“flagged” sequence</td>
</tr>
<tr>
<td>A flag</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

When an `mboxMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” label</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>D flag</td>
<td>“deleted” label</td>
</tr>
<tr>
<td>A flag</td>
<td>“answered” label</td>
</tr>
</tbody>
</table>

When a `Message` instance is created based upon an `MMDFMessage` instance, the “From ” line is copied and all flags directly correspond:
18.4.2.3. MHMessage

```python
class mailbox.MHMessage([message])
```

A message with MH-specific behaviors. Parameter `message` has the same meaning as with the `Message` constructor.

MH messages do not support marks or flags in the traditional sense, but they do support sequences, which are logical groupings of arbitrary messages. Some mail reading programs (although not the standard `mh` and `nmh`) use sequences in much the same way flags are used with other formats, as follows:

<table>
<thead>
<tr>
<th>Sequence</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>unseen</td>
<td>Not read, but previously detected by MUA</td>
</tr>
<tr>
<td>replied</td>
<td>Replied to</td>
</tr>
<tr>
<td>flagged</td>
<td>Marked as important</td>
</tr>
</tbody>
</table>

`MHMessage` instances offer the following methods:

```python
def get_sequences():
    Return a list of the names of sequences that include this message.
```

```python
def set_sequences(sequences):
    Set the list of sequences that include this message.
```

```python
def add_sequence(sequence):
```

---

**Resulting state** | **MMDFMessage state**
--- | ---
R flag | R flag
O flag | O flag
D flag | D flag
F flag | F flag
A flag | A flag
Add *sequence* to the list of sequences that include this message.

**remove_sequence**(sequence)
Remove *sequence* from the list of sequences that include this message.

When an **MHMessage** instance is created based upon a **MaildirMessage** instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” sequence</td>
<td>no S flag</td>
</tr>
<tr>
<td>“replied” sequence</td>
<td>R flag</td>
</tr>
<tr>
<td>“flagged” sequence</td>
<td>F flag</td>
</tr>
</tbody>
</table>

When an **MHMessage** instance is created based upon an **mboxMessage** or **MMDFMessage** instance, the **Status** and **X-Status** headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage or MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” sequence</td>
<td>no R flag</td>
</tr>
<tr>
<td>“replied” sequence</td>
<td>A flag</td>
</tr>
<tr>
<td>“flagged” sequence</td>
<td>F flag</td>
</tr>
</tbody>
</table>

When an **MHMessage** instance is created based upon a **BabylMessage** instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” sequence</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>“replied” sequence</td>
<td>“answered” label</td>
</tr>
</tbody>
</table>

**18.4.2.4. BabylMessage**

```
class mailbox.BabylMessage([message])
```
A message with Babyl-specific behaviors. Parameter `message` has the same meaning as with the `Message` constructor.

Certain message labels, called *attributes*, are defined by convention to have special meanings. The attributes are as follows:

<table>
<thead>
<tr>
<th>Label</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>unseen</td>
<td>Not read, but previously detected by MUA</td>
</tr>
<tr>
<td>deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>filed</td>
<td>Copied to another file or mailbox</td>
</tr>
<tr>
<td>answered</td>
<td>Replied to</td>
</tr>
<tr>
<td>forwarded</td>
<td>Forwarded</td>
</tr>
<tr>
<td>edited</td>
<td>Modified by the user</td>
</tr>
<tr>
<td>resent</td>
<td>Resent</td>
</tr>
</tbody>
</table>

By default, Rmail displays only visible headers. The `BabylMessage` class, though, uses the original headers because they are more complete. Visible headers may be accessed explicitly if desired.

`BabylMessage` instances offer the following methods:

**get_labels()**
Return a list of labels on the message.

**set_labels(labels)**
Set the list of labels on the message to `labels`.

**add_label(label)**
Add `label` to the list of labels on the message.

**remove_label(label)**
Remove `label` from the list of labels on the message.

**get_visible()**
Return an `Message` instance whose headers are the message's visible headers and whose body is empty.

**set_visible(visible)**

Set the message's visible headers to be the same as the headers in `message`. Parameter `visible` should be a `Message` instance, an `email.Message.Message` instance, a string, or a file-like object (which should be open in text mode).

**update_visible()**

When a `BabylMessage` instance's original headers are modified, the visible headers are not automatically modified to correspond. This method updates the visible headers as follows: each visible header with a corresponding original header is set to the value of the original header, each visible header without a corresponding original header is removed, and any of `Date`, `From`, `Reply-To`, `To`, `CC`, and `Subject` that are present in the original headers but not the visible headers are added to the visible headers.

When a `BabylMessage` instance is created based upon a `MaildirMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” label</td>
<td>no S flag</td>
</tr>
<tr>
<td>“deleted” label</td>
<td>T flag</td>
</tr>
<tr>
<td>“answered” label</td>
<td>R flag</td>
</tr>
<tr>
<td>“forwarded” label</td>
<td>P flag</td>
</tr>
</tbody>
</table>

When a `BabylMessage` instance is created based upon an `mboxMessage` or `MMDFMessage` instance, the `Status` and `X-Status` headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage or MMDFMessage state</th>
</tr>
</thead>
</table>
When a BabylMessage instance is created based upon an MHMessage instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” label</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>“answered” label</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

18.4.2.5. MMDFMessage

```python
class mailbox.MMDFMessage([message])
```

A message with MMDF-specific behaviors. Parameter message has the same meaning as with the Message constructor.

As with message in an mbox mailbox, MMDF messages are stored with the sender's address and the delivery date in an initial line beginning with “From “. Likewise, flags that indicate the state of the message are typically stored in Status and X-Status headers.

Conventional flags for MMDF messages are identical to those of mbox message and are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>Read</td>
<td>Read</td>
</tr>
<tr>
<td>O</td>
<td>Old</td>
<td>Previously detected by MUA</td>
</tr>
<tr>
<td>D</td>
<td>Deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>A</td>
<td>Answered</td>
<td>Replied to</td>
</tr>
</tbody>
</table>

The “R” and “O” flags are stored in the Status header, and the
“D”, “F”, and “A” flags are stored in the X-Status header. The flags and headers typically appear in the order mentioned.

**MMDFMessage** instances offer the following methods, which are identical to those offered by **mboxMessage**:

- **get_from()**
  Return a string representing the “From ” line that marks the start of the message in an mbox mailbox. The leading “From ” and the trailing newline are excluded.

- **set_from**(from_, time_=None)
  Set the “From ” line to from_, which should be specified without a leading “From ” or trailing newline. For convenience, time_ may be specified and will be formatted appropriately and appended to from_. If time_ is specified, it should be a struct_time instance, a tuple suitable for passing to time.strftime(), or True (to use time.gmtime()).

- **get_flags()**
  Return a string specifying the flags that are currently set. If the message complies with the conventional format, the result is the concatenation in the following order of zero or one occurrence of each of 'R', 'O', 'D', 'F', and 'A'.

- **set_flags**(flags)
  Set the flags specified by flags and unset all others. Parameter flags should be the concatenation in any order of zero or more occurrences of each of 'R', 'O', 'D', 'F', and 'A'.

- **add_flag**(flag)
  Set the flag(s) specified by flag without changing other flags. To add more than one flag at a time, flag may be a string of
more than one character.

**remove_flag(flag)**

Unset the flag(s) specified by *flag* without changing other flags. To remove more than one flag at a time, *flag* maybe a string of more than one character.

When an **MMDFMessage** instance is created based upon a **MaildirMessage** instance, a “From ” line is generated based upon the **MaildirMessage** instance’s delivery date, and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>S flag</td>
</tr>
<tr>
<td>O flag</td>
<td>“cur” subdirectory</td>
</tr>
<tr>
<td>D flag</td>
<td>T flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>R flag</td>
</tr>
</tbody>
</table>

When an **MMDFMessage** instance is created based upon an **MHMessage** instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” sequence</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>“flagged” sequence</td>
</tr>
<tr>
<td>A flag</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

When an **MMDFMessage** instance is created based upon a **BabylMessage** instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” label</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>Flag</td>
<td>Description</td>
</tr>
<tr>
<td>------</td>
<td>-------------------</td>
</tr>
<tr>
<td>D</td>
<td>“deleted” label</td>
</tr>
<tr>
<td>A</td>
<td>“answered” label</td>
</tr>
</tbody>
</table>

When an `MMDFMessage` instance is created based upon an `mboxMessage` instance, the “From ” line is copied and all flags directly correspond:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><code>mboxMessage</code> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>R flag</td>
</tr>
<tr>
<td>O flag</td>
<td>O flag</td>
</tr>
<tr>
<td>D flag</td>
<td>D flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>A flag</td>
</tr>
</tbody>
</table>
18.4.3. Exceptions

The following exception classes are defined in the `mailbox` module:

```python
exception mailbox.Error

    The based class for all other module-specific exceptions.
```

```python
exception mailbox.NoSuchMailboxError

    Raised when a mailbox is expected but is not found, such as when
    instantiating a Mailbox subclass with a path that does not
    exist (and with the create parameter set to False), or when
    opening a folder that does not exist.
```

```python
exception mailbox.NotEmptyError

    Raised when a mailbox is not empty but is expected to be, such
    as when deleting a folder that contains messages.
```

```python
exception mailbox.ExternalClashError

    Raised when some mailbox-related condition beyond the control
    of the program causes it to be unable to proceed, such as when
    failing to acquire a lock that another program already holds a
    lock, or when a uniquely-generated file name already exists.
```

```python
exception mailbox.FormatError

    Raised when the data in a file cannot be parsed, such as when
    an MH instance attempts to read a corrupted .mh_sequences file.
```
18.4.4. Deprecated classes and methods

Deprecated since version 2.6.

Older versions of the `mailbox` module do not support modification of mailboxes, such as adding or removing message, and do not provide classes to represent format-specific message properties. For backward compatibility, the older mailbox classes are still available, but the newer classes should be used in preference to them. The old classes will be removed in Python 3.0.

Older mailbox objects support only iteration and provide a single public method:

```python
oldmailbox.next()
```

Return the next message in the mailbox, created with the optional `factory` argument passed into the mailbox object’s constructor. By default this is an `rfc822.Message` object (see the `rfc822` module). Depending on the mailbox implementation the `fp` attribute of this object may be a true file object or a class instance simulating a file object, taking care of things like message boundaries if multiple mail messages are contained in a single file, etc. If no more messages are available, this method returns `None`.

Most of the older mailbox classes have names that differ from the current mailbox class names, except for `Maildir`. For this reason, the new `Maildir` class defines a `next()` method and its constructor differs slightly from those of the other new mailbox classes.

The older mailbox classes whose names are not the same as their newer counterparts are as follows:

```python
class mailbox.UnixMailbox(fp[, factory])
```
Access to a classic Unix-style mailbox, where all messages are contained in a single file and separated by **From** (a.k.a. **From_**) lines. The file object `fp` points to the mailbox file. The optional `factory` parameter is a callable that should create new message objects. `factory` is called with one argument, `fp` by the `next()` method of the mailbox object. The default is the `rfc822.Message` class (see the `rfc822` module – and the note below).

**Note:** For reasons of this module’s internal implementation, you will probably want to open the `fp` object in binary mode. This is especially important on Windows.

For maximum portability, messages in a Unix-style mailbox are separated by any line that begins exactly with the string `'From '` (note the trailing space) if preceded by exactly two newlines. Because of the wide-range of variations in practice, nothing else on the `From_` line should be considered. However, the current implementation doesn’t check for the leading two newlines. This is usually fine for most applications.

The `UnixMailbox` class implements a more strict version of `From_` line checking, using a regular expression that usually correctly matched `From_` delimiters. It considers delimiter line to be separated by `From name time` lines. For maximum portability, use the `PortableUnixMailbox` class instead. This class is identical to `UnixMailbox` except that individual messages are separated by only `From` lines.

```python
class mailbox. PortableUnixMailbox(fp[, factory])
```

A less-strict version of `UnixMailbox`, which considers only the `From` at the beginning of the line separating messages. The “name time” portion of the From line is ignored, to protect against some variations that are observed in practice. This works since
lines in the message which begin with 'From ' are quoted by mail handling software at delivery-time.

class mailbox. MmddfMailbox(fp[, factory])
Access an MMDF-style mailbox, where all messages are contained in a single file and separated by lines consisting of 4 control-A characters. The file object fp points to the mailbox file. Optional factory is as with the UnixMailbox class.

class mailbox. MHMailbox(dirname[, factory])
Access an MH mailbox, a directory with each message in a separate file with a numeric name. The name of the mailbox directory is passed in dirname. factory is as with the UnixMailbox class.

class mailbox. BabylMailbox(fp[, factory])
Access a Babyl mailbox, which is similar to an MMDF mailbox. In Babyl format, each message has two sets of headers, the original headers and the visible headers. The original headers appear before a line containing only '*** EOOH ***' (End-Of-Original-Headers) and the visible headers appear after the EOOH line. Babyl-compliant mail readers will show you only the visible headers, and BabylMailbox objects will return messages containing only the visible headers. You'll have to do your own parsing of the mailbox file to get at the original headers. Mail messages start with the EOOH line and end with a line containing only '\037\014'. factory is as with the UnixMailbox class.

If you wish to use the older mailbox classes with the email module rather than the deprecated rfc822 module, you can do so as follows:

```python
import email
import email.Errors
import mailbox
```
def msgfactory(fp):
    try:
        return email.message_from_file(fp)
    except email.Errors.MessageParseError:
        # Don't return None since that will
        # stop the mailbox iterator
        return ''

mbox = mailbox.UnixMailbox(fp, msgfactory)

Alternatively, if you know your mailbox contains only well-formed MIME messages, you can simplify this to:

import email
import mailbox

mbox = mailbox.UnixMailbox(fp, email.message_from_file)
A simple example of printing the subjects of all messages in a mailbox that seem interesting:

```python
import mailbox
for message in mailbox.mbox('~/mbox'):
    subject = message['subject']  # Could possibly be None
    if subject and 'python' in subject.lower():
        print(subject)
```

To copy all mail from a Babyl mailbox to an MH mailbox, converting all of the format-specific information that can be converted:

```python
import mailbox
destination = mailbox.MH('~/Mail')
destination.lock()
for message in mailbox.Babyl('~/RMAIL'):
    destination.add(mailbox.MHMessage(message))
destination.flush()
destination.unlock()
```

This example sorts mail from several mailing lists into different mailboxes, being careful to avoid mail corruption due to concurrent modification by other programs, mail loss due to interruption of the program, or premature termination due to malformed messages in the mailbox:

```python
import mailbox
import email.Errors
list_names = ('python-list', 'python-dev', 'python-bugs')
boxes = dict((name, mailbox.mbox('~/email/%s' % name)) for name in list_names)
inbox = mailbox.Maildir('~/Maildir', factory=None)
for key in inbox.iterkeys():
    try:
```
message = inbox[key]
except email.Errors.MessageParseError:
    continue  # The message is malformed. Just

for name in list_names:
    list_id = message['list-id']
    if list_id and name in list_id:
        # Get mailbox to use
        box = boxes[name]

        # Write copy to disk before removing original.
        # If there's a crash, you might duplicate a message
        # that's better than losing a message completely.
        box.lock()
        box.add(message)
        box.flush()
        box.unlock()

        # Remove original message
        inbox.lock()
        inbox.discard(key)
        inbox.flush()
        inbox.unlock()
        break  # Found destination, so stop looking.

for box in boxes.itervalues():
    box.close()}
18.5. mhlib — Access to MH mailboxes

*Deprecated since version 2.6:* The `mhlib` module has been removed in Python 3.0. Use the `mailbox` instead.

The `mhlib` module provides a Python interface to MH folders and their contents.

The module contains three basic classes, `MH`, which represents a particular collection of folders, `Folder`, which represents a single folder, and `Message`, which represents a single message.

```python
class mhlib.MH(path[, profile])
    MH represents a collection of MH folders.

class mhlib.Folder(mh, name)
    The Folder class represents a single folder and its messages.

class mhlib.Message(folder, number[, name])
    Message objects represent individual messages in a folder. The Message class is derived from mimetools.Message.
```
18.5.1. MH Objects

MH instances have the following methods:

MH. **error**(format[, ...])
   Print an error message – can be overridden.

MH. **getprofile**(key)
   Return a profile entry (None if not set).

MH. **getpath**()
   Return the mailbox pathname.

MH. **getcontext**()
   Return the current folder name.

MH. **setcontext**(name)
   Set the current folder name.

MH. **listfolders**()
   Return a list of top-level folders.

MH. **listallfolders**()
   Return a list of all folders.

MH. **listsubfolders**(name)
   Return a list of direct subfolders of the given folder.

MH. **listallsubfolders**(name)
   Return a list of all subfolders of the given folder.

MH. **makefolder**(name)
   Create a new folder.
`.deletefolder(name)`  
Delete a folder – must have no subfolders.

`.openfolder(name)`  
Return a new open folder object.
Folder instances represent open folders and have the following methods:

Folder. `error(format[, ...])`
   Print an error message – can be overridden.

Folder. `getfullname()`
   Return the folder’s full pathname.

Folder. `getsequencesfilename()`
   Return the full pathname of the folder’s sequences file.

Folder. `getmessagefilename(n)`
   Return the full pathname of message `n` of the folder.

Folder. `listmessages()`
   Return a list of messages in the folder (as numbers).

Folder. `getcurrent()`
   Return the current message number.

Folder. `setcurrent(n)`
   Set the current message number to `n`.

Folder. `parsesequence(seq)`
   Parse msgs syntax into list of messages.

Folder. `getlast()`
   Get last message, or 0 if no messages are in the folder.

Folder. `setlast(n)`
Set last message (internal use only).

Folder. `getsequences()`
Return dictionary of sequences in folder. The sequence names are used as keys, and the values are the lists of message numbers in the sequences.

Folder. `putsequences(dict)`
Return dictionary of sequences in folder name: list.

Folder. `removemessages(list)`
Remove messages in list from folder.

Folder. `refilemessages(list, tofolder)`
Move messages in list to other folder.

Folder. `movemessage(n, tofolder, ton)`
Move one message to a given destination in another folder.

Folder. `copymessage(n, tofolder, ton)`
Copy one message to a given destination in another folder.
18.5.3. Message Objects

The `Message` class adds one method to those of `mimetypes.Message`:

`Message.openmessage(n)`

Return a new open message object (costs a file descriptor).
18.6. mimetools — Tools for parsing MIME messages

**Deprecated since version 2.3:** The email package should be used in preference to the mimetools module. This module is present only to maintain backward compatibility, and it has been removed in 3.x.

This module defines a subclass of the rfc822 module's Message class and a number of utility functions that are useful for the manipulation for MIME multipart or encoded message.

It defines the following items:

```
class mimetools.Message(fp[, seekable])
```

Return a new instance of the Message class. This is a subclass of the rfc822.Message class, with some additional methods (see below). The seekable argument has the same meaning as for rfc822.Message.

```
mimetools.choose_boundary()
```

Return a unique string that has a high likelihood of being usable as a part boundary. The string has the form 'hostipaddr.uid.pid.timestamp.random'.

```
mimetools.decode(input, output, encoding)
```

Read data encoded using the allowed MIME encoding from open file object input and write the decoded data to open file object output. Valid values for encoding include 'base64', 'quoted-printable', 'uuencode', 'x-uuencode', 'uue', 'x-uue', '7bit', and '8bit'. Decoding messages encoded in '7bit' or '8bit' has no effect. The input is simply copied to the output.
mimetools. **encode**(input, output, encoding)

Read data from open file object *input* and write it encoded using the allowed MIME *encoding* to open file object *output*. Valid values for *encoding* are the same as for *decode()*. 

mimetools. **copyliteral**(input, output)

Read lines from open file *input* until EOF and write them to open file *output*. 

mimetools. **copybinary**(input, output)

Read blocks until EOF from open file *input* and write them to open file *output*. The block size is currently fixed at 8192.

**See also:**

**Module** email

Comprehensive email handling package; supersedes the mimetools module.

**Module** rfc822

Provides the base class for mimetools.Message.

**Module** multifile

Support for reading files which contain distinct parts, such as MIME data.

http://faqs.cs.uu.nl/na-dir/mail/mime-faq/.html

The MIME Frequently Asked Questions document. For an overview of MIME, see the answer to question 1.1 in Part 1 of this document.
18.6.1. Additional Methods of Message Objects

The `Message` class defines the following methods in addition to the `rfc822.Message` methods:

**Message.getplist()**

Return the parameter list of the `Content-Type` header. This is a list of strings. For parameters of the form `key=value`, `key` is converted to lower case but `value` is not. For example, if the message contains the header `Content-type: text/html; spam=1; Spam=2; Spam` then `getplist()` will return the Python list `['spam=1', 'spam=2', 'Spam']`.

**Message.getparam(name)**

Return the `value` of the first parameter (as returned by `getplist()`) of the form `name=value` for the given `name`. If `value` is surrounded by quotes of the form `'<...>'` or `"..."`, these are removed.

**Message.getencoding()**

Return the encoding specified in the `Content-Transfer-Encoding` message header. If no such header exists, return `'7bit'`. The encoding is converted to lower case.

**Message.gettype()**

Return the message type (of the form `type/subtype`) as specified in the `Content-Type` header. If no such header exists, return `'text/plain'`. The type is converted to lower case.

**Message.getmaintype()**
Return the main type as specified in the `Content-Type` header. If no such header exists, return `'text'`. The main type is converted to lower case.

Message. `getsubtype()`
Return the subtype as specified in the `Content-Type` header. If no such header exists, return `'plain'`. The subtype is converted to lower case.
18.7. mimetypes — Map filenames to MIME types

The `mimetypes` module converts between a filename or URL and the MIME type associated with the filename extension. Conversions are provided from filename to MIME type and from MIME type to filename extension; encodings are not supported for the latter conversion.

The module provides one class and a number of convenience functions. The functions are the normal interface to this module, but some applications may be interested in the class as well.

The functions described below provide the primary interface for this module. If the module has not been initialized, they will call `init()` if they rely on the information `init()` sets up.

```python
mimetypes.guess_type(filename[, strict])
```

Guess the type of a file based on its filename or URL, given by `filename`. The return value is a tuple `(type, encoding)` where `type` is `None` if the type can’t be guessed (missing or unknown suffix) or a string of the form `'type/subtype'`, usable for a MIME `content-type` header.

`encoding` is `None` for no encoding or the name of the program used to encode (e.g. `compress` or `gzip`). The encoding is suitable for use as a `Content-Encoding` header, not as a `Content-Transfer-Encoding` header. The mappings are table driven. Encoding suffixes are case sensitive; type suffixes are first tried case sensitively, then case insensitively.

Optional `strict` is a flag specifying whether the list of known MIME
types is limited to only the official types registered with IANA are recognized. When strict is true (the default), only the IANA types are supported; when strict is false, some additional non-standard but commonly used MIME types are also recognized.

mimetypes.guess_all_extensions(type[, strict])
Guess the extensions for a file based on its MIME type, given by type. The return value is a list of strings giving all possible filename extensions, including the leading dot (\'\.'\'). The extensions are not guaranteed to have been associated with any particular data stream, but would be mapped to the MIME type type by guess_type().

Optional strict has the same meaning as with the guess_type() function.

mimetypes.guess_extension(type[, strict])
Guess the extension for a file based on its MIME type, given by type. The return value is a string giving a filename extension, including the leading dot (\'\.'\'). The extension is not guaranteed to have been associated with any particular data stream, but would be mapped to the MIME type type by guess_type(). If no extension can be guessed for type, None is returned.

Optional strict has the same meaning as with the guess_type() function.

Some additional functions and data items are available for controlling the behavior of the module.

mimetypes.init([files])
Initialize the internal data structures. If given, files must be a sequence of file names which should be used to augment the default type map. If omitted, the file names to use are taken from
knownfiles; on Windows, the current registry settings are loaded. Each file named in files or knownfiles takes precedence over those named before it. Calling init() repeatedly is allowed.

Changed in version 2.7: Previously, Windows registry settings were ignored.

mimetypes.read_mime_types(filename)
Load the type map given in the file filename, if it exists. The type map is returned as a dictionary mapping filename extensions, including the leading dot ('.'), to strings of the form 'type/subtype'. If the file filename does not exist or cannot be read, None is returned.

mimetypes.add_type(type, ext[, strict])
Add a mapping from the mimetype type to the extension ext. When the extension is already known, the new type will replace the old one. When the type is already known the extension will be added to the list of known extensions.

When strict is True (the default), the mapping will added to the official MIME types, otherwise to the non-standard ones.

mimetypes.initiated
Flag indicating whether or not the global data structures have been initialized. This is set to true by init().

mimetypes.knownfiles
List of type map file names commonly installed. These files are typically named mime.types and are installed in different locations by different packages.

mimetypes.suffix_map
Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type
are indicated by the same extension. For example, the .tgz extension is mapped to .tar.gz to allow the encoding and type to be recognized separately.

mimetypes.encodings_map
Dictionary mapping filename extensions to encoding types.

mimetypes.types_map
Dictionary mapping filename extensions to MIME types.

mimetypes.common_types
Dictionary mapping filename extensions to non-standard, but commonly found MIME types.

The MimeTypes class may be useful for applications which may want more than one MIME-type database:

```
class mimetypes.MimeTypes([filenames])
```

This class represents a MIME-types database. By default, it provides access to the same database as the rest of this module. The initial database is a copy of that provided by the module, and may be extended by loading additional mime.types-style files into the database using the read() or readfp() methods. The mapping dictionaries may also be cleared before loading additional data if the default data is not desired.

The optional filenames parameter can be used to cause additional files to be loaded “on top” of the default database.

*New in version 2.2.*

An example usage of the module:

```python
>>> import mimetypes
>>> mimetypes.init()
>>> mimetypes.knownfiles
```
['/etc/mime.types', '/etc/httpd/mime.types', ... ]

>>> mimetypes.suffix_map['.tgz']
'.tar.gz'

>>> mimetypes.encodings_map['.gz']
'gzip'

>>> mimetypes.types_map['.tgz']
'application/x-tar-gz'
18.7.1. MimeTypes Objects

MimeTypes instances provide an interface which is very like that of the mimetypes module.

MimeTypes.suffix_map
Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the .tgz extension is mapped to .tar.gz to allow the encoding and type to be recognized separately. This is initially a copy of the global suffix_map defined in the module.

MimeTypes.encodings_map
Dictionary mapping filename extensions to encoding types. This is initially a copy of the global encodings_map defined in the module.

MimeTypes.types_map
Dictionary mapping filename extensions to MIME types. This is initially a copy of the global types_map defined in the module.

MimeTypes.common_types
Dictionary mapping filename extensions to non-standard, but commonly found MIME types. This is initially a copy of the global common_types defined in the module.

MimeTypes.guess_extension(type[, strict])
Similar to the guess_extension() function, using the tables stored as part of the object.

MimeTypes.guess_all_extensions(type[, strict])
Similar to the guess_all_extensions() function, using the tables
stored as part of the object.

MimeTypes. `guess_type(url[, strict])`
Similar to the `guess_type()` function, using the tables stored as part of the object.

MimeTypes. `read(path)`
Load MIME information from a file named `path`. This uses `readfp()` to parse the file.

MimeTypes. `readfp(file)`
Load MIME type information from an open file. The file must have the format of the standard `mime.types` files.

MimeTypes. `read_windows_registry()`
Load MIME type information from the Windows registry. Availability: Windows.

*New in version 2.7.*
18.8. MimeWriter — Generic MIME file writer

*Deprecated since version 2.3:* The `email` package should be used in preference to the `MimeWriter` module. This module is present only to maintain backward compatibility.

This module defines the class `MimeWriter`. The `MimeWriter` class implements a basic formatter for creating MIME multi-part files. It doesn't seek around the output file nor does it use large amounts of buffer space. You must write the parts out in the order that they should occur in the final file. `MimeWriter` does buffer the headers you add, allowing you to rearrange their order.

```python
class MimeWriter.

MimeWriter(fp)

Return a new instance of the `MimeWriter` class. The only argument passed, `fp`, is a file object to be used for writing. Note that a `StringIO` object could also be used.
18.8.1. MimeWriter Objects

MimeWriter instances have the following methods:

MimeWriter.**addheader**(key, value[, prefix])
Add a header line to the MIME message. The key is the name of the header, where the value obviously provides the value of the header. The optional argument prefix determines where the header is inserted; 0 means append at the end, 1 is insert at the start. The default is to append.

MimeWriter.**flushheaders**()
Causes all headers accumulated so far to be written out (and forgotten). This is useful if you don’t need a body part at all, e.g. for a subpart of type `message/rfc822` that’s (mis)used to store some header-like information.

MimeWriter.**startbody**(ctype[, plist[, prefix]])
Returns a file-like object which can be used to write to the body of the message. The content-type is set to the provided ctype, and the optional parameter plist provides additional parameters for the content-type declaration. prefix functions as in addheader() except that the default is to insert at the start.

MimeWriter.**startmultipartbody**(subtype[, boundary[, plist[, prefix]]])
Returns a file-like object which can be used to write to the body of the message. Additionally, this method initializes the multi-part code, where subtype provides the multipart subtype, boundary may provide a user-defined boundary specification, and plist provides optional parameters for the subtype. prefix functions as in startbody(). Subparts should be created using nextpart().
MimeWriter.nextpart()

Returns a new instance of `MimeWriter` which represents an individual part in a multipart message. This may be used to write the part as well as used for creating recursively complex multipart messages. The message must first be initialized with `startmultipartbody()` before using `nextpart()`.

MimeWriter.lastpart()

This is used to designate the last part of a multipart message, and should *always* be used when writing multipart messages.
18.9. mimify — MIME processing of mail messages

*Deprecated since version 2.3:* The `email` package should be used in preference to the `mimify` module. This module is present only to maintain backward compatibility.

The `mimify` module defines two functions to convert mail messages to and from MIME format. The mail message can be either a simple message or a so-called multipart message. Each part is treated separately. Mimifying (a part of) a message entails encoding the message as quoted-printable if it contains any characters that cannot be represented using 7-bit ASCII. Unmimifying (a part of) a message entails undoing the quoted-printable encoding. Mimify and unmimify are especially useful when a message has to be edited before being sent. Typical use would be:

```python
unmimify message
edit message
mimify message
send message
```

The modules defines the following user-callable functions and user-settable variables:

```python
mimify.mimify(infile, outfile)
```
Copy the message in `infile` to `outfile`, converting parts to quoted-printable and adding MIME mail headers when necessary. `infile` and `outfile` can be file objects (actually, any object that has a `readline()` method for `infile`) or a `write()` method for `outfile`) or strings naming the files. If `infile` and `outfile` are both strings, they may have the same value.
mimify.unmimify(infile, outfile[, decode_base64])

Copy the message in infile to outfile, decoding all quoted-printable parts. infile and outfile can be file objects (actually, any object that has a readline() method (for infile) or a write() method (for outfile)) or strings naming the files. If infile and outfile are both strings, they may have the same value. If the decode_base64 argument is provided and tests true, any parts that are coded in the base64 encoding are decoded as well.

mimify.mime_decode_header(line)

Return a decoded version of the encoded header line in line. This only supports the ISO 8859-1 charset (Latin-1).

mimify.mime_encode_header(line)

Return a MIME-encoded version of the header line in line.

mimify.MAXLEN

By default, a part will be encoded as quoted-printable when it contains any non-ASCII characters (characters with the 8th bit set), or if there are any lines longer than MAXLEN characters (default value 200).

mimify.CHARSET

When not specified in the mail headers, a character set must be filled in. The string used is stored in CHARSET, and the default value is ISO-8859-1 (also known as Latin1 (latin-one)).

This module can also be used from the command line. Usage is as follows:

```
mimify.py -e [-l length] [infile [outfile]]
mimify.py -d [-b] [infile [outfile]]
```

to encode (mimify) and decode (unmimify) respectively. infile defaults to standard input, outfile defaults to standard output. The
same file can be specified for input and output.

If the -I option is given when encoding, if there are any lines longer than the specified length, the containing part will be encoded.

If the -b option is given when decoding, any base64 parts will be decoded as well.

**See also:**

**Module quopri**

Encode and decode MIME quoted-printable files.
18.10. `multifile` — Support for files containing distinct parts

*Deprecation note:*

*Deprecated since version 2.5:* The `email` package should be used in preference to the `multifile` module. This module is present only to maintain backward compatibility.

The `MultiFile` object enables you to treat sections of a text file as file-like input objects, with '' being returned by `readline()` when a given delimiter pattern is encountered. The defaults of this class are designed to make it useful for parsing MIME multipart messages, but by subclassing it and overriding methods it can be easily adapted for more general use.

```python
class multifile.MultiFile(fp[, seekable])
```

Create a multi-file. You must instantiate this class with an input object argument for the `MultiFile` instance to get lines from, such as a file object returned by `open()`.

`MultiFile` only ever looks at the input object’s `readline()`, `seek()` and `tell()` methods, and the latter two are only needed if you want random access to the individual MIME parts. To use `MultiFile` on a non-seekable stream object, set the optional `seekable` argument to false; this will prevent using the input object’s `seek()` and `tell()` methods.

It will be useful to know that in `MultiFile`‘s view of the world, text is composed of three kinds of lines: data, section-dividers, and end-markers. `MultiFile` is designed to support parsing of messages that may have multiple nested message parts, each with its own pattern for section-divider and end-marker lines.
**See also:**

**Module** email

Comprehensive email handling package; supersedes the multifile module.
18.10.1. MultiFile Objects

A MultiFile instance has the following methods:

MultiFile.\texttt{readline}(\textit{str})

Read a line. If the line is data (not a section-divider or end-marker or real EOF) return it. If the line matches the most-recently-stacked boundary, return '' and set self.\texttt{last} to 1 or 0 according as the match is or is not an end-marker. If the line matches any other stacked boundary, raise an error. On encountering end-of-file on the underlying stream object, the method raises \texttt{Error} unless all boundaries have been popped.

MultiFile.\texttt{readlines}(\textit{str})

Return all lines remaining in this part as a list of strings.

MultiFile.\texttt{read}()

Read all lines, up to the next section. Return them as a single (multiline) string. Note that this doesn't take a size argument!

MultiFile.\texttt{seek}(\textit{pos[, whence]})

Seek. Seek indices are relative to the start of the current section. The pos and whence arguments are interpreted as for a file seek.

MultiFile.\texttt{tell}()

Return the file position relative to the start of the current section.

MultiFile.\texttt{next}()

Skip lines to the next section (that is, read lines until a section-divider or end-marker has been consumed). Return true if there is such a section, false if an end-marker is seen. Re-enable the most-recently-pushed boundary.
MultiFile.is_data(str)
Return true if str is data and false if it might be a section boundary. As written, it tests for a prefix other than '----' at start of line (which all MIME boundaries have) but it is declared so it can be overridden in derived classes.

Note that this test is used intended as a fast guard for the real boundary tests; if it always returns false it will merely slow processing, not cause it to fail.

MultiFile.push(str)
Push a boundary string. When a decorated version of this boundary is found as an input line, it will be interpreted as a section-divider or end-marker (depending on the decoration, see RFC 2045). All subsequent reads will return the empty string to indicate end-of-file, until a call to pop() removes the boundary a or next() call reenables it.

It is possible to push more than one boundary. Encountering the most-recently-pushed boundary will return EOF; encountering any other boundary will raise an error.

MultiFile.pop()
Pop a section boundary. This boundary will no longer be interpreted as EOF.

MultiFile.section_divider(str)
Turn a boundary into a section-divider line. By default, this method prepends '----' (which MIME section boundaries have) but it is declared so it can be overridden in derived classes. This method need not append LF or CR-LF, as comparison with the result ignores trailing whitespace.

MultiFile.end_marker(str)
Turn a boundary string into an end-marker line. By default, this method prepends '--' and appends '--' (like a MIME-multipart end-of-message marker) but it is declared so it can be overridden in derived classes. This method need not append LF or CR-LF, as comparison with the result ignores trailing whitespace.

Finally, *MultiFile* instances have two public instance variables:

*MultiFile*. level

Nesting depth of the current part.

*MultiFile*. last

True if the last end-of-file was for an end-of-message marker.
import mimetools
import multifile
import StringIO

def extract_mime_part_matching(stream, mimetype):

    return data.getvalue()
18.11. rfc822 — Parse RFC 2822 mail headers

*Deprecated since version 2.3:* The `email` package should be used in preference to the `rfc822` module. This module is present only to maintain backward compatibility, and has been removed in 3.0.

This module defines a class, `Message`, which represents an “email message” as defined by the Internet standard RFC 2822. Such messages consist of a collection of message headers, and a message body. This module also defines a helper class `AddressList` for parsing RFC 2822 addresses. Please refer to the RFC for information on the specific syntax of RFC 2822 messages.

The `mailbox` module provides classes to read mailboxes produced by various end-user mail programs.

```python
class rfc822.Message(file[, seekable])
```

A `Message` instance is instantiated with an input object as parameter. Message relies only on the input object having a `readline()` method; in particular, ordinary file objects qualify. Instantiation reads headers from the input object up to a delimiter line (normally a blank line) and stores them in the instance. The message body, following the headers, is not consumed.

This class can work with any input object that supports a `readline()` method. If the input object has seek and tell capability, the `rewindbody()` method will work; also, illegal lines will be pushed back onto the input stream. If the input object lacks seek but has an `unread()` method that can push back a line of input, `Message` will use that to push back illegal lines. Thus this
class can be used to parse messages coming from a buffered stream.

The optional seekable argument is provided as a workaround for certain stdio libraries in which tell() discards buffered data before discovering that the lseek() system call doesn't work. For maximum portability, you should set the seekable argument to zero to prevent that initial tell() when passing in an unseekable object such as a file object created from a socket object.

Input lines as read from the file may either be terminated by CR-LF or by a single linefeed; a terminating CR-LF is replaced by a single linefeed before the line is stored.

All header matching is done independent of upper or lower case; e.g. m["From"], m["from"] and m["FROM"] all yield the same result.

class rfc822.AddressList(field)
    You may instantiate the AddressList helper class using a single string parameter, a comma-separated list of RFC 2822 addresses to be parsed. (The parameter None yields an empty list.)

rfc822.quote(str)
    Return a new string with backslashes in str replaced by two backslashes and double quotes replaced by backslash-double quote.

rfc822.unquote(str)
    Return a new string which is an unquoted version of str. If str ends and begins with double quotes, they are stripped off. Likewise if str ends and begins with angle brackets, they are stripped off.

rfc822.parseaddr(address)
Parse *address*, which should be the value of some address-containing field such as *To* or *Cc*, into its constituent “realname” and “email address” parts. Returns a tuple of that information, unless the parse fails, in which case a 2-tuple (*None*, *None*) is returned.

**rfc822. dump_address_pair(pair)**

The inverse of *parseaddr()*, this takes a 2-tuple of the form (*realname*, *email_address*) and returns the string value suitable for a *To* or *Cc* header. If the first element of *pair* is false, then the second element is returned unmodified.

**rfc822. parsedate(date)**

Attempts to parse a date according to the rules in **RFC 2822**. However, some mailers don’t follow that format as specified, so *parsedate()* tries to guess correctly in such cases. *date* is a string containing an **RFC 2822** date, such as *'Mon, 20 Nov 1995 19:12:08 -0500'* . If it succeeds in parsing the date, *parsedate()* returns a 9-tuple that can be passed directly to *time.mktime()*; otherwise *None* will be returned. Note that indexes 6, 7, and 8 of the result tuple are not usable.

**rfc822. parsedate_tz(date)**

Performs the same function as *parsedate()* , but returns either *None* or a 10-tuple; the first 9 elements make up a tuple that can be passed directly to *time.mktime()* , and the tenth is the offset of the date’s timezone from UTC (which is the official term for Greenwich Mean Time). (Note that the sign of the timezone offset is the opposite of the sign of the *time.timezone* variable for the same timezone; the latter variable follows the POSIX standard while this module follows **RFC 2822**.) If the input string has no timezone, the last element of the tuple returned is *None*. Note that indexes 6, 7, and 8 of the result tuple are not usable.
**rfc822.mktime_tz(tuple)**

Turn a 10-tuple as returned by `parsedate_tz()` into a UTC timestamp. If the timezone item in the tuple is `None`, assume local time. Minor deficiency: this first interprets the first 8 elements as a local time and then compensates for the timezone difference; this may yield a slight error around daylight savings time switch dates. Not enough to worry about for common use.

---

**See also:**

**Module email**

Comprehensive email handling package; supersedes the `rfc822` module.

**Module mailbox**

Classes to read various mailbox formats produced by end-user mail programs.

**Module mimetools**

Subclass of `rfc822.Message` that handles MIME encoded messages.
18.11.1. Message Objects

A `Message` instance has the following methods:

**Message.** `rewindbody()`
Seek to the start of the message body. This only works if the file object is seekable.

**Message.** `isheader(line)`
Returns a line's canonicalized fieldname (the dictionary key that will be used to index it) if the line is a legal RFC 2822 header; otherwise returns `None` (implying that parsing should stop here and the line be pushed back on the input stream). It is sometimes useful to override this method in a subclass.

**Message.** `islast(line)`
Return `True` if the given line is a delimiter on which Message should stop. The delimiter line is consumed, and the file object's read location positioned immediately after it. By default this method just checks that the line is blank, but you can override it in a subclass.

**Message.** `iscomment(line)`
Return `True` if the given line should be ignored entirely, just skipped. By default this is a stub that always returns `False`, but you can override it in a subclass.

**Message.** `getallmatchingheaders(name)`
Return a list of lines consisting of all headers matching `name`, if any. Each physical line, whether it is a continuation line or not, is a separate list item. Return the empty list if no header matches `name`. 
Message. **getfirstmatchingheader**(*name*)

Return a list of lines comprising the first header matching *name*, and its continuation line(s), if any. Return **None** if there is no header matching *name*.

Message. **getrawheader**(*name*)

Return a single string consisting of the text after the colon in the first header matching *name*. This includes leading whitespace, the trailing linefeed, and internal linefeeds and whitespace if there any continuation line(s) were present. Return **None** if there is no header matching *name*.

Message. **getheader**(*name*, [*, default]*)

Return a single string consisting of the last header matching *name*, but strip leading and trailing whitespace. Internal whitespace is not stripped. The optional *default* argument can be used to specify a different default to be returned when there is no header matching *name*; it defaults to **None**. This is the preferred way to get parsed headers.

Message. **get**(*name*, [*, default]*)

An alias for **getheader()**, to make the interface more compatible with regular dictionaries.

Message. **getaddr**(*name*)

Return a pair (full name, email address) parsed from the string returned by **getheader**(*name*). If no header matching *name* exists, return (**None**, **None**); otherwise both the full name and the address are (possibly empty) strings.

Example: If *m*'s first From header contains the string 'j**ack@**cwi.nl (Jack Jansen)', then *m.getaddr('From')* will yield the pair ('Jack Jansen', 'jack@cwi.nl'). If the header contained
'Jack Jansen <jack@cwi.nl>' instead, it would yield the exact same result.

Message. **getaddrlist**(*name*)
This is similar to **getaddr**(*list*), but parses a header containing a list of email addresses (e.g. a To header) and returns a list of (full name, email address) pairs (even if there was only one address in the header). If there is no header matching *name*, return an empty list.

If multiple headers exist that match the named header (e.g. if there are several Cc headers), all are parsed for addresses. Any continuation lines the named headers contain are also parsed.

Message. **getdate**(*name*)
Retrieve a header using **getheader**() and parse it into a 9-tuple compatible with **time.mktime**(); note that fields 6, 7, and 8 are not usable. If there is no header matching *name*, or it is unparsable, return **None**.

Date parsing appears to be a black art, and not all mailers adhere to the standard. While it has been tested and found correct on a large collection of email from many sources, it is still possible that this function may occasionally yield an incorrect result.

Message. **getdate**_**_tz**(*name*)
Retrieve a header using **getheader**() and parse it into a 10-tuple; the first 9 elements will make a tuple compatible with **time.mktime**(), and the 10th is a number giving the offset of the date's timezone from UTC. Note that fields 6, 7, and 8 are not usable. Similarly to **getdate**(), if there is no header matching *name*, or it is unparsable, return **None**.

Message instances also support a limited mapping interface. In
particular: m[name] is like m.getheader(name) but raises **KeyError** if there is no matching header; and len(m), m.get(name[, default]), name in m, m.keys(), m.values(), m.items(), and m.setdefault(name[, default]) act as expected, with the one difference that setdefault() uses an empty string as the default value. **Message** instances also support the mapping writable interface m[name] = value and del m[name]. **Message** objects do not support the clear(), copy(), popitem(), or update() methods of the mapping interface. (Support for get() and setdefault() was only added in Python 2.2.)

Finally, **Message** instances have some public instance variables:

**Message.headers**

A list containing the entire set of header lines, in the order in which they were read (except that setitem calls may disturb this order). Each line contains a trailing newline. The blank line terminating the headers is not contained in the list.

**Message.fp**

The file or file-like object passed at instantiation time. This can be used to read the message content.

**Message.unixfrom**

The Unix **From** line, if the message had one, or an empty string. This is needed to regenerate the message in some contexts, such as an **mbox**-style mailbox file.
18.11.2. AddressList Objects

An AddressList instance has the following methods:

AddressList.__len__()  
Return the number of addresses in the address list.

AddressList.__str__()  
Return a canonicalized string representation of the address list. Addresses are rendered in “name” <host@domain> form, comma-separated.

AddressList.__add__(alist)  
Return a new AddressList instance that contains all addresses in both AddressList operands, with duplicates removed (set union).

AddressList.__iadd__(alist)  
In-place version of __add__(); turns this AddressList instance into the union of itself and the right-hand instance, alist.

AddressList.__sub__(alist)  
Return a new AddressList instance that contains every address in the left-hand AddressList operand that is not present in the right-hand address operand (set difference).

AddressList.__isub__(alist)  
In-place version of __sub__(), removing addresses in this list which are also in alist.

Finally, AddressList instances have one public instance variable:

AddressList.addresslist  
A list of tuple string pairs, one per address. In each member, the
first is the canonicalized name part, the second is the actual route-address (\'@\'-separated username-host.domain pair).

Footnotes

This module originally conformed to RFC 822, hence the name. Since then, RFC 2822 has been released as an update to RFC 822. This module should be considered RFC 2822-conformant, especially in cases where the syntax or semantics have changed since RFC 822.
18.12. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings

This module provides data encoding and decoding as specified in RFC 3548. This standard defines the Base16, Base32, and Base64 algorithms for encoding and decoding arbitrary binary strings into text strings that can be safely sent by email, used as parts of URLs, or included as part of an HTTP POST request. The encoding algorithm is not the same as the uuencode program.

There are two interfaces provided by this module. The modern interface supports encoding and decoding string objects using all three alphabets. The legacy interface provides for encoding and decoding to and from file-like objects as well as strings, but only using the Base64 standard alphabet.

The modern interface, which was introduced in Python 2.4, provides:

```python
base64. b64encode(s[, altchars])
```

Encode a string use Base64.

- `s` is the string to encode. Optional `altchars` must be a string of at least length 2 (additional characters are ignored) which specifies an alternative alphabet for the `+` and `/` characters. This allows an application to e.g. generate URL or filesystem safe Base64 strings. The default is `None`, for which the standard Base64 alphabet is used.

The encoded string is returned.

```python
base64. b64decode(s[, altchars])
```
Decode a Base64 encoded string.

`s` is the string to decode. Optional `altchars` must be a string of at least length 2 (additional characters are ignored) which specifies the alternative alphabet used instead of the `+` and `/` characters.

The decoded string is returned. A `TypeError` is raised if `s` were incorrectly padded or if there are non-alphabet characters present in the string.

```python
base64.standard_b64encode(s)
```
Encode string `s` using the standard Base64 alphabet.

```python
base64.standard_b64decode(s)
```
Decode string `s` using the standard Base64 alphabet.

```python
base64.urlsafe_b64encode(s)
```
Encode string `s` using a URL-safe alphabet, which substitutes `-` instead of `+` and `_` instead of `/` in the standard Base64 alphabet. The result can still contain `=`.

```python
base64.urlsafe_b64decode(s)
```
Decode string `s` using a URL-safe alphabet, which substitutes `-` instead of `+` and `_` instead of `/` in the standard Base64 alphabet.

```python
base64.b32encode(s)
```
Encode a string using Base32. `s` is the string to encode. The encoded string is returned.

```python
base64.b32decode(s[, casefold[, map01]])
```
Decode a Base32 encoded string.

`s` is the string to decode. Optional `casefold` is a flag specifying whether a lowercase alphabet is acceptable as input. For security
purposes, the default is `False`.

**RFC 3548** allows for optional mapping of the digit 0 (zero) to the letter O (oh), and for optional mapping of the digit 1 (one) to either the letter I (eye) or letter L (el). The optional argument `map01` when not `None`, specifies which letter the digit 1 should be mapped to (when `map01` is not `None`, the digit 0 is always mapped to the letter O). For security purposes the default is `None`, so that 0 and 1 are not allowed in the input.

The decoded string is returned. A `TypeError` is raised if `s` were incorrectly padded or if there are non-alphabet characters present in the string.

```
base64. b16encode(s)
Encode a string using Base16.

s is the string to encode. The encoded string is returned.
```

```
base64. b16decode(s[, casefold])
Decode a Base16 encoded string.

s is the string to decode. Optional `casefold` is a flag specifying whether a lowercase alphabet is acceptable as input. For security purposes, the default is `False`.

The decoded string is returned. A `TypeError` is raised if `s` were incorrectly padded or if there are non-alphabet characters present in the string.
```

The legacy interface:

```
base64. decode(input, output)
Decode the contents of the `input` file and write the resulting binary data to the `output` file. `input` and `output` must either be file objects
or objects that mimic the file object interface. input will be read until input.read() returns an empty string.

**base64.** `decodestring(s)`

Decode the string s, which must contain one or more lines of base64 encoded data, and return a string containing the resulting binary data.

**base64.** `encode(input, output)`

Encode the contents of the input file and write the resulting base64 encoded data to the output file. input and output must either be file objects or objects that mimic the file object interface. input will be read until input.read() returns an empty string. encode() returns the encoded data plus a trailing newline character (\n).

**base64.** `encodestring(s)`

Encode the string s, which can contain arbitrary binary data, and return a string containing one or more lines of base64-encoded data. encodestring() returns a string containing one or more lines of base64-encoded data always including an extra trailing newline (\n).

An example usage of the module:

```python
>>> import base64
>>> encoded = base64.b64encode('data to be encoded')
>>> encoded
'ZGF0YSB0byBiZSBlbmNvZGVk'
>>> data = base64.b64decode(encoded)
>>> data
'data to be encoded'
```

**See also:**

**Module** `binascii`
Support module containing ASCII-to-binary and binary-to-ASCII conversions.

**RFC 1521 - MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies**

Section 5.2, “Base64 Content-Transfer-Encoding,” provides the definition of the base64 encoding.
18.13. binhex — Encode and decode binhex4 files

This module encodes and decodes files in binhex4 format, a format allowing representation of Macintosh files in ASCII. On the Macintosh, both forks of a file and the finder information are encoded (or decoded), on other platforms only the data fork is handled.

Note: In Python 3.x, special Macintosh support has been removed.

The binhex module defines the following functions:

binhex. binhex(input, output)
Convert a binary file with filename input to binhex file output. The output parameter can either be a filename or a file-like object (any object supporting a write() and close() method).

binhex. hexbin(input[, output])
Decode a binhex file input. input may be a filename or a file-like object supporting read() and close() methods. The resulting file is written to a file named output, unless the argument is omitted in which case the output filename is read from the binhex file.

The following exception is also defined:

exception binhex. Error
Exception raised when something can’t be encoded using the binhex format (for example, a filename is too long to fit in the filename field), or when input is not properly encoded binhex data.
See also:

Module binascii
Support module containing ASCII-to-binary and binary-to-ASCII conversions.
18.13.1. Notes

There is an alternative, more powerful interface to the coder and decoder, see the source for details.

If you code or decode textfiles on non-Macintosh platforms they will still use the old Macintosh newline convention (carriage-return as end of line).

As of this writing, `hexbin()` appears to not work in all cases.
18.14. binascii — Convert between binary and ASCII

The binascii module contains a number of methods to convert between binary and various ASCII-encoded binary representations. Normally, you will not use these functions directly but use wrapper modules like uu, base64, or binhex instead. The binascii module contains low-level functions written in C for greater speed that are used by the higher-level modules.

The binascii module defines the following functions:

binascii.a2b_uu(string)

Convert a single line of uuencoded data back to binary and return the binary data. Lines normally contain 45 (binary) bytes, except for the last line. Line data may be followed by whitespace.

binascii.b2a_uu(data)

Convert binary data to a line of ASCII characters, the return value is the converted line, including a newline char. The length of data should be at most 45.

binascii.a2b_base64(string)

Convert a block of base64 data back to binary and return the binary data. More than one line may be passed at a time.

binascii.b2a_base64(data)

Convert binary data to a line of ASCII characters in base64 coding. The return value is the converted line, including a newline char. The length of data should be at most 57 to adhere to the base64 standard.

binascii.a2b_qp(string[, header])
Convert a block of quoted-printable data back to binary and return the binary data. More than one line may be passed at a time. If the optional argument header is present and true, underscores will be decoded as spaces.

\texttt{binascii.b2a_qp(data[, quotetabs, istext, header])}

Convert binary data to a line(s) of ASCII characters in quoted-printable encoding. The return value is the converted line(s). If the optional argument quotetabs is present and true, all tabs and spaces will be encoded. If the optional argument istext is present and true, newlines are not encoded but trailing whitespace will be encoded. If the optional argument header is present and true, spaces will be encoded as underscores per RFC1522. If the optional argument header is present and false, newline characters will be encoded as well; otherwise linefeed conversion might corrupt the binary data stream.

\texttt{binascii.a2b_hqx(string)}

Convert binhex4 formatted ASCII data to binary, without doing RLE-decompression. The string should contain a complete number of binary bytes, or (in case of the last portion of the binhex4 data) have the remaining bits zero.

\texttt{binascii.rledecode_hqx(data)}

Perform RLE-decompression on the data, as per the binhex4 standard. The algorithm uses \texttt{0x90} after a byte as a repeat indicator, followed by a count. A count of \texttt{0} specifies a byte value of \texttt{0x90}. The routine returns the decompressed data, unless data input data ends in an orphaned repeat indicator, in which case the \texttt{Incomplete} exception is raised.

\texttt{binascii.rlecode_hqx(data)}

Perform binhex4 style RLE-compression on \texttt{data} and return the result.
**binascii.b2a_hqx(data)**

Perform hexbin4 binary-to-ASCII translation and return the resulting string. The argument should already be RLE-coded, and have a length divisible by 3 (except possibly the last fragment).

**binascii.crc_hqx(data, crc)**

Compute the binhex4 crc value of `data`, starting with an initial `crc` and returning the result.

**binascii.crc32(data[, crc])**

Compute CRC-32, the 32-bit checksum of `data`, starting with an initial `crc`. This is consistent with the ZIP file checksum. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm. Use as follows:

```python
print binascii.crc32("hello world")
# Or, in two pieces:
crc = binascii.crc32("hello")
crc = binascii.crc32("world", crc) & 0xffffffff
print 'crc32 = 0x%08x' % crc
```

**Note:** To generate the same numeric value across all Python versions and platforms use `crc32(data) & 0xffffffff`. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32bit binary representation regardless of sign.

*Changed in version 2.6:* The return value is in the range \([-2^{31}, 2^{31}-1]\) regardless of platform. In the past the value would be signed on some platforms and unsigned on others. Use \(0xffffffff\) on the value if you want it to match 3.0 behavior.

*Changed in version 3.0:* The return value is unsigned and in the range \([0, 2^{32}-1]\) regardless of platform.
binascii.\texttt{b2a\_hex}(\textit{data})
binascii.\texttt{hexlify}(\textit{data})

Return the hexadecimal representation of the binary \textit{data}. Every byte of \textit{data} is converted into the corresponding 2-digit hex representation. The resulting string is therefore twice as long as the length of \textit{data}.

binascii.\texttt{a2b\_hex}(\textit{hexstr})
binascii.\texttt{unhexlify}(\textit{hexstr})

Return the binary data represented by the hexadecimal string \textit{hexstr}. This function is the inverse of \texttt{b2a\_hex()}. \textit{hexstr} must contain an even number of hexadecimal digits (which can be upper or lower case), otherwise a \texttt{TypeError} is raised.

\textit{exception} binascii.\texttt{Error}

Exception raised on errors. These are usually programming errors.

\textit{exception} binascii.\texttt{Incomplete}

Exception raised on incomplete data. These are usually not programming errors, but may be handled by reading a little more data and trying again.

\textbf{See also:}

\textbf{Module} base64
Support for base64 encoding used in MIME email messages.

\textbf{Module} binhex
Support for the binhex format used on the Macintosh.

\textbf{Module} uu
Support for UU encoding used on Unix.

\textbf{Module} quopri
Support for quoted-printable encoding used in MIME email
messages.
This module performs quoted-printable transport encoding and decoding, as defined in RFC 1521: “MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies”. The quoted-printable encoding is designed for data where there are relatively few nonprintable characters; the base64 encoding scheme available via the base64 module is more compact if there are many such characters, as when sending a graphics file.

```python
quopri.decode(input, output[, header])
```

Decode the contents of the `input` file and write the resulting decoded binary data to the `output` file. `input` and `output` must either be file objects or objects that mimic the file object interface. `input` will be read until `input.readline()` returns an empty string. If the optional argument `header` is present and true, underscore will be decoded as space. This is used to decode “Q”-encoded headers as described in RFC 1522: “MIME (Multipurpose Internet Mail Extensions) Part Two: Message Header Extensions for Non-ASCII Text”.

```python
quopri.encode(input, output, quotetabs)
```

Encode the contents of the `input` file and write the resulting quoted-printable data to the `output` file. `input` and `output` must either be file objects or objects that mimic the file object interface. `input` will be read until `input.readline()` returns an empty string. `quotetabs` is a flag which controls whether to encode embedded spaces and tabs; when true it encodes such embedded whitespace, and when false it leaves them unencoded. Note that spaces and tabs appearing at the end of lines are always
encoded, as per RFC 1521.

quopri. **decodestring**(s[, *header*])

Like `decode()`, except that it accepts a source string and returns the corresponding decoded string.

quopri. **encodestring**(s[, *quotetabs]*)

Like `encode()`, except that it accepts a source string and returns the corresponding encoded string. *quotetabs* is optional (defaulting to 0), and is passed straight through to `encode()`.

See also:

**Module mimify**

General utilities for processing of MIME messages.

**Module base64**

Encode and decode MIME base64 data
This module encodes and decodes files in uuencode format, allowing arbitrary binary data to be transferred over ASCII-only connections. Wherever a file argument is expected, the methods accept a file-like object. For backwards compatibility, a string containing a pathname is also accepted, and the corresponding file will be opened for reading and writing; the pathname `-` is understood to mean the standard input or output. However, this interface is deprecated; it’s better for the caller to open the file itself, and be sure that, when required, the mode is `'rb'` or `'wb'` on Windows.

This code was contributed by Lance Ellinghouse, and modified by Jack Jansen.

The `uu` module defines the following functions:

```python
uu.encode(in_file, out_file[, name[, mode]])
```

Uuencode file `in_file` into file `out_file`. The uuencoded file will have the header specifying `name` and `mode` as the defaults for the results of decoding the file. The default defaults are taken from `in_file`, or `-` and `0666` respectively.

```python
uu.decode(in_file[, out_file[, mode[, quiet]]])
```

This call decodes uuencoded file `in_file` placing the result on file `out_file`. If `out_file` is a pathname, `mode` is used to set the permission bits if the file must be created. Defaults for `out_file` and `mode` are taken from the uuencode header. However, if the file specified in the header already exists, a `uu.Error` is raised.
decode() may print a warning to standard error if the input was produced by an incorrect uuencoder and Python could recover from that error. Setting quiet to a true value silences this warning.

exception uu.Error
Subclass of Exception, this can be raised by uu.decode() under various situations, such as described above, but also including a badly formatted header, or truncated input file.

Module binascii
Support module containing ASCII-to-binary and binary-to-ASCII conversions.
19. Structured Markup Processing Tools

Python supports a variety of modules to work with various forms of structured data markup. This includes modules to work with the Standard Generalized Markup Language (SGML) and the Hypertext Markup Language (HTML), and several interfaces for working with the Extensible Markup Language (XML).

It is important to note that modules in the xml package require that there be at least one SAX-compliant XML parser available. Starting with Python 2.3, the Expat parser is included with Python, so the xml.parsers.expat module will always be available. You may still want to be aware of the PyXML add-on package; that package provides an extended set of XML libraries for Python.

The documentation for the xml.dom and xml.sax packages are the definition of the Python bindings for the DOM and SAX interfaces.

19.1. HTMLParser — Simple HTML and XHTML parser

**Note:** The `HTMLParser` module has been renamed to `html.parser` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

*New in version 2.2.*

This module defines a class `HTMLParser` which serves as the basis for parsing text files formatted in HTML (HyperText Mark-up Language) and XHTML. Unlike the parser in `httplib`, this parser is not based on the SGML parser in `sgmllib`.

```python
class HTMLParser

The `HTMLParser` class is instantiated without arguments.

An `HTMLParser` instance is fed HTML data and calls handler functions when tags begin and end. The `HTMLParser` class is meant to be overridden by the user to provide a desired behavior.

Unlike the parser in `httplib`, this parser does not check that end tags match start tags or call the end-tag handler for elements which are closed implicitly by closing an outer element.

An exception is defined as well:

```python
exception HTMLParser.HTMLParseError

Exception raised by the `HTMLParser` class when it encounters an error while parsing. This exception provides three attributes: `msg` is a brief message explaining the error, `lineno` is the number of the line on which the broken construct was detected, and `offset`
is the number of characters into the line at which the construct starts.

**HTMLParser** instances have the following methods:

**HTMLParser**. `reset()`
Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.

**HTMLParser**. `feed(data)`
Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or `close()` is called.

**HTMLParser**. `close()`
Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call the **HTMLParser** base class method `close()`.

**HTMLParser**. `getpos()`
Return current line number and offset.

**HTMLParser**. `get_starttag_text()`
Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML “as deployed” or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

**HTMLParser**. `handle_starttag(tag, attrs)`
This method is called to handle the start of a tag. It is intended to be overridden by a derived class; the base class implementation
does nothing.

The tag argument is the name of the tag converted to lower case. The attrs argument is a list of (name, value) pairs containing the attributes found inside the tag's <> brackets. The name will be translated to lower case, and quotes in the value have been removed, and character and entity references have been replaced. For instance, for the tag <A HREF="http://www.cwi.nl/">, this method would be called as handle_starttag('a', [('href', 'http://www.cwi.nl/')]).

*Changed in version 2.6:* All entity references from `htmlentitydefs` are now replaced in the attribute values.

**HTMLParser.** `handle_startendtag(tag, attrs)`

Similar to `handle_starttag()`, but called when the parser encounters an XHTML-style empty tag (<a .../>). This method may be overridden by subclasses which require this particular lexical information; the default implementation simple calls `handle_starttag()` and `handle_endtag()`.

**HTMLParser.** `handle_endtag(tag)`

This method is called to handle the end tag of an element. It is intended to be overridden by a derived class; the base class implementation does nothing. The tag argument is the name of the tag converted to lower case.

**HTMLParser.** `handle_data(data)`

This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

**HTMLParser.** `handle_charref(name)`

This method is called to process a character reference of the
form &ref;. It is intended to be overridden by a derived class; the base class implementation does nothing.

**HTMLParser.handle_entityref(name)**

This method is called to process a general entity reference of the form &name; where name is an general entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

**HTMLParser.handle_comment(data)**

This method is called when a comment is encountered. The comment argument is a string containing the text between the -- and -- delimiters, but not the delimiters themselves. For example, the comment <!--text--> will cause this method to be called with the argument 'text'. It is intended to be overridden by a derived class; the base class implementation does nothing.

**HTMLParser.handle_decl(decl)**

Method called when an SGML declaration is read by the parser. The decl parameter will be the entire contents of the declaration inside the <!...> markup. It is intended to be overridden by a derived class; the base class implementation does nothing.

**HTMLParser.handle_pi(data)**

Method called when a processing instruction is encountered. The data parameter will contain the entire processing instruction. For example, for the processing instruction <?proc color='red'>, this method would be called as handle_pi("proc color='red'"). It is intended to be overridden by a derived class; the base class implementation does nothing.

**Note:** The HTMLParser class uses the SGML syntactic rules for processing instructions. An XHTML processing instruction using
the trailing '?' will cause the '?' to be included in data.
19.1.1. Example HTML Parser Application

As a basic example, below is a very basic HTML parser that uses the `HTMLParser` class to print out tags as they are encountered:

```python
from HTMLParser import HTMLParser

class MyHTMLParser(HTMLParser):
    def handle_starttag(self, tag, attrs):
        print "Encountered the beginning of a %s tag" % tag

    def handle_endtag(self, tag):
        print "Encountered the end of a %s tag" % tag
```
19.2. sgmllib — Simple SGML parser

* Deprecated since version 2.6: The sgmllib module has been removed in Python 3.0. *

This module defines a class `SGMLParser` which serves as the basis for parsing text files formatted in SGML (Standard Generalized Mark-up Language). In fact, it does not provide a full SGML parser — it only parses SGML insofar as it is used by HTML, and the module only exists as a base for the `htmllib` module. Another HTML parser which supports XHTML and offers a somewhat different interface is available in the `HTMLParser` module.

```python
class sgmllib.SGMLParser
    The SGMLParser class is instantiated without arguments. The parser is hardcoded to recognize the following constructs:

    - Opening and closing tags of the form `<tag attr="value" ...>` and `</tag>`, respectively.
    - Numeric character references of the form `&#name;`.
    - Entity references of the form `&name;`.
    - SGML comments of the form `<!--text-->`. Note that spaces, tabs, and newlines are allowed between the trailing `>` and the immediately preceding `-->`.

A single exception is defined as well:

```exception sgmllib.SGMParseError
    Exception raised by the SGMLParser class when it encounters an error while parsing.
```
New in version 2.1.

SGMLParser instances have the following methods:

SGMLParser. **reset()**
Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.

SGMLParser. **setnomoretags()**
Stop processing tags. Treat all following input as literal input (CDATA). (This is only provided so the HTML tag <PLAINTEXT> can be implemented.)

SGMLParser. **setliteral()**
Enter literal mode (CDATA mode).

SGMLParser. **feed(data)**
Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or close() is called.

SGMLParser. **close()**
Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call close().

SGMLParser. **get_starttag_text()**
Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML “as deployed” or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

SGMLParser. **handle_starttag(tag, method, attributes)***
This method is called to handle start tags for which either a `start_tag()` or `do_tag()` method has been defined. The `tag` argument is the name of the tag converted to lower case, and the `method` argument is the bound method which should be used to support semantic interpretation of the start tag. The `attributes` argument is a list of `(name, value)` pairs containing the attributes found inside the tag’s <> brackets.

The `name` has been translated to lower case. Double quotes and backslashes in the `value` have been interpreted, as well as known character references and known entity references terminated by a semicolon (normally, entity references can be terminated by any non-alphanumerical character, but this would break the very common case of `<A HREF="url?spam=1&eggs=2">` when eggs is a valid entity name).

For instance, for the tag `<A HREF="http://www.cwi.nl/">`, this method would be called as `unknown_starttag('a', [('href', 'http://www.cwi.nl/')])`. The base implementation simply calls `method` with `attributes` as the only argument.

*New in version 2.5:* Handling of entity and character references within attribute values.

SGMLParser. `handle_endtag(tag, method)`

This method is called to handle endtags for which an `end_tag()` method has been defined. The `tag` argument is the name of the tag converted to lower case, and the `method` argument is the bound method which should be used to support semantic interpretation of the end tag. If no `end_tag()` method is defined for the closing element, this handler is not called. The base implementation simply calls `method`.

SGMLParser. `handle_data(data)`
This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

**SGMLParser.**\texttt{handle\_charref(ref)}

This method is called to process a character reference of the form \&\#ref;'. The base implementation uses \texttt{convert\_charref()} to convert the reference to a string. If that method returns a string, it is passed to \texttt{handle\_data()}, otherwise \texttt{unknown\_charref(ref)} is called to handle the error.

*Changed in version 2.5:* Use \texttt{convert\_charref()} instead of hard-coding the conversion.

**SGMLParser.**\texttt{convert\_charref(ref)}

Convert a character reference to a string, or \texttt{None}. \texttt{ref} is the reference passed in as a string. In the base implementation, \texttt{ref} must be a decimal number in the range 0-255. It converts the code point found using the \texttt{convert\_codepoint()} method. If \texttt{ref} is invalid or out of range, this method returns \texttt{None}. This method is called by the default \texttt{handle\_charref()} implementation and by the attribute value parser.

*New in version 2.5.*

**SGMLParser.**\texttt{convert\_codepoint(codepoint)}

Convert a codepoint to a \texttt{str} value. Encodings can be handled here if appropriate, though the rest of \texttt{sgmllib} is oblivious on this matter.

*New in version 2.5.*

**SGMLParser.**\texttt{handle\_entityref(ref)}

This method is called to process a general entity reference of the
form &ref; where ref is an general entity reference. It converts ref by passing it to convert_entityref(). If a translation is returned, it calls the method handle_data() with the translation; otherwise, it calls the method unknown_entityref(ref). The default entitydefs defines translations for &amp;, &apos, &gt;, &lt;, and &quot;.

Changed in version 2.5: Use convert_entityref() instead of hard-coding the conversion.

SGMLParser.convert_entityref(ref)
Convert a named entity reference to a str value, or None. The resulting value will not be parsed. ref will be only the name of the entity. The default implementation looks for ref in the instance (or class) variable entitydefs which should be a mapping from entity names to corresponding translations. If no translation is available for ref, this method returns None. This method is called by the default handle_entityref() implementation and by the attribute value parser.

New in version 2.5.

SGMLParser.handle_comment(comment)
This method is called when a comment is encountered. The comment argument is a string containing the text between the <!-- and --> delimiters, but not the delimiters themselves. For example, the comment <!--text--> will cause this method to be called with the argument 'text'. The default method does nothing.

SGMLParser.handle_decl(data)
Method called when an SGML declaration is read by the parser. In practice, the DOCTYPE declaration is the only thing observed in
HTML, but the parser does not discriminate among different (or broken) declarations. Internal subsets in a `DOCTYPE` declaration are not supported. The `data` parameter will be the entire contents of the declaration inside the `<!...>` markup. The default implementation does nothing.

**SGMLParser**. `report_unbalanced(tag)`

This method is called when an end tag is found which does not correspond to any open element.

**SGMLParser**. `unknown_starttag(tag, attributes)`

This method is called to process an unknown start tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

**SGMLParser**. `unknown_endtag(tag)`

This method is called to process an unknown end tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

**SGMLParser**. `unknown_charref(ref)`

This method is called to process unresolvable numeric character references. Refer to `handle_charref()` to determine what is handled by default. It is intended to be overridden by a derived class; the base class implementation does nothing.

**SGMLParser**. `unknown_entityref(ref)`

This method is called to process an unknown entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

Apart from overriding or extending the methods listed above, derived classes may also define methods of the following form to define processing of specific tags. Tag names in the input stream are case
independent; the *tag* occurring in method names must be in lower case:

SGMLParser.\texttt{start\_tag}(\texttt{attributes})

This method is called to process an opening tag *tag*. It has preference over \texttt{do\_tag()}. The \texttt{attributes} argument has the same meaning as described for \texttt{handle\_starttag()} above.

SGMLParser.\texttt{do\_tag}(\texttt{attributes})

This method is called to process an opening tag *tag* for which no \texttt{start\_tag()} method is defined. The \texttt{attributes} argument has the same meaning as described for \texttt{handle\_starttag()} above.

SGMLParser.\texttt{end\_tag}()

This method is called to process a closing tag *tag*.

Note that the parser maintains a stack of open elements for which no end tag has been found yet. Only tags processed by \texttt{start\_tag()} are pushed on this stack. Definition of an \texttt{end\_tag()} method is optional for these tags. For tags processed by \texttt{do\_tag()} or by \texttt{unknown\_tag()}, no \texttt{end\_tag()} method must be defined; if defined, it will not be used. If both \texttt{start\_tag()} and \texttt{do\_tag()} methods exist for a tag, the \texttt{start\_tag()} method takes precedence.
19.3. `htmllib` — A parser for HTML documents

*Deprecated since version 2.6:* The `htmllib` module has been removed in Python 3.0.

This module defines a class which can serve as a base for parsing text files formatted in the HyperText Mark-up Language (HTML). The class is not directly concerned with I/O — it must be provided with input in string form via a method, and makes calls to methods of a “formatter” object in order to produce output. The `HTMLParser` class is designed to be used as a base class for other classes in order to add functionality, and allows most of its methods to be extended or overridden. In turn, this class is derived from and extends the `SGMLParser` class defined in module `sgmllib`. The `HTMLParser` implementation supports the HTML 2.0 language as described in RFC 1866. Two implementations of formatter objects are provided in the `formatter` module; refer to the documentation for that module for information on the formatter interface.

The following is a summary of the interface defined by `sgmllib.SGMLParser`:

- The interface to feed data to an instance is through the `feed()` method, which takes a string argument. This can be called with as little or as much text at a time as desired; `p.feed(a); p.feed(b)` has the same effect as `p.feed(a+b)`. When the data contains complete HTML markup constructs, these are processed immediately; incomplete constructs are saved in a buffer. To force processing of all unprocessed data, call the `close()` method.
For example, to parse the entire contents of a file, use:

```python
parser.feed(open('myfile.html').read())
parser.close()
```

- The interface to define semantics for HTML tags is very simple: derive a class and define methods called `start_tag()`, `end_tag()`, or `do_tag()`. The parser will call these at appropriate moments: `start_tag()` or `do_tag()` is called when an opening tag of the form `<tag ...>` is encountered; `end_tag()` is called when a closing tag of the form `<tag>` is encountered. If an opening tag requires a corresponding closing tag, like `<H1> ... </H1>`, the class should define the `start_tag()` method; if a tag requires no closing tag, like `<P>`, the class should define the `do_tag()` method.

The module defines a parser class and an exception:

```python
class htmlib.HTMLParser(formatter)
```

This is the basic HTML parser class. It supports all entity names required by the XHTML 1.0 Recommendation (http://www.w3.org/TR/xhtml1). It also defines handlers for all HTML 2.0 and many HTML 3.0 and 3.2 elements.

```python
exception htmlib.HTMLParseError
```

Exception raised by the `HTMLParser` class when it encounters an error while parsing.

*New in version 2.4.*

**See also:**

**Module `formatter`**

Interface definition for transforming an abstract flow of formatting events into specific output events on writer objects.
Module HTMLParser
Alternate HTML parser that offers a slightly lower-level view of the input, but is designed to work with XHTML, and does not implement some of the SGML syntax not used in “HTML as deployed” and which isn’t legal for XHTML.

Module htmlentitydefs
Definition of replacement text for XHTML 1.0 entities.

Module sgmllib
Base class for HTMLParser.
19.3.1. HTMLParser Objects

In addition to tag methods, the HTMLParser class provides some additional methods and instance variables for use within tag methods.

**HTMLParser.formatter**

This is the formatter instance associated with the parser.

**HTMLParser.nofill**

Boolean flag which should be true when whitespace should not be collapsed, or false when it should be. In general, this should only be true when character data is to be treated as “preformatted” text, as within a `<PRE>` element. The default value is false. This affects the operation of `handle_data()` and `save_end()`.

**HTMLParser.anchor_bgn(href, name, type)**

This method is called at the start of an anchor region. The arguments correspond to the attributes of the `<A>` tag with the same names. The default implementation maintains a list of hyperlinks (defined by the `HREF` attribute for `<A>` tags) within the document. The list of hyperlinks is available as the data attribute `anchorlist`.

**HTMLParser.anchor_end()**

This method is called at the end of an anchor region. The default implementation adds a textual footnote marker using an index into the list of hyperlinks created by `anchor_bgn()`.

**HTMLParser.handle_image(source, alt, ismap, align, width, height)**
This method is called to handle images. The default implementation simply passes the alt value to the handle_data() method.

**HTMLParser.** `save_bgn()`

Begins saving character data in a buffer instead of sending it to the formatter object. Retrieve the stored data via `save_end()`. Use of the `save_bgn()` / `save_end()` pair may not be nested.

**HTMLParser.** `save_end()`

Ends buffering character data and returns all data saved since the preceding call to `save_bgn()`. If the `nofill` flag is false, whitespace is collapsed to single spaces. A call to this method without a preceding call to `save_bgn()` will raise a `TypeError` exception.
19.4. htmlentitydefs — Definitions of HTML general entities

**Note:** The htmlentitydefs module has been renamed to html.entities in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

This module defines three dictionaries, `name2codepoint`, `codepoint2name`, and `entitydefs`. `entitydefs` is used by the `htmllib` module to provide the `entitydefs` member of the `HTMLParser` class. The definition provided here contains all the entities defined by XHTML 1.0 that can be handled using simple textual substitution in the Latin-1 character set (ISO-8859-1).

`htmlentitydefs.entitydefs`

A dictionary mapping XHTML 1.0 entity definitions to their replacement text in ISO Latin-1.

`htmlentitydefs.name2codepoint`

A dictionary that maps HTML entity names to the Unicode codepoints.

*New in version 2.3.*

`htmlentitydefs.codepoint2name`

A dictionary that maps Unicode codepoints to HTML entity names.

*New in version 2.3.*
19.5. `xml.parsers.expat` — Fast XML parsing using Expat

New in version 2.0.

The `xml.parsers.expat` module is a Python interface to the Expat non-validating XML parser. The module provides a single extension type, `xmlparser`, that represents the current state of an XML parser. After an `xmlparser` object has been created, various attributes of the object can be set to handler functions. When an XML document is then fed to the parser, the handler functions are called for the character data and markup in the XML document.

This module uses the `pyexpat` module to provide access to the Expat parser. Direct use of the `pyexpat` module is deprecated.

This module provides one exception and one type object:

- **exception** `xml.parsers.expat.ExpatError`
  - The exception raised when Expat reports an error. See section `ExpatError Exceptions` for more information on interpreting Expat errors.

- **exception** `xml.parsers.expat.error`
  - Alias for `ExpatError`.

- `xml.parsers.expat.XMLParserType`
  - The type of the return values from the `ParserCreate()` function.

The `xml.parsers.expat` module contains two functions:

- `xml.parsers.expat.ErrorString(errno)`
  - Returns an explanatory string for a given error number `errno`. 
xml.parsers.expat.ParserCreate([encoding, namespace_separator]])

Creates and returns a new xmlparser object. encoding, if specified, must be a string naming the encoding used by the XML data. Expat doesn’t support as many encodings as Python does, and its repertoire of encodings can’t be extended; it supports UTF-8, UTF-16, ISO-8859-1 (Latin1), and ASCII. If encoding [1] is given it will override the implicit or explicit encoding of the document.

Expat can optionally do XML namespace processing for you, enabled by providing a value for namespace_separator. The value must be a one-character string; a ValueError will be raised if the string has an illegal length (None is considered the same as omission). When namespace processing is enabled, element type names and attribute names that belong to a namespace will be expanded. The element name passed to the element handlersStartElementHandler andEndElementHandler will be the concatenation of the namespace URI, the namespace separator character, and the local part of the name. If the namespace separator is a zero byte (chr(0)) then the namespace URI and the local part will be concatenated without any separator.

For example, if namespace_separator is set to a space character (' ') and the following document is parsed:

```xml
<?xml version="1.0"?>
<root xmlns = "http://default-namespace.org/"
    xmlns:py = "http://www.python.org/ns/">
    <py:elem1 />
    <elem2 xmlns="" />
</root>
```

StartElementHandler will receive the following strings for each element:
See also:

The Expat XML Parser
Home page of the Expat project.
19.5.1. XMLParser Objects

`xmlparser` objects have the following methods:

**xmlparser.**`Parse(data[, isfinal])`

Parses the contents of the string `data`, calling the appropriate handler functions to process the parsed data. `isfinal` must be true on the final call to this method. `data` can be the empty string at any time.

**xmlparser.**`ParseFile(file)`

Parse XML data reading from the object `file`. `file` only needs to provide the `read(nbytes)` method, returning the empty string when there's no more data.

**xmlparser.**`SetBase(base)`

Sets the base to be used for resolving relative URIs in system identifiers in declarations. Resolving relative identifiers is left to the application: this value will be passed through as the `base` argument to the `ExternalEntityRefHandler()`, `NotationDeclHandler()`, and `UnparsedEntityDeclHandler()` functions.

**xmlparser.**`GetBase()`

Returns a string containing the base set by a previous call to `SetBase()`, or `None` if `SetBase()` hasn't been called.

**xmlparser.**`GetInputContext()`

Returns the input data that generated the current event as a string. The data is in the encoding of the entity which contains the text. When called while an event handler is not active, the return value is `None`. 
New in version 2.1.

```python
xmlparser.ExternalEntityParserCreate(context[, encoding])
```
Create a “child” parser which can be used to parse an external parsed entity referred to by content parsed by the parent parser. The `context` parameter should be the string passed to the `ExternalEntityRefHandler()` handler function, described below. The child parser is created with the `ordered_attributes`, `returns_unicode` and `specified_attributes` set to the values of this parser.

```python
xmlparser.UseForeignDTD([flag])
```
Calling this with a true value for `flag` (the default) will cause Expat to call the `ExternalEntityRefHandler` with `None` for all arguments to allow an alternate DTD to be loaded. If the document does not contain a document type declaration, the `ExternalEntityRefHandler` will still be called, but the `StartDoctypeDeclHandler` and `EndDoctypeDeclHandler` will not be called.

Passing a false value for `flag` will cancel a previous call that passed a true value, but otherwise has no effect.

This method can only be called before the `Parse()` or `ParseFile()` methods are called; calling it after either of those have been called causes `ExpatError` to be raised with the `code` attribute set to `errors.XML_ERROR_CANT_CHANGE_FEATURE_ONCE_PARSING`.

New in version 2.3.

```python
xmlparser.buffer_size
```

`xmlparser` objects have the following attributes:
The size of the buffer used when `buffer_text` is true. A new buffer size can be set by assigning a new integer value to this attribute. When the size is changed, the buffer will be flushed.

*New in version 2.3.*

*Changed in version 2.6:* The buffer size can now be changed.

```
xmllparser.buffer_text
```

Setting this to true causes the `xmllparser` object to buffer textual content returned by Expat to avoid multiple calls to the `CharacterDataHandler()` callback whenever possible. This can improve performance substantially since Expat normally breaks character data into chunks at every line ending. This attribute is false by default, and may be changed at any time.

*New in version 2.3.*

```
xmllparser.buffer_used
```

If `buffer_text` is enabled, the number of bytes stored in the buffer. These bytes represent UTF-8 encoded text. This attribute has no meaningful interpretation when `buffer_text` is false.

*New in version 2.3.*

```
xmllparser.ordered_attributes
```

Setting this attribute to a non-zero integer causes the attributes to be reported as a list rather than a dictionary. The attributes are presented in the order found in the document text. For each attribute, two list entries are presented: the attribute name and the attribute value. (Older versions of this module also used this format.) By default, this attribute is false; it may be changed at any time.

*New in version 2.1.*
xmlparser.\texttt{returns\_unicode}

If this attribute is set to a non-zero integer, the handler functions will be passed Unicode strings. If \texttt{returns\_unicode} is \texttt{False}, 8-bit strings containing UTF-8 encoded data will be passed to the handlers. This is \texttt{True} by default when Python is built with Unicode support.

\textit{Changed in version 1.6:} Can be changed at any time to affect the result type.

xmlparser.\texttt{specified\_attributes}

If set to a non-zero integer, the parser will report only those attributes which were specified in the document instance and not those which were derived from attribute declarations. Applications which set this need to be especially careful to use what additional information is available from the declarations as needed to comply with the standards for the behavior of XML processors. By default, this attribute is false; it may be changed at any time.

\textit{New in version 2.1.}

The following attributes contain values relating to the most recent error encountered by an \texttt{xmlparser} object, and will only have correct values once a call to \texttt{Parse()} or \texttt{ParseFile()} has raised a \texttt{xml.parsers.expat.ExpatError} exception.

xmlparser.\texttt{ErrorByteIndex}

Byte index at which an error occurred.

xmlparser.\texttt{ErrorCode}

Numeric code specifying the problem. This value can be passed to the \texttt{ErrorString()} function, or compared to one of the constants defined in the \texttt{errors} object.
The following attributes contain values relating to the current parse location in an `xmlparser` object. During a callback reporting a parse event they indicate the location of the first of the sequence of characters that generated the event. When called outside of a callback, the position indicated will be just past the last parse event (regardless of whether there was an associated callback).

*New in version 2.4.*

- `xmlparser.ErrorColumnNumber`  
  Column number at which an error occurred.

- `xmlparser.ErrorLineNumber`  
  Line number at which an error occurred.

Here is the list of handlers that can be set. To set a handler on an `xmlparser` object `o`, use `o.handlername = func`. `handlername` must be taken from the following list, and `func` must be a callable object accepting the correct number of arguments. The arguments are all strings, unless otherwise stated.

- `xmlparser.XmlDeclHandler(version, encoding, standalone)`  
  Called when the XML declaration is parsed. The XML declaration is the (optional) declaration of the applicable version of the XML recommendation, the encoding of the document text, and an optional “standalone” declaration. `version` and `encoding` will be strings of the type dictated by the `returns_unicode` attribute, and
standalone will be 1 if the document is declared standalone, 0 if it is declared not to be standalone, or -1 if the standalone clause was omitted. This is only available with Expat version 1.95.0 or newer.

New in version 2.1.

xmlparser.StartDoctypeDeclHandler(doctypeName, systemId, publicId, has_internal_subset)

Called when Expat begins parsing the document type declaration (<!DOCTYPE ...>). The doctypeName is provided exactly as presented. The systemId and publicId parameters give the system and public identifiers if specified, or None if omitted. has_internal_subset will be true if the document contains and internal document declaration subset. This requires Expat version 1.2 or newer.

xmlparser.EndDoctypeDeclHandler()

Called when Expat is done parsing the document type declaration. This requires Expat version 1.2 or newer.

xmlparser.ElementDeclHandler(name, model)

Called once for each element type declaration. name is the name of the element type, and model is a representation of the content model.

xmlparser.AttlistDeclHandler(elname, attname, type, default, required)

Called for each declared attribute for an element type. If an attribute list declaration declares three attributes, this handler is called three times, once for each attribute. elname is the name of the element to which the declaration applies and attname is the name of the attribute declared. The attribute type is a string passed as type; the possible values are 'CDATA', 'ID', 'IDREF',
... default gives the default value for the attribute used when the attribute is not specified by the document instance, or None if there is no default value (#IMPLIED values). If the attribute is required to be given in the document instance, required will be true. This requires Expat version 1.95.0 or newer.

xmlparser. **StartElementHandler**(name, attributes)
Called for the start of every element. name is a string containing the element name, and attributes is a dictionary mapping attribute names to their values.

xmlparser. **EndElementHandler**(name)
Called for the end of every element.

xmlparser. **ProcessingInstructionHandler**(target, data)
Called for every processing instruction.

xmlparser. **CharacterDataHandler**(data)
Called for character data. This will be called for normal character data, CDATA marked content, and ignorable whitespace. Applications which must distinguish these cases can use the StartCdataSectionHandler, EndCdataSectionHandler, and ElementDeclHandler callbacks to collect the required information.

xmlparser. **UnparsedEntityDeclHandler**(entityName, base, systemId, publicId, notationName)
Called for unparsed (NDATA) entity declarations. This is only present for version 1.2 of the Expat library; for more recent versions, use EntityDeclHandler instead. (The underlying function in the Expat library has been declared obsolete.)

xmlparser. **EntityDeclHandler**(entityName, is_parameter_entity, value, base, systemId, publicId, notationName)
Called for all entity declarations. For parameter and internal
entities, \textit{value} will be a string giving the declared contents of the entity; this will be \texttt{None} for external entities. The \textit{notationName} parameter will be \texttt{None} for parsed entities, and the name of the notation for unparsed entities. \textit{is\_parameter\_entity} will be true if the entity is a parameter entity or false for general entities (most applications only need to be concerned with general entities). This is only available starting with version 1.95.0 of the Expat library.

\textit{New in version 2.1.}

\texttt{xmlparser.\texttt{NotationDeclHandler}(notationName, base, systemId, publicId)}

Called for notation declarations. \textit{notationName}, \textit{base}, and \textit{systemId}, and \textit{publicId} are strings if given. If the public identifier is omitted, \texttt{publicId} will be \texttt{None}.

\texttt{xmlparser.\texttt{StartNamespaceDeclHandler}(prefix, uri)}

Called when an element contains a namespace declaration. Namespace declarations are processed before the \texttt{StartElementHandler} is called for the element on which declarations are placed.

\texttt{xmlparser.\texttt{EndNamespaceDeclHandler}(prefix)}

Called when the closing tag is reached for an element that contained a namespace declaration. This is called once for each namespace declaration on the element in the reverse of the order for which the \texttt{StartNamespaceDeclHandler} was called to indicate the start of each namespace declaration’s scope. Calls to this handler are made after the corresponding \texttt{EndElementHandler} for the end of the element.

\texttt{xmlparser.\texttt{CommentHandler}(data)}

Called for comments. \texttt{data} is the text of the comment, excluding
the leading '<!--' and trailing '-->'.

`xmlparser.StartCdataSectionHandler()`
Called at the start of a CDATA section. This and `EndCdataSectionHandler` are needed to be able to identify the syntactical start and end for CDATA sections.

`xmlparser.EndCdataSectionHandler()`
Called at the end of a CDATA section.

`xmlparser.DefaultHandler(data)`
Called for any characters in the XML document for which no applicable handler has been specified. This means characters that are part of a construct which could be reported, but for which no handler has been supplied.

`xmlparser.DefaultHandlerExpand(data)`
This is the same as the `DefaultHandler()`, but doesn’t inhibit expansion of internal entities. The entity reference will not be passed to the default handler.

`xmlparser.NotStandaloneHandler()`
Called if the XML document hasn’t been declared as being a standalone document. This happens when there is an external subset or a reference to a parameter entity, but the XML declaration does not set standalone to `yes` in an XML declaration. If this handler returns 0, then the parser will throw an `XML_ERROR_NOT_STANDALONE` error. If this handler is not set, no exception is raised by the parser for this condition.

`xmlparser.ExternalEntityRefHandler(context, base, systemId, publicId)`
Called for references to external entities. `base` is the current base, as set by a previous call to `SetBase()`. The public and
system identifiers, *systemId* and *publicId*, are strings if given; if the public identifier is not given, *publicId* will be *None*. The *context* value is opaque and should only be used as described below.

For external entities to be parsed, this handler must be implemented. It is responsible for creating the sub-parser using `ExternalEntityParserCreate(context)`, initializing it with the appropriate callbacks, and parsing the entity. This handler should return an integer; if it returns `0`, the parser will throw an `XML_ERROR_EXTERNAL_ENTITY_HANDLING` error, otherwise parsing will continue.

If this handler is not provided, external entities are reported by the `DefaultHandler` callback, if provided.
19.5.2. ExpatError Exceptions

`ExpatError` exceptions have a number of interesting attributes:

`ExpatError.code`
Expat's internal error number for the specific error. This will match one of the constants defined in the `errors` object from this module.

*New in version 2.1.*

`ExpatError.lineno`
Line number on which the error was detected. The first line is numbered 1.

*New in version 2.1.*

`ExpatError.offset`
Character offset into the line where the error occurred. The first column is numbered 0.

*New in version 2.1.*
19.5.3. Example

The following program defines three handlers that just print out their arguments.

```python
import xml.parsers.expat

# 3 handler functions
def start_element(name, attrs):
    print 'Start element:', name, attrs
def end_element(name):
    print 'End element:', name
def char_data(data):
    print 'Character data:', repr(data)

p = xml.parsers.expat.ParserCreate()
p.StartElementHandler = start_element
p.EndElementHandler = end_element
p.CharacterDataHandler = char_data

p.Parse("""<?xml version="1.0"?>
<parent id="top"><child1 name="paul">Text goes here</child1>
<child2 name="fred">More text</child2>
</parent>""", 1)
```

The output from this program is:

```plaintext
Start element: parent {'id': 'top'}
Start element: child1 {'name': 'paul'}
Character data: 'Text goes here'
End element: child1
Character data: '
'
Start element: child2 {'name': 'fred'}
Character data: 'More text'
End element: child2
Character data: '
'
End element: parent
```
Content modules are described using nested tuples. Each tuple contains four values: the type, the quantifier, the name, and a tuple of children. Children are simply additional content module descriptions.

The values of the first two fields are constants defined in the `model` object of the `xml.parsers.expat` module. These constants can be collected in two groups: the model type group and the quantifier group.

The constants in the model type group are:

```python
xml.parsers.expat.XML_CTYPE_ANY
    The element named by the model name was declared to have a content model of `ANY`.
```

```python
xml.parsers.expat.XML_CTYPE_CHOICE
    The named element allows a choice from a number of options; this is used for content models such as `(A | B | C)`.
```

```python
xml.parsers.expat.XML_CTYPE_EMPTY
    Elements which are declared to be `EMPTY` have this model type.
```

```python
xml.parsers.expat.XML_CTYPE_MIXED
xml.parsers.expat.XML_CTYPE_NAME
xml.parsers.expat.XML_CTYPE_SEQ
    Models which represent a series of models which follow one after the other are indicated with this model type. This is used for models such as `(A, B, C)`,
```

The constants in the quantifier group are:
xml.parsers.expat.XML_CQUANT_NONE
   No modifier is given, so it can appear exactly once, as for A.

xml.parsers.expat.XML_CQUANT_OPT
   The model is optional: it can appear once or not at all, as for A?.

xml.parsers.expat.XML_CQUANT_PLUS
   The model must occur one or more times (like A+).

xml.parsers.expat.XML_CQUANT_REP
   The model must occur zero or more times, as for A*.
19.5.5. Expat error constants

The following constants are provided in the `errors` object of the `xml.parsers.expat` module. These constants are useful in interpreting some of the attributes of the `ExpatError` exception objects raised when an error has occurred.

The `errors` object has the following attributes:

- `xml.parsers.expat.XML_ERROR_ASYNC_ENTITY`
- `xml.parsers.expat.XML_ERROR_ATTRIBUTE_EXTERNAL_ENTITY_REF`
  - An entity reference in an attribute value referred to an external entity instead of an internal entity.
- `xml.parsers.expat.XML_ERROR_BAD_CHAR_REF`
  - A character reference referred to a character which is illegal in XML (for example, character \&, or 'UTF-8').
- `xml.parsers.expat.XML_ERROR_BINARY_ENTITY_REF`
  - An entity reference referred to an entity which was declared with a notation, so cannot be parsed.
- `xml.parsers.expat.XML_ERROR_DUPLICATE_ATTRIBUTE`
  - An attribute was used more than once in a start tag.
- `xml.parsers.expat.XML_ERROR_INCORRECT_ENCODING`
- `xml.parsers.expat.XML_ERROR_INVALID_TOKEN`
  - Raised when an input byte could not properly be assigned to a character; for example, a NUL byte (value \0) in a UTF-8 input stream.
- `xml.parsers.expat.XML_ERROR_JUNK_AFTER_DOC_ELEMENT`
  - Something other than whitespace occurred after the document
element.

xml.parsers.expat.XML_ERROR_MISPLACED_XML_PI
An XML declaration was found somewhere other than the start of
the input data.

xml.parsers.expat.XML_ERROR_NO_ELEMENTS
The document contains no elements (XML requires all
documents to contain exactly one top-level element).

xml.parsers.expat.XML_ERROR_NO_MEMORY
Expat was not able to allocate memory internally.

xml.parsers.expat.XML_ERROR_PARAM_ENTITY_REF
A parameter entity reference was found where it was not allowed.

xml.parsers.expat.XML_ERROR_PARTIAL_CHAR
An incomplete character was found in the input.

xml.parsers.expat.XML_ERROR_RECURSIVE_ENTITY_REF
An entity reference contained another reference to the same
entity; possibly via a different name, and possibly indirectly.

xml.parsers.expat.XML_ERROR_SYNTAX
Some unspecified syntax error was encountered.

xml.parsers.expat.XML_ERROR_TAG_MISMATCH
An end tag did not match the innermost open start tag.

xml.parsers.expat.XML_ERROR_UNCLOSED_TOKEN
Some token (such as a start tag) was not closed before the end
of the stream or the next token was encountered.

xml.parsers.expat.XML_ERROR_UNDEFINED_ENTITY
A reference was made to a entity which was not defined.

xml.parsers.expat.XML_ERROR_UNKNOWN_ENCODING
The document encoding is not supported by Expat.
xml.parsers.expat.XML_ERROR_UNCLOSED_CDATA_SECTION
   A CDATA marked section was not closed.

xml.parsers.expat.XML_ERROR_EXTERNAL_ENTITY_HANDLING

xml.parsers.expat.XML_ERROR_NOT_STANDALONE
   The parser determined that the document was not “standalone”
   though it declared itself to be in the XML declaration, and the
   NotStandaloneHandler was set and returned 0.

xml.parsers.expat.XML_ERROR_UNEXPECTED_STATE

xml.parsers.expat.XML_ERROR_ENTITY_DECLARED_IN_PE

xml.parsers.expat.XML_ERROR_FEATURE_REQUIRES_XML_DTD
   An operation was requested that requires DTD support to be
   compiled in, but Expat was configured without DTD support. This
   should never be reported by a standard build of the
   xml.parsers.expat module.

xml.parsers.expat.XML_ERROR_CANT_CHANGE_FEATURE_ONCE_PARSING
   A behavioral change was requested after parsing started that can
   only be changed before parsing has started. This is (currently)
   only raised by UseForeignDTD().

xml.parsers.expat.XML_ERROR_UNBOUND_PREFIX
   An undeclared prefix was found when namespace processing
   was enabled.

xml.parsers.expat.XML_ERROR_UNDECLARING_PREFIX
   The document attempted to remove the namespace declaration
   associated with a prefix.

xml.parsers.expat.XML_ERROR_INCOMPLETE_PE
   A parameter entity contained incomplete markup.

xml.parsers.expat.XML_ERROR_XML_DECL
The document contained no document element at all.

xml.parsers.expat.XML_ERROR_TEXT_DECL
There was an error parsing a text declaration in an external entity.

xml.parsers.expat.XML_ERROR_PUBLICID
Characters were found in the public id that are not allowed.

xml.parsers.expat.XML_ERROR_SUSPENDED
The requested operation was made on a suspended parser, but isn’t allowed. This includes attempts to provide additional input or to stop the parser.

xml.parsers.expat.XML_ERROR_NOT_SUSPENDED
An attempt to resume the parser was made when the parser had not been suspended.

xml.parsers.expat.XML_ERROR_ABORTED
This should not be reported to Python applications.

xml.parsers.expat.XML_ERROR_FINISHED
The requested operation was made on a parser which was finished parsing input, but isn’t allowed. This includes attempts to provide additional input or to stop the parser.

xml.parsers.expat.XML_ERROR_SUSPEND_PE

Footnotes

The encoding string included in XML output should conform to the appropriate standards. For example, “UTF-8” is valid, but “UTF8” is not. See http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl and http://www.iana.org/assignments/character-sets.

[1]
19.6. `xml.dom` — The Document Object Model API

`New in version 2.0.`

The Document Object Model, or “DOM,” is a cross-language API from the World Wide Web Consortium (W3C) for accessing and modifying XML documents. A DOM implementation presents an XML document as a tree structure, or allows client code to build such a structure from scratch. It then gives access to the structure through a set of objects which provided well-known interfaces.

The DOM is extremely useful for random-access applications. SAX only allows you a view of one bit of the document at a time. If you are looking at one SAX element, you have no access to another. If you are looking at a text node, you have no access to a containing element. When you write a SAX application, you need to keep track of your program’s position in the document somewhere in your own code. SAX does not do it for you. Also, if you need to look ahead in the XML document, you are just out of luck.

Some applications are simply impossible in an event driven model with no access to a tree. Of course you could build some sort of tree yourself in SAX events, but the DOM allows you to avoid writing that code. The DOM is a standard tree representation for XML data.

The Document Object Model is being defined by the W3C in stages, or “levels” in their terminology. The Python mapping of the API is substantially based on the DOM Level 2 recommendation.

DOM applications typically start by parsing some XML into a DOM. How this is accomplished is not covered at all by DOM Level 1, and Level 2 provides only limited improvements: There is a
DOMImplementation object class which provides access to Document creation methods, but no way to access an XML reader/parser/Document builder in an implementation-independent way. There is also no well-defined way to access these methods without an existing Document object. In Python, each DOM implementation will provide a function getDOMImplementation(). DOM Level 3 adds a Load/Store specification, which defines an interface to the reader, but this is not yet available in the Python standard library.

Once you have a DOM document object, you can access the parts of your XML document through its properties and methods. These properties are defined in the DOM specification; this portion of the reference manual describes the interpretation of the specification in Python.

The specification provided by the W3C defines the DOM API for Java, ECMAScript, and OMG IDL. The Python mapping defined here is based in large part on the IDL version of the specification, but strict compliance is not required (though implementations are free to support the strict mapping from IDL). See section Conformance for a detailed discussion of mapping requirements.

See also:

Document Object Model (DOM) Level 2 Specification
The W3C recommendation upon which the Python DOM API is based.

Document Object Model (DOM) Level 1 Specification
The W3C recommendation for the DOM supported by xml.dom.minidom.

Python Language Mapping Specification
This specifies the mapping from OMG IDL to Python.
19.6.1. Module Contents

The xml.dom contains the following functions:

xml.dom.registerDOMImplementation(name, factory)

Register the factory function with the name name. The factory function should return an object which implements the DOMImplementation interface. The factory function can return the same object every time, or a new one for each call, as appropriate for the specific implementation (e.g. if that implementation supports some customization).

xml.dom.getDOMImplementation([name[, features]])

Return a suitable DOM implementation. The name is either well-known, the module name of a DOM implementation, or None. If it is not None, imports the corresponding module and returns a DOMImplementation object if the import succeeds. If no name is given, and if the environment variable PYTHON_DOM is set, this variable is used to find the implementation.

If name is not given, this examines the available implementations to find one with the required feature set. If no implementation can be found, raise an ImportError. The features list must be a sequence of (feature, version) pairs which are passed to the hasFeature() method on available DOMImplementation objects.

Some convenience constants are also provided:

xml.dom.EMPTY_NAMESPACE

The value used to indicate that no namespace is associated with a node in the DOM. This is typically found as the namespaceURI of a node, or used as the namespaceURI parameter to a
namespaces-specific method.

New in version 2.2.

`xml.dom.XML_NAMESPACE`

The namespace URI associated with the reserved prefix `xml`, as defined by Namespaces in XML (section 4).

New in version 2.2.

`xml.dom.XMLNS_NAMESPACE`

The namespace URI for namespace declarations, as defined by Document Object Model (DOM) Level 2 Core Specification (section 1.1.8).

New in version 2.2.

`xml.dom.XHTML_NAMESPACE`

The URI of the XHTML namespace as defined by XHTML 1.0: The Extensible HyperText Markup Language (section 3.1.1).

New in version 2.2.

In addition, `xml.dom` contains a base `Node` class and the DOM exception classes. The `Node` class provided by this module does not implement any of the methods or attributes defined by the DOM specification; concrete DOM implementations must provide those. The `Node` class provided as part of this module does provide the constants used for the `nodeType` attribute on concrete `Node` objects; they are located within the class rather than at the module level to conform with the DOM specifications.
19.6.2. Objects in the DOM

The definitive documentation for the DOM is the DOM specification from the W3C.

Note that DOM attributes may also be manipulated as nodes instead of as simple strings. It is fairly rare that you must do this, however, so this usage is not yet documented.

An additional section describes the exceptions defined for working with the DOM in Python.

19.6.2.1. DOMImplementation Objects

The DOMImplementation interface provides a way for applications to determine the availability of particular features in the DOM they are using. DOM Level 2 added the ability to create new Document and DocumentType objects using the DOMImplementation as well.

DOMImplementation. hasFeature(feature, version)

Return true if the feature identified by the pair of strings feature and version is implemented.

DOMImplementation. createDocument(namespaceUri, qualifiedName, doctype)

Return a new Document object (the root of the DOM), with a child Element object having the given namespaceUri and qualifiedName. The doctype must be a DocumentType object created by createDocumentType(), or None. In the Python DOM API, the first two arguments can also be None in order to indicate that no Element child is to be created.

DOMImplementation. createDocumentType(qualifiedName, publicId, systemId)

Return a new DocumentType object that encapsulates the given qualifiedName, publicId, and systemId strings, representing the
information contained in an XML document type declaration.

### 19.6.2.2. Node Objects

All of the components of an XML document are subclasses of Node.

**Node. nodeType**

An integer representing the node type. Symbolic constants for the types are on the Node object: ELEMENT_NODE, ATTRIBUTE_NODE, TEXT_NODE, CDATA_SECTION_NODE, ENTITY_NODE, PROCESSING_INSTRUCTION_NODE, COMMENT_NODE, DOCUMENT_NODE, DOCUMENT_TYPE_NODE, NOTATION_NODE. This is a read-only attribute.

**Node. parentNode**

The parent of the current node, or None for the document node. The value is always a Node object or None. For Element nodes, this will be the parent element, except for the root element, in which case it will be the Document object. For Attr nodes, this is always None. This is a read-only attribute.

**Node. attributes**

A NamedNodeMap of attribute objects. Only elements have actual values for this; others provide None for this attribute. This is a read-only attribute.

**Node. previousSibling**

The node that immediately precedes this one with the same parent. For instance the element with an end-tag that comes just before the self element's start-tag. Of course, XML documents are made up of more than just elements so the previous sibling could be text, a comment, or something else. If this node is the first child of the parent, this attribute will be None. This is a read-only attribute.
Node. **nextSibling**

The node that immediately follows this one with the same parent. See also **previousSibling**. If this is the last child of the parent, this attribute will be `None`. This is a read-only attribute.

Node. **childNodes**

A list of nodes contained within this node. This is a read-only attribute.

Node. **firstChild**

The first child of the node, if there are any, or `None`. This is a read-only attribute.

Node. **lastChild**

The last child of the node, if there are any, or `None`. This is a read-only attribute.

Node. **localName**

The part of the `tagName` following the colon if there is one, else the entire `tagName`. The value is a string.

Node. **prefix**

The part of the `tagName` preceding the colon if there is one, else the empty string. The value is a string, or `None`.

Node. **namespaceURI**

The namespace associated with the element name. This will be a string or `None`. This is a read-only attribute.

Node. **nodeName**

This has a different meaning for each node type; see the DOM specification for details. You can always get the information you would get here from another property such as the `tagName` property for elements or the `name` property for attributes. For all node types, the value of this attribute will be either a string or
Node. **nodeValue**

This has a different meaning for each node type; see the DOM specification for details. The situation is similar to that with **nodeName**. The value is a string or **None**.

Node. **hasAttributes()**

Returns true if the node has any attributes.

Node. **hasChildNodes()**

Returns true if the node has any child nodes.

Node. **isSameNode(other)**

Returns true if `other` refers to the same node as this node. This is especially useful for DOM implementations which use any sort of proxy architecture (because more than one object can refer to the same node).

**Note:** This is based on a proposed DOM Level 3 API which is still in the “working draft” stage, but this particular interface appears uncontroversial. Changes from the W3C will not necessarily affect this method in the Python DOM interface (though any new W3C API for this would also be supported).

Node. **appendChild(newChild)**

Add a new child node to this node at the end of the list of children, returning `newChild`. If the node was already in in the tree, it is removed first.

Node. **insertBefore(newChild, refChild)**

Insert a new child node before an existing child. It must be the case that `refChild` is a child of this node; if not, **ValueError** is raised. `newChild` is returned. If `refChild` is **None**, it inserts
newChild at the end of the children’s list.

Node. **removeChild**(oldChild)
Remove a child node. *oldChild* must be a child of this node; if not, *ValueError* is raised. *oldChild* is returned on success. If *oldChild* will not be used further, its *unlink()* method should be called.

Node. **replaceChild**(newChild, oldChild)
Replace an existing node with a new node. It must be the case that *oldChild* is a child of this node; if not, *ValueError* is raised.

Node. **normalize**()
Join adjacent text nodes so that all stretches of text are stored as single Text instances. This simplifies processing text from a DOM tree for many applications.

*New in version 2.1.*

Node. **cloneNode**(deep)
Clone this node. Setting *deep* means to clone all child nodes as well. This returns the clone.

### 19.6.2.3. NodeList Objects

A NodeList represents a sequence of nodes. These objects are used in two ways in the DOM Core recommendation: the Element objects provides one as its list of child nodes, and the getElementsByTagName() and getElementsByTagNameNS() methods of Node return objects with this interface to represent query results.

The DOM Level 2 recommendation defines one method and one attribute for these objects:

NodeList. **item**(i)
Return the \( i \)th item from the sequence, if there is one, or \texttt{None}. The index \( i \) is not allowed to be less than zero or greater than or equal to the length of the sequence.

\texttt{NodeList.length}  
The number of nodes in the sequence.

In addition, the Python DOM interface requires that some additional support is provided to allow \texttt{NodeList} objects to be used as Python sequences. All \texttt{NodeList} implementations must include support for \texttt{__len__()} and \texttt{__getitem__()}; this allows iteration over the \texttt{NodeList} in \texttt{for} statements and proper support for the \texttt{len()} built-in function.

If a DOM implementation supports modification of the document, the \texttt{NodeList} implementation must also support the \texttt{__setitem__()} and \texttt{__delitem__()} methods.

19.6.2.4. DocumentType Objects

Information about the notations and entities declared by a document (including the external subset if the parser uses it and can provide the information) is available from a \texttt{DocumentType} object. The \texttt{DocumentType} for a document is available from the \texttt{Document} object’s \texttt{doctype} attribute; if there is no \texttt{DOCTYPE} declaration for the document, the document’s \texttt{doctype} attribute will be set to \texttt{None} instead of an instance of this interface.

\texttt{DocumentType} is a specialization of \texttt{Node}, and adds the following attributes:

\texttt{DocumentType.publicId}  
The public identifier for the external subset of the document type definition. This will be a string or \texttt{None}.  

DocumentType. **systemId**

The system identifier for the external subset of the document type definition. This will be a URI as a string, or **None**.

DocumentType. **internalSubset**

A string giving the complete internal subset from the document. This does not include the brackets which enclose the subset. If the document has no internal subset, this should be **None**.

DocumentType. **name**

The name of the root element as given in the **DOCTYPE** declaration, if present.

DocumentType. **entities**

This is a **NamedNodeMap** giving the definitions of external entities. For entity names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be **None** if the information is not provided by the parser, or if no entities are defined.

DocumentType. **notations**

This is a **NamedNodeMap** giving the definitions of notations. For notation names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be **None** if the information is not provided by the parser, or if no notations are defined.

### 19.6.2.5. Document Objects

A **Document** represents an entire XML document, including its constituent elements, attributes, processing instructions, comments etc. Remember that it inherits properties from **Node**.

**Document. documentElement**

The one and only root element of the document.
Document.createElement(tagName)
Create and return a new element node. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as insertBefore() or appendChild().

Document.createElementNS(namespaceURI, tagName)
Create and return a new element with a namespace. The tagName may have a prefix. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as insertBefore() or appendChild().

Document.createTextNode(data)
Create and return a text node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

Document.createComment(data)
Create and return a comment node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

Document.createProcessingInstruction(target, data)
Create and return a processing instruction node containing the target and data passed as parameters. As with the other creation methods, this one does not insert the node into the tree.

Document.createAttribute(name)
Create and return an attribute node. This method does not associate the attribute node with any particular element. You must use setAttributeNode() on the appropriate Element object to use the newly created attribute instance.
Document. `createAttributeNS(namespaceURI, qualifiedName)`
Create and return an attribute node with a namespace. The `tagName` may have a prefix. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate `Element` object to use the newly created attribute instance.

Document. `getElementsByTagName(tagName)`
Search for all descendants (direct children, children's children, etc.) with a particular element type name.

Document. `getElementsByTagNameNS(namespaceURI, localName)`
Search for all descendants (direct children, children's children, etc.) with a particular namespace URI and localname. The localname is the part of the namespace after the prefix.

19.6.2.6. Element Objects

`Element` is a subclass of `Node`, so inherits all the attributes of that class.

`Element.tagName`
The element type name. In a namespace-using document it may have colons in it. The value is a string.

`Element.getElementsByTagName(tagName)`
Same as equivalent method in the `Document` class.

`Element.getElementsByTagNameNS(namespaceURI, localName)`
Same as equivalent method in the `Document` class.

`Element.hasAttribute(name)`
Returns true if the element has an attribute named by `name`.
Element. **hasAttributeNS**(namespaceURI, localName)
Returns true if the element has an attribute named by namespaceURI and localName.

Element. **getAttribute**(name)
Return the value of the attribute named by name as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

Element. **getAttributeNode**(attrname)
Return the Attr node for the attribute named by attrname.

Element. **getAttributeNS**(namespaceURI, localName)
Return the value of the attribute named by namespaceURI and localName as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

Element. **getAttributeNodeNS**(namespaceURI, localName)
Return an attribute value as a node, given a namespaceURI and localName.

Element. **removeAttribute**(name)
Remove an attribute by name. If there is no matching attribute, a **NotFoundErr** is raised.

Element. **removeAttributeNode**(oldAttr)
Remove and return oldAttr from the attribute list, if present. If oldAttr is not present, **NotFoundErr** is raised.

Element. **removeAttributeNS**(namespaceURI, localName)
Remove an attribute by name. Note that it uses a localName, not a qname. No exception is raised if there is no matching attribute.

Element. **setAttribute**(name, value)
Set an attribute value from a string.

**Element. `setAttributeNode(newAttr)`**
Add a new attribute node to the element, replacing an existing attribute if necessary if the `name` attribute matches. If a replacement occurs, the old attribute node will be returned. If `newAttr` is already in use, `InuseAttributeErr` will be raised.

**Element. `setAttributeNodeNS(newAttr)`**
Add a new attribute node to the element, replacing an existing attribute if necessary if the `namespaceURI` and `localName` attributes match. If a replacement occurs, the old attribute node will be returned. If `newAttr` is already in use, `InuseAttributeErr` will be raised.

**Element. `setAttributeNS(namespaceURI, qname, value)`**
Set an attribute value from a string, given a `namespaceURI` and a `qname`. Note that a qname is the whole attribute name. This is different than above.

### 19.6.2.7. Attr Objects

**Attr** inherits from **Node**, so inherits all its attributes.

**Attr. `name`**
The attribute name. In a namespace-using document it may include a colon.

**Attr. `localName`**
The part of the name following the colon if there is one, else the entire name. This is a read-only attribute.

**Attr. `prefix`**
The part of the name preceding the colon if there is one, else the empty string.
**Attr. value**
The text value of the attribute. This is a synonym for the `nodeValue` attribute.

### 19.6.2.8. NamedNodeMap Objects

**NamedNodeMap** does not inherit from **Node**.

**NamedNodeMap.length**
The length of the attribute list.

**NamedNodeMap.item(index)**
Return an attribute with a particular index. The order you get the attributes in is arbitrary but will be consistent for the life of a DOM. Each item is an attribute node. Get its value with the `value` attribute.

There are also experimental methods that give this class more mapping behavior. You can use them or you can use the standardized `getAttribute*()` family of methods on the **Element** objects.

### 19.6.2.9. Comment Objects

**Comment** represents a comment in the XML document. It is a subclass of **Node**, but cannot have child nodes.

**Comment.data**
The content of the comment as a string. The attribute contains all characters between the leading `<!--` and trailing `-->`, but does not include them.

### 19.6.2.10. Text and CDATASection Objects
The **Text** interface represents text in the XML document. If the parser and DOM implementation support the DOM’s XML extension, portions of the text enclosed in CDATA marked sections are stored in **CDATASection** objects. These two interfaces are identical, but provide different values for the **nodeType** attribute.

These interfaces extend the **Node** interface. They cannot have child nodes.

**Text.data**

The content of the text node as a string.

**Note:** The use of a **CDATASection** node does not indicate that the node represents a complete CDATA marked section, only that the content of the node was part of a CDATA section. A single CDATA section may be represented by more than one node in the document tree. There is no way to determine whether two adjacent **CDATASection** nodes represent different CDATA marked sections.

### 19.6.2.11. ProcessingInstruction Objects

Represents a processing instruction in the XML document; this inherits from the **Node** interface and cannot have child nodes.

**ProcessingInstruction.target**

The content of the processing instruction up to the first whitespace character. This is a read-only attribute.

**ProcessingInstruction.data**

The content of the processing instruction following the first whitespace character.

### 19.6.2.12. Exceptions
New in version 2.1.

The DOM Level 2 recommendation defines a single exception, **DOMException**, and a number of constants that allow applications to determine what sort of error occurred. **DOMException** instances carry a code attribute that provides the appropriate value for the specific exception.

The Python DOM interface provides the constants, but also expands the set of exceptions so that a specific exception exists for each of the exception codes defined by the DOM. The implementations must raise the appropriate specific exception, each of which carries the appropriate value for the code attribute.

**exception** `xml.dom.DOMException`  
Base exception class used for all specific DOM exceptions. This exception class cannot be directly instantiated.

**exception** `xml.dom.DomstringSizeErr`  
Raised when a specified range of text does not fit into a string. This is not known to be used in the Python DOM implementations, but may be received from DOM implementations not written in Python.

**exception** `xml.dom.HierarchyRequestErr`  
Raised when an attempt is made to insert a node where the node type is not allowed.

**exception** `xml.dom.IndexSizeErr`  
Raised when an index or size parameter to a method is negative or exceeds the allowed values.

**exception** `xml.dom.InuseAttributeErr`  
Raised when an attempt is made to insert an Attr node that is already present elsewhere in the document.
**exception** `xml.dom.InvalidAccessErr`  
Raised if a parameter or an operation is not supported on the underlying object.

**exception** `xml.dom.InvalidCharacterErr`  
This exception is raised when a string parameter contains a character that is not permitted in the context it's being used in by the XML 1.0 recommendation. For example, attempting to create an `Element` node with a space in the element type name will cause this error to be raised.

**exception** `xml.dom.InvalidModificationErr`  
Raised when an attempt is made to modify the type of a node.

**exception** `xml.dom.InvalidStateErr`  
Raised when an attempt is made to use an object that is not defined or is no longer usable.

**exception** `xml.dom.NamespaceErr`  
If an attempt is made to change any object in a way that is not permitted with regard to the Namespaces in XML recommendation, this exception is raised.

**exception** `xml.dom.NotFoundErr`  
Exception when a node does not exist in the referenced context. For example, `NamedNodeMap.removeNamedItem()` will raise this if the node passed in does not exist in the map.

**exception** `xml.dom.NotSupportedErr`  
Raised when the implementation does not support the requested type of object or operation.

**exception** `xml.dom.NoDataAllowedErr`  
This is raised if data is specified for a node which does not support data.
**exception** xml.dom. NoModificationAllowedErr

Raised on attempts to modify an object where modifications are not allowed (such as for read-only nodes).

**exception** xml.dom. SyntaxErr

Raised when an invalid or illegal string is specified.

**exception** xml.dom. WrongDocumentErr

Raised when a node is inserted in a different document than it currently belongs to, and the implementation does not support migrating the node from one document to the other.

The exception codes defined in the DOM recommendation map to the exceptions described above according to this table:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Exception</th>
</tr>
</thead>
<tbody>
<tr>
<td>DOMSTRING_SIZE_ERR</td>
<td>DomstringSizeErr</td>
</tr>
<tr>
<td>HIERARCHY_REQUEST_ERR</td>
<td>HierarchyRequestErr</td>
</tr>
<tr>
<td>INDEX_SIZE_ERR</td>
<td>IndexSizeErr</td>
</tr>
<tr>
<td>INUSE_ATTRIBUTE_ERR</td>
<td>InuseAttributeErr</td>
</tr>
<tr>
<td>INVALID_ACCESS_ERR</td>
<td>InvalidAccessErr</td>
</tr>
<tr>
<td>INVALID_CHARACTER_ERR</td>
<td>InvalidCharacterErr</td>
</tr>
<tr>
<td>INVALID_MODIFICATION_ERR</td>
<td>InvalidModificationErr</td>
</tr>
<tr>
<td>INVALID_STATE_ERR</td>
<td>InvalidStateErr</td>
</tr>
<tr>
<td>NAMESPACE_ERR</td>
<td>NamespaceErr</td>
</tr>
<tr>
<td>NOT_FOUND_ERR</td>
<td>NotFoundErr</td>
</tr>
<tr>
<td>NOT_SUPPORTED_ERR</td>
<td>NotSupportedErr</td>

<tr>
<td>NO_DATA_ALLOWED_ERR</td>
<td>NoDataAllowedErr</td>
</tr>
<tr>
<td>NO_MODIFICATION_ALLOWED_ERR</td>
<td>NoModificationAllowedErr</td>
</tr>
<tr>
<td>SYNTAX_ERR</td>
<td>SyntaxErr</td>
</tr>
<tr>
<td>WRONG_DOCUMENT_ERR</td>
<td>WrongDocumentErr</td>
</tr>
</tbody>
</table>
19.6.3. Conformance

This section describes the conformance requirements and relationships between the Python DOM API, the W3C DOM recommendations, and the OMG IDL mapping for Python.

19.6.3.1. Type Mapping

The primitive IDL types used in the DOM specification are mapped to Python types according to the following table.

<table>
<thead>
<tr>
<th>IDL Type</th>
<th>Python Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>boolean</td>
<td>IntegerType (with a value of 0 or 1)</td>
</tr>
<tr>
<td>int</td>
<td>IntegerType</td>
</tr>
<tr>
<td>long int</td>
<td>IntegerType</td>
</tr>
<tr>
<td>unsigned int</td>
<td>IntegerType</td>
</tr>
</tbody>
</table>

Additionally, the `DOMString` defined in the recommendation is mapped to a Python string or Unicode string. Applications should be able to handle Unicode whenever a string is returned from the DOM.

The IDL `null` value is mapped to `None`, which may be accepted or provided by the implementation whenever `null` is allowed by the API.

19.6.3.2. Accessor Methods

The mapping from OMG IDL to Python defines accessor functions for IDL `attribute` declarations in much the way the Java mapping does. Mapping the IDL declarations

```plaintext
readonly attribute string someValue;
attribute string anotherValue;
```
yields three accessor functions: a “get” method for `someValue` (_get_someValue()), and “get” and “set” methods for `anotherValue` (_get_anotherValue() and _set_anotherValue()). The mapping, in particular, does not require that the IDL attributes are accessible as normal Python attributes: `object.someValue` is *not* required to work, and may raise an `AttributeError`.

The Python DOM API, however, *does* require that normal attribute access work. This means that the typical surrogates generated by Python IDL compilers are not likely to work, and wrapper objects may be needed on the client if the DOM objects are accessed via CORBA. While this does require some additional consideration for CORBA DOM clients, the implementers with experience using DOM over CORBA from Python do not consider this a problem. Attributes that are declared `readonly` may not restrict write access in all DOM implementations.

In the Python DOM API, accessor functions are not required. If provided, they should take the form defined by the Python IDL mapping, but these methods are considered unnecessary since the attributes are accessible directly from Python. “Set” accessors should never be provided for `readonly` attributes.

The IDL definitions do not fully embody the requirements of the W3C DOM API, such as the notion of certain objects, such as the return value of `getElementsByTagName()`, being “live”. The Python DOM API does not require implementations to enforce such requirements.
19.7. `xml.dom.minidom` — Lightweight DOM implementation

*New in version 2.0.*

`xml.dom.minidom` is a light-weight implementation of the Document Object Model interface. It is intended to be simpler than the full DOM and also significantly smaller.

DOM applications typically start by parsing some XML into a DOM. With `xml.dom.minidom`, this is done through the parse functions:

```python
from xml.dom.minidom import parse, parseString

dom1 = parse('c:\temp\mydata.xml')  # parse an XML file by name

datasource = open('c:\temp\mydata.xml')
dom2 = parse(datasource)  # parse an open file

dom3 = parseString('<myxml>Some data<empty/> some more data</myxml>')
```

The `parse()` function can take either a filename or an open file object.

`xml.dom.minidom.parse(filename_or_file[, parser[, bufsize]])`

Return a `Document` from the given input. `filename_or_file` may be either a file name, or a file-like object. `parser`, if given, must be a SAX2 parser object. This function will change the document handler of the parser and activate namespace support; other parser configuration (like setting an entity resolver) must have been done in advance.

If you have XML in a string, you can use the `parseString()` function instead:
xml.dom.minidom.\texttt{parseString}(\texttt{string[, parser]})

Return a \texttt{Document} that represents the \texttt{string}. This method creates a \texttt{StringIO} object for the string and passes that on to \texttt{parse()}.

Both functions return a \texttt{Document} object representing the content of the document.

What the \texttt{parse()} and \texttt{parseString()} functions do is connect an XML parser with a “DOM builder” that can accept parse events from any SAX parser and convert them into a DOM tree. The name of the functions are perhaps misleading, but are easy to grasp when learning the interfaces. The parsing of the document will be completed before these functions return; it’s simply that these functions do not provide a parser implementation themselves.

You can also create a \texttt{Document} by calling a method on a “DOM Implementation” object. You can get this object either by calling the \texttt{getDOMImplementation()} function in the \texttt{xml.dom} package or the \texttt{xml.dom.minidom} module. Using the implementation from the \texttt{xml.dom.minidom} module will always return a \texttt{Document} instance from the minidom implementation, while the version from \texttt{xml.dom} may provide an alternate implementation (this is likely if you have the PyXML package installed). Once you have a \texttt{Document}, you can add child nodes to it to populate the DOM:

```python
def parse_string(xml_string):
    return xml.dom.minidom.parseString(xml_string)
```

```python
from xml.dom.minidom import getDOMImplementation

impl = getDOMImplementation()

newdoc = impl.createDocument(None, "some_tag", None)
top_element = newdoc.documentElement

xml_text = newdoc.createTextNode('Some textual content.')
top_element.appendChild(xml_text)
```

Once you have a DOM document object, you can access the parts of
your XML document through its properties and methods. These properties are defined in the DOM specification. The main property of the document object is the `documentElement` property. It gives you the main element in the XML document: the one that holds all others. Here is an example program:

```python
dom3 = parseString("<myxml>Some data</myxml>")
assert dom3.documentElement.tagName == "myxml"
```

When you are finished with a DOM tree, you may optionally call the `unlink()` method to encourage early cleanup of the now-unneeded objects. `unlink()` is a `xml.dom.minidom`-specific extension to the DOM API that renders the node and its descendants are essentially useless. Otherwise, Python’s garbage collector will eventually take care of the objects in the tree.

**See also:**

**Document Object Model (DOM) Level 1 Specification**

The W3C recommendation for the DOM supported by `xml.dom.minidom`. 
19.7.1. DOM Objects

The definition of the DOM API for Python is given as part of the xml.dom module documentation. This section lists the differences between the API and xml.dom.minidom.

Node. **unlink()**

Break internal references within the DOM so that it will be garbage collected on versions of Python without cyclic GC. Even when cyclic GC is available, using this can make large amounts of memory available sooner, so calling this on DOM objects as soon as they are no longer needed is good practice. This only needs to be called on the **Document** object, but may be called on child nodes to discard children of that node.

Node. **writexml(writer[, indent=""[, addindent=""[, newl=""[, encoding=""]]]]])**

Write XML to the writer object. The writer should have a write() method which matches that of the file object interface. The **indent** parameter is the indentation of the current node. The **addindent** parameter is the incremental indentation to use for subnodes of the current one. The **newl** parameter specifies the string to use to terminate newlines.

*Changed in version 2.1:* The optional keyword parameters **indent**, **addindent**, and **newl** were added to support pretty output.

*Changed in version 2.3:* For the **Document** node, an additional keyword argument **encoding** can be used to specify the encoding field of the XML header.

Node. **toxml([encoding])**
Return the XML that the DOM represents as a string.

With no argument, the XML header does not specify an encoding, and the result is Unicode string if the default encoding cannot represent all characters in the document. Encoding this string in an encoding other than UTF-8 is likely incorrect, since UTF-8 is the default encoding of XML.

With an explicit `encoding` [1] argument, the result is a byte string in the specified encoding. It is recommended that this argument is always specified. To avoid `UnicodeError` exceptions in case of unrepresentable text data, the encoding argument should be specified as “utf-8”.

*Changed in version 2.3:* the `encoding` argument was introduced; see `writexml()`.

```python
Node.toprettyxml([indent='', newl='', encoding=''])
```

Return a pretty-printed version of the document. `indent` specifies the indentation string and defaults to a tabulator; `newl` specifies the string emitted at the end of each line and defaults to `\n`.

*New in version 2.1.*

*Changed in version 2.3:* the `encoding` argument was introduced; see `writexml()`.

The following standard DOM methods have special considerations with `xml.dom.minidom`:

```python
Node.cloneNode(deep)
```

Although this method was present in the version of `xml.dom.minidom` packaged with Python 2.0, it was seriously broken. This has been corrected for subsequent releases.
19.7.2. DOM Example

This example program is a fairly realistic example of a simple program. In this particular case, we do not take much advantage of the flexibility of the DOM.

```python
import xml.dom.minidom

document = ""
<slideshow>
<title>Demo slideshow</title>
<slide><title>Slide title</title>
<point>This is a demo</point>
<point>Of a program for processing slides</point>
</slide>

<slide><title>Another demo slide</title>
<point>It is important</point>
<point>To have more than</point>
<point>one slide</point>
</slide>
</slideshow>
"

dom = xml.dom.minidom.parseString(document)

def getText(nodelist):
    rc = []
    for node in nodelist:
        if node.nodeType == node.TEXT_NODE:
            rc.append(node.data)
    return ''.join(rc)

def handleSlideshow(slideshow):
    print "<html>"
    handleSlideshowTitle(slideshow.getElementsByTagName("title"))
    slides = slideshow.getElementsByTagName("slide")
    handleToc(slides)
    handleSlides(slides)
    print "</html>"

def handleSlides(slides):
    for slide in slides:
```
def handleSlide(slide):
    handleSlideTitle(slide.getElementsByTagName("title")[0])
    handlePoints(slide.getElementsByTagName("point"))

def handleSlideshowTitle(title):
    print "<title>%s</title>" % getText(title.childNodes)

def handleSlideTitle(title):
    print "<h2>%s</h2>" % getText(title.childNodes)

def handlePoints(points):
    print "<ul>
    for point in points:
        handlePoint(point)
    print "</ul>"

def handlePoint(point):
    print "<li>%s</li>" % getText(point.childNodes)

def handleToc(slides):
    for slide in slides:
        title = slide.getElementsByTagName("title")[0]
        print "<p>%s</p>" % getText(title.childNodes)

handleSlideshow(dom)
19.7.3. minidom and the DOM standard

The xml.dom.minidom module is essentially a DOM 1.0-compatible DOM with some DOM 2 features (primarily namespace features).

Usage of the DOM interface in Python is straight-forward. The following mapping rules apply:

- Interfaces are accessed through instance objects. Applications should not instantiate the classes themselves; they should use the creator functions available on the Document object. Derived interfaces support all operations (and attributes) from the base interfaces, plus any new operations.
- Operations are used as methods. Since the DOM uses only in parameters, the arguments are passed in normal order (from left to right). There are no optional arguments. void operations return None.
- IDL attributes map to instance attributes. For compatibility with the OMG IDL language mapping for Python, an attribute foo can also be accessed through accessor methods _get_foo() and _set_foo(). readonly attributes must not be changed; this is not enforced at runtime.
- The types short int, unsigned int, unsigned long long, and boolean all map to Python integer objects.
- The type DOMString maps to Python strings. xml.dom.minidom supports either byte or Unicode strings, but will normally produce Unicode strings. Values of type DOMString may also be None where allowed to have the IDL null value by the DOM specification from the W3C.
- const declarations map to variables in their respective scope (e.g. xml.dom.minidom.Node.PROCESSING_INSTRUCTION_NODE); they must not be changed.
• DOMException is currently not supported in xml.dom.minidom. Instead, xml.dom.minidom uses standard Python exceptions such as TypeError and AttributeError.

• NodeList objects are implemented using Python's built-in list type. Starting with Python 2.2, these objects provide the interface defined in the DOM specification, but with earlier versions of Python they do not support the official API. They are, however, much more “Pythonic” than the interface defined in the W3C recommendations.

The following interfaces have no implementation in xml.dom.minidom:

• DOMTimeStamp
• DocumentType (added in Python 2.1)
• DOMImplementation (added in Python 2.1)
• CharacterData
• CDATASection
• Notation
• Entity
• EntityReference
• DocumentFragment

Most of these reflect information in the XML document that is not of general utility to most DOM users.

Footnotes

The encoding string included in XML output should conform to the appropriate standards. For example, “UTF-8” is valid, but “UTF8” is not. See http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl and http://www.iana.org/assignments/character-sets.

[1]
19.8. `xml.dom.pulldom` — Support for building partial DOM trees

New in version 2.0.

`xml.dom.pulldom` allows building only selected portions of a Document Object Model representation of a document from SAX events.

```python
class xml.dom.pulldom.PullDOM([documentFactory])
    xml.sax.handler.ContentHandler implementation that ...
```

```python
class xml.dom.pulldom.DOMEventStream(stream, parser, bufsize)
...
```

```python
class xml.dom.pulldom.SAX2DOM([documentFactory])
    xml.sax.handler.ContentHandler implementation that ...
```

```python
xml.dom.pulldom.parse(stream_or_string[, parser[, bufsize]])
...
```

```python
xml.dom.pulldom.parseString(string[, parser])
...
```

```python
xml.dom.pulldom.default_bufsize
    Default value for the bufsize parameter to parse().
```

Changed in version 2.1: The value of this variable can be changed before calling `parse()` and the new value will take effect.
19.8.1. DOMEventStream Objects

DOMEventStream.getEvent()
...

DOMEventStream.expandNode(node)
...

DOMEventStream.reset()
...
19.9. **xml.sax** — Support for SAX2 parsers

*New in version 2.0.*

The `xml.sax` package provides a number of modules which implement the Simple API for XML (SAX) interface for Python. The package itself provides the SAX exceptions and the convenience functions which will be most used by users of the SAX API.

The convenience functions are:

```python
xml.sax.make_parser([parser_list])
```

Create and return a SAX `XMLReader` object. The first parser found will be used. If `parser_list` is provided, it must be a sequence of strings which name modules that have a function named `create_parser()`. Modules listed in `parser_list` will be used before modules in the default list of parsers.

```python
xml.sax.parse(filename_or_stream, handler[, error_handler])
```

Create a SAX parser and use it to parse a document. The document, passed in as `filename_or_stream`, can be a filename or a file object. The `handler` parameter needs to be a SAX `ContentHandler` instance. If `error_handler` is given, it must be a SAX `ErrorHandler` instance; if omitted, `SAXParseException` will be raised on all errors. There is no return value; all work must be done by the `handler` passed in.

```python
xml.sax.parseString(string, handler[, error_handler])
```

Similar to `parse()`, but parses from a buffer `string` received as a parameter.
A typical SAX application uses three kinds of objects: readers, handlers and input sources. “Reader” in this context is another term for parser, i.e. some piece of code that reads the bytes or characters from the input source, and produces a sequence of events. The events then get distributed to the handler objects, i.e. the reader invokes a method on the handler. A SAX application must therefore obtain a reader object, create or open the input sources, create the handlers, and connect these objects all together. As the final step of preparation, the reader is called to parse the input. During parsing, methods on the handler objects are called based on structural and syntactic events from the input data.

For these objects, only the interfaces are relevant; they are normally not instantiated by the application itself. Since Python does not have an explicit notion of interface, they are formally introduced as classes, but applications may use implementations which do not inherit from the provided classes. The `InputSource`, `Locator`, `Attributes`, `AttributesNS`, and `XMLReader` interfaces are defined in the module `xml.sax.xmlreader`. The handler interfaces are defined in `xml.sax.handler`. For convenience, `InputSource` (which is often instantiated directly) and the handler classes are also available from `xml.sax`. These interfaces are described below.

In addition to these classes, `xml.sax` provides the following exception classes.

```
exception xml.sax.SAXException(msg[, exception])
```

Encapsulate an XML error or warning. This class can contain basic error or warning information from either the XML parser or the application: it can be subclassed to provide additional functionality or to add localization. Note that although the handlers defined in the `ErrorHandler` interface receive instances of this exception, it is not required to actually raise the exception — it is also useful as a container for information.
When instantiated, \textit{msg} should be a human-readable description of the error. The optional \textit{exception} parameter, if given, should be \texttt{None} or an exception that was caught by the parsing code and is being passed along as information.

This is the base class for the other SAX exception classes.

\texttt{exception xml.sax.SAXParseException(msg, exception, locator)}

Subclass of \texttt{SAXException} raised on parse errors. Instances of this class are passed to the methods of the SAX ErrorHandler interface to provide information about the parse error. This class supports the SAX Locator interface as well as the \texttt{SAXException} interface.

\texttt{exception xml.sax.SAXNotRecognizedException(msg[, exception])}

Subclass of \texttt{SAXException} raised when a SAX XMLReader is confronted with an unrecognized feature or property. SAX applications and extensions may use this class for similar purposes.

\texttt{exception xml.sax.SAXNotSupportedException(msg[, exception])}

Subclass of \texttt{SAXException} raised when a SAX XMLReader is asked to enable a feature that is not supported, or to set a property to a value that the implementation does not support. SAX applications and extensions may use this class for similar purposes.

\textbf{SAX: The Simple API for XML}

This site is the focal point for the definition of the SAX API. It provides a Java implementation and online documentation. Links to implementations and historical information are also available.

\textbf{Module xml.sax.handler}
Definitions of the interfaces for application-provided objects.

**Module** `xml.sax.saxutils`

Convenience functions for use in SAX applications.

**Module** `xml.sax.xmlreader`

Definitions of the interfaces for parser-provided objects.
19.9.1. SAXException Objects

The `SAXException` exception class supports the following methods:

**SAXException. `getMessage()`**

Return a human-readable message describing the error condition.

**SAXException. `getException()`**

Return an encapsulated exception object, or `None`. 
19.10. `xml.sax.handler` — Base classes for SAX handlers

*New in version 2.0.*

The SAX API defines four kinds of handlers: content handlers, DTD handlers, error handlers, and entity resolvers. Applications normally only need to implement those interfaces whose events they are interested in; they can implement the interfaces in a single object or in multiple objects. Handler implementations should inherit from the base classes provided in the module `xml.sax.handler`, so that all methods get default implementations.

```python
class xml.sax.handler.ContentHandler

This is the main callback interface in SAX, and the one most important to applications. The order of events in this interface mirrors the order of the information in the document.
```

```python
class xml.sax.handler/DTDHandler

This interface specifies only those DTD events required for basic parsing (unparsed entities and attributes).
```

```python
class xml.sax.handler.EntityResolver

Basic interface for resolving entities. If you create an object implementing this interface, then register the object with your Parser, the parser will call the method in your object to resolve all external entities.
```

```python
class xml.sax.handler.ErrorHandler

Interface used by the parser to present error and warning messages to the application. The methods of this object control whether errors are immediately converted to exceptions or are
handled in some other way.

In addition to these classes, `xml.sax.handler` provides symbolic constants for the feature and property names.

`xml.sax.handler.feature_namespaces`  
Value: "http://xml.org/sax/features/namespaces" — true: Perform Namespace processing. — false: Optionally do not perform Namespace processing (implies namespace-prefixes; default). — access: (parsing) read-only; (not parsing) read/write

`xml.sax.handler.feature_namespace_prefixes`  
Value: "http://xml.org/sax/features/namespace-prefixes" — true: Report the original prefixed names and attributes used for Namespace declarations. — false: Do not report attributes used for Namespace declarations, and optionally do not report original prefixed names (default). — access: (parsing) read-only; (not parsing) read/write

`xml.sax.handler.feature_string_interning`  
Value: "http://xml.org/sax/features/string-interning" — true: All element names, prefixes, attribute names, Namespace URIs, and local names are interned using the built-in intern function. — false: Names are not necessarily interned, although they may be (default). — access: (parsing) read-only; (not parsing) read/write

`xml.sax.handler.feature_validation`  
Value: "http://xml.org/sax/features/validation" — true: Report all validation errors (implies external-general-entities and external-parameter-entities). — false: Do not report validation errors. — access: (parsing) read-only; (not parsing) read/write

`xml.sax.handler.feature_external_ges`  
Value: "http://xml.org/sax/features/external-general-entities" — true: Include all external general (text) entities. —
false: Do not include external general entities. — access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.feature_external_pes
Value: "http://xml.org/sax/features/external-parameter-entities" — true: Include all external parameter entities, including the external DTD subset. — false: Do not include any external parameter entities, even the external DTD subset. — access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.all_features
List of all features.

xml.sax.handler.property_lexical_handler
Value: "http://xml.org/sax/properties/lexical-handler" — data type: xml.sax.sax2lib.LexicalHandler (not supported in Python 2) — description: An optional extension handler for lexical events like comments. — access: read/write

xml.sax.handler.property_declaration_handler
Value: "http://xml.org/sax/properties/declaration-handler" — data type: xml.sax.sax2lib.DeclHandler (not supported in Python 2) — description: An optional extension handler for DTD-related events other than notations and unparsed entities. — access: read/write

xml.sax.handler.property_dom_node
Value: "http://xml.org/sax/properties/dom-node" — data type: org.w3c.dom.Node (not supported in Python 2) — description: When parsing, the current DOM node being visited if this is a DOM iterator; when not parsing, the root DOM node for iteration. — access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.property_xml_string
Value: "http://xml.org/sax/properties/xml-string" — data
type: String — description: The literal string of characters that was the source for the current event. — access: read-only

`xml.sax.handler.all_properties`
List of all known property names.
19.10.1. ContentHandler Objects

Users are expected to subclass `ContentHandler` to support their application. The following methods are called by the parser on the appropriate events in the input document:

`ContentHandler.setDocumentLocator(locator)`

Called by the parser to give the application a locator for locating the origin of document events.

SAX parsers are strongly encouraged (though not absolutely required) to supply a locator: if it does so, it must supply the locator to the application by invoking this method before invoking any of the other methods in the DocumentHandler interface.

The locator allows the application to determine the end position of any document-related event, even if the parser is not reporting an error. Typically, the application will use this information for reporting its own errors (such as character content that does not match an application's business rules). The information returned by the locator is probably not sufficient for use with a search engine.

Note that the locator will return correct information only during the invocation of the events in this interface. The application should not attempt to use it at any other time.

`ContentHandler.startDocument()`

Receive notification of the beginning of a document.

The SAX parser will invoke this method only once, before any other methods in this interface or in DTDHandler (except for `setDocumentLocator()`).
ContentHandler. **endDocument()**

Receive notification of the end of a document.

The SAX parser will invoke this method only once, and it will be
the last method invoked during the parse. The parser shall not
invoke this method until it has either abandoned parsing
(because of an unrecoverable error) or reached the end of input.

ContentHandler. **startPrefixMapping**(prefix, uri)

Begin the scope of a prefix-URI Namespace mapping.

The information from this event is not necessary for normal
Namespace processing: the SAX XML reader will automatically
replace prefixes for element and attribute names when the
feature_namespaces feature is enabled (the default).

There are cases, however, when applications need to use
prefixes in character data or in attribute values, where they
cannot safely be expanded automatically; the
startPrefixMapping() and endPrefixMapping() events supply the
information to the application to expand prefixes in those contexts
itself, if necessary.

Note that startPrefixMapping() and endPrefixMapping() events
are not guaranteed to be properly nested relative to each-other:
all startPrefixMapping() events will occur before the
corresponding startElement() event, and all endPrefixMapping()
events will occur after the corresponding endElement() event, but
their order is not guaranteed.

ContentHandler. **endPrefixMapping**(prefix)

End the scope of a prefix-URI mapping.

See startPrefixMapping() for details. This event will always
occur after the corresponding \texttt{endElement()} event, but the order of \texttt{endPrefixMapping()} events is not otherwise guaranteed.

\texttt{ContentHandler.\texttt{startElement\(\texttt{name, attrs}\)}}

Signals the start of an element in non-namespace mode.

The \texttt{name} parameter contains the raw XML 1.0 name of the element type as a string and the \texttt{attrs} parameter holds an object of the \texttt{Attributes} interface (see \textit{The Attributes Interface}) containing the attributes of the element. The object passed as \texttt{attrs} may be re-used by the parser; holding on to a reference to it is not a reliable way to keep a copy of the attributes. To keep a copy of the attributes, use the \texttt{copy()} method of the \texttt{attrs} object.

\texttt{ContentHandler.\texttt{endElement\(\texttt{name}\)}}

Signals the end of an element in non-namespace mode.

The \texttt{name} parameter contains the name of the element type, just as with the \texttt{startElement()} event.

\texttt{ContentHandler.\texttt{startElementNS\(\texttt{name, qname, attrs}\)}}

Signals the start of an element in namespace mode.

The \texttt{name} parameter contains the name of the element type as a \texttt{(uri, localname)} tuple, the \texttt{qname} parameter contains the raw XML 1.0 name used in the source document, and the \texttt{attrs} parameter holds an instance of the \texttt{AttributesNS} interface (see \textit{The AttributesNS Interface}) containing the attributes of the element. If no namespace is associated with the element, the \texttt{uri} component of \texttt{name} will be \texttt{None}. The object passed as \texttt{attrs} may be re-used by the parser; holding on to a reference to it is not a reliable way to keep a copy of the attributes. To keep a copy of the attributes, use the \texttt{copy()} method of the \texttt{attrs} object.
Parsers may set the `qname` parameter to `None`, unless the `feature_namespace_prefixes` feature is activated.

```python
ContentHandler.endElementNS(name, qname)
```
Signals the end of an element in namespace mode.

The `name` parameter contains the name of the element type, just as with the `startElementNS()` method, likewise the `qname` parameter.

```python
ContentHandler.characters(content)
```
Receive notification of character data.

The Parser will call this method to report each chunk of character data. SAX parsers may return all contiguous character data in a single chunk, or they may split it into several chunks; however, all of the characters in any single event must come from the same external entity so that the Locator provides useful information.

`content` may be a Unicode string or a byte string; the `expat` reader module produces always Unicode strings.

**Note:** The earlier SAX 1 interface provided by the Python XML Special Interest Group used a more Java-like interface for this method. Since most parsers used from Python did not take advantage of the older interface, the simpler signature was chosen to replace it. To convert old code to the new interface, use `content` instead of slicing content with the old `offset` and `length` parameters.

```python
ContentHandler.ignorableWhitespace(whitespace)
```
Receive notification of ignorable whitespace in element content.

Validating Parsers must use this method to report each chunk of
ignorable whitespace (see the W3C XML 1.0 recommendation, section 2.10): non-validating parsers may also use this method if they are capable of parsing and using content models.

SAX parsers may return all contiguous whitespace in a single chunk, or they may split it into several chunks; however, all of the characters in any single event must come from the same external entity, so that the Locator provides useful information.

ContentHandler.**processingInstruction**(target, data)
Receive notification of a processing instruction.

The Parser will invoke this method once for each processing instruction found: note that processing instructions may occur before or after the main document element.

A SAX parser should never report an XML declaration (XML 1.0, section 2.8) or a text declaration (XML 1.0, section 4.3.1) using this method.

ContentHandler.**skippedEntity**(name)
Receive notification of a skipped entity.

The Parser will invoke this method once for each entity skipped. Non-validating processors may skip entities if they have not seen the declarations (because, for example, the entity was declared in an external DTD subset). All processors may skip external entities, depending on the values of the `feature_external_ges` and the `feature_external_pes` properties.
19.10.2. DTDHandler Objects

**DTHandler** instances provide the following methods:

**`DTHandler`**. `notationDecl(name, publicId, systemId)`
- Handle a notation declaration event.

**`DTHandler`**. `unparsedEntityDecl(name, publicId, systemId, ndata)`
- Handle an unparsed entity declaration event.
19.10.3. EntityResolver Objects

EntityResolver. **resolveEntity**(publicId, systemId)

Resolve the system identifier of an entity and return either the system identifier to read from as a string, or an InputSource to read from. The default implementation returns systemId.
19.10.4. ErrorHandler Objects

Objects with this interface are used to receive error and warning information from the XMLReader. If you create an object that implements this interface, then register the object with your XMLReader, the parser will call the methods in your object to report all warnings and errors. There are three levels of errors available: warnings, (possibly) recoverable errors, and unrecoverable errors. All methods take a SAXParseException as the only parameter. Errors and warnings may be converted to an exception by raising the passed-in exception object.

ErrorHandler.error(exception)
Called when the parser encounters a recoverable error. If this method does not raise an exception, parsing may continue, but further document information should not be expected by the application. Allowing the parser to continue may allow additional errors to be discovered in the input document.

ErrorHandler.fatalError(exception)
Called when the parser encounters an error it cannot recover from; parsing is expected to terminate when this method returns.

ErrorHandler.warning(exception)
Called when the parser presents minor warning information to the application. Parsing is expected to continue when this method returns, and document information will continue to be passed to the application. Raising an exception in this method will cause parsing to end.
19.11. xml.sax.saxutils — SAX Utilities

New in version 2.0.

The module xml.sax.saxutils contains a number of classes and functions that are commonly useful when creating SAX applications, either in direct use, or as base classes.

xml.sax.saxutils.escape(data[, entities])

Escape '&', '<', and '>' in a string of data.

You can escape other strings of data by passing a dictionary as the optional entities parameter. The keys and values must all be strings; each key will be replaced with its corresponding value. The characters '&', '<' and '>' are always escaped, even if entities is provided.

xml.sax.saxutils.unescape(data[, entities])

Unescape '&amp;', '&lt;', and '&gt;' in a string of data.

You can unescape other strings of data by passing a dictionary as the optional entities parameter. The keys and values must all be strings; each key will be replaced with its corresponding value. '&amp;', '&lt;', and '&gt;' are always unescaped, even if entities is provided.

New in version 2.3.

xml.sax.saxutils.quoteattr(data[, entities])

Similar to escape(), but also prepares data to be used as an attribute value. The return value is a quoted version of data with
any additional required replacements. `quoteattr()` will select a quote character based on the content of `data`, attempting to avoid encoding any quote characters in the string. If both single- and double-quote characters are already in `data`, the double-quote characters will be encoded and `data` will be wrapped in double-quotes. The resulting string can be used directly as an attribute value:

```python
>>> print '<element attr=%s>' % quoteattr("ab ' cd " ef")
<element attr="ab ' cd \\
\" ef">
```

This function is useful when generating attribute values for HTML or any SGML using the reference concrete syntax.

*New in version 2.2.*

```python
class xml.sax.saxutils.XMLGenerator([out[, encoding]])
```

This class implements the `ContentHandler` interface by writing SAX events back into an XML document. In other words, using an `XMLGenerator` as the content handler will reproduce the original document being parsed. `out` should be a file-like object which will default to `sys.stdout`. `encoding` is the encoding of the output stream which defaults to `iso-8859-1`.

```python
class xml.sax.saxutils/XMLFilterBase(base)
```

This class is designed to sit between an `XMLReader` and the client application’s event handlers. By default, it does nothing but pass requests up to the reader and events on to the handlers unmodified, but subclasses can override specific methods to modify the event stream or the configuration requests as they pass through.

```python
xml.sax.saxutils.prepare_input_source(source[, base])
```

This function takes an input source and an optional base URL
and returns a fully resolved **InputSource** object ready for reading. The input source can be given as a string, a file-like object, or an **InputSource** object; parsers will use this function to implement the polymorphic `source` argument to their `parse()` method.
19.12. `xml.sax.xmlreader` — Interface for XML parsers

*New in version 2.0.*

SAX parsers implement the `XMLReader` interface. They are implemented in a Python module, which must provide a function `create_parser()`. This function is invoked by `xml.sax.make_parser()` with no arguments to create a new parser object.

```python
class xml.sax.xmlreader.XMLReader
    Base class which can be inherited by SAX parsers.

class xml.sax.xmlreader.IncrementalParser
    In some cases, it is desirable not to parse an input source at once, but to feed chunks of the document as they get available. Note that the reader will normally not read the entire file, but read it in chunks as well; still `parse()` won’t return until the entire document is processed. So these interfaces should be used if the blocking behaviour of `parse()` is not desirable.

    When the parser is instantiated it is ready to begin accepting data from the feed method immediately. After parsing has been finished with a call to close the reset method must be called to make the parser ready to accept new data, either from feed or using the parse method.

    Note that these methods must not be called during parsing, that is, after parse has been called and before it returns.

    By default, the class also implements the parse method of the XMLReader interface using the feed, close and reset methods of the IncrementalParser interface as a convenience to SAX 2.0
```
driver writers.

```java
class xml.sax.xmlreader.Locator
```
Interface for associating a SAX event with a document location. A locator object will return valid results only during calls to DocumentHandler methods; at any other time, the results are unpredictable. If information is not available, methods may return None.

```java
class xml.sax.xmlreader.InputSource([systemId])
```
Encapsulation of the information needed by the XMLReader to read entities.

This class may include information about the public identifier, system identifier, byte stream (possibly with character encoding information) and/or the character stream of an entity.

Applications will create objects of this class for use in the XMLReader.parse() method and for returning from EntityResolver.resolveEntity.

An InputSource belongs to the application, the XMLReader is not allowed to modify InputSource objects passed to it from the application, although it may make copies and modify those.

```java
class xml.sax.xmlreader.AttributesImpl(attr)
```
This is an implementation of the Attributes interface (see section The Attributes Interface). This is a dictionary-like object which represents the element attributes in a startElement() call. In addition to the most useful dictionary operations, it supports a number of other methods as described by the interface. Objects of this class should be instantiated by readers; attrs must be a dictionary-like object containing a mapping from attribute names to attribute values.
Namespace-aware variant of `AttributesImpl`, which will be passed to `startElementNS()`. It is derived from `AttributesImpl`, but understands attribute names as two-tuples of `namespaceURI` and `localname`. In addition, it provides a number of methods expecting qualified names as they appear in the original document. This class implements the `AttributesNS` interface (see section *The AttributesNS Interface*).
19.12.1. XMLReader Objects

The XMLReader interface supports the following methods:

**XMLReader**.\texttt{parse(source)}

Process an input source, producing SAX events. The source object can be a system identifier (a string identifying the input source – typically a file name or an URL), a file-like object, or an \texttt{InputSource} object. When \texttt{parse()} returns, the input is completely processed, and the parser object can be discarded or reset. As a limitation, the current implementation only accepts byte streams; processing of character streams is for further study.

**XMLReader**.\texttt{getContentHandler()}

Return the current \texttt{ContentHandler}.

**XMLReader**.\texttt{setContentHandler(handler)}

Set the current \texttt{ContentHandler}. If no \texttt{ContentHandler} is set, content events will be discarded.

**XMLReader**.\texttt{getDTDHandler()} 

Return the current \texttt{DTDHandler}.

**XMLReader**.\texttt{setDTDHandler(handler)}

Set the current \texttt{DTDHandler}. If no \texttt{DTDHandler} is set, DTD events will be discarded.

**XMLReader**.\texttt{getEntityResolver()}

Return the current \texttt{EntityResolver}.

**XMLReader**.\texttt{setEntityResolver(handler)}

Set the current \texttt{EntityResolver}. If no \texttt{EntityResolver} is set,
attempts to resolve an external entity will result in opening the system identifier for the entity, and fail if it is not available.

XMLReader.getErrorHandler()
Return the current ErrorHandler.

XMLReader setErrorHandler(handler)
Set the current error handler. If no ErrorHandler is set, errors will be raised as exceptions, and warnings will be printed.

XMLReader.setLocale(locale)
Allow an application to set the locale for errors and warnings.

SAX parsers are not required to provide localization for errors and warnings; if they cannot support the requested locale, however, they must throw a SAX exception. Applications may request a locale change in the middle of a parse.

XMLReader.getFeature(featurename)
Return the current setting for feature featurename. If the feature is not recognized, SAXNotRecognizedException is raised. The well-known featurenames are listed in the module xml.sax.handler.

XMLReader.setFeature(featurename, value)
Set the featurename to value. If the feature is not recognized, SAXNotRecognizedException is raised. If the feature or its setting is not supported by the parser, SAXNotSupportedException is raised.

XMLReader.getProperty(propertyname)
Return the current setting for property propertyname. If the property is not recognized, a SAXNotRecognizedException is raised. The well-known propertynames are listed in the module xml.sax.handler.
XMLReader. **setProperty** *(propertyName, value)*

Set the *propertyName* to *value*. If the property is not recognized, `SAXNotRecognizedException` is raised. If the property or its setting is not supported by the parser, `SAXNotSupportedError` is raised.
19.12.2. IncrementalParser Objects

Instances of `IncrementalParser` offer the following additional methods:

`IncrementalParser.feed(data)`
- Process a chunk of `data`.

`IncrementalParser.close()`
- Assume the end of the document. That will check well-formedness conditions that can be checked only at the end, invoke handlers, and may clean up resources allocated during parsing.

`IncrementalParser.reset()`
- This method is called after close has been called to reset the parser so that it is ready to parse new documents. The results of calling parse or feed after close without calling reset are undefined.
19.12.3. Locator Objects

Instances of **Locator** provide these methods:

**Locator**. `getColumnNumber()`  
Return the column number where the current event ends.

**Locator**. `getLineNumber()`  
Return the line number where the current event ends.

**Locator**. `getPublicId()`  
Return the public identifier for the current event.

**Locator**. `getSystemId()`  
Return the system identifier for the current event.
### 19.12.4. InputSource Objects

**InputSource**. `setPublicId(id)`

Sets the public identifier of this `InputSource`.

**InputSource**. `getPublicId()`

Returns the public identifier of this `InputSource`.

**InputSource**. `setSystemId(id)`

Sets the system identifier of this `InputSource`.

**InputSource**. `getSystemId()`

Returns the system identifier of this `InputSource`.

**InputSource**. `setEncoding(encoding)`

Sets the character encoding of this `InputSource`.

The encoding must be a string acceptable for an XML encoding declaration (see section 4.3.3 of the XML recommendation).

The encoding attribute of the `InputSource` is ignored if the `InputSource` also contains a character stream.

**InputSource**. `getEncoding()`

Get the character encoding of this `InputSource`.

**InputSource**. `setByteStream(bytefile)`

Set the byte stream (a Python file-like object which does not perform byte-to-character conversion) for this input source.

The SAX parser will ignore this if there is also a character stream specified, but it will use a byte stream in preference to opening a URI connection itself.
If the application knows the character encoding of the byte stream, it should set it with the `setEncoding` method.

`InputSource.getByteStream()`
Get the byte stream for this input source.

The `getEncoding` method will return the character encoding for this byte stream, or None if unknown.

`InputSource.setCharacterStream(charfile)`
Set the character stream for this input source. (The stream must be a Python 1.6 Unicode-wrapped file-like that performs conversion to Unicode strings.)

If there is a character stream specified, the SAX parser will ignore any byte stream and will not attempt to open a URI connection to the system identifier.

`InputSource.setCharacterStream()`
Get the character stream for this input source.
19.12.5. The Attributes Interface

Attributes objects implement a portion of the mapping protocol, including the methods `copy()`, `get()`, `has_key()`, `items()`, `keys()`, and `values()`. The following methods are also provided:

Attributes. **getLength()**
  Return the number of attributes.

Attributes. **getNames()**
  Return the names of the attributes.

Attributes. **getType(name)**
  Returns the type of the attribute `name`, which is normally 'CDATA'.

Attributes. **getValue(name)**
  Return the value of attribute `name`. 
19.12.6. The AttributesNS Interface

This interface is a subtype of the Attributes interface (see section The Attributes Interface). All methods supported by that interface are also available on AttributesNS objects.

The following methods are also available:

AttributesNS. **getValueByQName**(name)

   Return the value for a qualified name.

AttributesNS. **getNameByQName**(name)

   Return the (namespace, localname) pair for a qualified name.

AttributesNS. **getQNameByName**(name)

   Return the qualified name for a (namespace, localname) pair.

AttributesNS. **getQNames**()

   Return the qualified names of all attributes.
19.13. xml.etree.ElementTree — The ElementTree XML API

New in version 2.5.

The `Element` type is a flexible container object, designed to store hierarchical data structures in memory. The type can be described as a cross between a list and a dictionary.

Each element has a number of properties associated with it:

- a tag which is a string identifying what kind of data this element represents (the element type, in other words).
- a number of attributes, stored in a Python dictionary.
- a text string.
- an optional tail string.
- a number of child elements, stored in a Python sequence.

To create an element instance, use the `Element` constructor or the `SubElement()` factory function.

The `ElementTree` class can be used to wrap an element structure, and convert it from and to XML.

A C implementation of this API is available as `xml.etree.cElementTree`.

See http://effbot.org/zone/element-index.htm for tutorials and links to other docs. Fredrik Lundh’s page is also the location of the development version of the xml.etree.ElementTree.

*Changed in version 2.7:* The ElementTree API is updated to 1.3. For more information, see *Introducing ElementTree 1.3.*
19.13.1. Functions

xml.etree.ElementTree.Comment(text=None)
Comment element factory. This factory function creates a special element that will be serialized as an XML comment by the standard serializer. The comment string can be either a bytestring or a Unicode string. text is a string containing the comment string. Returns an element instance representing a comment.

xml.etree.ElementTree.dump(elem)
Writes an element tree or element structure to sys.stdout. This function should be used for debugging only.

The exact output format is implementation dependent. In this version, it's written as an ordinary XML file.

elem is an element tree or an individual element.

xml.etree.ElementTree.fromstring(text)
Parses an XML section from a string constant. Same as XML(). text is a string containing XML data. Returns an Element instance.

xml.etree.ElementTree.fromstringlist(sequence, parser=None)
Parses an XML document from a sequence of string fragments. sequence is a list or other sequence containing XML data fragments. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns an Element instance.

New in version 2.7.

xml.etree.ElementTree.iselement(element)
Checks if an object appears to be a valid element object. element is an element instance. Returns a true value if this is an element
object.

xml.etree.ElementTree.iterparse(source, events=None, parser=None)

Parses an XML section into an element tree incrementally, and reports what’s going on to the user. source is a filename or file object containing XML data. events is a list of events to report back. If omitted, only “end” events are reported. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns an iterator providing (event, elem) pairs.

Note: iterparse() only guarantees that it has seen the “>” character of a starting tag when it emits a “start” event, so the attributes are defined, but the contents of the text and tail attributes are undefined at that point. The same applies to the element children; they may or may not be present. If you need a fully populated element, look for “end” events instead.

xml.etree.ElementTree.parse(source, parser=None)

Parses an XML section into an element tree. source is a filename or file object containing XML data. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns an ElementTree instance.

xml.etree.ElementTree.ProcessingInstruction(target, text=None)

PI element factory. This factory function creates a special element that will be serialized as an XML processing instruction. target is a string containing the PI target. text is a string containing the PI contents, if given. Returns an element instance, representing a processing instruction.
xml.etree.ElementTree.register_namespace(prefix, uri)

Registers a namespace prefix. The registry is global, and any existing mapping for either the given prefix or the namespace URI will be removed. prefix is a namespace prefix. uri is a namespace uri. Tags and attributes in this namespace will be serialized with the given prefix, if at all possible.

New in version 2.7.

xml.etree.ElementTree.SubElement(parent, tag, attrib={}, **extra)

Subelement factory. This function creates an element instance, and appends it to an existing element.

The element name, attribute names, and attribute values can be either bytestrings or Unicode strings. parent is the parent element. tag is the subelement name. attrib is an optional dictionary, containing element attributes. extra contains additional attributes, given as keyword arguments. Returns an element instance.

xml.etree.ElementTree.tostring(element, encoding="us-ascii", method="xml")

Generates a string representation of an XML element, including all subelements. element is an Element instance. encoding [1] is the output encoding (default is US-ASCII). method is either "xml", "html" or "text" (default is "xml"). Returns an encoded string containing the XML data.

xml.etree.ElementTree.tostringlist(element, encoding="us-ascii", method="xml")

Generates a string representation of an XML element, including all subelements. element is an Element instance. encoding [1] is the output encoding (default is US-ASCII). method is either "xml", "html" or "text" (default is "xml"). Returns a list of
encoded strings containing the XML data. It does not guarantee any specific sequence, except that 
"".join(tostringlist(element)) == tostring(element).

New in version 2.7.

xml.etree.ElementTree.XML(text, parser=None)

Parses an XML section from a string constant. This function can be used to embed “XML literals” in Python code. text is a string containing XML data. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns an Element instance.

xml.etree.ElementTree.XMLID(text, parser=None)

Parses an XML section from a string constant, and also returns a dictionary which maps from element id:s to elements. text is a string containing XML data. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns a tuple containing an Element instance and a dictionary.
19.13.2. Element Objects

```python
class xml.etree.ElementTree.Element(tag, attrib={}, **extra)
```

Element class. This class defines the Element interface, and provides a reference implementation of this interface.

The element name, attribute names, and attribute values can be either bytestrings or Unicode strings. `tag` is the element name. `attrib` is an optional dictionary, containing element attributes. `extra` contains additional attributes, given as keyword arguments.

**tag**
A string identifying what kind of data this element represents (the element type, in other words).

**text**
The `text` attribute can be used to hold additional data associated with the element. As the name implies this attribute is usually a string but may be any application-specific object. If the element is created from an XML file the attribute will contain any text found between the element tags.

**tail**
The `tail` attribute can be used to hold additional data associated with the element. This attribute is usually a string but may be any application-specific object. If the element is created from an XML file the attribute will contain any text found after the element’s end tag and before the next tag.

**attrib**
A dictionary containing the element’s attributes. Note that while the `attrib` value is always a real mutable Python dictionary, an ElementTree implementation may choose to use another internal representation, and create the dictionary only if someone asks for it. To take advantage of such
implementations, use the dictionary methods below whenever possible.

The following dictionary-like methods work on the element attributes.

**clear()**
Resets an element. This function removes all subelements, clears all attributes, and sets the text and tail attributes to None.

**get**(key, default=None)
Gets the element attribute named key.

Returns the attribute value, or default if the attribute was not found.

**items()**
Returns the element attributes as a sequence of (name, value) pairs. The attributes are returned in an arbitrary order.

**keys()**
Returns the elements attribute names as a list. The names are returned in an arbitrary order.

**set**(key, value)
Set the attribute key on the element to value.

The following methods work on the element's children (subelements).

**append**(subelement)
Adds the element subelement to the end of this elements internal list of subelements.

**extend**(subelements)
Appends subelements from a sequence object with zero or
more elements. Raises `AssertionError` if a subelement is not a valid object.

*New in version 2.7.*

**find(match)**

Finds the first subelement matching `match`. `match` may be a tag name or path. Returns an element instance or `None`.

**findall(match)**

Finds all matching subelements, by tag name or path. Returns a list containing all matching elements in document order.

**findtext(match, default=None)**

Finds text for the first subelement matching `match`. `match` may be a tag name or path. Returns the text content of the first matching element, or `default` if no element was found. Note that if the matching element has no text content an empty string is returned.

**getchildren()**

*Deprecated since version 2.7: Use `list(elem)` or iteration.*

**getiterator(tag=None)**

*Deprecated since version 2.7: Use method `Element.iter()` instead.*

**insert(index, element)**

Inserts a subelement at the given position in this element.

**iter(tag=None)**

Creates a tree *iterator* with the current element as the root. The iterator iterates over this element and all elements below it, in document (depth first) order. If `tag` is not `None` or `'*'`, only
elements whose tag equals *tag* are returned from the iterator. If the tree structure is modified during iteration, the result is undefined.

**iterfind**(match)
Finds all matching subelements, by tag name or path. Returns an iterable yielding all matching elements in document order.

*New in version 2.7.*

**itertext()**
Creates a text iterator. The iterator loops over this element and all subelements, in document order, and returns all inner text.

*New in version 2.7.*

**makeelement**(tag, attrib)
Creates a new element object of the same type as this element. Do not call this method, use the `SubElement()` factory function instead.

**remove**(subelement)
Removes *subelement* from the element. Unlike the find* methods this method compares elements based on the instance identity, not on tag value or contents.

Element objects also support the following sequence type methods for working with subelements: `__delitem__()`, `__getitem__()`, `__setitem__()`, `__len__()`.

Caution: Elements with no subelements will test as *False*. This behavior will change in future versions. Use specific `len(elem)` or `elem is None` test instead.
element = root.find('foo')

if not element:    # careful!
    print "element not found, or element has no subelements"

if element is None:
    print "element not found"
class xml.etree.ElementTree.ElementTree(element=None, file=None)

ElementTree wrapper class. This class represents an entire element hierarchy, and adds some extra support for serialization to and from standard XML.

element is the root element. The tree is initialized with the contents of the XML file if given.

_setroot(element)
Replaces the root element for this tree. This discards the current contents of the tree, and replaces it with the given element. Use with care. element is an element instance.

find(match)
Finds the first toplevel element matching match. match may be a tag name or path. Same as getroot().find(match). Returns the first matching element, or None if no element was found.

findall(match)
Finds all matching subelements, by tag name or path. Same as getroot().findall(match). match may be a tag name or path. Returns a list containing all matching elements, in document order.

findtext(match, default=None)
Finds the element text for the first toplevel element with given tag. Same as getroot().findtext(match). match may be a tag name or path. default is the value to return if the element was not found. Returns the text content of the first matching element, or the default value no element was found. Note that
if the element is found, but has no text content, this method
returns an empty string.

getiterator\(\text{tag}=\text{None}\)\n
\textit{Deprecated since version 2.7: Use method ElementTree.iter() instead.}\n
getroot()\n
Returns the root element for this tree.

iter\(\text{tag}=\text{None}\)\n
Creates and returns a tree iterator for the root element. The
iterator loops over all elements in this tree, in section order.
\textit{tag} is the tag to look for (default is to return all elements)

iterfind\(\text{match}\)\n
Finds all matching subelements, by tag name or path. Same
as getroot().iterfind\(\text{match}\). Returns an iterable yielding all
matching elements in document order.

\textit{New in version 2.7.}\n
parse\(\text{source, parser=}\text{None}\)\n
Loads an external XML section into this element tree. \textit{source}
is a file name or file object. \textit{parser} is an optional parser
instance. If not given, the standard XMLParser parser is used.
Returns the section root element.

write\(\text{file, encoding=}\text{us-ascii}, \text{xml_declaration=}\text{None, method=}\text{xml}\)\n
Writes the element tree to a file, as XML. \textit{file} is a file name, or
a file object opened for writing. \textit{encoding} \cite{1} is the output
encoding (default is US-ASCII). \textit{xml_declaration} controls if an
XML declaration should be added to the file. Use False for
never, True for always, None for only if not US-ASCII or UTF-
8 (default is None). *method* is either "xml", "html" or "text" (default is "xml"). Returns an encoded string.

This is the XML file that is going to be manipulated:

```xml
<html>
  <head>
    <title>Example page</title>
  </head>
  <body>
    <p>Moved to <a href="http://example.org/">example.org</a> or <a href="http://example.com/">example.com</a>.</p>
  </body>
</html>
```

Example of changing the attribute “target” of every link in first paragraph:

```python
>>> from xml.etree.ElementTree import ElementTree
>>> tree = ElementTree()
>>> tree.parse("index.xhtml")
<Element 'html' at 0xb77e6fac>
>>> p = tree.find("body/p")  # Finds first occurrence of tag
>>> p
<Element 'p' at 0xb77ec26c>
>>> links = list(p.iter("a"))  # Returns list of all links
>>> links
[<Element 'a' at 0xb77ec2ac>, <Element 'a' at 0xb77ec1cc>]
>>> for i in links:  # Iterates through all found links
...    i.attrib["target"] = "blank"
>>> tree.write("output.xhtml")
```
19.13.4. QName Objects

class xml.etree.ElementTree.QName(text_or_uri, tag=None)

QName wrapper. This can be used to wrap a QName attribute value, in order to get proper namespace handling on output. text_or_uri is a string containing the QName value, in the form {uri}local, or, if the tag argument is given, the URI part of a QName. If tag is given, the first argument is interpreted as an URI, and this argument is interpreted as a local name. QName instances are opaque.
19.13.5. TreeBuilder Objects

```
class xml.etree.ElementTree.TreeBuilder(element_factory=None)
    Generic element structure builder. This builder converts a
    sequence of start, data, and end method calls to a well-formed
    element structure. You can use this class to build an element
    structure using a custom XML parser, or a parser for some other
    XML-like format. The `element_factory` is called to create new
    `Element` instances when given.
```

close()
    Flushes the builder buffers, and returns the toplevel document
    element. Returns an `Element` instance.

data(data)
    Adds text to the current element. `data` is a string. This should
    be either a bytestring, or a Unicode string.

data(tag)
    Closes the current element. `tag` is the element name. Returns
    the closed element.

start(tag, attrs)
    Opens a new element. `tag` is the element name. `attrs` is a
    dictionary containing element attributes. Returns the opened
    element.

In addition, a custom `TreeBuilder` object can provide the
following method:

doctype(name, pubid, system)
    Handles a doctype declaration. `name` is the doctype name.
    `pubid` is the public identifier. `system` is the system identifier.
    This method does not exist on the default `TreeBuilder` class.
New in version 2.7.
19.13.6. XMLParser Objects

class xml.etree.ElementTree.XMLParser(html=0, target=None, encoding=None)

Element structure builder for XML source data, based on the expat parser. html are predefined HTML entities. This flag is not supported by the current implementation. target is the target object. If omitted, the builder uses an instance of the standard TreeBuilder class. encoding [1] is optional. If given, the value overrides the encoding specified in the XML file.

close()

Finishes feeding data to the parser. Returns an element structure.

doctype(name, pubid, system)

Deprecated since version 2.7: Define the TreeBuilder.doctype() method on a custom TreeBuilder target.

feed(data)

Feeds data to the parser. data is encoded data.

XMLParser.feed() calls target's start() method for each opening tag, its end() method for each closing tag, and data is processed by method data(). XMLParser.close() calls target's method close(). XMLParser can be used not only for building a tree structure. This is an example of counting the maximum depth of an XML file:

```python
>>> from xml.etree.ElementTree import XMLParser
>>> class MaxDepth:
...     # The target object of
...     maxDepth = 0
...     depth = 0
```
...    def start(self, tag, attrib):
...        # Called for each opening tag.
...        self.depth += 1
...    if self.depth > self.maxDepth:
...        self.maxDepth = self.depth
...    def end(self, tag):
...        # Called for each closing tag.
...        self.depth -= 1
...    def data(self, data):
...        pass  # We do not need to do anything with data.
...    def close(self):
...        # Called when all data has been parsed.
...        return self.maxDepth
...
>>> target = MaxDepth()
>>> parser = XMLParser(target=target)
>>> exampleXml = ""
... <a>
...     <b>
...         <c>
...             <d>
...         </d>
...     </c>
... </b>
... </a>"
>>> parser.feed(exampleXml)
>>> parser.close()
4

Footnotes

The encoding string included in XML output should conform to the appropriate standards. For example, "UTF-8" is valid, but "UTF8" is not. See http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl and http://www.iana.org/assignments/character-sets.
20. Internet Protocols and Support

The modules described in this chapter implement Internet protocols and support for related technology. They are all implemented in Python. Most of these modules require the presence of the system-dependent module `socket`, which is currently supported on most popular platforms. Here is an overview:

- **20.1. `webbrowser` — Convenient Web-browser controller**
  - 20.1.1. Browser Controller Objects
- **20.2. `cgi` — Common Gateway Interface support**
  - 20.2.1. Introduction
  - 20.2.2. Using the `cgi` module
  - 20.2.3. Higher Level Interface
  - 20.2.4. Old classes
  - 20.2.5. Functions
  - 20.2.6. Caring about security
  - 20.2.7. Installing your CGI script on a Unix system
  - 20.2.8. Testing your CGI script
  - 20.2.9. Debugging CGI scripts
  - 20.2.10. Common problems and solutions
- **20.3. `cgitb` — Traceback manager for CGI scripts**
- **20.4. `wsgiref` — WSGI Utilities and Reference Implementation**
  - 20.4.1. `wsgiref.util` — WSGI environment utilities
  - 20.4.2. `wsgiref.headers` — WSGI response header tools
  - 20.4.3. `wsgiref.simple_server` — a simple WSGI HTTP server
  - 20.4.4. `wsgiref.validate` — WSGI conformance checker
  - 20.4.5. `wsgiref.handlers` — server/gateway base classes
  - 20.4.6. Examples
- **20.5. `urllib` — Open arbitrary resources by URL**
  - 20.5.1. High-level interface
20.5.2. Utility functions
20.5.3. URL Opener objects
20.5.4. **urllib** Restrictions
20.5.5. Examples

20.6. **urllib2** — extensible library for opening URLs
   20.6.1. Request Objects
   20.6.2. OpenerDirector Objects
   20.6.3. BaseHandler Objects
   20.6.4. HTTPRedirectHandler Objects
   20.6.5. HTTPCookieProcessor Objects
   20.6.6. ProxyHandler Objects
   20.6.7. HTTPPasswordMgr Objects
   20.6.8. AbstractBasicAuthHandler Objects
   20.6.9. HTTPBasicAuthHandler Objects
   20.6.10. ProxyBasicAuthHandler Objects
   20.6.11. AbstractDigestAuthHandler Objects
   20.6.12. HTTPDigestAuthHandler Objects
   20.6.13. ProxyDigestAuthHandler Objects
   20.6.14. HTTPHandler Objects
   20.6.15. HTTPSHandler Objects
   20.6.16. FileHandler Objects
   20.6.17. FTPHandler Objects
   20.6.18. CacheFTPHandler Objects
   20.6.19. UnknownHandler Objects
   20.6.20. HTTPErrorProcessor Objects
   20.6.21. Examples

20.7. **httplib** — HTTP protocol client
   20.7.1. HTTPConnection Objects
   20.7.2. HTTPResponse Objects
   20.7.3. Examples

20.8. **ftplib** — FTP protocol client
   20.8.1. FTP Objects
   20.8.2. FTP_TLS Objects

20.9. **poplib** — POP3 protocol client
• 20.9.1. POP3 Objects
  • 20.9.2. POP3 Example
• 20.10. `imaplib` — IMAP4 protocol client
  • 20.10.1. IMAP4 Objects
  • 20.10.2. IMAP4 Example
• 20.11. `nntplib` — NNTP protocol client
  • 20.11.1. NNTP Objects
• 20.12. `smtplib` — SMTP protocol client
  • 20.12.1. SMTP Objects
  • 20.12.2. SMTP Example
• 20.13. `smtpd` — SMTP Server
  • 20.13.1. SMTPServer Objects
  • 20.13.2. DebuggingServer Objects
  • 20.13.3. PureProxy Objects
  • 20.13.4. MailmanProxy Objects
• 20.14. `telnetlib` — Telnet client
  • 20.14.1. Telnet Objects
  • 20.14.2. Telnet Example
• 20.15. `uuid` — UUID objects according to RFC 4122
  • 20.15.1. Example
• 20.16. `urlparse` — Parse URLs into components
  • 20.16.1. Results of `urlparse()` and `urlsplit()`
• 20.17. `SocketServer` — A framework for network servers
  • 20.17.1. Server Creation Notes
  • 20.17.2. Server Objects
  • 20.17.3. RequestHandler Objects
  • 20.17.4. Examples
    • 20.17.4.1. `SocketServer.TCPServer` Example
    • 20.17.4.2. `SocketServer.UDPServer` Example
    • 20.17.4.3. Asynchronous Mixins
• 20.18. `BaseHTTPServer` — Basic HTTP server
  • 20.18.1. More examples
• 20.19. `SimpleHTTPServer` — Simple HTTP request handler
• 20.20. **CGIHTTPServer** — CGI-capable HTTP request handler

• 20.21. **cookielib** — Cookie handling for HTTP clients
  - 20.21.2. FileCookieJar subclasses and co-operation with web browsers
  - 20.21.3. CookiePolicy Objects
  - 20.21.4. DefaultCookiePolicy Objects
  - 20.21.5. Cookie Objects
  - 20.21.6. Examples

• 20.22. **Cookie** — HTTP state management
  - 20.22.1. Cookie Objects
  - 20.22.2. Morsel Objects
  - 20.22.3. Example

• 20.23. **xmlrpclib** — XML-RPC client access
  - 20.23.1. ServerProxy Objects
  - 20.23.2. Boolean Objects
  - 20.23.3. DateTime Objects
  - 20.23.4. Binary Objects
  - 20.23.5. Fault Objects
  - 20.23.6. ProtocolError Objects
  - 20.23.7. MultiCall Objects
  - 20.23.8. Convenience Functions
  - 20.23.9. Example of Client Usage
  - 20.23.10. Example of Client and Server Usage

• 20.24. **SimpleXMLRPCServer** — Basic XML-RPC server
  - 20.24.1. SimpleXMLRPCServer Objects
    - 20.24.1.1. SimpleXMLRPCServer Example
  - 20.24.2. CGIXMLRPCRequestHandler

• 20.25. **DocXMLRPCServer** — Self-documenting XML-RPC server
  - 20.25.1. DocXMLRPCServer Objects
  - 20.25.2. DocCGIXMLRPCRequestHandler
20.1. **webbrowser** — Convenient Web-browser controller

The `webbrowser` module provides a high-level interface to allow displaying Web-based documents to users. Under most circumstances, simply calling the `open()` function from this module will do the right thing.

Under Unix, graphical browsers are preferred under X11, but text-mode browsers will be used if graphical browsers are not available or an X11 display isn’t available. If text-mode browsers are used, the calling process will block until the user exits the browser.

If the environment variable `BROWSER` exists, it is interpreted to override the platform default list of browsers, as a `os.pathsep`-separated list of browsers to try in order. When the value of a list part contains the string `%s`, then it is interpreted as a literal browser command line to be used with the argument URL substituted for `%s`; if the part does not contain `%s`, it is simply interpreted as the name of the browser to launch. [1]

For non-Unix platforms, or when a remote browser is available on Unix, the controlling process will not wait for the user to finish with the browser, but allow the remote browser to maintain its own windows on the display. If remote browsers are not available on Unix, the controlling process will launch a new browser and wait.

The script `webbrowser` can be used as a command-line interface for the module. It accepts an URL as the argument. It accepts the following optional parameters: `-n` opens the URL in a new browser window, if possible; `-t` opens the URL in a new browser page (“tab”). The options are, naturally, mutually exclusive.
The following exception is defined:

```
exception webbrowser.Error
    Exception raised when a browser control error occurs.
```

The following functions are defined:

```
webbrowser.open(url[, new=0[, autoraise=True]])
    Display url using the default browser. If new is 0, the url is opened in the same browser window if possible. If new is 1, a new browser window is opened if possible. If new is 2, a new browser page ("tab") is opened if possible. If autoraise is True, the window is raised if possible (note that under many window managers this will occur regardless of the setting of this variable).

    Note that on some platforms, trying to open a filename using this function, may work and start the operating system's associated program. However, this is neither supported nor portable.

    Changed in version 2.5: new can now be 2.
```

```
webbrowser.open_new(url)
    Open url in a new window of the default browser, if possible, otherwise, open url in the only browser window.
```

```
webbrowser.open_new_tab(url)
    Open url in a new page ("tab") of the default browser, if possible, otherwise equivalent to open_new().

    New in version 2.5.
```

```
webbrowser.get([name])
    Return a controller object for the browser type name. If name is empty, return a controller for a default browser appropriate to the caller's environment.
```
webbrowser.register(name, constructor[, instance])

Register the browser type name. Once a browser type is registered, the get() function can return a controller for that browser type. If instance is not provided, or is None, constructor will be called without parameters to create an instance when needed. If instance is provided, constructor will never be called, and may be None.

This entry point is only useful if you plan to either set the BROWSER variable or call get() with a nonempty argument matching the name of a handler you declare.

A number of browser types are predefined. This table gives the type names that may be passed to the get() function and the corresponding instantiations for the controller classes, all defined in this module.

Notes:

1. “Konqueror” is the file manager for the KDE desktop environment for Unix, and only makes sense to use if KDE is running. Some way of reliably detecting KDE would be nice; the KDEDIR variable is not sufficient. Note also that the name “kfm” is used even when using the konqueror command with KDE 2 — the implementation selects the best strategy for running Konqueror.

2. Only on Windows platforms.

3. Only on Mac OS platforms; requires the standard MacPython ic module.

4. Only on Mac OS X platform.

Here are some simple examples:

```python
url = 'http://www.python.org/

# Open URL in a new tab, if a browser window is already open.
webbrowser.open_new_tab(url + 'doc/')

# Open URL in new window, raising the window if possible.
webbrowser.open_new(url)
```
20.1.1. Browser Controller Objects

Browser controllers provide these methods which parallel three of the module-level convenience functions:

```python
controller.open(url[, new=0[, autoraise=True]])
```
Display `url` using the browser handled by this controller. If `new` is 1, a new browser window is opened if possible. If `new` is 2, a new browser page ("tab") is opened if possible.

```python
controller.open_new(url)
```
Open `url` in a new window of the browser handled by this controller, if possible, otherwise, open `url` in the only browser window. Alias `open_new()`.

```python
controller.open_new_tab(url)
```
Open `url` in a new page ("tab") of the browser handled by this controller, if possible, otherwise equivalent to `open_new()`.

*New in version 2.5.*

**Footnotes**

[1] Executables named here without a full path will be searched in the directories given in the **PATH** environment variable.
20.2. *cgi* — Common Gateway Interface support

Support module for Common Gateway Interface (CGI) scripts.

This module defines a number of utilities for use by CGI scripts written in Python.
A CGI script is invoked by an HTTP server, usually to process user input submitted through an HTML `<FORM>` or `<ISINDEX>` element.

Most often, CGI scripts live in the server’s special `cgi-bin` directory. The HTTP server places all sorts of information about the request (such as the client’s hostname, the requested URL, the query string, and lots of other goodies) in the script’s shell environment, executes the script, and sends the script’s output back to the client.

The script’s input is connected to the client too, and sometimes the form data is read this way; at other times the form data is passed via the “query string” part of the URL. This module is intended to take care of the different cases and provide a simpler interface to the Python script. It also provides a number of utilities that help in debugging scripts, and the latest addition is support for file uploads from a form (if your browser supports it).

The output of a CGI script should consist of two sections, separated by a blank line. The first section contains a number of headers, telling the client what kind of data is following. Python code to generate a minimal header section looks like this:

```python
print "Content-Type: text/html" # HTML is following
print # blank line, end of header
```

The second section is usually HTML, which allows the client software to display nicely formatted text with header, in-line images, etc. Here’s Python code that prints a simple piece of HTML:

```python
print "<TITLE>CGI script output</TITLE>"
print "<H1>This is my first CGI script</H1>"
print "Hello, world!"
```
20.2.2. Using the cgi module

Begin by writing `import cgi`. Do not use `from cgi import *` — the module defines all sorts of names for its own use or for backward compatibility that you don’t want in your namespace.

When you write a new script, consider adding these lines:

```python
import cgitb
cgitb.enable()
```

This activates a special exception handler that will display detailed reports in the Web browser if any errors occur. If you’d rather not show the guts of your program to users of your script, you can have the reports saved to files instead, with code like this:

```python
import cgitb
cgitb.enable(display=0, logdir="/tmp")
```

It’s very helpful to use this feature during script development. The reports produced by `cgitb` provide information that can save you a lot of time in tracking down bugs. You can always remove the `cgitb` line later when you have tested your script and are confident that it works correctly.

To get at submitted form data, it’s best to use the `FieldStorage` class. The other classes defined in this module are provided mostly for backward compatibility. Instantiate it exactly once, without arguments. This reads the form contents from standard input or the environment (depending on the value of various environment variables set according to the CGI standard). Since it may consume standard input, it should be instantiated only once.

The `FieldStorage` instance can be indexed like a Python dictionary. It
allows membership testing with the `in` operator, and also supports the standard dictionary method `keys()` and the built-in function `len()`. Form fields containing empty strings are ignored and do not appear in the dictionary; to keep such values, provide a true value for the optional `keep_blank_values` keyword parameter when creating the `FieldStorage` instance.

For instance, the following code (which assumes that the `Content-Type` header and blank line have already been printed) checks that the fields `name` and `addr` are both set to a non-empty string:

```python
form = cgi.FieldStorage()
if "name" not in form or "addr" not in form:
    print "<H1>Error</H1>"
    print "Please fill in the name and addr fields."
    return
print "<p>name:", form["name"].value
print "<p>addr:", form["addr"].value
...further form processing here...
```

Here the fields, accessed through `form[key]`, are themselves instances of `FieldStorage` (or `MiniFieldStorage`, depending on the form encoding). The `value` attribute of the instance yields the string value of the field. The `getValue()` method returns this string value directly; it also accepts an optional second argument as a default to return if the requested key is not present.

If the submitted form data contains more than one field with the same name, the object retrieved by `form[key]` is not a `FieldStorage` or `MiniFieldStorage` instance but a list of such instances. Similarly, in this situation, `form.getValue(key)` would return a list of strings. If you expect this possibility (when your HTML form contains multiple fields with the same name), use the `getlist()` function, which always returns a list of values (so that you do not need to special-case the single item case). For example, this code concatenates any
number of username fields, separated by commas:

```python
value = form.getlist("username")
usernames = ",".join(value)
```

If a field represents an uploaded file, accessing the value via the `value` attribute or the `getvalue()` method reads the entire file in memory as a string. This may not be what you want. You can test for an uploaded file by testing either the `filename` attribute or the `file` attribute. You can then read the data at leisure from the `file` attribute:

```python
fileitem = form["userfile"]
if fileitem.file:
    # It's an uploaded file; count lines
    linecount = 0
    while 1:
        line = fileitem.file.readline()
        if not line: break
        linecount = linecount + 1
```

If an error is encountered when obtaining the contents of an uploaded file (for example, when the user interrupts the form submission by clicking on a Back or Cancel button) the `done` attribute of the object for the field will be set to the value -1.

The file upload draft standard entertains the possibility of uploading multiple files from one field (using a recursive `multipart/*` encoding). When this occurs, the item will be a dictionary-like `FieldStorage` item. This can be determined by testing its `type` attribute, which should be `multipart/form-data` (or perhaps another MIME type matching `multipart/*`). In this case, it can be iterated over recursively just like the top-level form object.

When a form is submitted in the “old” format (as the query string or as a single data part of type `application/x-www-form-urlencoded`), the
items will actually be instances of the class MiniFieldStorage. In this case, the list, file, and filename attributes are always None.

A form submitted via POST that also has a query string will contain both FieldStorage and MiniFieldStorage items.
20.2.3. Higher Level Interface

New in version 2.2.

The previous section explains how to read CGI form data using the FieldStorage class. This section describes a higher level interface which was added to this class to allow one to do it in a more readable and intuitive way. The interface doesn't make the techniques described in previous sections obsolete — they are still useful to process file uploads efficiently, for example.

The interface consists of two simple methods. Using the methods you can process form data in a generic way, without the need to worry whether only one or more values were posted under one name.

In the previous section, you learned to write following code anytime you expected a user to post more than one value under one name:

```python
item = form.getvalue("item")
if isinstance(item, list):
    # The user is requesting more than one item.
else:
    # The user is requesting only one item.
```

This situation is common for example when a form contains a group of multiple checkboxes with the same name:

```html
<input type="checkbox" name="item" value="1" />
<input type="checkbox" name="item" value="2" />
```

In most situations, however, there's only one form control with a particular name in a form and then you expect and need only one value associated with this name. So you write a script containing for example this code:
The problem with the code is that you should never expect that a client will provide valid input to your scripts. For example, if a curious user appends another `user=foo` pair to the query string, then the script would crash, because in this situation the `form.getvalue("user")` method call returns a list instead of a string. Calling the `form.getvalue("user").upper()` method on a list is not valid (since lists do not have a method of this name) and results in an `AttributeError` exception.

Therefore, the appropriate way to read form data values was to always use the code which checks whether the obtained value is a single value or a list of values. That's annoying and leads to less readable scripts.

A more convenient approach is to use the methods `getfirst()` and `getlist()` provided by this higher level interface.

```python
FieldStorage.getfirst(name[, default])
```

This method always returns only one value associated with form field `name`. The method returns only the first value in case that more values were posted under such name. Please note that the order in which the values are received may vary from browser to browser and should not be counted on. [1] If no such form field or value exists then the method returns the value specified by the optional parameter `default`. This parameter defaults to `None` if not specified.

```python
FieldStorage.getlist(name)
```

This method always returns a list of values associated with form field `name`. The method returns an empty list if no such form field or value exists for `name`. It returns a list consisting of one item if only one such value exists.
Using these methods you can write nice compact code:

```python
import cgi
form = cgi.FieldStorage()
user = form.getfirst("user", ").upper()  # This way it's safe
for item in form.getlist("item"):
    do_something(item)
```
20.2.4. Old classes

**Deprecated since version 2.6.**

*SvFormContentDict* stores single value form content as dictionary; it assumes each field name occurs in the form only once.

*FormContentDict* stores multiple value form content as a dictionary (the form items are lists of values). Useful if your form contains multiple fields with the same name.

Other classes (*FormContent*, *InterpFormContentDict*) are present for backwards compatibility with really old applications only.
20.2.5. Functions

These are useful if you want more control, or if you want to employ some of the algorithms implemented in this module in other circumstances.

cgi.parse(fp[, keep_blank_values[, strict_parsing]])

Parse a query in the environment or from a file (the file defaults to sys.stdin). The keep_blank_values and strict_parsing parameters are passed to urlparse.parse_qs() unchanged.

cgi.parse_qs(qs[, keep_blank_values[, strict_parsing]])

This function is deprecated in this module. Use urlparse.parse_qs() instead. It is maintained here only for backward compatibility.

cgi.parse_qsl(qs[, keep_blank_values[, strict_parsing]])

This function is deprecated in this module. Use urlparse.parse_qsl() instead. It is maintained here only for backward compatibility.

cgi.parse_multipart(fp, pdict)

Parse input of type multipart/form-data (for file uploads). Arguments are fp for the input file and pdict for a dictionary containing other parameters in the Content-Type header.

Returns a dictionary just like urlparse.parse_qs() keys are the field names, each value is a list of values for that field. This is easy to use but not much good if you are expecting megabytes to be uploaded — in that case, use the FieldStorage class instead which is much more flexible.
Note that this does not parse nested multipart parts — use FieldStorage for that.

cgi.\texttt{parse\_header}(\texttt{string})
\hspace{1em}
Parse a MIME header (such as \texttt{Content-Type}) into a main value and a dictionary of parameters.

cgi.\texttt{test}()
\hspace{1em}
Robust test CGI script, usable as main program. Writes minimal HTTP headers and formats all information provided to the script in HTML form.

cgi.\texttt{print\_environ}()
\hspace{1em}
Format the shell environment in HTML.

cgi.\texttt{print\_form}(\texttt{form})
\hspace{1em}
Format a form in HTML.

cgi.\texttt{print\_directory}()
\hspace{1em}
Format the current directory in HTML.

cgi.\texttt{print\_environ\_usage}()
\hspace{1em}
Print a list of useful (used by CGI) environment variables in HTML.

cgi.\texttt{escape}(\texttt{s}, \texttt{quote})
\hspace{1em}
Convert the characters '&', '<' and '>' in string \texttt{s} to HTML-safe sequences. Use this if you need to display text that might contain such characters in HTML. If the optional flag \texttt{quote} is true, the quotation mark character (""') is also translated; this helps for inclusion in an HTML attribute value, as in \texttt{<A HREF="..."}>. If the value to be quoted might include single- or double-quote characters, or both, consider using the \texttt{quoteattr()} function in the \texttt{xml.sax.saxutils} module instead.
20.2.6. Caring about security

There's one important rule: if you invoke an external program (via the `os.system()` or `os.popen()` functions, or others with similar functionality), make very sure you don't pass arbitrary strings received from the client to the shell. This is a well-known security hole whereby clever hackers anywhere on the Web can exploit a gullible CGI script to invoke arbitrary shell commands. Even parts of the URL or field names cannot be trusted, since the request doesn't have to come from your form!

To be on the safe side, if you must pass a string gotten from a form to a shell command, you should make sure the string contains only alphanumeric characters, dashes, underscores, and periods.
20.2.7. Installing your CGI script on a Unix system

Read the documentation for your HTTP server and check with your local system administrator to find the directory where CGI scripts should be installed; usually this is in a directory `cgi-bin` in the server tree.

Make sure that your script is readable and executable by “others”; the Unix file mode should be 0755 octal (use `chmod 0755 filename`). Make sure that the first line of the script contains `#!` starting in column 1 followed by the pathname of the Python interpreter, for instance:

```
#!/usr/local/bin/python
```

Make sure the Python interpreter exists and is executable by “others”.

Make sure that any files your script needs to read or write are readable or writable, respectively, by “others” — their mode should be 0644 for readable and 0666 for writable. This is because, for security reasons, the HTTP server executes your script as user “nobody”, without any special privileges. It can only read (write, execute) files that everybody can read (write, execute). The current directory at execution time is also different (it is usually the server’s cgi-bin directory) and the set of environment variables is also different from what you get when you log in. In particular, don’t count on the shell’s search path for executables (PATH) or the Python module search path (PYTHONPATH) to be set to anything interesting.

If you need to load modules from a directory which is not on Python’s
default module search path, you can change the path in your script, before importing other modules. For example:

```python
import sys
sys.path.insert(0, "/usr/home/joe/lib/python")
sys.path.insert(0, "/usr/local/lib/python")
```

(This way, the directory inserted last will be searched first!)

Instructions for non-Unix systems will vary; check your HTTP server's documentation (it will usually have a section on CGI scripts).
20.2.8. Testing your CGI script

Unfortunately, a CGI script will generally not run when you try it from the command line, and a script that works perfectly from the command line may fail mysteriously when run from the server. There's one reason why you should still test your script from the command line: if it contains a syntax error, the Python interpreter won't execute it at all, and the HTTP server will most likely send a cryptic error to the client.

Assuming your script has no syntax errors, yet it does not work, you have no choice but to read the next section.
20.2.9. Debugging CGI scripts

First of all, check for trivial installation errors — reading the section above on installing your CGI script carefully can save you a lot of time. If you wonder whether you have understood the installation procedure correctly, try installing a copy of this module file (cgi.py) as a CGI script. When invoked as a script, the file will dump its environment and the contents of the form in HTML form. Give it the right mode etc, and send it a request. If it's installed in the standard cgi-bin directory, it should be possible to send it a request by entering a URL into your browser of the form:

```
http://yourhostname/cgi-bin/cgi.py?name=Joe+Blow&addr=At+Home
```

If this gives an error of type 404, the server cannot find the script – perhaps you need to install it in a different directory. If it gives another error, there's an installation problem that you should fix before trying to go any further. If you get a nicely formatted listing of the environment and form content (in this example, the fields should be listed as “addr” with value “At Home” and “name” with value “Joe Blow”), thecgi.py script has been installed correctly. If you follow the same procedure for your own script, you should now be able to debug it.

The next step could be to call the **cgi** module's `test()` function from your script: replace its main code with the single statement

```
cgi.test()
```

This should produce the same results as those gotten from installing the **cgi.py** file itself.

When an ordinary Python script raises an unhandled exception (for
whatever reason: of a typo in a module name, a file that can’t be opened, etc.), the Python interpreter prints a nice traceback and exits. While the Python interpreter will still do this when your CGI script raises an exception, most likely the traceback will end up in one of the HTTP server’s log files, or be discarded altogether.

Fortunately, once you have managed to get your script to execute some code, you can easily send tracebacks to the Web browser using the cgitb module. If you haven’t done so already, just add the lines:

```python
import cgitb
cgitb.enable()
```

to the top of your script. Then try running it again; when a problem occurs, you should see a detailed report that will likely make apparent the cause of the crash.

If you suspect that there may be a problem in importing the cgitb module, you can use an even more robust approach (which only uses built-in modules):

```python
import sys
sys.stderr = sys.stdout
print "Content-Type: text/plain"
print "...your code here..."
```

This relies on the Python interpreter to print the traceback. The content type of the output is set to plain text, which disables all HTML processing. If your script works, the raw HTML will be displayed by your client. If it raises an exception, most likely after the first two lines have been printed, a traceback will be displayed. Because no HTML interpretation is going on, the traceback will be readable.
Most HTTP servers buffer the output from CGI scripts until the script is completed. This means that it is not possible to display a progress report on the client's display while the script is running.

- Check the installation instructions above.
- Check the HTTP server's log files. (tail -f logfile in a separate window may be useful!)
- Always check a script for syntax errors first, by doing something like python script.py.
- If your script does not have any syntax errors, try adding import cgitb; cgitb.enable() to the top of the script.
- When invoking external programs, make sure they can be found. Usually, this means using absolute path names — PATH is usually not set to a very useful value in a CGI script.
- When reading or writing external files, make sure they can be read or written by the userid under which your CGI script will be running: this is typically the userid under which the web server is running, or some explicitly specified userid for a web server's suexec feature.
- Don't try to give a CGI script a set-uid mode. This doesn't work on most systems, and is a security liability as well.

Footnotes

Note that some recent versions of the HTML specification do state what order the field values should be supplied in, but knowing whether a request was received from a conforming browser, or even from a browser at all, is tedious and error-prone.
20.3. cgitb — Traceback manager for CGI scripts

New in version 2.2.

The cgitb module provides a special exception handler for Python scripts. (Its name is a bit misleading. It was originally designed to display extensive traceback information in HTML for CGI scripts. It was later generalized to also display this information in plain text.) After this module is activated, if an uncaught exception occurs, a detailed, formatted report will be displayed. The report includes a traceback showing excerpts of the source code for each level, as well as the values of the arguments and local variables to currently running functions, to help you debug the problem. Optionally, you can save this information to a file instead of sending it to the browser.

To enable this feature, simply add this to the top of your CGI script:

```python
import cgitb
cgitb.enable()
```

The options to the `enable()` function control whether the report is displayed in the browser and whether the report is logged to a file for later analysis.

```python
cgitb.enable([display[, logdir[, context[, format]]]])
```

This function causes the cgitb module to take over the interpreter’s default handling for exceptions by setting the value of `sys.excepthook`.

The optional argument `display` defaults to 1 and can be set to 0 to suppress sending the traceback to the browser. If the
argument *logdir* is present, the traceback reports are written to files. The value of *logdir* should be a directory where these files will be placed. The optional argument *context* is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5. If the optional argument *format* is "html", the output is formatted as HTML. Any other value forces plain text output. The default value is "html".

```python
cgitb.handler([info])
```

This function handles an exception using the default settings (that is, show a report in the browser, but don’t log to a file). This can be used when you’ve caught an exception and want to report it using cgitb. The optional *info* argument should be a 3-tuple containing an exception type, exception value, and traceback object, exactly like the tuple returned by `sys.exc_info()`. If the *info* argument is not supplied, the current exception is obtained from `sys.exc_info()`.
New in version 2.5.

The Web Server Gateway Interface (WSGI) is a standard interface between web server software and web applications written in Python. Having a standard interface makes it easy to use an application that supports WSGI with a number of different web servers.

Only authors of web servers and programming frameworks need to know every detail and corner case of the WSGI design. You don’t need to understand every detail of WSGI just to install a WSGI application or to write a web application using an existing framework.

wsgiref is a reference implementation of the WSGI specification that can be used to add WSGI support to a web server or framework. It provides utilities for manipulating WSGI environment variables and response headers, base classes for implementing WSGI servers, a demo HTTP server that serves WSGI applications, and a validation tool that checks WSGI servers and applications for conformance to the WSGI specification (PEP 333).

See http://www.wsgi.org for more information about WSGI, and links to tutorials and other resources.
20.4.1. wsgiref.util – WSGI environment utilities

This module provides a variety of utility functions for working with WSGI environments. A WSGI environment is a dictionary containing HTTP request variables as described in PEP 333. All of the functions taking an `environ` parameter expect a WSGI-compliant dictionary to be supplied; please see PEP 333 for a detailed specification.

**wsgiref.util.guess_scheme**(`environ`)

Return a guess for whether `wsgi.url_scheme` should be “http” or “https”, by checking for a `HTTPS` environment variable in the `environ` dictionary. The return value is a string.

This function is useful when creating a gateway that wraps CGI or a CGI-like protocol such as FastCGI. Typically, servers providing such protocols will include a `HTTPS` variable with a value of “1” “yes”, or “on” when a request is received via SSL. So, this function returns “https” if such a value is found, and “http” otherwise.

**wsgiref.util.request_uri**(`environ[, include_query=1]`)

Return the full request URI, optionally including the query string, using the algorithm found in the “URL Reconstruction” section of PEP 333. If `include_query` is false, the query string is not included in the resulting URI.

**wsgiref.util.application_uri**(`environ`)

Similar to `request_uri()`, except that the `PATH_INFO` and `QUERY_STRING` variables are ignored. The result is the base URI of the application object addressed by the request.
wsgiref.util.shift_path_info(environ)

Shift a single name from PATH_INFO to SCRIPT_NAME and return the name. The environ dictionary is modified in-place; use a copy if you need to keep the original PATH_INFO or SCRIPT_NAME intact.

If there are no remaining path segments in PATH_INFO, None is returned.

Typically, this routine is used to process each portion of a request URI path, for example to treat the path as a series of dictionary keys. This routine modifies the passed-in environment to make it suitable for invoking another WSGI application that is located at the target URI. For example, if there is a WSGI application at /foo, and the request URI path is /foo/bar/baz, and the WSGI application at /foo calls shift_path_info(), it will receive the string “bar”, and the environment will be updated to be suitable for passing to a WSGI application at /foo/bar. That is, SCRIPT_NAME will change from /foo to /foo/bar, and PATH_INFO will change from /bar/baz to /baz.

When PATH_INFO is just a “/”, this routine returns an empty string and appends a trailing slash to SCRIPT_NAME, even though empty path segments are normally ignored, and SCRIPT_NAME doesn’t normally end in a slash. This is intentional behavior, to ensure that an application can tell the difference between URIs ending in /x from ones ending in /x/ when using this routine to do object traversal.

wsgiref.util.setup_testing_defaults(environ)

Update environ with trivial defaults for testing purposes.

This routine adds various parameters required for WSGI, including HTTP_HOST, SERVER_NAME, SERVER_PORT, REQUEST_METHOD,
SCRIPT_NAME, PATH_INFO, and all of the PEP 333-defined wsgi.* variables. It only supplies default values, and does not replace any existing settings for these variables.

This routine is intended to make it easier for unit tests of WSGI servers and applications to set up dummy environments. It should NOT be used by actual WSGI servers or applications, since the data is fake!

Example usage:

```python
from wsgiref.util import setup_testing_defaults
from wsgiref.simple_server import make_server

# A relatively simple WSGI application. It's going to print
# environment dictionary after being updated by setup_testing_defaults

def simple_app(environ, start_response):
    setup_testing_defaults(environ)

    status = '200 OK'
    headers = [('Content-type', 'text/plain')]

    start_response(status, headers)

    ret = ['%s: %s
' % (key, value)
           for key, value in environ.iteritems()]

    return ret

httpd = make_server('', 8000, simple_app)
print "Serving on port 8000..."
httpd.serve_forever()
```

In addition to the environment functions above, the wsgiref.util module also provides these miscellaneous utilities:

wsgiref.util.is_hop_by_hop(header_name)

Return true if ‘header_name’ is an HTTP/1.1 “Hop-by-Hop” header, as defined by RFC 2616.
class wsgiref.util.FileWrapper(filelike[, blksize=8192])

A wrapper to convert a file-like object to an iterator. The resulting objects support both __getitem__() and __iter__() iteration styles, for compatibility with Python 2.1 and Jython. As the object is iterated over, the optional blksize parameter will be repeatedly passed to the filelike object's read() method to obtain strings to yield. When read() returns an empty string, iteration is ended and is not resumable.

If filelike has a close() method, the returned object will also have a close() method, and it will invoke the filelike object's close() method when called.

Example usage:

```python
from StringIO import StringIO
from wsgiref.util import FileWrapper

# We're using a StringIO-buffer for as the file-like object
filelike = StringIO("This is an example file-like object"*10)
wrapper = FileWrapper(filelike, blksize=5)

for chunk in wrapper:
    print chunk
```
20.4.2. wsgiref.headers – WSGI response header tools

This module provides a single class, `Headers`, for convenient manipulation of WSGI response headers using a mapping-like interface.

```python
class wsgiref.headers.Headers(headers)
```

Create a mapping-like object wrapping `headers`, which must be a list of header name/value tuples as described in PEP 333. Any changes made to the new `Headers` object will directly update the `headers` list it was created with.

`Headers` objects support typical mapping operations including `__getitem__()`, `get()`, `__setitem__()`, `setdefault()`, `__delitem__()`, `__contains__()` and `has_key()`. For each of these methods, the key is the header name (treated case-insensitively), and the value is the first value associated with that header name. Setting a header deletes any existing values for that header, then adds a new value at the end of the wrapped header list. Headers' existing order is generally maintained, with new headers added to the end of the wrapped list.

Unlike a dictionary, `Headers` objects do not raise an error when you try to get or delete a key that isn’t in the wrapped header list. Getting a nonexistent header just returns `None`, and deleting a nonexistent header does nothing.

`Headers` objects also support `keys()`, `values()`, and `items()` methods. The lists returned by `keys()` and `items()` can include the same key more than once if there is a multi-valued header. The `len()` of a `Headers` object is the same as the length of its
items(), which is the same as the length of the wrapped header list. In fact, the items() method just returns a copy of the wrapped header list.

Calling str() on a Headers object returns a formatted string suitable for transmission as HTTP response headers. Each header is placed on a line with its value, separated by a colon and a space. Each line is terminated by a carriage return and line feed, and the string is terminated with a blank line.

In addition to their mapping interface and formatting features, Headers objects also have the following methods for querying and adding multi-valued headers, and for adding headers with MIME parameters:

get_all(name)

Return a list of all the values for the named header.

The returned list will be sorted in the order they appeared in the original header list or were added to this instance, and may contain duplicates. Any fields deleted and re-inserted are always appended to the header list. If no fields exist with the given name, returns an empty list.

add_header(name, value, **params)

Add a (possibly multi-valued) header, with optional MIME parameters specified via keyword arguments.

del the header field to add. Keyword arguments can be used to set MIME parameters for the header field. Each parameter must be a string or None. Underscores in parameter names are converted to dashes, since dashes are illegal in Python identifiers, but many MIME parameter names include dashes. If the parameter value is a string, it is added to the header value parameters in the form name="value". If it
is `None`, only the parameter name is added. (This is used for MIME parameters without a value.) Example usage:

```python
h.add_header('content-disposition', 'attachment', filename='bud.gif')
```

The above will add a header that looks like this:

```
Content-Disposition: attachment; filename="bud.gif"
```
20.4.3. wsgiref.simple_server – a simple WSGI HTTP server

This module implements a simple HTTP server (based on BaseHTTPServer) that serves WSGI applications. Each server instance serves a single WSGI application on a given host and port. If you want to serve multiple applications on a single host and port, you should create a WSGI application that parses **PATH_INFO** to select which application to invoke for each request. (E.g., using the `shift_path_info()` function from wsgiref.util.)

```python
wsgiref.simple_server.make_server(host, port, app[, server_class=WSGIServer[, handler_class=WSGIRequestHandler]])
```

Create a new WSGI server listening on host and port, accepting connections for app. The return value is an instance of the supplied server_class, and will process requests using the specified handler_class. app must be a WSGI application object, as defined by PEP 333.

Example usage:

```python
from wsgiref.simple_server import make_server, demo_app

httpd = make_server('', 8000, demo_app)
print "Serving HTTP on port 8000..."

# Respond to requests until process is killed
httpd.serve_forever()

# Alternative: serve one request, then exit
httpd.handle_request()

wsgiref.simple_server.demo_app(environ, start_response)
```
This function is a small but complete WSGI application that returns a text page containing the message “Hello world!” and a list of the key/value pairs provided in the `environ` parameter. It’s useful for verifying that a WSGI server (such as `wsgiref.simple_server`) is able to run a simple WSGI application correctly.

```python
class wsgiref.simple_server.WSGIServer(server_address, RequestHandlerClass)
```

Create a `WSGIServer` instance. `server_address` should be a `(host, port)` tuple, and `RequestHandlerClass` should be the subclass of `BaseHTTPServer.BaseHTTPRequestHandler` that will be used to process requests.

You do not normally need to call this constructor, as the `make_server()` function can handle all the details for you.

`WSGIServer` is a subclass of `BaseHTTPServer.HTTPServer`, so all of its methods (such as `serve_forever()` and `handle_request()`) are available. `WSGIServer` also provides these WSGI-specific methods:

```python
set_app(application)
```

Sets the callable `application` as the WSGI application that will receive requests.

```python
get_app()
```

Returns the currently-set application callable.

Normally, however, you do not need to use these additional methods, as `set_app()` is normally called by `make_server()`, and the `get_app()` exists mainly for the benefit of request handler instances.
class wsgiref.simple_server.WSGIRequestHandler(request, client_address, server)

Create an HTTP handler for the given request (i.e. a socket), client_address (a (host, port) tuple), and server (WSGIServer instance).

You do not need to create instances of this class directly; they are automatically created as needed by WSGIServer objects. You can, however, subclass this class and supply it as a handler_class to the make_server() function. Some possibly relevant methods for overriding in subclasses:

get_environ()
Returns a dictionary containing the WSGI environment for a request. The default implementation copies the contents of the WSGIServer object’s base_environ dictionary attribute and then adds various headers derived from the HTTP request. Each call to this method should return a new dictionary containing all of the relevant CGI environment variables as specified in PEP 333.

get_stderr()
Return the object that should be used as the wsgi.errors stream. The default implementation just returns sys.stderr.

handle()
Process the HTTP request. The default implementation creates a handler instance using a wsgiref.handlers class to implement the actual WSGI application interface.
20.4.4. wsgiref.validate — WSGI conformance checker

When creating new WSGI application objects, frameworks, servers, or middleware, it can be useful to validate the new code’s conformance using `wsgiref.validate`. This module provides a function that creates WSGI application objects that validate communications between a WSGI server or gateway and a WSGI application object, to check both sides for protocol conformance.

Note that this utility does not guarantee complete PEP 333 compliance; an absence of errors from this module does not necessarily mean that errors do not exist. However, if this module does produce an error, then it is virtually certain that either the server or application is not 100% compliant.

This module is based on the `paste.lint` module from Ian Bicking’s “Python Paste” library.

```python
wsgiref.validate.validator(application)
```

Wrap `application` and return a new WSGI application object. The returned application will forward all requests to the original `application`, and will check that both the `application` and the server invoking it are conforming to the WSGI specification and to RFC 2616.

Any detected nonconformance results in an `AssertionError` being raised; note, however, that how these errors are handled is server-dependent. For example, `wsgiref.simple_server` and other servers based on `wsgiref.handlers` (that don’t override the error handling methods to do something else) will simply output a message that an error has occurred, and dump the traceback to
sys.stderr or some other error stream.

This wrapper may also generate output using the `warnings` module to indicate behaviors that are questionable but which may not actually be prohibited by PEP 333. Unless they are suppressed using Python command-line options or the `warnings` API, any such warnings will be written to `sys.stderr` (not `wsgi.errors`, unless they happen to be the same object).

Example usage:

```python
from wsgiref.validate import validator
from wsgiref.simple_server import make_server

# Our callable object which is intentionally not compliant to the standard, so the validator is going to break
def simple_app(environ, start_response):
    status = '200 OK'  # HTTP Status
    headers = [('Content-type', 'text/plain')]  # HTTP Header
    start_response(status, headers)

    # This is going to break because we need to return a list
    # the validator is going to inform us
    return "Hello World"

# This is the application wrapped in a validator
validator_app = validator(simple_app)

httpd = make_server('', 8000, validator_app)
print "Listening on port 8000...."
httpd.serve_forever()
```
20.4.5. `wsgiref.handlers` — server/gateway base classes

This module provides base handler classes for implementing WSGI servers and gateways. These base classes handle most of the work of communicating with a WSGI application, as long as they are given a CGI-like environment, along with input, output, and error streams.

```python
class wsgiref.handlers.CGIHandler

CGI-based invocation via `sys.stdin`, `sys.stdout`, `sys.stderr` and `os.environ`. This is useful when you have a WSGI application and want to run it as a CGI script. Simply invoke `CGIHandler().run(app)`, where `app` is the WSGI application object you wish to invoke.

This class is a subclass of `BaseCGIHandler` that sets `wsgi.run_once` to `true`, `wsgi.multithread` to `false`, and `wsgi.multiprocess` to `true`, and always uses `sys` and `os` to obtain the necessary CGI streams and environment.
```
```
```python
class wsgiref.handlers.BaseCGIHandler(stdin, stdout, stderr, environ[, multithread=True[, multiprocess=False]])
```

Similar to `CGIHandler`, but instead of using the `sys` and `os` modules, the CGI environment and I/O streams are specified explicitly. The `multithread` and `multiprocess` values are used to set the `wsgi.multithread` and `wsgi.multiprocess` flags for any applications run by the handler instance.

This class is a subclass of `SimpleHandler` intended for use with software other than HTTP “origin servers”. If you are writing a gateway protocol implementation (such as CGI, FastCGI, SCGI, etc.) that uses a `status:` header to send an HTTP status, you
probably want to subclass this instead of `SimpleHandler`.

```python
class wsgiref.handlers.SimpleHandler(stdin, stdout, stderr, environ[, multithread=True[, multiprocessing=False]])
```

This class is a subclass of `BaseHandler`. It overrides the `__init__`, `get_stdin`, `get_stderr`, `add_cgi_vars`, `_write`, and `_flush` methods to support explicitly setting the environment and streams via the constructor. The supplied environment and streams are stored in the `stdin`, `stdout`, `stderr`, and `environ` attributes.

```python
class wsgiref.handlers.BaseHandler
```

This is an abstract base class for running WSGI applications. Each instance will handle a single HTTP request, although in principle you could create a subclass that was reusable for multiple requests.

`BaseHandler` instances have only one method intended for external use:

```python
run(app)
```

Run the specified WSGI application, `app`.

All of the other `BaseHandler` methods are invoked by this method in the process of running the application, and thus exist primarily to allow customizing the process.

The following methods MUST be overridden in a subclass:

```python
_write(data)
```
Buffer the string `data` for transmission to the client. It's okay if this method actually transmits the data; `BaseHandler` just separates write and flush operations for greater efficiency when the underlying system actually has such a distinction.

`_flush()`
Force buffered data to be transmitted to the client. It's okay if this method is a no-op (i.e., if `_write()` actually sends the data).

`get_stdin()`
Return an input stream object suitable for use as the `wsgi.input` of the request currently being processed.

`get_stderr()`
Return an output stream object suitable for use as the `wsgi.errors` of the request currently being processed.

`add_cgi_vars()`
Insert CGI variables for the current request into the `environ` attribute.

Here are some other methods and attributes you may wish to override. This list is only a summary, however, and does not include every method that can be overridden. You should consult the docstrings and source code for additional information before attempting to create a customized `BaseHandler` subclass.

Attributes and methods for customizing the WSGI environment:

`wsgi_multithread`
The value to be used for the `wsgi.multithread` environment variable. It defaults to true in `BaseHandler`, but may have a different default (or be set by the constructor) in the other subclasses.
wsgi_multiprocess

The value to be used for the `wsgi.multiprocess` environment variable. It defaults to true in `BaseHandler`, but may have a different default (or be set by the constructor) in the other subclasses.

wsgi_run_once

The value to be used for the `wsgi.run_once` environment variable. It defaults to false in `BaseHandler`, but `CGIHandler` sets it to true by default.

os_environ

The default environment variables to be included in every request’s WSGI environment. By default, this is a copy of `os.environ` at the time that `wsgiref.handlers` was imported, but subclasses can either create their own at the class or instance level. Note that the dictionary should be considered read-only, since the default value is shared between multiple classes and instances.

server_software

If the `origin_server` attribute is set, this attribute's value is used to set the default `SERVER_SOFTWARE` WSGI environment variable, and also to set a default `Server:` header in HTTP responses. It is ignored for handlers (such as `BaseCGIHandler` and `CGIHandler`) that are not HTTP origin servers.

get_scheme()

Return the URL scheme being used for the current request. The default implementation uses the `guess_scheme()` function from `wsgiref.util` to guess whether the scheme should be “http” or “https”, based on the current request’s `environ` variables.

setup_environ()
Set the `environ` attribute to a fully-populated WSGI environment. The default implementation uses all of the above methods and attributes, plus the `get_stdin()`, `get_stderr()`, and `add_cgi_vars()` methods and the `wsgi_file_wrapper` attribute. It also inserts a `SERVER_SOFTWARE` key if not present, as long as the `origin_server` attribute is a true value and the `server_software` attribute is set.

Methods and attributes for customizing exception handling:

```python
log_exception(exc_info)
```
Log the `exc_info` tuple in the server log. `exc_info` is a `(type, value, traceback)` tuple. The default implementation simply writes the traceback to the request's `wsgi.errors` stream and flushes it. Subclasses can override this method to change the format or retarget the output, mail the traceback to an administrator, or whatever other action may be deemed suitable.

```python
traceback_limit
```
The maximum number of frames to include in tracebacks output by the default `log_exception()` method. If None, all frames are included.

```python
error_output(environ, start_response)
```
This method is a WSGI application to generate an error page for the user. It is only invoked if an error occurs before headers are sent to the client.

This method can access the current error information using `sys.exc_info()`, and should pass that information to `start_response` when calling it (as described in the “Error Handling” section of PEP 333).
The default implementation just uses the `error_status`, `error_headers`, and `error_body` attributes to generate an output page. Subclasses can override this to produce more dynamic error output.

Note, however, that it's not recommended from a security perspective to spit out diagnostics to any old user; ideally, you should have to do something special to enable diagnostic output, which is why the default implementation doesn’t include any.

**error_status**
The HTTP status used for error responses. This should be a status string as defined in PEP 333; it defaults to a 500 code and message.

**error_headers**
The HTTP headers used for error responses. This should be a list of WSGI response headers `((name, value) tuples)`, as described in PEP 333. The default list just sets the content type to `text/plain`.

**error_body**
The error response body. This should be an HTTP response body string. It defaults to the plain text, “A server error occurred. Please contact the administrator.”

Methods and attributes for PEP 333's “Optional Platform-Specific File Handling” feature:

**wsgi_file_wrapper**
A `wsgi.file_wrapper` factory, or `None`. The default value of this attribute is the `FileWrapper` class from `wsgiref.util`.

**sendfile()**
Override to implement platform-specific file transmission. This
method is called only if the application's return value is an instance of the class specified by the \texttt{wsgi\_file\_wrapper} attribute. It should return a true value if it was able to successfully transmit the file, so that the default transmission code will not be executed. The default implementation of this method just returns a false value.

Miscellaneous methods and attributes:

\textbf{origin\_server}

This attribute should be set to a true value if the handler's \texttt{\_write()} and \texttt{\_flush()} are being used to communicate directly to the client, rather than via a CGI-like gateway protocol that wants the HTTP status in a special Status: header.

This attribute's default value is true in \texttt{BaseHandler}, but false in \texttt{BaseCGIHandler} and \texttt{CGIHandler}.

\textbf{http\_version}

If \texttt{origin\_server} is true, this string attribute is used to set the HTTP version of the response set to the client. It defaults to "1.0".
20.4.6. Examples

This is a working “Hello World” WSGI application:

```python
from wsgiref.simple_server import make_server

def hello_world_app(environ, start_response):
    status = '200 OK'  # HTTP Status
    headers = [('Content-type', 'text/plain')]  # HTTP Headers

    start_response(status, headers)

    # The returned object is going to be printed
    return ['Hello World']

httpd = make_server('', 8000, hello_world_app)
print "Serving on port 8000..."

# Serve until process is killed
httpd.serve_forever()
```
20.5. `urllib` — Open arbitrary resources by URL

**Note:** The `urllib` module has been split into parts and renamed in Python 3.0 to `urllib.request`, `urllib.parse`, and `urllib.error`. The `2to3` tool will automatically adapt imports when converting your sources to 3.0. Also note that the `urllib.urlopen()` function has been removed in Python 3.0 in favor of `urllib2.urlopen()`.

This module provides a high-level interface for fetching data across the World Wide Web. In particular, the `urlopen()` function is similar to the built-in function `open()`, but accepts Universal Resource Locators (URLs) instead of filenames. Some restrictions apply — it can only open URLs for reading, and no seek operations are available.
20.5.1. High-level interface

```
urllib.urlopen(url[, data[, proxies]])
```

Open a network object denoted by a URL for reading. If the URL does not have a scheme identifier, or if it has `file:` as its scheme identifier, this opens a local file (without universal newlines); otherwise it opens a socket to a server somewhere on the network. If the connection cannot be made the `IOError` exception is raised. If all went well, a file-like object is returned. This supports the following methods: `read()`, `readline()`, `readlines()`, `fileno()`, `close()`, `info()`, `getcode()` and `geturl()`. It also has proper support for the `iterator` protocol. One caveat: the `read()` method, if the size argument is omitted or negative, may not read until the end of the data stream; there is no good way to determine that the entire stream from a socket has been read in the general case.

Except for the `info()`, `getcode()` and `geturl()` methods, these methods have the same interface as for file objects — see section `File Objects` in this manual. (It is not a built-in file object, however, so it can’t be used at those few places where a true built-in file object is required.)

The `info()` method returns an instance of the class `mimetools.Message` containing meta-information associated with the URL. When the method is HTTP, these headers are those returned by the server at the head of the retrieved HTML page (including Content-Length and Content-Type). When the method is FTP, a Content-Length header will be present if (as is now usual) the server passed back a file length in response to the FTP retrieval request. A Content-Type header will be present if the MIME type can be guessed. When the method is local-file,
returned headers will include a Date representing the file’s last-modified time, a Content-Length giving file size, and a Content-Type containing a guess at the file’s type. See also the description of the `mimetypes` module.

The `geturl()` method returns the real URL of the page. In some cases, the HTTP server redirects a client to another URL. The `urlopen()` function handles this transparently, but in some cases the caller needs to know which URL the client was redirected to. The `geturl()` method can be used to get at this redirected URL.

The `getcode()` method returns the HTTP status code that was sent with the response, or `None` if the URL is no HTTP URL.

If the `url` uses the `http:` scheme identifier, the optional `data` argument may be given to specify a `POST` request (normally the request type is `GET`). The `data` argument must be in standard `application/x-www-form-urlencoded` format; see the `urlencode()` function below.

The `urlopen()` function works transparently with proxies which do not require authentication. In a Unix or Windows environment, set the `http_proxy`, or `ftp_proxy` environment variables to a URL that identifies the proxy server before starting the Python interpreter. For example (the '%' is the command prompt):

```bash
% http_proxy="http://www.someproxy.com:3128"
% export http_proxy
% python
...
```

The `no_proxy` environment variable can be used to specify hosts which shouldn't be reached via proxy; if set, it should be a comma-separated list of hostname suffixes, optionally with :port appended, for example `cern.ch,ncsa.uiuc.edu,some.host:8080`. 
In a Windows environment, if no proxy environment variables are set, proxy settings are obtained from the registry's Internet Settings section.

In a Mac OS X environment, `urlopen()` will retrieve proxy information from the OS X System Configuration Framework, which can be managed with Network System Preferences panel.

Alternatively, the optional `proxies` argument may be used to explicitly specify proxies. It must be a dictionary mapping scheme names to proxy URLs, where an empty dictionary causes no proxies to be used, and `None` (the default value) causes environmental proxy settings to be used as discussed above. For example:

```python
# Use http://www.someproxy.com:3128 for http proxying
proxies = {'http': 'http://www.someproxy.com:3128'}
filehandle = urllib.urlopen(some_url, proxies=proxies)
# Don't use any proxies
filehandle = urllib.urlopen(some_url, proxies={})
# Use proxies from environment - both versions are equivalent
filehandle = urllib.urlopen(some_url, proxies=None)
filehandle = urllib.urlopen(some_url)
```

Proxies which require authentication for use are not currently supported; this is considered an implementation limitation.

*Changed in version 2.3:* Added the `proxies` support.

*Changed in version 2.6:* Added `getcode()` to returned object and support for the `no_proxy` environment variable.

*Deprecated since version 2.6:* The `urlopen()` function has been removed in Python 3.0 in favor of `urllib2.urlopen()`.

```
urllib.urlretrieve(url[, filename[, reporthook[, data]]]])
```
Copy a network object denoted by a URL to a local file, if necessary. If the URL points to a local file, or a valid cached copy of the object exists, the object is not copied. Return a tuple (filename, headers) where filename is the local file name under which the object can be found, and headers is whatever the info() method of the object returned by urlopen() returned (for a remote object, possibly cached). Exceptions are the same as for urlopen().

The second argument, if present, specifies the file location to copy to (if absent, the location will be a tempfile with a generated name). The third argument, if present, is a hook function that will be called once on establishment of the network connection and once after each block read thereafter. The hook will be passed three arguments; a count of blocks transferred so far, a block size in bytes, and the total size of the file. The third argument may be -1 on older FTP servers which do not return a file size in response to a retrieval request.

If the url uses the http: scheme identifier, the optional data argument may be given to specify a POST request (normally the request type is GET). The data argument must in standard application/x-www-form-urlencoded format; see the urlencode() function below.

Changed in version 2.5: urlretrieve() will raise ContentTooShortError when it detects that the amount of data available was less than the expected amount (which is the size reported by a Content-Length header). This can occur, for example, when the download is interrupted.

The Content-Length is treated as a lower bound: if there’s more data to read, urlretrieve reads more data, but if less data is available, it raises the exception.
You can still retrieve the downloaded data in this case, it is stored in the `content` attribute of the exception instance.

If no `Content-Length` header was supplied, `urlretrieve` can not check the size of the data it has downloaded, and just returns it. In this case you just have to assume that the download was successful.

`urllib._urlopener`

The public functions `urlopen()` and `urlretrieve()` create an instance of the `FancyURLopener` class and use it to perform their requested actions. To override this functionality, programmers can create a subclass of `URLopener` or `FancyURLopener`, then assign an instance of that class to the `urllib._urlopener` variable before calling the desired function. For example, applications may want to specify a different `User-Agent` header than `URLopener` defines. This can be accomplished with the following code:

```python
import urllib

class AppURLopener(urllib.FancyURLopener):
    version = "App/1.7"

urllib._urlopener = AppURLopener()
```

`urllib.urlcleanup()`

Clear the cache that may have been built up by previous calls to `urlretrieve()`.
20.5.2. Utility functions

urllib.quote(string[, safe])

Replace special characters in string using the %xx escape. Letters, digits, and the characters '_.-' are never quoted. By default, this function is intended for quoting the path section of the URL. The optional safe parameter specifies additional characters that should not be quoted — its default value is '/'.

Example: `quote('/~connolly/')` yields '/%7econnolly/'

urllib.quote_plus(string[, safe])

Like quote(), but also replaces spaces by plus signs, as required for quoting HTML form values when building up a query string to go into a URL. Plus signs in the original string are escaped unless they are included in safe. It also does not have safe default to '/'.

urllib.unquote(string)

Replace %xx escapes by their single-character equivalent.

Example: `unquote('/%7Econnolly/')` yields '/~connolly/'

urllib.unquote_plus(string)

Like unquote(), but also replaces plus signs by spaces, as required for unquoting HTML form values.

urllib.urlencode(query[, doseq])

Convert a mapping object or a sequence of two-element tuples to a “url-encoded” string, suitable to pass to urlopen() above as the optional data argument. This is useful to pass a dictionary of form
fields to a `post` request. The resulting string is a series of `key=value` pairs separated by `&` characters, where both `key` and `value` are quoted using `quote_plus()` above. When a sequence of two-element tuples is used as the `query` argument, the first element of each tuple is a key and the second is a value. The value element in itself can be a sequence and in that case, if the optional parameter `doseq` is evaluates to `True`, individual `key=value` pairs separated by `&` are generated for each element of the value sequence for the key. The order of parameters in the encoded string will match the order of parameter tuples in the sequence. The `urllib.parse` module provides the functions `parse_qs()` and `parse_qsl()` which are used to parse query strings into Python data structures.

`urllib.pathname2url(path)`

Convert the pathname `path` from the local syntax for a path to the form used in the path component of a URL. This does not produce a complete URL. The return value will already be quoted using the `quote()` function.

`urllib.url2pathname(path)`

Convert the path component `path` from an encoded URL to the local syntax for a path. This does not accept a complete URL. This function uses `unquote()` to decode `path`.

`urllib.getproxies()`

This helper function returns a dictionary of scheme to proxy server URL mappings. It scans the environment for variables named `<scheme>_proxy` for all operating systems first, and when it cannot find it, looks for proxy information from Mac OSX System Configuration for Mac OS X and Windows Systems Registry for Windows.
20.5.3. URL Opener objects

```python
class urllib.URLopener([proxies, **x509])
```

Base class for opening and reading URLs. Unless you need to support opening objects using schemes other than `http:`, `ftp:`, or `file:`, you probably want to use `FancyURLopener`.

By default, the `URLopener` class sends a `User-Agent` header of `urllib/VVV`, where `VVV` is the `urllib` version number. Applications can define their own `User-Agent` header by subclassing `URLopener` or `FancyURLopener` and setting the class attribute `version` to an appropriate string value in the subclass definition.

The optional `proxies` parameter should be a dictionary mapping scheme names to proxy URLs, where an empty dictionary turns proxies off completely. Its default value is `None`, in which case environmental proxy settings will be used if present, as discussed in the definition of `urlopen()`, above.

Additional keyword parameters, collected in `x509`, may be used for authentication of the client when using the `https:` scheme. The keywords `key_file` and `cert_file` are supported to provide an SSL key and certificate; both are needed to support client authentication.

`URLopener` objects will raise an `IOError` exception if the server returns an error code.

```python
open(fullurl[, data])
```

Open `fullurl` using the appropriate protocol. This method sets up cache and proxy information, then calls the
appropriate open method with its input arguments. If the scheme is not recognized, \texttt{open\_unknown()} is called. The \textit{data} argument has the same meaning as the \textit{data} argument of \texttt{urlopen()}.

\texttt{open\_unknown([\texttt{fullurl}], [\texttt{data}]])}

Overridable interface to open unknown URL types.

\texttt{retrieve([\texttt{url}], [\texttt{filename}], [\texttt{reporthook}], [\texttt{data}]])}

Retrieves the contents of \textit{url} and places it in \textit{filename}. The return value is a tuple consisting of a local filename and either a \texttt{mimetypes.Message} object containing the response headers (for remote URLs) or \texttt{None} (for local URLs). The caller must then open and read the contents of \textit{filename}. If \textit{filename} is not given and the URL refers to a local file, the input filename is returned. If the URL is non-local and \textit{filename} is not given, the filename is the output of \texttt{tempfile.mktemp()} with a suffix that matches the suffix of the last path component of the input URL. If \textit{reporthook} is given, it must be a function accepting three numeric parameters. It will be called after each chunk of data is read from the network. \textit{reporthook} is ignored for local URLs.

If the \textit{url} uses the \texttt{http:} scheme identifier, the optional \textit{data} argument may be given to specify a \texttt{POST} request (normally the request type is \texttt{GET}). The \textit{data} argument must in standard \texttt{application/x-www-form-urlencoded} format; see the \texttt{urlencode()} function below.

\texttt{version}

Variable that specifies the user agent of the opener object. To get \texttt{urllib} to tell servers that it is a particular user agent, set this in a subclass as a class variable or in
the constructor before calling the base constructor.

```python
class urllib.FancyURLopener(...)
```

FancyURLopener subclasses URLopener providing default handling for the following HTTP response codes: 301, 302, 303, 307 and 401. For the 30x response codes listed above, the Location header is used to fetch the actual URL. For 401 response codes (authentication required), basic HTTP authentication is performed. For the 30x response codes, recursion is bounded by the value of the maxtries attribute, which defaults to 10.

For all other response codes, the method http_error_default() is called which you can override in subclasses to handle the error appropriately.

**Note:** According to the letter of RFC 2616, 301 and 302 responses to POST requests must not be automatically redirected without confirmation by the user. In reality, browsers do allow automatic redirection of these responses, changing the POST to a GET, and urllib reproduces this behaviour.

The parameters to the constructor are the same as those for URLopener.

**Note:**

When performing basic authentication, a FancyURLopener instance calls its prompt_user_passwd() method. The default implementation asks the users for the required information on the controlling terminal. A subclass may override this method to support more appropriate behavior if needed.

The FancyURLopener class offers one additional method that
should be overloaded to provide the appropriate behavior:

prompt_user_passwd(host, realm)

Return information needed to authenticate the user at the given host in the specified security realm. The return value should be a tuple, (user, password), which can be used for basic authentication.

The implementation prompts for this information on the terminal; an application should override this method to use an appropriate interaction model in the local environment.

exception urllib.ContentTooShortError(msg[, content])

This exception is raised when the urlretrieve() function detects that the amount of the downloaded data is less than the expected amount (given by the Content-Length header). The content attribute stores the downloaded (and supposedly truncated) data.

New in version 2.5.
20.5.4. urllib Restrictions

- Currently, only the following protocols are supported: HTTP, (versions 0.9 and 1.0), FTP, and local files.

- The caching feature of `urlretrieve()` has been disabled until I find the time to hack proper processing of Expiration time headers.

- There should be a function to query whether a particular URL is in the cache.

- For backward compatibility, if a URL appears to point to a local file but the file can’t be opened, the URL is re-interpreted using the FTP protocol. This can sometimes cause confusing error messages.

- The `urlopen()` and `urlretrieve()` functions can cause arbitrarily long delays while waiting for a network connection to be set up. This means that it is difficult to build an interactive Web client using these functions without using threads.

- The data returned by `urlopen()` or `urlretrieve()` is the raw data returned by the server. This may be binary data (such as an image), plain text or (for example) HTML. The HTTP protocol provides type information in the reply header, which can be inspected by looking at the `Content-Type` header. If the returned data is HTML, you can use the module `htmllib` to parse it.

- The code handling the FTP protocol cannot differentiate between a file and a directory. This can lead to unexpected behavior when attempting to read a URL that points to a file that is not accessible. If the URL ends in a '/', it is assumed to refer to a directory and will be handled accordingly. But if an attempt to
read a file leads to a 550 error (meaning the URL cannot be found or is not accessible, often for permission reasons), then the path is treated as a directory in order to handle the case when a directory is specified by a URL but the trailing / has been left off. This can cause misleading results when you try to fetch a file whose read permissions make it inaccessible; the FTP code will try to read it, fail with a 550 error, and then perform a directory listing for the unreadable file. If fine-grained control is needed, consider using the ftplib module, subclassing FancyURLopener, or changing _urlopener to meet your needs.

- This module does not support the use of proxies which require authentication. This may be implemented in the future.

- Although the urllib module contains (undocumented) routines to parse and unpars e URL strings, the recommended interface for URL manipulation is in module urlparse.
20.5.5. Examples

Here is an example session that uses the **GET** method to retrieve a URL containing parameters:

```python
>>> import urllib
>>> params = urllib.urlencode({'spam': 1, 'eggs': 2, 'bacon': 0})
>>> f = urllib.urlopen("http://www.musical.com/cgi-bin/query?%s")
>>> print f.read()
```

The following example uses the **POST** method instead:

```python
>>> import urllib
>>> params = urllib.urlencode({'spam': 1, 'eggs': 2, 'bacon': 0})
>>> f = urllib.urlopen("http://www.musical.com/cgi-bin/query", params)
>>> print f.read()
```

The following example uses an explicitly specified HTTP proxy, overriding environment settings:

```python
>>> import urllib
>>> proxies = {'http': 'http://proxy.example.com:8080/'}
>>> opener = urllib.FancyURLopener(proxies)
>>> f = opener.open("http://www.python.org")
>>> f.read()
```

The following example uses no proxies at all, overriding environment settings:

```python
>>> import urllib
>>> opener = urllib.FancyURLopener({})
>>> f = opener.open("http://www.python.org")
>>> f.read()
```
The `urllib2` module defines functions and classes which help in opening URLs (mostly HTTP) in a complex world — basic and digest authentication, redirections, cookies and more.

The `urllib2` module defines the following functions:

```
urllib2.urlopen(url[, data][, timeout])
```

Open the URL `url`, which can be either a string or a `Request` object.

`data` may be a string specifying additional data to send to the server, or `None` if no such data is needed. Currently HTTP requests are the only ones that use `data`; the HTTP request will be a POST instead of a GET when the `data` parameter is provided. `data` should be a buffer in the standard `application/x-www-form-urlencoded` format. The `urllib.urlopen()` function takes a mapping or sequence of 2-tuples and returns a string in this format.

The optional `timeout` parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used). This actually only works for HTTP, HTTPS, FTP and FTPS connections.
This function returns a file-like object with two additional methods:

- `geturl()` — return the URL of the resource retrieved, commonly used to determine if a redirect was followed
- `info()` — return the meta-information of the page, such as headers, in the form of an `mimetools.Message` instance (see Quick Reference to HTTP Headers)

Raises `URLLError` on errors.

Note that `None` may be returned if no handler handles the request (though the default installed global `OpenerDirector` uses `UnknownHandler` to ensure this never happens).

In addition, default installed `ProxyHandler` makes sure the requests are handled through the proxy when they are set.

*Changed in version 2.6: timeout was added.*

**urllib2. install_opener(opener)**

Install an `OpenerDirector` instance as the default global opener. Installing an opener is only necessary if you want `urlopen` to use that opener; otherwise, simply call `OpenerDirector.open()` instead of `urlopen()`. The code does not check for a real `OpenerDirector`, and any class with the appropriate interface will work.

**urllib2. build_opener([handler, ...])**

Return an `OpenerDirector` instance, which chains the handlers in the order given. `handlers` can be either instances of `BaseHandler`, or subclasses of `BaseHandler` (in which case it must be possible to call the constructor without any parameters). Instances of the following classes will be in front of the `handlers`, unless the `handlers` contain them, instances of them or subclasses of them:
ProxyHandler, UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, HTTPErrorProcessor.

If the Python installation has SSL support (i.e., if the ssl module can be imported), HTTPSHandler will also be added.

Beginning in Python 2.3, a BaseHandler subclass may also change its handler_order member variable to modify its position in the handlers list.

The following exceptions are raised as appropriate:

**exception urllib2.URLError**
The handlers raise this exception (or derived exceptions) when they run into a problem. It is a subclass of IOError.

(reason)
The reason for this error. It can be a message string or another exception instance (socket.error for remote URLs, OSError for local URLs).

**exception urllib2.HTTPError**
Though being an exception (a subclass of URLError), an HTTPError can also function as a non-exceptional file-like return value (the same thing that urlopen() returns). This is useful when handling exotic HTTP errors, such as requests for authentication.

(code)
An HTTP status code as defined in RFC 2616. This numeric value corresponds to a value found in the dictionary of codes as found in BaseHTTPServer.BaseHTTPRequestHandler.responses.
The following classes are provided:

```python
class urllib2.Request(url[, data][, headers][, origin_req_host][, unverifiable])
```

This class is an abstraction of a URL request.

* url should be a string containing a valid URL.

* data may be a string specifying additional data to send to the server, or `None` if no such data is needed. Currently HTTP requests are the only ones that use `data`; the HTTP request will be a POST instead of a GET when the `data` parameter is provided. `data` should be a buffer in the standard `application/x-www-form-urlencoded` format. The `urllib.urlencode()` function takes a mapping or sequence of 2-tuples and returns a string in this format.

* headers should be a dictionary, and will be treated as if `add_header()` was called with each key and value as arguments. This is often used to “spoof” the `User-Agent` header, which is used by a browser to identify itself – some HTTP servers only allow requests coming from common browsers as opposed to scripts. For example, Mozilla Firefox may identify itself as "Mozilla/5.0 (X11; U; Linux i686) Gecko/20071127 Firefox/2.0.0.11", while `urllib2`'s default user agent string is "Python-urllib/2.6" (on Python 2.6).

The final two arguments are only of interest for correct handling of third-party HTTP cookies:

* origin_req_host should be the request-host of the origin transaction, as defined by `RFC 2965`. It defaults to `cookielib.request_host(self)`. This is the host name or IP address of the original request that was initiated by the user. For
example, if the request is for an image in an HTML document, this should be the request-host of the request for the page containing the image.

unverifiable should indicate whether the request is unverifiable, as defined by RFC 2965. It defaults to False. An unverifiable request is one whose URL the user did not have the option to approve. For example, if the request is for an image in an HTML document, and the user had no option to approve the automatic fetching of the image, this should be true.

class urllib2.OpenerDirector

The OpenerDirector class opens URLs via BaseHandler s chained together. It manages the chaining of handlers, and recovery from errors.

class urllib2.BaseHandler

This is the base class for all registered handlers — and handles only the simple mechanics of registration.

class urllib2.HTTPDefaultErrorHandler

A class which defines a default handler for HTTP error responses; all responses are turned into HTTPError exceptions.

class urllib2.HTTPRedirectHandler

A class to handle redirections.

class urllib2.HTTPCookieProcessor([cookiejar])

A class to handle HTTP Cookies.

class urllib2.ProxyHandler([proxies])

Cause requests to go through a proxy. If proxies is given, it must be a dictionary mapping protocol names to URLs of proxies. The default is to read the list of proxies from the environment variables. If no proxy environment variables are set, in a
Windows environment, proxy settings are obtained from the registry’s Internet Settings section and in a Mac OS X environment, proxy information is retrieved from the OS X System Configuration Framework.

To disable autodetected proxy pass an empty dictionary.

```python
class urllib2.HTTPPasswordMgr
    Keep a database of (realm, uri) -> (user, password) mappings.

class urllib2.HTTPPasswordMgrWithDefaultRealm
    Keep a database of (realm, uri) -> (user, password) mappings. A realm of None is considered a catch-all realm, which is searched if no other realm fits.

class urllib2.AbstractBasicAuthHandler([password_mgr])
    This is a mixin class that helps with HTTP authentication, both to the remote host and to a proxy. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class urllib2.HTTPBasicAuthHandler([password_mgr])
    Handle authentication with the remote host. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class urllib2.ProxyBasicAuthHandler([password_mgr])
    Handle authentication with the proxy. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.
```
class urllib2.AbstractDigestAuthHandler([password_mgr])

This is a mixin class that helps with HTTP authentication, both to the remote host and to a proxy. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class urllib2.HTTPDigestAuthHandler([password_mgr])

Handle authentication with the remote host. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class urllib2.ProxyDigestAuthHandler([password_mgr])

Handle authentication with the proxy. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class urllib2.HTTPHandler

A class to handle opening of HTTP URLs.

class urllib2.HTTPSHandler

A class to handle opening of HTTPS URLs.

class urllib2.FileHandler

Open local files.

class urllib2.FTPHandler

Open FTP URLs.

class urllib2.CacheFTPHandler

Open FTP URLs, keeping a cache of open FTP connections to minimize delays.
class urllib2. UnknownHandler

A catch-all class to handle unknown URLs.
20.6.1. Request Objects

The following methods describe all of `Request`'s public interface, and so all must be overridden in subclasses.

Request. **add_data**(data)

Set the `Request` data to `data`. This is ignored by all handlers except HTTP handlers — and there it should be a byte string, and will change the request to be `POST` rather than `GET`.

Request. **get_method**()

Return a string indicating the HTTP request method. This is only meaningful for HTTP requests, and currently always returns 'GET' or 'POST'.

Request. **has_data**()

Return whether the instance has a non-`None` data.

Request. **get_data**()

Return the instance's data.

Request. **add_header**(key, val)

Add another header to the request. Headers are currently ignored by all handlers except HTTP handlers, where they are added to the list of headers sent to the server. Note that there cannot be more than one header with the same name, and later calls will overwrite previous calls in case the key collides. Currently, this is no loss of HTTP functionality, since all headers which have meaning when used more than once have a (header-specific) way of gaining the same functionality using only one header.

Request. **add_unredirected_header**(key, header)

Add a header that will not be added to a redirected request.
New in version 2.4.

Request. has_header(header)
   Return whether the instance has the named header (checks both regular and unredirected).

New in version 2.4.

Request. get_full_url()
   Return the URL given in the constructor.

Request. get_type()
   Return the type of the URL — also known as the scheme.

Request. get_host()
   Return the host to which a connection will be made.

Request. get_selector()
   Return the selector — the part of the URL that is sent to the server.

Request. set_proxy(host, type)
   Prepare the request by connecting to a proxy server. The host and type will replace those of the instance, and the instance’s selector will be the original URL given in the constructor.

Request. get_origin_req_host()
   Return the request-host of the origin transaction, as defined by RFC 2965. See the documentation for the Request constructor.

Request. is_unverifiable()
   Return whether the request is unverifiable, as defined by RFC 2965. See the documentation for the Request constructor.
20.6.2. OpenerDirector Objects

OpenerDirector instances have the following methods:

OpenerDirector. **add_handler**(handler)

*handler* should be an instance of BaseHandler. The following methods are searched, and added to the possible chains (note that HTTP errors are a special case).

- **protocol_open** — signal that the handler knows how to open *protocol* URLs.
- **http_error_type** — signal that the handler knows how to handle HTTP errors with HTTP error code *type*.
- **protocol_error** — signal that the handler knows how to handle errors from (non-http) *protocol*.
- **protocol_request** — signal that the handler knows how to pre-process *protocol* requests.
- **protocol_response** — signal that the handler knows how to post-process *protocol* responses.

OpenerDirector. **open**(url[, data][, timeout])

Open the given *url* (which can be a request object or a string), optionally passing the given *data*. Arguments, return values and exceptions raised are the same as those of urlopen() (which simply calls the open() method on the currently installed global OpenerDirector). The optional *timeout* parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used). The timeout feature actually works only for HTTP, HTTPS, FTP and FTPS connections.

*Changed in version 2.6: timeout was added.*
OpenerDirector.error(proto[, arg[, ...]])

Handle an error of the given protocol. This will call the registered error handlers for the given protocol with the given arguments (which are protocol specific). The HTTP protocol is a special case which uses the HTTP response code to determine the specific error handler; refer to the http_error_*() methods of the handler classes.

Return values and exceptions raised are the same as those of uropen().

OpenerDirector objects open URLs in three stages:

The order in which these methods are called within each stage is determined by sorting the handler instances.

1. Every handler with a method named like protocol_request has that method called to pre-process the request.

2. Handlers with a method named like protocol_open are called to handle the request. This stage ends when a handler either returns a non-None value (ie. a response), or raises an exception (usually URLError). Exceptions are allowed to propagate.

In fact, the above algorithm is first tried for methods named default_open(). If all such methods return None, the algorithm is repeated for methods named like protocol_open. If all such methods return None, the algorithm is repeated for methods named unknown_open().

Note that the implementation of these methods may involve calls of the parent OpenerDirector instance’s open() and error() methods.
3. Every handler with a method named like `protocol_response` has that method called to post-process the response.
20.6.3. BaseHandler Objects

BaseHandler objects provide a couple of methods that are directly useful, and others that are meant to be used by derived classes. These are intended for direct use:

BaseHandler. **add_parent**(director)

Add a director as parent.

BaseHandler. **close**( )
Remove any parents.

The following members and methods should only be used by classes derived from BaseHandler.

**Note:** The convention has been adopted that subclasses defining `protocol_request()` or `protocol_response()` methods are named *Processor; all others are named *Handler.

BaseHandler. **parent**

A valid OpenerDirector, which can be used to open using a different protocol, or handle errors.

BaseHandler. **default_open**(req)

This method is not defined in BaseHandler, but subclasses should define it if they want to catch all URLs.

This method, if implemented, will be called by the parent OpenerDirector. It should return a file-like object as described in the return value of the `open()` of OpenerDirector, or None. It should raise URLError, unless a truly exceptional thing happens (for example, MemoryError should not be mapped to URLError).
This method will be called before any protocol-specific open method.

BaseHandler.\texttt{protocol\_open}(\textit{req})

(“protocol” is to be replaced by the protocol name.)

This method is \textit{not} defined in \texttt{BaseHandler}, but subclasses should define it if they want to handle URLs with the given \textit{protocol}.

This method, if defined, will be called by the parent \texttt{OpenerDirector}. Return values should be the same as for \texttt{default\_open()}.

BaseHandler.\texttt{unknown\_open}(\textit{req})

This method is \textit{not} defined in \texttt{BaseHandler}, but subclasses should define it if they want to catch all URLs with no specific registered handler to open it.

This method, if implemented, will be called by the parent \texttt{OpenerDirector}. Return values should be the same as for \texttt{default\_open()}.

BaseHandler.\texttt{http\_error\_default}(\textit{req, fp, code, msg, hdrs})

This method is \textit{not} defined in \texttt{BaseHandler}, but subclasses should override it if they intend to provide a catch-all for otherwise unhandled HTTP errors. It will be called automatically by the \texttt{OpenerDirector} getting the error, and should not normally be called in other circumstances.

\textit{req} will be a \texttt{Request} object, \textit{fp} will be a file-like object with the HTTP error body, \textit{code} will be the three-digit code of the error, \textit{msg} will be the user-visible explanation of the code and \textit{hdrs} will be a mapping object with the headers of the error.
Return values and exceptions raised should be the same as those of \texttt{urlopen()}. 

\texttt{BaseHandler.http\_error\_nnn(req, fp, code, msg, hdrs)}

\textit{nnn} should be a three-digit HTTP error code. This method is also not defined in \texttt{BaseHandler}, but will be called, if it exists, on an instance of a subclass, when an HTTP error with code \textit{nnn} occurs.

Subclasses should override this method to handle specific HTTP errors.

Arguments, return values and exceptions raised should be the same as for \texttt{http\_error\_default()}. 

\texttt{BaseHandler.protocol\_request(req)}

(“protocol” is to be replaced by the protocol name.)

This method is \textit{not} defined in \texttt{BaseHandler}, but subclasses should define it if they want to pre-process requests of the given \textit{protocol}.

This method, if defined, will be called by the parent \texttt{OpenerDirector}. \textit{req} will be a \texttt{Request} object. The return value should be a \texttt{Request} object.

\texttt{BaseHandler.protocol\_response(req, response)}

(“protocol” is to be replaced by the protocol name.)

This method is \textit{not} defined in \texttt{BaseHandler}, but subclasses should define it if they want to post-process responses of the given \textit{protocol}.

This method, if defined, will be called by the parent \texttt{OpenerDirector}. \textit{req} will be a \texttt{Request} object. \textit{response} will be an
object implementing the same interface as the return value of `urlopen()`. The return value should implement the same interface as the return value of `urlopen()`.
20.6.4. HTTPRedirectHandler Objects

**Note:** Some HTTP redirections require action from this module's client code. If this is the case, `HTTPError` is raised. See RFC 2616 for details of the precise meanings of the various redirection codes.

HTTPRedirectHandler. `redirect_request(req, fp, code, msg, hdrs, newurl)`

Return a `Request` or `None` in response to a redirect. This is called by the default implementations of the `http_error_30*()` methods when a redirection is received from the server. If a redirection should take place, return a new `Request` to allow `http_error_30*()` to perform the redirect to `newurl`. Otherwise, raise `HTTPError` if no other handler should try to handle this URL, or return `None` if you can’t but another handler might.

**Note:** The default implementation of this method does not strictly follow RFC 2616, which says that 301 and 302 responses to `POST` requests must not be automatically redirected without confirmation by the user. In reality, browsers do allow automatic redirection of these responses, changing the `POST` to a `GET`, and the default implementation reproduces this behavior.

HTTPRedirectHandler. `http_error_301(req, fp, code, msg, hdrs)`

Redirect to the `Location:` or `URI:` URL. This method is called by the parent `OpenerDirector` when getting an HTTP ‘moved permanently’ response.

HTTPRedirectHandler. `http_error_302(req, fp, code, msg, hdrs)`

The same as `http_error_301()`, but called for the ‘found’
HTTPRedirectHandler.\texttt{http\_error\_303}(\texttt{req, fp, code, msg, hdrs})

The same as \texttt{http\_error\_301()}, but called for the ‘see other’ response.

HTTPRedirectHandler.\texttt{http\_error\_307}(\texttt{req, fp, code, msg, hdrs})

The same as \texttt{http\_error\_301()}, but called for the ‘temporary redirect’ response.
20.6.5. HTTPCookieProcessor Objects

*New in version 2.4.*

HTTPCookieProcessor instances have one attribute:

HTTPCookieProcessor. **cookiejar**

The *cookielib.CookieJar* in which cookies are stored.
20.6.6. ProxyHandler Objects

ProxyHandler. **protocol_open**(*request*)

("protocol" is to be replaced by the protocol name.)

The **ProxyHandler** will have a method **protocol_open** for every protocol which has a proxy in the **proxies** dictionary given in the constructor. The method will modify requests to go through the proxy, by calling **request.set_proxy()**, and call the next handler in the chain to actually execute the protocol.
20.6.7. HTTPPasswordMgr Objects

These methods are available on HTTPPasswordMgr and HTTPPasswordMgrWithDefaultRealm objects.

HTTPPasswordMgr.\texttt{add\_password}(\texttt{realm, uri, user, passwd})

\textit{uri} can be either a single URI, or a sequence of URIs. \textit{realm}, \textit{user} and \textit{passwd} must be strings. This causes (\texttt{user, passwd}) to be used as authentication tokens when authentication for \textit{realm} and a super-URI of any of the given URIs is given.

HTTPPasswordMgr.\texttt{find\_user\_password}(\texttt{realm, authuri})

Get user/password for given realm and URI, if any. This method will return (\texttt{None, None}) if there is no matching user/password.

For HTTPPasswordMgrWithDefaultRealm objects, the realm \texttt{None} will be searched if the given \textit{realm} has no matching user/password.
AbstractBasicAuthHandler. `http_error_auth_reqed(authreq, host, req, headers)`

Handle an authentication request by getting a user/password pair, and re-trying the request. `authreq` should be the name of the header where the information about the realm is included in the request, `host` specifies the URL and path to authenticate for, `req` should be the (failed) `Request` object, and `headers` should be the error headers.

`host` is either an authority (e.g. "python.org") or a URL containing an authority component (e.g. "http://python.org/"). In either case, the authority must not contain a userinfo component (so, "python.org" and "python.org:80" are fine, "joe:password@python.org" is not).
20.6.9. HTTPBasicAuthHandler Objects

HTTPBasicAuthHandler.**http_error_401**(req, fp, code, msg, hdrs)

Retry the request with authentication information, if available.
20.6.10. ProxyBasicAuthHandler Objects

ProxyBasicAuthHandler.\texttt{http\_error\_407}(\texttt{req}, \texttt{fp}, \texttt{code}, \texttt{msg}, \texttt{hdrs})

Retry the request with authentication information, if available.
20.6.11. AbstractDigestAuthHandler

Objects

AbstractDigestAuthHandler.\texttt{http\_error\_auth\_reqed}(\texttt{authreq}, \texttt{host}, \texttt{req}, \texttt{headers})

\texttt{authreq} should be the name of the header where the information about the realm is included in the request, \texttt{host} should be the host to authenticate to, \texttt{req} should be the (failed) Request object, and \texttt{headers} should be the error headers.
20.6.12. HTTPDigestAuthHandler Objects

HTTPDigestAuthHandler.http_error_401(req, fp, code, msg, hdrs)

Retry the request with authentication information, if available.
ProxyDigestAuthHandler.\texttt{http\_error\_407}(req, fp, code, msg, hdrs)

Retry the request with authentication information, if available.
20.6.14. HTTPHandler Objects

HTTPHandler.\texttt{http\_open}(\textit{req})

Send an HTTP request, which can be either GET or POST, depending on \texttt{req.has\_data()}. 
20.6.15. HTTPSHandler Objects

HTTPSHandler. `https_open(req)`

Send an HTTPS request, which can be either GET or POST, depending on `req.has_data()`.
Open the file locally, if there is no host name, or the host name is 'localhost'. Change the protocol to ftp otherwise, and retry opening it using parent.
FTPHandler. `ftp_open(req)`

Open the FTP file indicated by `req`. The login is always done with empty username and password.
20.6.18. CacheFTPHandler Objects

`CacheFTPHandler` objects are `FTPHandler` objects with the following additional methods:

`CacheFTPHandler.setTimeout(t)`
Set timeout of connections to \( t \) seconds.

`CacheFTPHandler.setMaxConns(m)`
Set maximum number of cached connections to \( m \).
20.6.19. UnknownHandler Objects

UnknownHandler.\texttt{unknown\_open}()

Raise a \texttt{URLError} exception.
New in version 2.4.

`HTTPErrorProcessor.unknown_open()`  
Process HTTP error responses.

For 200 error codes, the response object is returned immediately.

For non-200 error codes, this simply passes the job on to the `protocol_error_code` handler methods, via `OpenerDirector.error()`.

Eventually, `urllib2.HTTPDefaultErrorHandler` will raise an `HTTPError` if no other handler handles the error.
20.6.21. Examples

This example gets the python.org main page and displays the first 100 bytes of it:

```python
>>> import urllib2
>>> f = urllib2.urlopen('http://www.python.org/)
>>> print f.read(100)
<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01 Transitional//EN">
<?xml-stylesheet href="/css/ht2html
```

Here we are sending a data-stream to the stdin of a CGI and reading the data it returns to us. Note that this example will only work when the Python installation supports SSL.

```python
>>> import urllib2
>>> req = urllib2.Request(url='https://localhost/cgi-bin/test.cgi',
...    data='This data is passed to stdin of the CGI')
>>> f = urllib2.urlopen(req)
>>> print f.read()
Got Data: "This data is passed to stdin of the CGI"
```

The code for the sample CGI used in the above example is:

```python
#!/usr/bin/env python
import sys
data = sys.stdin.read()
print 'Content-type: text-plain
Got Data: "%s"' % data
```

Use of Basic HTTP Authentication:

```python
import urllib2
# Create an OpenerDirector with support for Basic HTTP Authentication
auth_handler = urllib2.HTTPBasicAuthHandler()
auth_handler.add_password(realm='PDQ Application',
    uri='https://mahler:8092/site-updates.py',
    user='klem',
    passwd='kadidd!ehopper')
```
opener = urllib2.build_opener(auth_handler)
# ...and install it globally so it can be used with urlopen.
urllib2.install_opener(opener)
urllib2.urlopen('http://www.example.com/login.html')

build_opener() provides many handlers by default, including a
ProxyHandler. By default, ProxyHandler uses the environment
variables named <scheme>_proxy, where <scheme> is the URL
scheme involved. For example, the http_proxy environment variable
is read to obtain the HTTP proxy's URL.

This example replaces the default ProxyHandler with one that uses
programmatically-supplied proxy URLs, and adds proxy
authorization support with ProxyBasicAuthHandler.

proxy_handler = urllib2.ProxyHandler({'http': 'http://www.example.com:3128/'}
proxy_auth_handler = urllib2.ProxyBasicAuthHandler()
proxy_auth_handler.add_password('realm', 'host', 'username', 'p

opener = urllib2.build_opener(proxy_handler, proxy_auth_handler
# This time, rather than install the OpenerDirector, we use it
opener.open('http://www.example.com/login.html')

Adding HTTP headers:

Use the headers argument to the Request constructor, or:

import urllib2
req = urllib2.Request('http://www.example.com/)
req.add_header('Referer', 'http://www.python.org/)
r = urllib2.urlopen(req)

OpenerDirector automatically adds a User-Agent header to every
Request. To change this:

import urllib2
opener = urllib2.build_opener()
opener.addheaders = [('User-agent', 'Mozilla/5.0')]
opener.open('http://www.example.com/')

Also, remember that a few standard headers (Content-Length, Content-Type and Host) are added when the Request is passed to urllib.open() (or OpenerDirector.open()).
20.7. **httplib — HTTP protocol client**

**Note:** The `httplib` module has been renamed to `http.client` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

This module defines classes which implement the client side of the HTTP and HTTPS protocols. It is normally not used directly — the module `urllib` uses it to handle URLs that use HTTP and HTTPS.

**Note:** HTTPS support is only available if the `socket` module was compiled with SSL support.

**Note:** The public interface for this module changed substantially in Python 2.0. The `HTTP` class is retained only for backward compatibility with 1.5.2. It should not be used in new code. Refer to the online docstrings for usage.

The module provides the following classes:

```python
class httplib.HTTPConnection(host[, port[, strict[, timeout[, source_address]]]])
```

An `HTTPConnection` instance represents one transaction with an HTTP server. It should be instantiated passing it a host and optional port number. If no port number is passed, the port is extracted from the host string if it has the form `host:port`, else the default HTTP port (80) is used. When True, the optional parameter `strict` (which defaults to a false value) causes `BadStatusLine` to be raised if the status line can’t be parsed as a valid HTTP/1.0 or 1.1 status line. If the optional `timeout`
parameter is given, blocking operations (like connection attempts) will timeout after that many seconds (if it is not given, the global default timeout setting is used). The optional source_address parameter may be a tuple of a (host, port) to use as the source address the HTTP connection is made from.

For example, the following calls all create instances that connect to the server at the same host and port:

```python
>>> h1 = httplib.HTTPConnection('www.cwi.nl')
>>> h2 = httplib.HTTPConnection('www.cwi.nl:80')
>>> h3 = httplib.HTTPConnection('www.cwi.nl', 80)
>>> h3 = httplib.HTTPConnection('www.cwi.nl', 80, timeout=10)
```

New in version 2.0.

Changed in version 2.6: timeout was added.

Changed in version 2.7: source_address was added.

class httplib.HTTPSConnection(host[, port[, key_file[, cert_file[, strict[, timeout[, source_address]]]]]])

A subclass of HTTPConnection that uses SSL for communication with secure servers. Default port is 443. key_file is the name of a PEM formatted file that contains your private key. cert_file is a PEM formatted certificate chain file.

Note: This does not do any certificate verification.

New in version 2.0.

Changed in version 2.6: timeout was added.

Changed in version 2.7: source_address was added.
```
class httplib.HTTPResponse(sock[, debuglevel=0][, strict=0])
    Class whose instances are returned upon successful connection.
    Not instantiated directly by user.

    New in version 2.0.

class httplib.HTTPMessage
    An HTTPMessage instance is used to hold the headers from an HTTP response. It is implemented using the mimetools.Message class and provides utility functions to deal with HTTP Headers. It is not directly instantiated by the users.

    The following exceptions are raised as appropriate:

    exception httplib.HTTPException
        The base class of the other exceptions in this module. It is a subclass of Exception.

        New in version 2.0.

    exception httplib.NotConnected
        A subclass of HTTPException.

        New in version 2.0.

    exception httplib.InvalidURL
        A subclass of HTTPException, raised if a port is given and is either non-numeric or empty.

        New in version 2.3.

    exception httplib.UnknownProtocol
        A subclass of HTTPException.

        New in version 2.0.
```
exception `http.client.UnknownTransferEncoding`
   A subclass of `HTTPException`.

   New in version 2.0.

exception `http.client.UnimplementedFileMode`
   A subclass of `HTTPException`.

   New in version 2.0.

exception `http.client.IncompleteRead`
   A subclass of `HTTPException`.

   New in version 2.0.

exception `http.client.ImproperConnectionState`
   A subclass of `HTTPException`.

   New in version 2.0.

exception `http.client.CannotSendRequest`
   A subclass of `ImproperConnectionState`.

   New in version 2.0.

exception `http.client.CannotSendHeader`
   A subclass of `ImproperConnectionState`.

   New in version 2.0.

exception `http.client.ResponseNotReady`
   A subclass of `ImproperConnectionState`.

   New in version 2.0.

exception `http.client.BadStatusLine`
A subclass of HTTPException. Raised if a server responds with a HTTP status code that we don’t understand.

*New in version 2.0.*

The constants defined in this module are:

`httplib.HTTP_PORT`

The default port for the HTTP protocol (always 80).

`httplib.HTTPS_PORT`

The default port for the HTTPS protocol (always 443).

and also the following constants for integer status codes:

`httplib.responses`

This dictionary maps the HTTP 1.1 status codes to the W3C names.

Example: `httplib.responses[httplib.NOT_FOUND]` is 'Not Found'.

*New in version 2.5.*
20.7.1. HTTPConnection Objects

HTTPConnection instances have the following methods:

HTTPConnection.request\((method, url[, body[, headers]])\)

This will send a request to the server using the HTTP request method `method` and the selector `url`. If the `body` argument is present, it should be a string of data to send after the headers are finished. Alternatively, it may be an open file object, in which case the contents of the file is sent; this file object should support `fileno()` and `read()` methods. The header Content-Length is automatically set to the correct value. The `headers` argument should be a mapping of extra HTTP headers to send with the request.

*Changed in version 2.6:* `body` can be a file object.

HTTPConnection.getresponse()

Should be called after a request is sent to get the response from the server. Returns an HTTPResponse instance.

**Note:** Note that you must have read the whole response before you can send a new request to the server.

HTTPConnection.set_debuglevel\((level)\)

Set the debugging level (the amount of debugging output printed). The default debug level is 0, meaning no debugging output is printed.

HTTPConnection.set_tunnel\((host, port=None, headers=None)\)

Set the host and the port for HTTP Connect Tunnelling. Normally used when it is required to do HTTPS Conection through a proxy.
server.

The headers argument should be a mapping of extra HTTP headers to be sent with the CONNECT request.

*New in version 2.7.*

HTTPConnection.**connect()**

Connect to the server specified when the object was created.

HTTPConnection.**close()**

Close the connection to the server.

As an alternative to using the `request()` method described above, you can also send your request step by step, by using the four functions below.

HTTPConnection.**putrequest(request, selector[, skip_host[, skip_accept_encoding]])**

This should be the first call after the connection to the server has been made. It sends a line to the server consisting of the `request` string, the `selector` string, and the HTTP version (HTTP/1.1). To disable automatic sending of `Host:` or `Accept-Encoding:` headers (for example to accept additional content encodings), specify `skip_host` or `skip_accept_encoding` with non-False values.

*Changed in version 2.4: skip_accept_encoding argument added.*

HTTPConnection.**putheader(header, argument[, ...])**

Send an **RFC 822**-style header to the server. It sends a line to the server consisting of the header, a colon and a space, and the first argument. If more arguments are given, continuation lines are sent, each consisting of a tab and an argument.
HTTPConnection. **endheaders()**

Send a blank line to the server, signalling the end of the headers.

HTTPConnection. **send(data)**

Send data to the server. This should be used directly only after the **endheaders()** method has been called and before **getresponse()** is called.
20.7.2. HTTPResponse Objects

**HTTPResponse** instances have the following methods and attributes:

**HTTPResponse**. **read**(*amt*)
Reads and returns the response body, or up to the next *amt* bytes.

**HTTPResponse**. **getheader**(*name[, default]*)
Get the contents of the header *name*, or *default* if there is no matching header.

**HTTPResponse**. **getheaders**()
Return a list of (header, value) tuples.

*New in version 2.4.*

**HTTPResponse**. **msg**
A **mimetypes.Message** instance containing the response headers.

**HTTPResponse**. **version**
HTTP protocol version used by server. 10 for HTTP/1.0, 11 for HTTP/1.1.

**HTTPResponse**. **status**
Status code returned by server.

**HTTPResponse**. **reason**
Reason phrase returned by server.
Here is an example session that uses the GET method:

```python
>>> import httplib
>>> conn = httplib.HTTPConnection("www.python.org")
>>> conn.request("GET", "/index.html")
>>> r1 = conn.getresponse()
>>> print r1.status, r1.reason
200 OK
>>> data1 = r1.read()
>>> conn.request("GET", "/parrot.spam")
>>> r2 = conn.getresponse()
>>> print r2.status, r2.reason
404 Not Found
>>> data2 = r2.read()
>>> conn.close()
```

Here is an example session that uses the HEAD method. Note that the HEAD method never returns any data.

```python
>>> import httplib
>>> conn = httplib.HTTPConnection("www.python.org")
>>> conn.request("HEAD","/index.html")
>>> res = conn.getresponse()
>>> print res.status, res.reason
200 OK
>>> data = res.read()
>>> print len(data)
0
>>> data == ''
True
```

Here is an example session that shows how to POST requests:

```python
>>> import httplib, urllib
>>> params = urllib.urlencode({'spam': 1, 'eggs': 2, 'bacon': 0})
>>> headers = {'Content-type': "application/x-www-form-urlencoded", "Accept": "text/plain"}
>>> conn = httplib.HTTPConnection("musi-cal.mojam.com:80")
```
```python
>>> conn.request("POST", "/cgi-bin/query", params, headers)
>>> response = conn.getresponse()
>>> print response.status, response.reason
200 OK
>>> data = response.read()
>>> conn.close()
```
20.8. ftplib — FTP protocol client

This module defines the class FTP and a few related items. The FTP class implements the client side of the FTP protocol. You can use this to write Python programs that perform a variety of automated FTP jobs, such as mirroring other ftp servers. It is also used by the module urllib to handle URLs that use FTP. For more information on FTP (File Transfer Protocol), see Internet RFC 959.

Here's a sample session using the ftplib module:

```python
>>> from ftplib import FTP
>>> ftp = FTP('ftp.cwi.nl')  # connect to host, default port
>>> ftp.login()  # user anonymous, passwd anonymous@
>>> ftp.retrlines('LIST')  # list directory contents
total 24418
   drwxrwsr-x  5 ftp-usr pdmaint  1536 Mar 20 09:48 .
   dr-xr-srwt 105 ftp-usr pdmaint  1536 Mar 21 14:32 ..
   -rw-r--r--  1 ftp-usr pdmaint   5305 Mar 20 09:48 INDEX
   ...
>>> ftp.retrbinary('RETR README', open('README', 'wb').write)
'226 Transfer complete.'
>>> ftp.quit()
```

The module defines the following items:

```python
class ftplib.FTP([host[, user[, passwd[, acct[, timeout]]]]])
```

Return a new instance of the FTP class. When host is given, the method call connect(host) is made. When user is given, additionally the method call login(user, passwd, acct) is made (where passwd and acct default to the empty string when not given). The optional timeout parameter specifies a timeout in seconds for blocking operations like the connection attempt (if is not specified, the global default timeout setting will be used).
Changed in version 2.6: timeout was added.

```python
class ftplib.FTP_TLS([host[, user[, passwd[, acct[, keyfile[, certfile[, timeout]]]]]])
```

A FTP subclass which adds TLS support to FTP as described in RFC 4217. Connect as usual to port 21 implicitly securing the FTP control connection before authenticating. Securing the data connection requires the user to explicitly ask for it by calling the `prot_p()` method. `keyfile` and `certfile` are optional – they can contain a PEM formatted private key and certificate chain file name for the SSL connection.

**New in version 2.7.**

Here’s a sample session using the `FTP_TLS` class:

```python
>>> from ftplib import FTP_TLS
>>> ftps = FTP_TLS('ftp.python.org')
>>> ftps.login()  # login anonymously before securing control channel
>>> ftps.prot_p()  # switch to secure data connection
>>> ftps.retrlines('LIST')  # list directory content securely
total 9

'226 Transfer complete.'
>>> ftps.quit()

```

`exception ftplib.error_reply`  
Exception raised when an unexpected reply is received from the server.
exception ftplib.error_temp
   Exception raised when an error code in the range 400–499 is received.

exception ftplib.error_perm
   Exception raised when an error code in the range 500–599 is received.

exception ftplib.error_proto
   Exception raised when a reply is received from the server that does not begin with a digit in the range 1–5.

ftplib.all_errors
   The set of all exceptions (as a tuple) that methods of FTP instances may raise as a result of problems with the FTP connection (as opposed to programming errors made by the caller). This set includes the four exceptions listed above as well as socket.error and IOError.

See also:

Module netrc
   Parser for the .netrc file format. The file .netrc is typically used by FTP clients to load user authentication information before prompting the user.

The file Tools/scripts/ftpmirror.py in the Python source distribution is a script that can mirror FTP sites, or portions thereof, using the ftplib module. It can be used as an extended example that applies this module.
Several methods are available in two flavors: one for handling text files and another for binary files. These are named for the command which is used followed by lines for the text version or binary for the binary version.

**FTP** instances have the following methods:

**FTP.set_debuglevel(level)**
Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the control connection.

**FTP.connect(host[, port[, timeout]])**
Connect to the given host and port. The default port number is 21, as specified by the FTP protocol specification. It is rarely needed to specify a different port number. This function should be called only once for each instance; it should not be called at all if a host was given when the instance was created. All other methods can only be used after a connection has been made.

The optional timeout parameter specifies a timeout in seconds for the connection attempt. If no timeout is passed, the global default timeout setting will be used.

*Changed in version 2.6: timeout was added.*

**FTP.getwelcome()**
Return the welcome message sent by the server in reply to the
initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

**FTP.login([user[, passwd[, acct]])**

Log in as the given `user`. The `passwd` and `acct` parameters are optional and default to the empty string. If no `user` is specified, it defaults to `'anonymous'`. If `user` is `'anonymous'`, the default `passwd` is `'anonymous@'`. This function should be called only once for each instance, after a connection has been established; it should not be called at all if a host and user were given when the instance was created. Most FTP commands are only allowed after the client has logged in. The `acct` parameter supplies “accounting information”; few systems implement this.

**FTP.abort()**

Abort a file transfer that is in progress. Using this does not always work, but it’s worth a try.

**FTP.sendcmd(command)**

Send a simple command string to the server and return the response string.

**FTP.voidcmd(command)**

Send a simple command string to the server and handle the response. Return nothing if a response code in the range 200–299 is received. Raise an exception otherwise.

**FTP.retrbinary(command, callback[, maxblocksize[, rest]])**

Retrieve a file in binary transfer mode. `command` should be an appropriate `RETR` command: `'RETR filename'`. The `callback` function is called for each block of data received, with a single string argument giving the data block. The optional `maxblocksize` argument specifies the maximum chunk size to read on the low-level socket object created to do the actual transfer (which will
also be the largest size of the data blocks passed to `callback`). A reasonable default is chosen. `rest` means the same thing as in the `transfercmd()` method.

**FTP. `retrlines(command[, callback])`**
Retrieve a file or directory listing in ASCII transfer mode. `command` should be an appropriate `retr` command (see `retrbinary()`) or a command such as `LIST`, `NLST` or `MLSD` (usually just the string `'LIST'`). The `callback` function is called for each line, with the trailing CRLF stripped. The default `callback` prints the line to `sys.stdout`.

**FTP. `set_pasv(boolean)`**
Enable “passive” mode if `boolean` is true, other disable passive mode. (In Python 2.0 and before, passive mode was off by default; in Python 2.1 and later, it is on by default.)

**FTP. `storbinary(command, file[, blocksize, callback, rest])`**
Store a file in binary transfer mode. `command` should be an appropriate `STOR` command: "STOR filename". `file` is an open file object which is read until EOF using its `read()` method in blocks of size `blocksize` to provide the data to be stored. The `blocksize` argument defaults to 8192. `callback` is an optional single parameter callable that is called on each block of data after it is sent. `rest` means the same thing as in the `transfercmd()` method.

*Changed in version 2.1:* default for `blocksize` added.

*Changed in version 2.6:* `callback` parameter added.

*Changed in version 2.7:* `rest` parameter added.

**FTP. `storlines(command, file[, callback])`**
Store a file in ASCII transfer mode. `command` should be an
appropriate **STOR** command (see **storbinary()**). Lines are read until EOF from the open file object **file** using its **readline()** method to provide the data to be stored. **callback** is an optional single parameter callable that is called on each line after it is sent.

*Changed in version 2.6: callback parameter added.*

**FTP.** **transfercmd**(**cmd**[, **rest**])

Initiate a transfer over the data connection. If the transfer is active, send a **EPRT** or **PORT** command and the transfer command specified by **cmd**, and accept the connection. If the server is passive, send a **EPSV** or **PASV** command, connect to it, and start the transfer command. Either way, return the socket for the connection.

If optional **rest** is given, a **REST** command is sent to the server, passing **rest** as an argument. **rest** is usually a byte offset into the requested file, telling the server to restart sending the file's bytes at the requested offset, skipping over the initial bytes. Note however that RFC 959 requires only that **rest** be a string containing characters in the printable range from ASCII code 33 to ASCII code 126. The **transfercmd()** method, therefore, converts **rest** to a string, but no check is performed on the string's contents. If the server does not recognize the **REST** command, an **error_reply** exception will be raised. If this happens, simply call **transfercmd()** without a **rest** argument.

**FTP.** **ntransfercmd**(**cmd**[, **rest**])

Like **transfercmd()**, but returns a tuple of the data connection and the expected size of the data. If the expected size could not be computed, **None** will be returned as the expected size. **cmd** and **rest** means the same thing as in **transfercmd()**.
FTP. **nlst**(*argument*, ...)
Return a list of files as returned by the **NLST** command. The optional *argument* is a directory to list (default is the current server directory). Multiple arguments can be used to pass non-standard options to the **NLST** command.

FTP. **dir**(*argument*, ...)
Produce a directory listing as returned by the **LIST** command, printing it to standard output. The optional *argument* is a directory to list (default is the current server directory). Multiple arguments can be used to pass non-standard options to the **LIST** command. If the last argument is a function, it is used as a *callback* function as for **retrlines()**; the default prints to `sys.stdout`. This method returns **None**.

FTP. **rename**(*fromname*, *toname*)
Rename file *fromname* on the server to *toname*.

FTP. **delete**(*filename*)
Remove the file named *filename* from the server. If successful, returns the text of the response, otherwise raises **error_perm** on permission errors or **error_reply** on other errors.

FTP. **cwd**(*pathname*)
Set the current directory on the server.

FTP. **mkd**(*pathname*)
Create a new directory on the server.

FTP. **pwd**()
Return the pathname of the current directory on the server.

FTP. **rmd**(*dirname*)
Remove the directory named `dirname` on the server.

**FTP. `size(filename)`**
Request the size of the file named `filename` on the server. On success, the size of the file is returned as an integer, otherwise `None` is returned. Note that the `SIZE` command is not standardized, but is supported by many common server implementations.

**FTP. `quit()`**
Send a `QUIT` command to the server and close the connection. This is the “polite” way to close a connection, but it may raise an exception if the server responds with an error to the `QUIT` command. This implies a call to the `close()` method which renders the `FTP` instance useless for subsequent calls (see below).

**FTP. `close()`**
Close the connection unilaterally. This should not be applied to an already closed connection such as after a successful call to `quit()`. After this call the `FTP` instance should not be used any more (after a call to `close()` or `quit()` you cannot reopen the connection by issuing another `login()` method).
20.8.2. FTP_TLS Objects

FTP_TLS class inherits from FTP, defining these additional objects:

FTP_TLS.ssl_version
   The SSL version to use (defaults to TLSv1).

FTP_TLS.auth()
   Set up secure control connection by using TLS or SSL, depending on what specified in ssl_version() attribute.

FTP_TLS.prot_p()
   Set up secure data connection.

FTP_TLS.prot_c()
   Set up clear text data connection.
This module defines a class, `POP3`, which encapsulates a connection to a POP3 server and implements the protocol as defined in RFC 1725. The `POP3` class supports both the minimal and optional command sets. Additionally, this module provides a class `POP3_SSL`, which provides support for connecting to POP3 servers that use SSL as an underlying protocol layer.

Note that POP3, though widely supported, is obsolescent. The implementation quality of POP3 servers varies widely, and too many are quite poor. If your mailserver supports IMAP, you would be better off using the `imaplib.IMAP4` class, as IMAP servers tend to be better implemented.

A single class is provided by the `poplib` module:

```python
class poplib.POP3(host[, port[, timeout]])
```
This class implements the actual POP3 protocol. The connection is created when the instance is initialized. If `port` is omitted, the standard POP3 port (110) is used. The optional `timeout` parameter specifies a timeout in seconds for the connection attempt (if not specified, the global default timeout setting will be used).

*Changed in version 2.6:* `timeout` was added.

```python
class poplib.POP3_SSL(host[, port[, keyfile[, certfile]]])
```
This is a subclass of `POP3` that connects to the server over an SSL encrypted socket. If `port` is not specified, 995, the standard POP3-over-SSL port is used. `keyfile` and `certfile` are also optional - they can contain a PEM formatted private key and certificate chain file for the SSL connection.
New in version 2.4.

One exception is defined as an attribute of the `poplib` module:

```python
exception poplib.error_proto
```

Exception raised on any errors from this module (errors from `socket` module are not caught). The reason for the exception is passed to the constructor as a string.

See also:

Module `imaplib`

The standard Python IMAP module.

Frequently Asked Questions About Fetchmail

The FAQ for the `fetchmail` POP/IMAP client collects information on POP3 server variations and RFC noncompliance that may be useful if you need to write an application based on the POP protocol.
20.9.1. POP3 Objects

All POP3 commands are represented by methods of the same name, in lower-case; most return the response text sent by the server.

An **POP3** instance has the following methods:

**POP3. `set_debuglevel(level)`**
Set the instance’s debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the control connection.

**POP3. `getwelcome()`**
Returns the greeting string sent by the POP3 server.

**POP3. `user(username)`**
Send user command, response should indicate that a password is required.

**POP3. `pass_(password)`**
Send password, response includes message count and mailbox size. Note: the mailbox on the server is locked until `quit()` is called.

**POP3. `apop(user, secret)`**
Use the more secure APOP authentication to log into the POP3 server.

**POP3. `rpop(user)`**
Use RPOP authentication (similar to UNIX r-commands) to log into POP3 server.

**POP3.** `stat()`  
Get mailbox status. The result is a tuple of 2 integers: `(message count, mailbox size)`.

**POP3.** `list([which])`  
Request message list, result is in the form `(response, ['mesg_num octets', ...], octets)`. If `which` is set, it is the message to list.

**POP3.** `retr(which)`  
Retrieve whole message number `which`, and set its seen flag. Result is in form `(response, ['line', ...], octets)`.

**POP3.** `dele(which)`  
Flag message number `which` for deletion. On most servers deletions are not actually performed until QUIT (the major exception is Eudora QPOP, which deliberately violates the RFCs by doing pending deletes on any disconnect).

**POP3.** `rset()`  
Remove any deletion marks for the mailbox.

**POP3.** `noop()`  
Do nothing. Might be used as a keep-alive.

**POP3.** `quit()`  
Signoff: commit changes, unlock mailbox, drop connection.

**POP3.** `top(which, howmuch)`  
Retrieves the message header plus `howmuch` lines of the message after the header of message number `which`. Result is in form `(response, ['line', ...], octets)`.
The POP3 TOP command this method uses, unlike the RETR command, doesn't set the message's seen flag; unfortunately, TOP is poorly specified in the RFCs and is frequently broken in off-brand servers. Test this method by hand against the POP3 servers you will use before trusting it.

\texttt{POP3.uidl([\textit{which}]])}

Return message digest (unique id) list. If \textit{which} is specified, result contains the unique id for that message in the form \texttt{response mesgnum uid}, otherwise result is list \texttt{(response, ['mesgnum uid', \ldots], octets)}.

Instances of \texttt{POP3_SSL} have no additional methods. The interface of this subclass is identical to its parent.
20.9.2. POP3 Example

Here is a minimal example (without error checking) that opens a mailbox and retrieves and prints all messages:

```python
import getpass, poplib

M = poplib.POP3('localhost')
M.user(getpass.getuser())
M.pass_(getpass.getpass())
numMessages = len(M.list()[1])
for i in range(numMessages):
    for j in M.retr(i+1)[1]:
        print j
```

At the end of the module, there is a test section that contains a more extensive example of usage.
This module defines three classes, `IMAP4`, `IMAP4_SSL` and `IMAP4_stream`, which encapsulate a connection to an IMAP4 server and implement a large subset of the IMAP4rev1 client protocol as defined in RFC 2060. It is backward compatible with IMAP4 (RFC 1730) servers, but note that the STATUS command is not supported in IMAP4.

Three classes are provided by the `imaplib` module, `IMAP4` is the base class:

```python
class imaplib.IMAP4([host[, port]])
```

This class implements the actual IMAP4 protocol. The connection is created and protocol version (IMAP4 or IMAP4rev1) is determined when the instance is initialized. If `host` is not specified, `''` (the local host) is used. If `port` is omitted, the standard IMAP4 port (143) is used.

Three exceptions are defined as attributes of the `IMAP4` class:

```python
exception IMAP4.error
```

Exception raised on any errors. The reason for the exception is passed to the constructor as a string.

```python
exception IMAP4.abort
```

IMAP4 server errors cause this exception to be raised. This is a sub-class of `IMAP4.error`. Note that closing the instance and instantiating a new one will usually allow recovery from this exception.

```python
exception IMAP4.readonly
```
This exception is raised when a writable mailbox has its status changed by the server. This is a sub-class of `IMAP4.error`. Some other client now has write permission, and the mailbox will need to be re-opened to re-obtain write permission.

There’s also a subclass for secure connections:

```python
class imaplib.IMAP4_SSL([host[, port[, keyfile[, certfile]]]]))
```
This is a subclass derived from `IMAP4` that connects over an SSL encrypted socket (to use this class you need a socket module that was compiled with SSL support). If `host` is not specified, `'.'` (the local host) is used. If `port` is omitted, the standard IMAP4-over-SSL port (993) is used. `keyfile` and `certfile` are also optional - they can contain a PEM formatted private key and certificate chain file for the SSL connection.

The second subclass allows for connections created by a child process:

```python
class imaplib.IMAP4_stream(command)
```
This is a subclass derived from `IMAP4` that connects to the `stdin/stdout` file descriptors created by passing `command` to `os.popen2()`.

*New in version 2.3.*

The following utility functions are defined:

```python
imaplib.Internaldate2tuple(datestr)
```
Converts an IMAP4 INTERNALDATE string to Coordinated Universal Time. Returns a `time` module tuple.

```python
imaplib.Int2AP(num)
```
Converts an integer into a string representation using characters
from the set \([A .. p]\).

**imaplib.ParseFlags(flagstr)**

Converts an IMAP4 FLAGS response to a tuple of individual flags.

**imaplib.Time2Internaldate(date_time)**

Converts a time module tuple to an IMAP4 INTERNALDATE representation. Returns a string in the form: "DD-Mmm-YYYY HH:MM:SS +HHMM" (including double-quotes).

Note that IMAP4 message numbers change as the mailbox changes; in particular, after an EXPUNGE command performs deletions the remaining messages are renumbered. So it is highly advisable to use UIDs instead, with the UID command.

At the end of the module, there is a test section that contains a more extensive example of usage.

**See also:** Documents describing the protocol, and sources and binaries for servers implementing it, can all be found at the University of Washington's IMAP Information Center (http://www.washington.edu/imap/).
20.10.1. IMAP4 Objects

All IMAP4rev1 commands are represented by methods of the same name, either upper-case or lower-case.

All arguments to commands are converted to strings, except for `AUTHENTICATE`, and the last argument to `APPEND` which is passed as an IMAP4 literal. If necessary (the string contains IMAP4 protocol-sensitive characters and isn’t enclosed with either parentheses or double quotes) each string is quoted. However, the `password` argument to the `LOGIN` command is always quoted. If you want to avoid having an argument string quoted (eg: the `flags` argument to `STORE`) then enclose the string in parentheses (eg: `r'(\Deleted)'`).

Each command returns a tuple: `(type, [data, ...])` where `type` is usually `'OK'` or `'NO'`, and `data` is either the text from the command response, or mandated results from the command. Each `data` is either a string, or a tuple. If a tuple, then the first part is the header of the response, and the second part contains the data (ie: ‘literal’ value).

The `message_set` options to commands below is a string specifying one or more messages to be acted upon. It may be a simple message number (`'1'`), a range of message numbers (`'2:4'`), or a group of non-contiguous ranges separated by commas (`'1:3,6:9'`). A range can contain an asterisk to indicate an infinite upper bound (`'3:*'`).

An `IMAP4` instance has the following methods:

`IMAP4.append(mailbox, flags, date_time, message)`

Append `message` to named mailbox.
**IMAP4. authenticate**(mechanism, authobject)

Authenticate command — requires response processing.

*mecanism* specifies which authentication mechanism is to be used - it should appear in the instance variable `capabilities` in the form `AUTH=mechanism`.

*authobject* must be a callable object:

```python
data = authobject(response)
```

It will be called to process server continuation responses. It should return `data` that will be encoded and sent to server. It should return `None` if the client abort response `*` should be sent instead.

**IMAP4. check()**

Checkpoint mailbox on server.

**IMAP4. close()**

Close currently selected mailbox. Deleted messages are removed from writable mailbox. This is the recommended command before `LOGOUT`.

**IMAP4. copy**(message_set, new_mailbox)

Copy `message_set` messages onto end of `new_mailbox`.

**IMAP4. create**(mailbox)

Create new mailbox named `mailbox`.

**IMAP4. delete**(mailbox)

Delete old mailbox named `mailbox`.

**IMAP4. deleteacl**(mailbox, who)

Delete the ACLs (remove any rights) set for who on mailbox.
New in version 2.4.

**IMAP4. expunge()**
Permanently remove deleted items from selected mailbox. Generates an `EXPUNGE` response for each deleted message. Returned data contains a list of `EXPUNGE` message numbers in order received.

**IMAP4. fetch(message_set, message_parts)**
Fetch (parts of) messages. `message_parts` should be a string of message part names enclosed within parentheses, eg: `"(UID BODY[TEXT])"`. Returned data are tuples of message part envelope and data.

**IMAP4. getacl(mailbox)**
Get the ACLS for `mailbox`. The method is non-standard, but is supported by the Cyrus server.

**IMAP4. getannotation(mailbox, entry, attribute)**
Retrieve the specified ANNOTATIONS for `mailbox`. The method is non-standard, but is supported by the Cyrus server.

New in version 2.5.

**IMAP4. getquota(root)**
Get the quota root's resource usage and limits. This method is part of the IMAP4 QUOTA extension defined in rfc2087.

New in version 2.3.

**IMAP4. getquotaroot(mailbox)**
Get the list of quota roots for the named `mailbox`. This method is part of the IMAP4 QUOTA extension defined in rfc2087.
New in version 2.3.

**IMAP4. list([directory[, pattern]])**
List mailbox names in directory matching pattern. directory defaults to the top-level mail folder, and pattern defaults to match anything. Returned data contains a list of LIST responses.

**IMAP4. login(user, password)**
Identify the client using a plaintext password. The password will be quoted.

**IMAP4. login_cram_md5(user, password)**
Force use of CRAM-MD5 authentication when identifying the client to protect the password. Will only work if the server CAPABILITY response includes the phrase AUTH=CRAM-MD5.

New in version 2.3.

**IMAP4. logout()**
Shutdown connection to server. Returns server BYE response.

**IMAP4. lsub([directory[, pattern]])**
List subscribed mailbox names in directory matching pattern. directory defaults to the top level directory and pattern defaults to match any mailbox. Returned data are tuples of message part envelope and data.

**IMAP4. myrights(mailbox)**
Show my ACLs for a mailbox (i.e. the rights that I have on mailbox).

New in version 2.4.

**IMAP4. namespace()**
Returns IMAP namespaces as defined in RFC2342.

*New in version 2.3.*

**IMAP4. `noop()`**

Send `NOOP` to server.

**IMAP4. `open(host, port)`**

Opens socket to `port` at `host`. The connection objects established by this method will be used in the `read`, `readline`, `send`, and `shutdown` methods. You may override this method.

**IMAP4. `partial(message_num, message_part, start, length)`**

Fetch truncated part of a message. Returned data is a tuple of message part envelope and data.

**IMAP4. `proxyauth(user)`**

Assume authentication as `user`. Allows an authorised administrator to proxy into any user’s mailbox.

*New in version 2.3.*

**IMAP4. `read(size)`**

Reads `size` bytes from the remote server. You may override this method.

**IMAP4. `readline()`**

Reads one line from the remote server. You may override this method.

**IMAP4. `recent()`**

Prompt server for an update. Returned data is `None` if no new messages, else value of `RECENT` response.

**IMAP4. `rename(oldmailbox, newmailbox)`**
Rename mailbox named oldmailbox to newmailbox.

**IMAP4. response(code)**

Return data for response code if received, or None. Returns the given code, instead of the usual type.

**IMAP4. search(charset, criterion[, ...])**

Search mailbox for matching messages. charset may be None, in which case no CHARSET will be specified in the request to the server. The IMAP protocol requires that at least one criterion be specified; an exception will be raised when the server returns an error.

Example:

```python
# M is a connected IMAP4 instance...
typ, msgnums = M.search(None, 'FROM', "LDJ")

# or:
typ, msgnums = M.search(None, '(FROM "LDJ")')
```

**IMAP4. select([mailbox[, readonly]])**

Select a mailbox. Returned data is the count of messages in mailbox ( EXISTS response). The default mailbox is 'INBOX'. If the readonly flag is set, modifications to the mailbox are not allowed.

**IMAP4. send(data)**

Sends data to the remote server. You may override this method.

**IMAP4. setacl(mailbox, who, what)**

Set an ACL for mailbox. The method is non-standard, but is supported by the cyrus server.

**IMAP4. setannotation(mailbox, entry, attribute[, ...])**
Set annotations for mailbox. The method is non-standard, but is supported by the cyrus server.

New in version 2.5.

IMAP4. `setquota(root, limits)`
Set the quota root's resource limits. This method is part of the IMAP4 QUOTA extension defined in rfc2087.

New in version 2.3.

IMAP4. `shutdown()`
Close connection established in open. You may override this method.

IMAP4. `socket()`
Returns socket instance used to connect to server.

IMAP4. `sort(sort_criteria, charset, search_criterion[, ...])`
The sort command is a variant of search with sorting semantics for the results. Returned data contains a space separated list of matching message numbers.

Sort has two arguments before the search_criterion argument(s); a parenthesized list of sort_criteria, and the searching charset. Note that unlike search, the searching charset argument is mandatory. There is also a uid sort command which corresponds to sort the way that uid search corresponds to search. The sort command first searches the mailbox for messages that match the given searching criteria using the charset argument for the interpretation of strings in the searching criteria. It then returns the numbers of matching messages.

This is an IMAP4rev1 extension command.
**IMAP4. status(mailbox, names)**
Request named status conditions for `mailbox`.

**IMAP4. store(message_set, command, flag_list)**
Alters flag dispositions for messages in `mailbox`. `command` is specified by section 6.4.6 of RFC 2060 as being one of “FLAGS”, “+FLAGS”, or “-FLAGS”, optionally with a suffix of “.SILENT”.

For example, to set the delete flag on all messages:

```python
typ, data = M.search(None, 'ALL')
for num in data[0].split():
    M.store(num, '+FLAGS', '\Deleted')
M.expunge()
```

**IMAP4. subscribe(mailbox)**
Subscribe to new `mailbox`.

**IMAP4. thread(threading_algorithm, charset, search_criterion[, ...])**
The `thread` command is a variant of `search` with threading semantics for the results. Returned data contains a space separated list of thread members.

Thread members consist of zero or more messages numbers, delimited by spaces, indicating successive parent and child.

Thread has two arguments before the `search_criterion` argument(s); a `threading_algorithm`, and the searching `charset`. Note that unlike `search`, the searching `charset` argument is mandatory. There is also a `uid` thread command which corresponds to `thread` the way that `uid search` corresponds to `search`. The `thread` command first searches the mailbox for messages that match the given searching criteria using the charset argument for the interpretation of strings in the searching criteria. It then returns the matching messages threaded
according to the specified threading algorithm.

This is an IMAP4rev1 extension command.

*New in version 2.4.*

**IMAP4.** \texttt{uid(command, arg[, ...])}
Execute command args with messages identified by UID, rather than message number. Returns response appropriate to command. At least one argument must be supplied; if none are provided, the server will return an error and an exception will be raised.

**IMAP4.** \texttt{unsubscribe(mailbox)}
Unsubscribe from old mailbox.

**IMAP4.** \texttt{xatom(name[, arg[, ...]])}
Allow simple extension commands notified by server in \texttt{CAPABILITY} response.

Instances of \texttt{IMAP4_SSL} have just one additional method:

**IMAP4_SSL.** \texttt{ssl()}
Returns SSLObject instance used for the secure connection with the server.

The following attributes are defined on instances of \texttt{IMAP4}:

**IMAP4.** \texttt{PROTOCOL_VERSION}
The most recent supported protocol in the \texttt{CAPABILITY} response from the server.

**IMAP4.** \texttt{debug}
Integer value to control debugging output. The initialize value is taken from the module variable \texttt{Debug}. Values greater than three
trace each command.
20.10.2. IMAP4 Example

Here is a minimal example (without error checking) that opens a mailbox and retrieves and prints all messages:

```python
import getpass, imaplib
M = imaplib.IMAP4()
M.login(getpass.getuser(), getpass.getpass())
M.select()
typ, data = M.search(None, 'ALL')
for num in data[0].split():
    typ, data = M.fetch(num, '(RFC822)')
    print 'Message %s
%s
' % (num, data[0][1])
M.close()
M.logout()
```
The Python Standard Library » 20. Internet Protocols and Support »
This module defines the class `NNTP` which implements the client side of the NNTP protocol. It can be used to implement a news reader or poster, or automated news processors. For more information on NNTP (Network News Transfer Protocol), see Internet RFC 977.

Here are two small examples of how it can be used. To list some statistics about a newsgroup and print the subjects of the last 10 articles:

```python
>>> s = NNTP('news.cwi.nl')
>>> resp, count, first, last, name = s.group('comp.lang.python')
>>> print 'Group', name, 'has', count, 'articles, range', first, 'to', last
Group comp.lang.python has 59 articles, range 3742 to 3803
>>> resp, subs = s.xhdr('subject', first + '-' + last)
>>> for id, sub in subs[-10:]: print id, sub
...
3792 Re: Removing elements from a list while iterating...
3793 Re: Who likes Info files?
3794 Emacs and doc strings
3795 a few questions about the Mac implementation
3796 Re: executable python scripts
3797 Re: executable python scripts
3798 Re: a few questions about the Mac implementation
3799 Re: PROPOSAL: A Generic Python Object Interface for Python
3802 Re: executable python scripts
3803 Re: `POSIX{}` wait and SIGCHLD
>>> s.quit()
'205 news.cwi.nl closing connection. Goodbye.'
```

To post an article from a file (this assumes that the article has valid headers):

```python
>>> s = NNTP('news.cwi.nl')
>>> f = open('/tmp/article')
>>> s.post(f)
```
The module itself defines the following items:

```python
class nntplib.NNTP(host[, port[, user[, password[, readermode][, usenetrc]]]])
```

Return a new instance of the `NNTP` class, representing a connection to the NNTP server running on host `host`, listening at port `port`. The default `port` is 119. If the optional `user` and `password` are provided, or if suitable credentials are present in `.netrc` and the optional flag `usenetrc` is true (the default), the `AUTHINFO USER` and `AUTHINFO PASS` commands are used to identify and authenticate the user to the server. If the optional flag `readermode` is true, then a `mode reader` command is sent before authentication is performed. Reader mode is sometimes necessary if you are connecting to an NNTP server on the local machine and intend to call reader-specific commands, such as `group`. If you get unexpected `NNTPPermanentErrors`, you might need to set `readermode`. `readermode` defaults to `None`. `usenetrc` defaults to `True`.

*Changed in version 2.4: usenetrc argument added.*

```python
exception nntplib.NNTPError
```

Derived from the standard exception `Exception`, this is the base class for all exceptions raised by the `nntplib` module.

```python
exception nntplib.NNTReplyError
```

Exception raised when an unexpected reply is received from the server. For backwards compatibility, the exception `error_reply` is equivalent to this class.
exception nntplib.NNTPTemporaryError
Exception raised when an error code in the range 400–499 is received. For backwards compatibility, the exception error_temp is equivalent to this class.

exception nntplib.NNTPPermanentError
Exception raised when an error code in the range 500–599 is received. For backwards compatibility, the exception error_perm is equivalent to this class.

exception nntplib.NNTPProtocolError
Exception raised when a reply is received from the server that does not begin with a digit in the range 1–5. For backwards compatibility, the exception error_proto is equivalent to this class.

exception nntplib.NNTPDataError
Exception raised when there is some error in the response data. For backwards compatibility, the exception error_data is equivalent to this class.
20.11.1. NNTP Objects

NNTP instances have the following methods. The response that is returned as the first item in the return tuple of almost all methods is the server’s response: a string beginning with a three-digit code. If the server’s response indicates an error, the method raises one of the above exceptions.

NNTP.getwelcome()

Return the welcome message sent by the server in reply to the initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

NNTP.set_debuglevel(level)

Set the instance’s debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request or response. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the connection (including message text).

NNTP.newgroups(date, time[, file])

Send a NEWGROUPS command. The date argument should be a string of the form 'ymd' indicating the date, and time should be a string of the form 'hms' indicating the time. Return a pair (response, groups) where groups is a list of group names that are new since the given date and time. If the file parameter is supplied, then the output of the NEWGROUPS command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command.
output. If file is supplied, then the returned list is an empty list.

**NNTP. newnews**(*group, date, time[, file]*)

Send a NEWNEWS command. Here, group is a group name or '*', and date and time have the same meaning as for newgroups(). Return a pair (response, articles) where articles is a list of message ids. If the file parameter is supplied, then the output of the NEWNEWS command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

**NNTP. list**([file])

Send a LIST command. Return a pair (response, list) where list is a list of tuples. Each tuple has the form (group, last, first, flag), where group is a group name, last and first are the last and first article numbers (as strings), and flag is 'y' if posting is allowed, 'n' if not, and 'm' if the newsgroup is moderated. (Note the ordering: last, first.) If the file parameter is supplied, then the output of the LIST command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

**NNTP. descriptions**(*grouppattern*)

Send a LIST NEWSGROUPS command, where grouppattern is a wildmat string as specified in RFC2980 (it's essentially the same as DOS or UNIX shell wildcard strings). Return a pair (response, list), where list is a list of tuples containing (name, title).
New in version 2.4.

**NNTP. `description(group)`**
Get a description for a single group `group`. If more than one group matches (if ‘group’ is a real wildmat string), return the first match. If no group matches, return an empty string.

This elides the response code from the server. If the response code is needed, use `descriptions()`.

New in version 2.4.

**NNTP. `group(name)`**
Send a `GROUP` command, where `name` is the group name. Return a tuple `(response, count, first, last, name)` where `count` is the (estimated) number of articles in the group, `first` is the first article number in the group, `last` is the last article number in the group, and `name` is the group name. The numbers are returned as strings.

**NNTP. `help([file])`**
Send a `HELP` command. Return a pair `(response, list)` where `list` is a list of help strings. If the `file` parameter is supplied, then the output of the `HELP` command is stored in a file. If `file` is a string, then the method will open a file object with that name, write to it then close it. If `file` is a file object, then it will start calling `write()` on it to store the lines of the command output. If `file` is supplied, then the returned `list` is an empty list.

**NNTP. `stat(id)`**
Send a `STAT` command, where `id` is the message id (enclosed in `'<' and '>'`) or an article number (as a string). Return a triple `(response, number, id)` where `number` is the article number (as a string) and `id` is the message id (enclosed in `'<' and '>'`).
NNTP. **next()**
Send a `NEXT` command. Return as for **stat()**.

NNTP. **last()**
Send a `LAST` command. Return as for **stat()**.

NNTP. **head(id)**
Send a `HEAD` command, where `id` has the same meaning as for **stat()**. Return a tuple `(response, number, id, list)` where the first three are the same as for **stat()**, and `list` is a list of the article's headers (an uninterpreted list of lines, without trailing newlines).

NNTP. **body(id[, file])**
Send a `BODY` command, where `id` has the same meaning as for **stat()**. If the `file` parameter is supplied, then the body is stored in a file. If `file` is a string, then the method will open a file object with that name, write to it then close it. If `file` is a file object, then it will start calling `write()` on it to store the lines of the body. Return as for **head()**. If `file` is supplied, then the returned `list` is an empty list.

NNTP. **article(id)**
Send an `ARTICLE` command, where `id` has the same meaning as for **stat()**. Return as for **head()**.

NNTP. **slave()**
Send a `SLAVE` command. Return the server's `response`.

NNTP. **xhdr(header, string[, file])**
Send an `XHDR` command. This command is not defined in the RFC but is a common extension. The `header` argument is a header keyword, e.g. `'subject'`. The `string` argument should
have the form 'first-last' where first and last are the first and last article numbers to search. Return a pair (response, list), where list is a list of pairs (id, text), where id is an article number (as a string) and text is the text of the requested header for that article. If the file parameter is supplied, then the output of the \texttt{XHDR} command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling \texttt{write()} on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

\texttt{NNTP.post(file)}
Post an article using the post command. The file argument is an open file object which is read until EOF using its \texttt{readline()} method. It should be a well-formed news article, including the required headers. The \texttt{post()} method automatically escapes lines beginning with ".

\texttt{NNTP.ihave(id, file)}
Send an \texttt{IHAVE} command. id is a message id (enclosed in '<' and '>'). If the response is not an error, treat file exactly as for the \texttt{post()} method.

\texttt{NNTP.date()}
Return a triple (response, date, time), containing the current date and time in a form suitable for the \texttt{newnews()} and \texttt{newgroups()} methods. This is an optional NNTP extension, and may not be supported by all servers.

\texttt{NNTP.xgtitle(name[, file])}
Process an \texttt{XGTITLE} command, returning a pair (response, list), where list is a list of tuples containing (name, title). If the
file parameter is supplied, then the output of the XGTITLE command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list. This is an optional NNTP extension, and may not be supported by all servers.

RFC2980 says “It is suggested that this extension be deprecated”. Use descriptions() or description() instead.

NNTP. xover(start, end[, file])
Return a pair (resp, list). list is a list of tuples, one for each article in the range delimited by the start and end article numbers. Each tuple is of the form (article number, subject, poster, date, id, references, size, lines). If the file parameter is supplied, then the output of the XOVER command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list. This is an optional NNTP extension, and may not be supported by all servers.

NNTP. xpath(id)
Return a pair (resp, path), where path is the directory path to the article with message ID id. This is an optional NNTP extension, and may not be supported by all servers.

NNTP. quit()
Send a QUIT command and close the connection. Once this method has been called, no other methods of the NNTP object should be called.
20.12. smtplib — SMTP protocol client

The `smtplib` module defines an SMTP client session object that can be used to send mail to any Internet machine with an SMTP or ESMTP listener daemon. For details of SMTP and ESMTP operation, consult RFC 821 (Simple Mail Transfer Protocol) and RFC 1869 (SMTP Service Extensions).

```python
class smtplib.SMTP([host[, port[, local_hostname[, timeout]]]])
```

A `SMTP` instance encapsulates an SMTP connection. It has methods that support a full repertoire of SMTP and ESMTP operations. If the optional host and port parameters are given, the SMTP `connect()` method is called with those parameters during initialization. An `SMTPConnectError` is raised if the specified host doesn’t respond correctly. The optional `timeout` parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

For normal use, you should only require the initialization/connect, `sendmail()`, and `quit()` methods. An example is included below.

*Changed in version 2.6*: `timeout` was added.

```python
class smtplib.SMTP_SSL([host[, port[, local_hostname[, keyfile[, certfile[, timeout]]]]])
```

A `SMTP_SSL` instance behaves exactly the same as instances of `SMTP`. `SMTP_SSL` should be used for situations where SSL is required from the beginning of the connection and using `starttls()` is not appropriate. If `host` is not specified, the local
host is used. If port is omitted, the standard SMTP-over-SSL port (465) is used. keyfile and certfile are also optional, and can contain a PEM formatted private key and certificate chain file for the SSL connection. The optional timeout parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Changed in version 2.6: timeout was added.

class smtplib.LMTP([host[, port[, local_hostname]]])

The LMTP protocol, which is very similar to ESMTP, is heavily based on the standard SMTP client. It's common to use Unix sockets for LMTP, so our connect() method must support that as well as a regular host:port server. To specify a Unix socket, you must use an absolute path for host, starting with a ‘/’.

Authentication is supported, using the regular SMTP mechanism. When using a Unix socket, LMTP generally don’t support or require any authentication, but your mileage might vary.

New in version 2.6.

A nice selection of exceptions is defined as well:

exception smtplib.SMTPException

Base exception class for all exceptions raised by this module.

exception smtplib.SMTPServerDisconnected

This exception is raised when the server unexpectedly disconnects, or when an attempt is made to use the SMTP instance before connecting it to a server.

exception smtplib.SMTPResponseException

Base class for all exceptions that include an SMTP error code.
These exceptions are generated in some instances when the SMTP server returns an error code. The error code is stored in the `smtp_code` attribute of the error, and the `smtp_error` attribute is set to the error message.

**exception smtplib.SMTPSenderRefused**

Sender address refused. In addition to the attributes set by on all `SMTPResponseException` exceptions, this sets ‘sender’ to the string that the SMTP server refused.

**exception smtplib.SMTPRecipientsRefused**

All recipient addresses refused. The errors for each recipient are accessible through the attribute `recipients`, which is a dictionary of exactly the same sort as `SMTP.sendmail()` returns.

**exception smtplib.SMTPDataError**

The SMTP server refused to accept the message data.

**exception smtplib.SMTPConnectError**

Error occurred during establishment of a connection with the server.

**exception smtplib.SMTPHeloError**

The server refused our HELO message.

**exception smtplib.SMTPAuthenticationError**

SMTP authentication went wrong. Most probably the server didn’t accept the username/password combination provided.

See also:

**RFC 821 - Simple Mail Transfer Protocol**

Protocol definition for SMTP. This document covers the model, operating procedure, and protocol details for SMTP.

**RFC 1869 - SMTP Service Extensions**
Definition of the ESMTP extensions for SMTP. This describes a framework for extending SMTP with new commands, supporting dynamic discovery of the commands provided by the server, and defines a few additional commands.
20.12.1. SMTP Objects

An SMTP instance has the following methods:

**SMTP. `set_debuglevel(level)`**
Set the debug output level. A true value for `level` results in debug messages for connection and for all messages sent to and received from the server.

**SMTP. `connect([host[, port]])`**
Connect to a host on a given port. The defaults are to connect to the local host at the standard SMTP port (25). If the hostname ends with a colon (`:`) followed by a number, that suffix will be stripped off and the number interpreted as the port number to use. This method is automatically invoked by the constructor if a host is specified during instantiation.

**SMTP. `docmd(cmd[, argstring])`**
Send a command `cmd` to the server. The optional argument `argstring` is simply concatenated to the command, separated by a space.

This returns a 2-tuple composed of a numeric response code and the actual response line (multiline responses are joined into one long line.)

In normal operation it should not be necessary to call this method explicitly. It is used to implement other methods and may be useful for testing private extensions.

If the connection to the server is lost while waiting for the reply, `SMTPServerDisconnected` will be raised.
**SMTP.** `helo([hostname])`  
Identify yourself to the SMTP server using **HELO**. The hostname argument defaults to the fully qualified domain name of the local host. The message returned by the server is stored as the `helo_resp` attribute of the object.

In normal operation it should not be necessary to call this method explicitly. It will be implicitly called by the `sendmail()` when necessary.

**SMTP.** `ehlo([hostname])`  
Identify yourself to an ESMTP server using **EHL0**. The hostname argument defaults to the fully qualified domain name of the local host. Examine the response for ESMTP option and store them for use by `has_extn()`. Also sets several informational attributes: the message returned by the server is stored as the `ehlo_resp` attribute, `does_esmtp` is set to true or false depending on whether the server supports ESMTP, and `esmtp_features` will be a dictionary containing the names of the SMTP service extensions this server supports, and their parameters (if any).

Unless you wish to use `has_extn()` before sending mail, it should not be necessary to call this method explicitly. It will be implicitly called by `sendmail()` when necessary.

**SMTP.** `ehlo_or_helo_if_needed()`  
This method call `ehlo()` and or `helo()` if there has been no previous **EHL0** or **HELO** command this session. It tries ESMTP **EHL0** first.

**SMTPHeloError**  
The server didn’t reply properly to the **HELO** greeting.
New in version 2.6.

SMTP. **has_extn**(name)

Return **True** if *name* is in the set of SMTP service extensions returned by the server, **False** otherwise. Case is ignored.

SMTP. **verify**(address)

Check the validity of an address on this server using SMTP **VRFY**. Returns a tuple consisting of code 250 and a full RFC 822 address (including human name) if the user address is valid. Otherwise returns an SMTP error code of 400 or greater and an error string.

**Note:** Many sites disable SMTP **VRFY** in order to foil spammers.

SMTP. **login**(user, password)

Log in on an SMTP server that requires authentication. The arguments are the username and the password to authenticate with. If there has been no previous **EHLO** or **HELO** command this session, this method tries ESMTP **EHLO** first. This method will return normally if the authentication was successful, or may raise the following exceptions:

**SMTPHeloError**

The server didn’t reply properly to the **HELO** greeting.

**SMTPAuthenticationError**

The server didn’t accept the username/password combination.

**SMTPException**

No suitable authentication method was found.
**SMTP.starttls([keyfile[, certfile]])**

Put the SMTP connection in TLS (Transport Layer Security) mode. All SMTP commands that follow will be encrypted. You should then call `ehlo()` again.

If `keyfile` and `certfile` are provided, these are passed to the `socket` module's `ssl()` function.

If there has been no previous `EHLO` or `HELO` command this session, this method tries ESMTP `EHLO` first.

*Changed in version 2.6.*

**SMTPHeloError**

The server didn't reply properly to the `HELO` greeting.

**SMTPException**

The server does not support the STARTTLS extension.

*Changed in version 2.6.*

**RuntimeError**

SSL/TLS support is not available to your Python interpreter.

**SMTP.sendmail(from_addr, to_addr, msg[, mail_options, rcpt_options])**

Send mail. The required arguments are an RFC 822 from-address string, a list of RFC 822 to-address strings (a bare string will be treated as a list with 1 address), and a message string. The caller may pass a list of ESMTP options (such as `8bitmime`) to be used in `MAIL FROM` commands as `mail_options`. ESMTP options (such as `DSN` commands) that should be used with all `RCPT` commands can be passed as `rcpt_options`. (If you need to use different ESMTP options to different recipients you have to
use the low-level methods such as `mail()`, `rcpt()` and `data()` to send the message.)

**Note:** The `from_addr` and `to_addrs` parameters are used to construct the message envelope used by the transport agents. The SMTP does not modify the message headers in any way.

If there has been no previous `EHLO` or `HELO` command this session, this method tries ESMTP `EHLO` first. If the server does ESMTP, message size and each of the specified options will be passed to it (if the option is in the feature set the server advertises). If `EHLO` fails, `HELO` will be tried and ESMTP options suppressed.

This method will return normally if the mail is accepted for at least one recipient. Otherwise it will throw an exception. That is, if this method does not throw an exception, then someone should get your mail. If this method does not throw an exception, it returns a dictionary, with one entry for each recipient that was refused. Each entry contains a tuple of the SMTP error code and the accompanying error message sent by the server.

This method may raise the following exceptions:

**SMTPRecipientsRefused**

All recipients were refused. Nobody got the mail. The `recipients` attribute of the exception object is a dictionary with information about the refused recipients (like the one returned when at least one recipient was accepted).

**SMTPHeloError**

The server didn’t reply properly to the `HELO` greeting.

**SMTPSenderRefused**

The server didn’t accept the `from_addr`. 
**SMTPDataError**

The server replied with an unexpected error code (other than a refusal of a recipient).

Unless otherwise noted, the connection will be open even after an exception is raised.

**SMTP.quit()**

Terminate the SMTP session and close the connection. Return the result of the SMTP **quit** command.

*Changed in version 2.6:* Return a value.

Low-level methods corresponding to the standard SMTP/ESMTP commands **HELP**, **RSET**, **NOOP**, **MAIL**, **RCPT**, and **DATA** are also supported. Normally these do not need to be called directly, so they are not documented here. For details, consult the module code.
20.12.2. SMTP Example

This example prompts the user for addresses needed in the message envelope ('To' and 'From' addresses), and the message to be delivered. Note that the headers to be included with the message must be included in the message as entered; this example doesn't do any processing of the RFC 822 headers. In particular, the 'To' and 'From' addresses must be included in the message headers explicitly.

```python
import smtplib

def prompt(prompt):
    return raw_input(prompt).strip()

fromaddr = prompt("From: ")
toaddrs = prompt("To: ").split()
print "Enter message, end with ^D (Unix) or ^Z (Windows):"

# Add the From: and To: headers at the start!
msg = ("From: %s\r\nTo: %s\r\n\n" % (fromaddr,", ".join(toaddrs)))
while 1:
    try:
        line = raw_input()
    except EOFError:
        break
    if not line:
        break
    msg = msg + line
print "Message length is " + repr(len(msg))

server = smtplib.SMTP('localhost')
server.set_debuglevel(1)
server.sendmail(fromaddr, toaddrs, msg)
server.quit()
```

Note: In general, you will want to use the email package's features to construct an email message, which you can then
convert to a string and send via `sendmail()`; see email: Examples.
This module offers several classes to implement SMTP servers. One is a generic do-nothing implementation, which can be overridden, while the other two offer specific mail-sending strategies.
20.13.1. SMTPServer Objects

```python
class smtpd.SMTPServer(localaddr, remoteaddr)
```

Create a new `SMTPServer` object, which binds to local address `localaddr`. It will treat `remoteaddr` as an upstream SMTP relayer. It inherits from `asyncore.dispatcher`, and so will insert itself into `asyncore`'s event loop on instantiation.

```python
process_message(peer, mailfrom, rcpttos, data)
```

Raise `NotImplementedError` exception. Override this in subclasses to do something useful with this message. Whatever was passed in the constructor as `remoteaddr` will be available as the `_remoteaddr` attribute. `peer` is the remote host's address, `mailfrom` is the envelope originator, `rcpttos` are the envelope recipients and `data` is a string containing the contents of the e-mail (which should be in RFC 2822 format).
20.13.2. DebuggingServer Objects

```
class smtpd.DebuggingServer(localaddr, remoteaddr)
    Create a new debugging server. Arguments are as per
    SMTPServer. Messages will be discarded, and printed on stdout.
```
20.13.3. PureProxy Objects

class smtpd.**PureProxy**(localaddr, remoteaddr)

Create a new pure proxy server. Arguments are as per **SMTPServer**. Everything will be relayed to *remoteaddr*. Note that running this has a good chance to make you into an open relay, so please be careful.
class smtpd.MailmanProxy(localaddr, remoteaddr)

Create a new pure proxy server. Arguments are as per SMTPServer. Everything will be relayed to remoteaddr, unless local mailman configurations knows about an address, in which case it will be handled via mailman. Note that running this has a good chance to make you into an open relay, so please be careful.
The telnetlib module provides a Telnet class that implements the Telnet protocol. See RFC 854 for details about the protocol. In addition, it provides symbolic constants for the protocol characters (see below), and for the telnet options. The symbolic names of the telnet options follow the definitions in arpa/telnet.h, with the leading TELOPT_ removed. For symbolic names of options which are traditionally not included in arpa/telnet.h, see the module source itself.

The symbolic constants for the telnet commands are: IAC, DONT, DO, WONT, WILL, SE (Subnegotiation End), NOP (No Operation), DM (Data Mark), BRK (Break), IP (Interrupt process), AO (Abort output), AYT (Are You There), EC (Erase Character), EL (Erase Line), GA (Go Ahead), SB (Subnegotiation Begin).

```python
class telnetlib.Telnet([host[, port[, timeout]]])
```

Telnet represents a connection to a Telnet server. The instance is initially not connected by default; the open() method must be used to establish a connection. Alternatively, the host name and optional port number can be passed to the constructor, to, in which case the connection to the server will be established before the constructor returns. The optional timeout parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Do not reopen an already connected instance.

This class has many read_*() methods. Note that some of them raise EOFError when the end of the connection is read, because they can return an empty string for other reasons. See the
individual descriptions below.

*Changed in version 2.6: timeout was added.*

See also:

**RFC 854 - Telnet Protocol Specification**

Definition of the Telnet protocol.
20.14.1. Telnet Objects

Telnet instances have the following methods:

**Telnet.** `read_until(expected[, timeout])`  
Read until a given string, `expected`, is encountered or until `timeout` seconds have passed.

When no match is found, return whatever is available instead, possibly the empty string. Raise `EOFError` if the connection is closed and no cooked data is available.

**Telnet.** `read_all()`  
Read all data until EOF; block until connection closed.

**Telnet.** `read_some()`  
Read at least one byte of cooked data unless EOF is hit. Return '' if EOF is hit. Block if no data is immediately available.

**Telnet.** `read_very_eager()`  
Read everything that can be without blocking in I/O (eager).

Raise `EOFError` if connection closed and no cooked data available. Return '' if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

**Telnet.** `read_eager()`  
Read readily available data.

Raise `EOFError` if connection closed and no cooked data available. Return '' if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.
Telnet. **read_lazy()**

Process and return data already in the queues (lazy).

Raise **EOFError** if connection closed and no data available. Return `'` if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

Telnet. **read_very_lazy()**

Return any data available in the cooked queue (very lazy).

Raise **EOFError** if connection closed and no data available. Return `'` if no cooked data available otherwise. This method never blocks.

Telnet. **read_sb_data()**

Return the data collected between a SB/SE pair (suboption begin/end). The callback should access these data when it was invoked with a SE command. This method never blocks.

*New in version 2.3.*

Telnet. **open**(host[, port[, timeout]])

Connect to a host. The optional second argument is the port number, which defaults to the standard Telnet port (23). The optional **timeout** parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Do not try to reopen an already connected instance.

*Changed in version 2.6: timeout was added.*

Telnet. **msg**(msg[, *args])**

Print a debug message when the debug level is $> 0$. If extra
arguments are present, they are substituted in the message using the standard string formatting operator.

Telnet. `set_debuglevel(debuglevel)`
Set the debug level. The higher the value of `debuglevel`, the more debug output you get (on `sys.stdout`).

Telnet. `close()`
Close the connection.

Telnet. `get_socket()`
Return the socket object used internally.

Telnet. `fileno()`
Return the file descriptor of the socket object used internally.

Telnet. `write(buffer)`
Write a string to the socket, doubling any IAC characters. This can block if the connection is blocked. May raise `socket.error` if the connection is closed.

Telnet. `interact()`
Interaction function, emulates a very dumb Telnet client.

Telnet. `mt_interact()`
Multithreaded version of `interact()`.

Telnet. `expect(list[, timeout])`  
Read until one from a list of a regular expressions matches.

The first argument is a list of regular expressions, either compiled (`re.RegexObject` instances) or uncompiled (strings). The optional second argument is a timeout, in seconds; the default is to block indefinitely.
Return a tuple of three items: the index in the list of the first regular expression that matches; the match object returned; and the text read up till and including the match.

If end of file is found and no text was read, raise `EOFError`. Otherwise, when nothing matches, return `(-1, None, text)` where `text` is the text received so far (may be the empty string if a timeout happened).

If a regular expression ends with a greedy match (such as `.*`) or if more than one expression can match the same input, the results are indeterministic, and may depend on the I/O timing.

Telnet. `set_option_negotiation_callback(callback)`
Each time a telnet option is read on the input flow, this `callback` (if set) is called with the following parameters : `callback(telnet socket, command (DO/DONT/WILL/WONT), option)`. No other action is done afterwards by telnetlib.
20.14.2. Telnet Example

A simple example illustrating typical use:

```python
import getpass
import sys
import telnetlib

HOST = "localhost"
user = raw_input("Enter your remote account: ")
password = getpass.getpass()
	n = telnetlib.Telnet(HOST)
	n.read_until("login: ")
	n.write(user + "\n")

if password:
    t.read_until("Password: ")
    t.write(password + "\n")
	n.write("ls\n")
	n.write("exit\n")

print t.read_all()
```
20.15. uuid — UUID objects according to RFC 4122

New in version 2.5.

This module provides immutable UUID objects (the UUID class) and the functions uuid1(), uuid3(), uuid4(), uuid5() for generating version 1, 3, 4, and 5 UUIDs as specified in RFC 4122.

If all you want is a unique ID, you should probably call uuid1() or uuid4(). Note that uuid1() may compromise privacy since it creates a UUID containing the computer's network address. uuid4() creates a random UUID.

```python
class uuid.UUID([hex[, bytes[, bytes_le[, fields[, int[, version]]]]]]))
```

Create a UUID from either a string of 32 hexadecimal digits, a string of 16 bytes as the bytes argument, a string of 16 bytes in little-endian order as the bytes_le argument, a tuple of six integers (32-bit time_low, 16-bit time_mid, 16-bit time_hi_version, 8-bit clock_seq_hi_variant, 8-bit clock_seq_low, 48-bit node) as the fields argument, or a single 128-bit integer as the int argument. When a string of hex digits is given, curly braces, hyphens, and aURN prefix are all optional. For example, these expressions all yield the same UUID:

- `UUID('{12345678-1234-5678-1234-567812345678}')`
- `UUID('12345678123456781234567812345678')`
- `UUID('urn:uuid:12345678-1234-5678-1234-567812345678')`
- `UUID(bytes='\x12\x34\x56\x78'*4)`
- `UUID(bytes_le='\x78\x56\x34\x12\x34\x12\x78\x56' + '\x12\x34\x56\x78\x12\x34\x56\x78')`
- `UUID(fields=(0x12345678, 0x1234, 0x5678, 0x12, 0x34, 0x56781))`
- `UUID(int=0x12345678123456781234567812345678)`
Exactly one of *hex*, *bytes*, *bytes_le*, *fields*, or *int* must be given. The *version* argument is optional; if given, the resulting UUID will have its variant and version number set according to RFC 4122, overriding bits in the given *hex*, *bytes*, *bytes_le*, *fields*, or *int*.

**UUID** instances have these read-only attributes:

**UUID. bytes**
The UUID as a 16-byte string (containing the six integer fields in big-endian byte order).

**UUID. bytes_le**
The UUID as a 16-byte string (with *time_low*, *time_mid*, and *time_hi_version* in little-endian byte order).

**UUID. fields**
A tuple of the six integer fields of the UUID, which are also available as six individual attributes and two derived attributes:

<table>
<thead>
<tr>
<th>Field</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>time_low</em></td>
<td>the first 32 bits of the UUID</td>
</tr>
<tr>
<td><em>time_mid</em></td>
<td>the next 16 bits of the UUID</td>
</tr>
<tr>
<td><em>time_hi_version</em></td>
<td>the next 16 bits of the UUID</td>
</tr>
<tr>
<td><em>clock_seq_hi_variant</em></td>
<td>the next 8 bits of the UUID</td>
</tr>
<tr>
<td><em>clock_seq_low</em></td>
<td>the next 8 bits of the UUID</td>
</tr>
<tr>
<td><em>node</em></td>
<td>the last 48 bits of the UUID</td>
</tr>
<tr>
<td><em>time</em></td>
<td>the 60-bit timestamp</td>
</tr>
<tr>
<td><em>clock_seq</em></td>
<td>the 14-bit sequence number</td>
</tr>
</tbody>
</table>

**UUID. hex**
The UUID as a 32-character hexadecimal string.

**UUID. int**
The UUID as a 128-bit integer.
**UUID. urn**

The UUID as aURN as specified in RFC 4122.

**UUID. variant**

The UUID variant, which determines the internal layout of the UUID. This will be one of the integer constants `RESERVED_NCS`, `RFC_4122`, `RESERVED_MICROSOFT`, or `RESERVED_FUTURE`.

**UUID. version**

The UUID version number (1 through 5, meaningful only when the variant is `RFC_4122`).

The `uuid` module defines the following functions:

**uuid.getnode()**

Get the hardware address as a 48-bit positive integer. The first time this runs, it may launch a separate program, which could be quite slow. If all attempts to obtain the hardware address fail, we choose a random 48-bit number with its eighth bit set to 1 as recommended in RFC 4122. “Hardware address” means the MAC address of a network interface, and on a machine with multiple network interfaces the MAC address of any one of them may be returned.

**uuid.uuid1([node[, clock_seq]])**

Generate a UUID from a host ID, sequence number, and the current time. If `node` is not given, `getnode()` is used to obtain the hardware address. If `clock_seq` is given, it is used as the sequence number; otherwise a random 14-bit sequence number is chosen.

**uuid.uuid3(namespace, name)**

Generate a UUID based on the MD5 hash of a namespace identifier (which is a UUID) and a name (which is a string).
The `uuid` module defines the following namespace identifiers for use with `uuid3()` or `uuid5()`.

- **NAMESPACE_DNS**
  When this namespace is specified, the `name` string is a fully-qualified domain name.

- **NAMESPACE_URL**
  When this namespace is specified, the `name` string is a URL.

- **NAMESPACE_OID**
  When this namespace is specified, the `name` string is an ISO OID.

- **NAMESPACE_X500**
  When this namespace is specified, the `name` string is an X.500 DN in DER or a text output format.

The `uuid` module defines the following constants for the possible values of the `variant` attribute:

- **RESERVED_NCS**
  Reserved for NCS compatibility.

- **RFC_4122**
  Specifies the UUID layout given in RFC 4122.

- **RESERVED_MICROSOFT**
  Reserved for Microsoft compatibility.
uuid. **RESERVED_FUTURE**

Reserved for future definition.

**See also:**

**RFC 4122 - A Universally Unique IDentifier (UUID) URN Namespace**

This specification defines a Uniform Resource Name namespace for UUIDs, the internal format of UUIDs, and methods of generating UUIDs.
20.15.1. Example

Here are some examples of typical usage of the `uuid` module:

```python
>>> import uuid

# make a UUID based on the host ID and current time
>>> uuid.uuid1()
UUID('a8098c1a-f86e-11da-bd1a-00112444be1e')

# make a UUID using an MD5 hash of a namespace UUID and a name
>>> uuid.uuid3(uuid.NAMESPACE_DNS, 'python.org')
UUID('6fa459ea-ee8a-3ca4-894e-db77e160355e')

# make a random UUID
>>> uuid.uuid4()
UUID('16fd2706-8baf-433b-82eb-8c7fada847da')

# make a UUID using a SHA-1 hash of a namespace UUID and a name
>>> uuid.uuid5(uuid.NAMESPACE_DNS, 'python.org')
UUID('886313e1-3b8a-5372-9b90-0c9aee199e5d')

# make a UUID from a string of hex digits (braces and hyphens ignored)
>>> x = uuid.UUID('{00010203-0405-0607-0809-0a0b0c0d0e0f}')

# convert a UUID to a string of hex digits in standard form
>>> str(x)
'00010203-0405-0607-0809-0a0b0c0d0e0f'

# get the raw 16 bytes of the UUID
>>> x.bytes
'\x00\x01\x02\x03\x04\x05\x06\x07\x08\t\n\x0b\x0c\r\xe\xf'

# make a UUID from a 16-byte string
>>> uuid.UUID(bytes=x.bytes)
UUID('00010203-0405-0607-0809-0a0b0c0d0e0f')
```
20.16. urlparse — Parse URLs into components

Note: The urlparse module is renamed to urllib.parse in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

This module defines a standard interface to break Uniform Resource Locator (URL) strings up in components (addressing scheme, network location, path etc.), to combine the components back into a URL string, and to convert a “relative URL” to an absolute URL given a “base URL.”

The module has been designed to match the Internet RFC on Relative Uniform Resource Locators (and discovered a bug in an earlier draft!). It supports the following URL schemes: file, ftp, gopher, hdl, http, https, imap, mailto, mms, news, nntp, prospero, rsync, rtsp, rtspu, sftp, shttp, sip, sips, snews, svn, svn+ssh, telnet, wais.

New in version 2.5: Support for the sftp and sips schemes.

The urlparse module defines the following functions:

`urlparse(urlstring[, scheme[, allowfragments]])`

Parse a URL into six components, returning a 6-tuple. This corresponds to the general structure of a URL: `scheme://netloc/path;parameters?query#fragment`. Each tuple item is a string, possibly empty. The components are not broken up in smaller parts (for example, the network location is a single string), and % escapes are not expanded. The delimiters as shown above are not part of the result, except for a leading slash.
in the *path* component, which is retained if present. For example:

```python
g>>> from urlparse import urlparse
g>>> o = urlparse('http://www.cwi.nl:80/%7Eguido/Python.html')
g>>> o  # doctest: +NORMALIZE_WHITESPACE
ParseResult(scheme='http', netloc='www.cwi.nl:80', path='/%7Eguido/Python.html', params='', query='', fragment='')
g>>> o.scheme
'http'
g>>> o.port
80
g>>> o.geturl()
'http://www.cwi.nl:80/%7Eguido/Python.html'
```

If the *scheme* argument is specified, it gives the default addressing scheme, to be used only if the URL does not specify one. The default value for this argument is the empty string.

If the *allow_fragments* argument is false, fragment identifiers are not allowed, even if the URL’s addressing scheme normally does support them. The default value for this argument is *True*.

The return value is actually an instance of a subclass of *tuple*. This class has the following additional read-only convenience attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Index</th>
<th>Value</th>
<th>Value if not present</th>
</tr>
</thead>
<tbody>
<tr>
<td>scheme</td>
<td>0</td>
<td>URL scheme specifier</td>
<td>empty string</td>
</tr>
<tr>
<td>netloc</td>
<td>1</td>
<td>Network location part</td>
<td>empty string</td>
</tr>
<tr>
<td>path</td>
<td>2</td>
<td>Hierarchical path</td>
<td>empty string</td>
</tr>
<tr>
<td>params</td>
<td>3</td>
<td>Parameters for last path element</td>
<td>empty string</td>
</tr>
<tr>
<td>query</td>
<td>4</td>
<td>Query component</td>
<td>empty string</td>
</tr>
<tr>
<td>fragment</td>
<td>5</td>
<td>Fragment identifier</td>
<td>empty string</td>
</tr>
<tr>
<td>username</td>
<td></td>
<td>User name</td>
<td>None</td>
</tr>
<tr>
<td>password</td>
<td></td>
<td>Password</td>
<td>None</td>
</tr>
<tr>
<td>hostname</td>
<td>Host name (lower case)</td>
<td>None</td>
<td></td>
</tr>
<tr>
<td>----------</td>
<td>------------------------</td>
<td>------</td>
<td></td>
</tr>
<tr>
<td>port</td>
<td>Port number as integer, if present</td>
<td>None</td>
<td></td>
</tr>
</tbody>
</table>

See section *Results of urlparse() and urlsplit()* for more information on the result object.

*Changed in version 2.5:* Added attributes to return value.

*Changed in version 2.7:* Added IPv6 URL parsing capabilities.

```python
code
urlparse.parse_qs(qs[, keep_blank_values[, strict_parsing]])
```

Parse a query string given as a string argument (data of type `application/x-www-form-urlencoded`). Data are returned as a dictionary. The dictionary keys are the unique query variable names and the values are lists of values for each name.

The optional argument `keep_blank_values` is a flag indicating whether blank values in URL encoded queries should be treated as blank strings. A true value indicates that blanks should be retained as blank strings. The default false value indicates that blank values are to be ignored and treated as if they were not included.

The optional argument `strict_parsing` is a flag indicating what to do with parsing errors. If false (the default), errors are silently ignored. If true, errors raise a `ValueError` exception.

Use the `urllib.urlencode()` function to convert such dictionaries into query strings.

*New in version 2.6:* Copied from the `cgi` module.

```python
code
urlparse.parse_qsl(qs[, keep_blank_values[, strict_parsing]])
```
Parse a query string given as a string argument (data of type `application/x-www-form-urlencoded`). Data are returned as a list of name, value pairs.

The optional argument `keep_blank_values` is a flag indicating whether blank values in URL encoded queries should be treated as blank strings. A true value indicates that blanks should be retained as blank strings. The default false value indicates that blank values are to be ignored and treated as if they were not included.

The optional argument `strict_parsing` is a flag indicating what to do with parsing errors. If false (the default), errors are silently ignored. If true, errors raise a `ValueError` exception.

Use the `urllib.urlencode()` function to convert such lists of pairs into query strings.

*New in version 2.6:* Copied from the `cgi` module.

**urllib.urlunparse**(parts)

Construct a URL from a tuple as returned by `urllib.parse()`. The `parts` argument can be any six-item iterable. This may result in a slightly different, but equivalent URL, if the URL that was parsed originally had unnecessary delimiters (for example, a ? with an empty query; the RFC states that these are equivalent).

**urllib.urlsplit**(urlstring[, scheme[, allow_fragments]])

This is similar to `urlparse()`, but does not split the params from the URL. This should generally be used instead of `urlparse()` if the more recent URL syntax allowing parameters to be applied to each segment of the `path` portion of the URL (see `RFC 2396`) is wanted. A separate function is needed to separate the path segments and parameters. This function returns a 5-tuple:
The return value is actually an instance of a subclass of \texttt{tuple}. This class has the following additional read-only convenience attributes:

\begin{table}[h]
\centering
\begin{tabular}{|l|c|p{6cm}|p{6cm}|}
\hline
\textbf{Attribute} & \textbf{Index} & \textbf{Value} & \textbf{Value if not present} \\
\hline
\text{scheme} & 0 & URL scheme specifier & empty string \\
\text{netloc} & 1 & Network location part & empty string \\
\text{path} & 2 & Hierarchical path & empty string \\
\text{query} & 3 & Query component & empty string \\
\text{fragment} & 4 & Fragment identifier & empty string \\
\text{username} & & User name & \text{None} \\
\text{password} & & Password & \text{None} \\
\text{hostname} & & Host name (lower case) & \text{None} \\
\text{port} & & Port number as integer, if present & \text{None} \\
\hline
\end{tabular}
\end{table}

See section \texttt{Results of urlparse() and urlsplit()} for more information on the result object.

\textit{New in version 2.2.}

\textit{Changed in version 2.5: Added attributes to return value.}

\texttt{urlparse.urlunsplit\(\textit{\text{parts}}\)}

Combine the elements of a tuple as returned by \texttt{urlsplit()} into a complete URL as a string. The \textit{parts} argument can be any five-item iterable. This may result in a slightly different, but equivalent URL, if the URL that was parsed originally had unnecessary delimiters (for example, a \texttt{?} with an empty query; the RFC states
that these are equivalent).

New in version 2.2.

`urlparse.urljoin(base, url[, allow_fragments])`

Construct a full ("absolute") URL by combining a "base URL" (*base*) with another URL (*url*). Informally, this uses components of the base URL, in particular the addressing scheme, the network location and (part of) the path, to provide missing components in the relative URL. For example:

```python
>>> from urlparse import urljoin
>>> urljoin('http://www.cwi.nl/%7Eguido/Python.html', 'FAQ.html')
'http://www.cwi.nl/%7Eguido/FAQ.html'
```

The *allow_fragments* argument has the same meaning and default as for `urlparse()`.

**Note:** If *url* is an absolute URL (that is, starting with // or scheme://), the *url*'s host name and/or scheme will be present in the result. For example:

```python
>>> urljoin('http://www.cwi.nl/%7Eguido/Python.html', ...  '://www.python.org/%7Eguido')
'http://www.python.org/%7Eguido'
```

If you do not want that behavior, preprocess the *url* with `urlsplit()` and `urlunsplit()`, removing possible scheme and netloc parts.

`urlparse.urldefrag(url)`

If *url* contains a fragment identifier, returns a modified version of *url* with no fragment identifier, and the fragment identifier as a separate string. If there is no fragment identifier in *url*, returns *url* unmodified and an empty string.
See also:

**RFC 3986 - Uniform Resource Identifiers**
This is the current standard (STD66). Any changes to urlparse module should conform to this. Certain deviations could be observed, which are mostly due backward compatibility purposes and for certain de-facto parsing requirements as commonly observed in major browsers.

**RFC 2732 - Format for Literal IPv6 Addresses in URL’s.**
This specifies the parsing requirements of IPv6 URLs.

**RFC 2396 - Uniform Resource Identifiers (URI): Generic Syntax**
Document describing the generic syntactic requirements for both Uniform Resource Names (URNs) and Uniform Resource Locators (URLs).

**RFC 2368 - The mailto URL scheme.**
Parsing requirements for mailto url schemes.

**RFC 1808 - Relative Uniform Resource Locators**
This Request For Comments includes the rules for joining an absolute and a relative URL, including a fair number of “Abnormal Examples” which govern the treatment of border cases.

**RFC 1738 - Uniform Resource Locators (URL)**
This specifies the formal syntax and semantics of absolute URLs.
The result objects from the `urllib.parse()` and `urllib.split()` functions are subclasses of the `tuple` type. These subclasses add the attributes described in those functions, as well as provide an additional method:

`ParseResult.geturl()`

Return the re-combined version of the original URL as a string. This may differ from the original URL in that the scheme will always be normalized to lower case and empty components may be dropped. Specifically, empty parameters, queries, and fragment identifiers will be removed.

The result of this method is a fixpoint if passed back through the original parsing function:

```python
>>> import urllib.parse
>>> url = 'HTTP://www.Python.org/doc/#'

>>> r1 = urllib.parse.urlsplit(url)
>>> r1.geturl()
'http://www.Python.org/doc/'

>>> r2 = urllib.parse.urlsplit(r1.geturl())
>>> r2.geturl()
'http://www.Python.org/doc/'
```

*New in version 2.5.*

The following classes provide the implementations of the parse results:

```python
class urllib.BaseResult

Base class for the concrete result classes. This provides most of
the attribute definitions. It does not provide a `geturl()` method. It is derived from `tuple`, but does not override the `__init__()` or `__new__()` methods.

```python
class urlparse.ParseResult(scheme, netloc, path, params, query, fragment)
```
Concrete class for `urlparse()` results. The `__new__()` method is overridden to support checking that the right number of arguments are passed.

```python
class urlparse.SplitResult(scheme, netloc, path, query, fragment)
```
Concrete class for `urlsplit()` results. The `__new__()` method is overridden to support checking that the right number of arguments are passed.
20.17. **SocketServer — A framework for network servers**

**Note:** The `SocketServer` module has been renamed to `socketserver` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

The `SocketServer` module simplifies the task of writing network servers.

There are four basic server classes: `TCPServer` uses the Internet TCP protocol, which provides for continuous streams of data between the client and server. `UDPServer` uses datagrams, which are discrete packets of information that may arrive out of order or be lost while in transit. The more infrequently used `UnixStreamServer` and `UnixDatagramServer` classes are similar, but use Unix domain sockets; they're not available on non-Unix platforms. For more details on network programming, consult a book such as W. Richard Steven's UNIX Network Programming or Ralph Davis's Win32 Network Programming.

These four classes process requests *synchronously*; each request must be completed before the next request can be started. This isn't suitable if each request takes a long time to complete, because it requires a lot of computation, or because it returns a lot of data which the client is slow to process. The solution is to create a separate process or thread to handle each request; the `ForkingMixIn` and `ThreadingMixIn` mix-in classes can be used to support asynchronous behaviour.

Creating a server requires several steps. First, you must create a request handler class by subclassing the `BaseRequestHandler` class
and overriding its `handle()` method; this method will process incoming requests. Second, you must instantiate one of the server classes, passing it the server’s address and the request handler class. Finally, call the `handle_request()` or `serve_forever()` method of the server object to process one or many requests.

When inheriting from `ThreadingMixIn` for threaded connection behavior, you should explicitly declare how you want your threads to behave on an abrupt shutdown. The `ThreadingMixIn` class defines an attribute `daemon_threads`, which indicates whether or not the server should wait for thread termination. You should set the flag explicitly if you would like threads to behave autonomously; the default is `False`, meaning that Python will not exit until all threads created by `ThreadingMixIn` have exited.

Server classes have the same external methods and attributes, no matter what network protocol they use.
20.17.1. Server Creation Notes

There are five classes in an inheritance diagram, four of which represent synchronous servers of four types:

```
+------------+
| BaseServer |
+------------+
    |
    v
+------------+ +------------------+
| TCPServer |------>| UnixStreamServer |
+------------+ +------------------+
    |
    v
+------------+ +------------------+
| UDPServer |------>| UnixDatagramServer |
+------------+ +------------------+
```

Note that `UnixDatagramServer` derives from `UDPServer`, not from `UnixStreamServer` — the only difference between an IP and a Unix stream server is the address family, which is simply repeated in both Unix server classes.

Forking and threading versions of each type of server can be created using the `ForkingMixIn` and `ThreadingMixIn` mix-in classes. For instance, a threading UDP server class is created as follows:

```python
class ThreadingUDPServer(ThreadingMixIn, UDPServer): pass
```

The mix-in class must come first, since it overrides a method defined in `UDPServer`. Setting the various member variables also changes the behavior of the underlying server mechanism.

To implement a service, you must derive a class from `BaseRequestHandler` and redefine its `handle()` method. You can then
run various versions of the service by combining one of the server classes with your request handler class. The request handler class must be different for datagram or stream services. This can be hidden by using the handler subclasses StreamRequestHandler or DatagramRequestHandler.

Of course, you still have to use your head! For instance, it makes no sense to use a forking server if the service contains state in memory that can be modified by different requests, since the modifications in the child process would never reach the initial state kept in the parent process and passed to each child. In this case, you can use a threading server, but you will probably have to use locks to protect the integrity of the shared data.

On the other hand, if you are building an HTTP server where all data is stored externally (for instance, in the file system), a synchronous class will essentially render the service “deaf” while one request is being handled – which may be for a very long time if a client is slow to receive all the data it has requested. Here a threading or forking server is appropriate.

In some cases, it may be appropriate to process part of a request synchronously, but to finish processing in a forked child depending on the request data. This can be implemented by using a synchronous server and doing an explicit fork in the request handler class handle() method.

Another approach to handling multiple simultaneous requests in an environment that supports neither threads nor fork() (or where these are too expensive or inappropriate for the service) is to maintain an explicit table of partially finished requests and to use select() to decide which request to work on next (or whether to handle a new incoming request). This is particularly important for stream services where each client can potentially be connected for a
long time (if threads or subprocesses cannot be used). See \texttt{asyncore}
for another way to manage this.
20.17.2. Server Objects

`class` SocketServer. **BaseServer**

This is the superclass of all Server objects in the module. It defines the interface, given below, but does not implement most of the methods, which is done in subclasses.

**BaseServer. `fileno()`**

Return an integer file descriptor for the socket on which the server is listening. This function is most commonly passed to `select.select()`, to allow monitoring multiple servers in the same process.

**BaseServer. `handle_request()`**

Process a single request. This function calls the following methods in order: `get_request()`, `verify_request()`, and `process_request()`. If the user-provided `handle()` method of the handler class raises an exception, the server’s `handle_error()` method will be called. If no request is received within `self.timeout` seconds, `handle_timeout()` will be called and `handle_request()` will return.

**BaseServer. `serve_forever`**

Handle requests until an explicit `shutdown()` request. Polls for shutdown every `poll_interval` seconds.

**BaseServer. `shutdown()`**

Tells the `serve_forever()` loop to stop and waits until it does.

*New in version 2.6.*

**BaseServer. `address_family`**

The family of protocols to which the server’s socket belongs.
Common examples are `socket.AF_INET` and `socket.AF_UNIX`.

**BaseServer.** RequestHandlerClass
The user-provided request handler class; an instance of this class is created for each request.

**BaseServer.** server_address
The address on which the server is listening. The format of addresses varies depending on the protocol family; see the documentation for the socket module for details. For Internet protocols, this is a tuple containing a string giving the address, and an integer port number: (`'127.0.0.1'`, 80), for example.

**BaseServer.** socket
The socket object on which the server will listen for incoming requests.

The server classes support the following class variables:

**BaseServer.** allow_reuse_address
Whether the server will allow the reuse of an address. This defaults to `False`, and can be set in subclasses to change the policy.

**BaseServer.** request_queue_size
The size of the request queue. If it takes a long time to process a single request, any requests that arrive while the server is busy are placed into a queue, up to `request_queue_size` requests. Once the queue is full, further requests from clients will get a “Connection denied” error. The default value is usually 5, but this can be overridden by subclasses.

**BaseServer.** socket_type
The type of socket used by the server; `socket.SOCK_STREAM` and `socket.SOCK_DGRAM` are two common values.
BaseServer. **timeout**

Timeout duration, measured in seconds, or **None** if no timeout is desired. If **handle_request()** receives no incoming requests within the timeout period, the **handle_timeout()** method is called.

There are various server methods that can be overridden by subclasses of base server classes like **TCPServer**; these methods aren’t useful to external users of the server object.

BaseServer. **finish_request()**

Actually processes the request by instantiating **RequestHandlerClass** and calling its **handle()** method.

BaseServer. **get_request()**

Must accept a request from the socket, and return a 2-tuple containing the **new** socket object to be used to communicate with the client, and the client’s address.

BaseServer. **handle_error**(*request*, *client_address*)

This function is called if the **RequestHandlerClass**'s **handle()** method raises an exception. The default action is to print the traceback to standard output and continue handling further requests.

BaseServer. **handle_timeout()**

This function is called when the **timeout** attribute has been set to a value other than **None** and the timeout period has passed with no requests being received. The default action for forking servers is to collect the status of any child processes that have exited, while in threading servers this method does nothing.

BaseServer. **process_request**(*request*, *client_address*)

Calls **finish_request()** to create an instance of the **RequestHandlerClass**. If desired, this function can create a new
process or thread to handle the request; the `ForkingMixIn` and `ThreadingMixIn` classes do this.

**BaseServer.** `server_activate()`  
Called by the server’s constructor to activate the server. The default behavior just `listen()`s to the server’s socket. May be overridden.

**BaseServer.** `server_bind()`  
Called by the server’s constructor to bind the socket to the desired address. May be overridden.

**BaseServer.** `verify_request(request, client_address)`  
Must return a Boolean value; if the value is `True`, the request will be processed, and if it’s `False`, the request will be denied. This function can be overridden to implement access controls for a server. The default implementation always returns `True`. 
20.17.3. RequestHandler Objects

The request handler class must define a new `handle()` method, and can override any of the following methods. A new instance is created for each request.

RequestHandler. **finish()**

Called after the `handle()` method to perform any clean-up actions required. The default implementation does nothing. If `setup()` or `handle()` raise an exception, this function will not be called.

RequestHandler. **handle()**

This function must do all the work required to service a request. The default implementation does nothing. Several instance attributes are available to it; the request is available as `self.request`; the client address as `self.client_address`; and the server instance as `self.server`, in case it needs access to per-server information.

The type of `self.request` is different for datagram or stream services. For stream services, `self.request` is a socket object; for datagram services, `self.request` is a pair of string and socket. However, this can be hidden by using the request handler subclasses `StreamRequestHandler` or `DatagramRequestHandler`, which override the `setup()` and `finish()` methods, and provide `self.rfile` and `self.wfile` attributes. `self.rfile` and `self.wfile` can be read or written, respectively, to get the request data or return data to the client.

RequestHandler. **setup()**

Called before the `handle()` method to perform any initialization actions required. The default implementation does nothing.
20.17.4. Examples

20.17.4.1. SocketServer.TCPServer Example

This is the server side:

```python
import SocketServer

class MyTCPHandler(SocketServer.BaseRequestHandler):
    
    # The RequestHandler class for our server.

    def handle(self):
        # self.request is the TCP socket connected to the client
        self.data = self.request.recv(1024).strip()
        print "%s wrote:" % self.client_address[0]
        print self.data
        # just send back the same data, but upper-cased
        self.request.send(self.data.upper())

if __name__ == '__main__':
    HOST, PORT = "localhost", 9999

    # Create the server, binding to localhost on port 9999
    server = SocketServer.TCPServer((HOST, PORT), MyTCPHandler)

    # Activate the server; this will keep running until you
    # interrupt the program with Ctrl-C
    server.serve_forever()
```

An alternative request handler class that makes use of streams (file-like objects that simplify communication by providing the standard file interface):

```python
class MyTCPHandler(SocketServer.StreamRequestHandler):
```

def handle(self):
    # self.rfile is a file-like object created by the handler;
    # we can now use e.g. readline() instead of raw recv() calls
    self.data = self.rfile.readline().strip()
    print "%s wrote:" % self.client_address[0]
    print self.data
    # Likewise, self.wfile is a file-like object used to write
    # to the client
    self.wfile.write(self.data.upper())

The difference is that the readline() call in the second handler will call recv() multiple times until it encounters a newline character, while the single recv() call in the first handler will just return what has been sent from the client in one send() call.

This is the client side:

```python
import socket
import sys

HOST, PORT = "localhost", 9999
data = " ".join(sys.argv[1:])

# Create a socket (SOCK_STREAM means a TCP socket)
sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)

# Connect to server and send data
sock.connect((HOST, PORT))
sock.send(data + "\n")

# Receive data from the server and shut down
received = sock.recv(1024)
sock.close()

print "Sent: %s" % data
print "Received: %s" % received
```

The output of the example should look something like this:

Server:
Client:

$ python TCPServer.py
127.0.0.1 wrote:
hello world with TCP
127.0.0.1 wrote:
python is nice

$ python TCPClient.py hello world with TCP
Sent: hello world with TCP
Received: HELLO WORLD WITH TCP
$ python TCPClient.py python is nice
Sent: python is nice
Received: PYTHON IS NICE

20.17.4.2. **SocketServer.UDPServer Example**

This is the server side:

```python
import SocketServer

class MyUDPHandler(SocketServer.BaseRequestHandler):
    """
    This class works similar to the TCP handler class, except that
    self.request consists of a pair of data and client socket, and
    there is no connection the client address must be given exp
    when sending data back via sendto().
    """
    def handle(self):
        data = self.request[0].strip()
        socket = self.request[1]
        print "%s wrote:" % self.client_address[0]
        print data
        socket.sendto(data.upper(), self.client_address)

if __name__ == "__main__":
    HOST, PORT = "localhost", 9999
    server = SocketServer.UDPServer((HOST, PORT), MyUDPHandler)
    server.serve_forever()
```

This is the client side:
import socket
import sys

HOST, PORT = "localhost", 9999
data = " ".join(sys.argv[1:])

# SOCK_DGRAM is the socket type to use for UDP sockets
sock = socket.socket(socket.AF_INET, socket.SOCK_DGRAM)

# As you can see, there is no connect() call; UDP has no connection.
# Instead, data is directly sent to the recipient via sendto().
sock.sendto(data + "\n", (HOST, PORT))
received = sock.recv(1024)

print "Sent: %s" % data
print "Received: %s" % received

The output of the example should look exactly like for the TCP server example.

20.17.4.3. Asynchronous Mixins

To build asynchronous handlers, use the ThreadingMixIn and ForkingMixIn classes.

An example for the ThreadingMixIn class:

import socket
import threading
import SocketServer

class ThreadedTCPRequestHandler(SocketServer.BaseRequestHandler):
    def handle(self):
        data = self.request.recv(1024)
        cur_thread = threading.currentThread()
        response = "%s: %s" % (cur_thread.getName(), data)
        self.request.send(response)

class ThreadedTCPServer(SocketServer.ThreadingMixIn, SocketServer.TCPServer): pass
```python
def client(ip, port, message):
    sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
    sock.connect((ip, port))
    sock.send(message)
    response = sock.recv(1024)
    print "Received: %s" % response
    sock.close()

if __name__ == "__main__":
    # Port 0 means to select an arbitrary unused port
    HOST, PORT = "localhost", 0

    server = ThreadedTCPServer((HOST, PORT), ThreadedTCPRequestHandler)
    ip, port = server.server_address

    # Start a thread with the server -- that thread will then spin
    # more thread for each request
    server_thread = threading.Thread(target=server.serve_forever)
    # Exit the server thread when the main thread terminates
    server_thread.setDaemon(True)
    server_thread.start()
    print "Server loop running in thread: ", server_thread.getName()

    client(ip, port, "Hello World 1")
    client(ip, port, "Hello World 2")
    client(ip, port, "Hello World 3")

    server.shutdown()
```

The output of the example should look something like this:

```
$ python ThreadedTCPServer.py
Server loop running in thread: Thread-1
Received: Thread-2: Hello World 1
Received: Thread-3: Hello World 2
Received: Thread-4: Hello World 3
```

The **ForkingMixIn** class is used in the same way, except that the server will spawn a new process for each request.
20.18. **BaseHTTPServer — Basic HTTP server**

**Note:** The **BaseHTTPServer** module has been merged into **http.server** in Python 3.0. The **2to3** tool will automatically adapt imports when converting your sources to 3.0.

This module defines two classes for implementing HTTP servers (Web servers). Usually, this module isn’t used directly, but is used as a basis for building functioning Web servers. See the **SimpleHTTPServer** and **CGIHTTPServer** modules.

The first class, **HTTPServer**, is a **SocketServer.TCPServer** subclass, and therefore implements the **SocketServer.BaseServer** interface. It creates and listens at the HTTP socket, dispatching the requests to a handler. Code to create and run the server looks like this:

```python
def run(server_class=BaseHTTPServer.HTTPServer,
       handler_class=BaseHTTPServer.BaseHTTPRequestHandler):
    server_address = ('', 8000)
    httpd = server_class(server_address, handler_class)
    httpd.serve_forever()
```

**class** **BaseHTTPServer.HTTPServer** *(server_address, RequestHandlerClass)*

This class builds on the **TCPServer** class by storing the server address as instance variables named **server_name** and **server_port**. The server is accessible by the handler, typically through the handler’s **server** instance variable.

**class** **BaseHTTPServer.BaseHTTPRequestHandler** *(request, client_address, server)*

This class is used to handle the HTTP requests that arrive at the
server. By itself, it cannot respond to any actual HTTP requests; it must be subclassed to handle each request method (e.g. GET or POST). BaseHTTPRequestHandler provides a number of class and instance variables, and methods for use by subclasses.

The handler will parse the request and the headers, then call a method specific to the request type. The method name is constructed from the request. For example, for the request method _SPAM_, the _do_SPAM_() method will be called with no arguments. All of the relevant information is stored in instance variables of the handler. Subclasses should not need to override or extend the _`__init__`_ method.

BaseHTTPRequestHandler has the following instance variables:

**client_address**
Contains a tuple of the form (host, port) referring to the client’s address.

**server**
Contains the server instance.

**command**
Contains the command (request type). For example, 'GET'.

**path**
Contains the request path.

**request_version**
Contains the version string from the request. For example, 'HTTP/1.0'.

**headers**
Holds an instance of the class specified by the MessageClass class variable. This instance parses and manages the headers in the HTTP request.
rfile
Contains an input stream, positioned at the start of the optional input data.

wfile
Contains the output stream for writing a response back to the client. Proper adherence to the HTTP protocol must be used when writing to this stream.

**BaseHTTPRequestHandler** has the following class variables:

**server_version**
Specifies the server software version. You may want to override this. The format is multiple whitespace-separated strings, where each string is of the form name[/version]. For example, 'BaseHTTP/0.2'.

**sys_version**
Contains the Python system version, in a form usable by the **version_string** method and the **server_version** class variable. For example, 'Python/1.4'.

**error_message_format**
Specifies a format string for building an error response to the client. It uses parenthesized, keyed format specifiers, so the format operand must be a dictionary. The *code* key should be an integer, specifying the numeric HTTP error code value. *message* should be a string containing a (detailed) error message of what occurred, and *explain* should be an explanation of the error code number. Default *message* and *explain* values can found in the **responses** class variable.

**error_content_type**
Specifies the Content-Type HTTP header of error responses sent to the client. The default value is 'text/html'.

*New in version 2.6:* Previously, the content type was always
protocol_version

This specifies the HTTP protocol version used in responses. If set to 'HTTP/1.1', the server will permit HTTP persistent connections; however, your server must then include an accurate Content-Length header (using send_header()) in all of its responses to clients. For backwards compatibility, the setting defaults to 'HTTP/1.0'.

MessageClass

Specifies a rfc822.Message-like class to parse HTTP headers. Typically, this is not overridden, and it defaults to mimetools.Message.

responses

This variable contains a mapping of error code integers to two-element tuples containing a short and long message. For example, {code: (shortmessage, longmessage)}. The shortmessage is usually used as the message key in an error response, and longmessage as the explain key (see the error_message_format class variable).

A BaseHTTPRequestHandler instance has the following methods:

handle()

Calls handle_one_request() once (or, if persistent connections are enabled, multiple times) to handle incoming HTTP requests. You should never need to override it; instead, implement appropriate do_*( ) methods.

handle_one_request()

This method will parse and dispatch the request to the appropriate do_*( ) method. You should never need to override it.
**send_error**(code[, message])

Sends and logs a complete error reply to the client. The numeric *code* specifies the HTTP error code, with *message* as optional, more specific text. A complete set of headers is sent, followed by text composed using the *error_message_format* class variable.

**send_response**(code[, message])

Sends a response header and logs the accepted request. The HTTP response line is sent, followed by *Server* and *Date* headers. The values for these two headers are picked up from the *version_string()* and *date_time_string()* methods, respectively.

**send_header**(keyword, value)

Writes a specific HTTP header to the output stream. *keyword* should specify the header keyword, with *value* specifying its value.

**end_headers**()

Sends a blank line, indicating the end of the HTTP headers in the response.

**log_request**(code[, size])

Logs an accepted (successful) request. *code* should specify the numeric HTTP code associated with the response. If a size of the response is available, then it should be passed as the *size* parameter.

**log_error**(...)

Logs an error when a request cannot be fulfilled. By default, it passes the message to *log_message()* , so it takes the same arguments (*format* and additional values).

**log_message**(format, ...)

Logs an arbitrary message to `sys.stderr`. This is typically overridden to create custom error logging mechanisms. The `format` argument is a standard printf-style format string, where the additional arguments to `log_message()` are applied as inputs to the formatting. The client address and current date and time are prefixed to every message logged.

**version_string()**

Returns the server software's version string. This is a combination of the `server_version` and `sys_version` class variables.

**date_time_string([timestamp])**

Returns the date and time given by `timestamp` (which must be in the format returned by `time.time()`), formatted for a message header. If `timestamp` is omitted, it uses the current date and time.

The result looks like 'Sun, 06 Nov 1994 08:49:37 GMT'.

*New in version 2.5:* The `timestamp` parameter.

**log_date_time_string()**

Returns the current date and time, formatted for logging.

**address_string()**

Returns the client address, formatted for logging. A name lookup is performed on the client's IP address.
20.18.1. More examples

To create a server that doesn’t run forever, but until some condition is fulfilled:

```python
def run_while_true(server_class=BaseHTTPServer.HTTPServer,
                   handler_class=BaseHTTPServer.BaseHTTPRequestHandler):
    """
    This assumes that keep_running() is a function of no arguments which
    is tested initially and after each request. If its return is true, the server continues.
    """
    server_address = ('', 8000)
    httpd = server_class(server_address, handler_class)
    while keep_running():
        httpd.handle_request()
```

See also:

**Module** CGIHTTPServer

Extended request handler that supports CGI scripts.

**Module** SimpleHTTPServer

Basic request handler that limits response to files actually under the document root.
20.19. SimpleHTTPServer — Simple HTTP request handler

**Note:** The SimpleHTTPServer module has been merged into http.server in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The SimpleHTTPServer module defines a single class, SimpleHTTPRequestHandler, which is interface-compatible with BaseHTTPServer.BaseHTTPRequestHandler.

The SimpleHTTPServer module defines the following class:

```python
class SimpleHTTPServer.SimpleHTTPRequestHandler(request, client_address, server)
```

This class serves files from the current directory and below, directly mapping the directory structure to HTTP requests.

A lot of the work, such as parsing the request, is done by the base class BaseHTTPServer.BaseHTTPRequestHandler. This class implements the `do_GET()` and `do_HEAD()` functions.

The following are defined as class-level attributes of SimpleHTTPRequestHandler:

```plaintext
server_version
```

This will be "SimpleHTTP/" + __version__, where __version__ is defined at the module level.

```plaintext
extensions_map
```

A dictionary mapping suffixes into MIME types. The default is signified by an empty string, and is considered to be
application/octet-stream. The mapping is used case-insensitively, and so should contain only lower-cased keys.

The **SimpleHTTPRequestHandler** class defines the following methods:

**do_HEAD()**
This method serves the 'HEAD' request type: it sends the headers it would send for the equivalent **GET** request. See the **do_GET()** method for a more complete explanation of the possible headers.

**do_GET()**
The request is mapped to a local file by interpreting the request as a path relative to the current working directory.

If the request was mapped to a directory, the directory is checked for a file named `index.html` or `index.htm` (in that order). If found, the file's contents are returned; otherwise a directory listing is generated by calling the **list_directory()** method. This method uses `os.listdir()` to scan the directory, and returns a 404 error response if the **listdir()** fails.

If the request was mapped to a file, it is opened and the contents are returned. Any **IOError** exception in opening the requested file is mapped to a 404, 'File not found' error. Otherwise, the content type is guessed by calling the **guess_type()** method, which in turn uses the **extensions_map** variable.

A 'Content-type:' header with the guessed content type is output, followed by a 'Content-Length:' header with the file's size and a 'Last-Modified:' header with the file's modification time.
Then follows a blank line signifying the end of the headers, and then the contents of the file are output. If the file's MIME type starts with `text/` the file is opened in text mode; otherwise binary mode is used.

The `test()` function in the `SimpleHTTPServer` module is an example which creates a server using the `SimpleHTTPRequestHandler` as the Handler.

*New in version 2.5:* The 'Last-Modified' header.

The `SimpleHTTPServer` module can be used in the following manner in order to set up a very basic web server serving files relative to the current directory.

```python
import SimpleHTTPServer
import SocketServer

PORT = 8000

Handler = SimpleHTTPServer.SimpleHTTPRequestHandler

httpd = SocketServer.TCPServer(('', PORT), Handler)

print "serving at port", PORT
httpd.serve_forever()
```

The `SimpleHTTPServer` module can also be invoked directly using the `-m` switch of the interpreter with a `port number` argument. Similar to the previous example, this serves the files relative to the current directory.

```bash
python -m SimpleHTTPServer 8000
```

**See also:**

**Module** `BaseHTTPServer`
Base class implementation for Web server and request handler.
20.20. CGIHTTPServer — CGI-capable HTTP request handler

**Note:** The CGIHTTPServer module has been merged into http.server in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The CGIHTTPServer module defines a request-handler class, interface compatible with BaseHTTPServer.BaseHTTPRequestHandler and inherits behavior from SimpleHTTPServer.SimpleHTTPRequestHandler but can also run CGI scripts.

**Note:** This module can run CGI scripts on Unix and Windows systems.

**Note:** CGI scripts run by the CGIHTTPRequestHandler class cannot execute redirects (HTTP code 302), because code 200 (script output follows) is sent prior to execution of the CGI script. This pre-empts the status code.

The CGIHTTPServer module defines the following class:

```python
class CGIHTTPServer.CGIHTTPRequestHandler(request, client_address, server)
```

This class is used to serve either files or output of CGI scripts from the current directory and below. Note that mapping HTTP hierarchic structure to local directory structure is exactly as in SimpleHTTPServer.SimpleHTTPRequestHandler.

The class will however, run the CGI script, instead of serving it as a file, if it guesses it to be a CGI script. Only directory-based CGI are used — the other common server configuration is to treat
special extensions as denoting CGI scripts.

The `do_GET()` and `do_HEAD()` functions are modified to run CGI scripts and serve the output, instead of serving files, if the request leads to somewhere below the `cgi_directories` path.

The `CGIHTTPRequestHandler` defines the following data member:

**cgi_directories**
This defaults to `['/cgi-bin', '/htbin']` and describes directories to treat as containing CGI scripts.

The `CGIHTTPRequestHandler` defines the following methods:

**do_POST()**
This method serves the `POST` request type, only allowed for CGI scripts. Error 501, “Can only POST to CGI scripts”, is output when trying to POST to a non-CGI url.

Note that CGI scripts will be run with UID of user nobody, for security reasons. Problems with the CGI script will be translated to error 403.

For example usage, see the implementation of the `test()` function.

**Module BaseHTTPServer**
Base class implementation for Web server and request handler.
20.21. `cookielib` — Cookie handling for HTTP clients

**Note:** The `cookielib` module has been renamed to `http.cookiejar` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

*New in version 2.4.*

The `cookielib` module defines classes for automatic handling of HTTP cookies. It is useful for accessing web sites that require small pieces of data – *cookies* – to be set on the client machine by an HTTP response from a web server, and then returned to the server in later HTTP requests.

Both the regular Netscape cookie protocol and the protocol defined by [RFC 2965](https://www.rfc-editor.org/rfc/rfc2965) are handled. RFC 2965 handling is switched off by default. [RFC 2109](https://www.rfc-editor.org/rfc/rfc2109) cookies are parsed as Netscape cookies and subsequently treated either as Netscape or RFC 2965 cookies according to the ‘policy’ in effect. Note that the great majority of cookies on the Internet are Netscape cookies. `cookielib` attempts to follow the de-facto Netscape cookie protocol (which differs substantially from that set out in the original Netscape specification), including taking note of the `max-age` and `port` cookie-attributes introduced with RFC 2965.

**Note:** The various named parameters found in *Set-Cookie* and *Set-Cookie2* headers (eg. `domain` and `expires`) are conventionally referred to as *attributes*. To distinguish them from Python attributes, the documentation for this module uses the term *cookie-attribute* instead.
The module defines the following exception:

```
exception cookielib.LoadError
```

Instances of `FileCookieJar` raise this exception on failure to load cookies from a file.

**Note:** For backwards-compatibility with Python 2.4 (which raised an `IOError`), `LoadError` is a subclass of `IOError`.

The following classes are provided:

```
class cookielib.CookieJar(policy=None)
```

`policy` is an object implementing the `CookiePolicy` interface.

The `CookieJar` class stores HTTP cookies. It extracts cookies from HTTP requests, and returns them in HTTP responses. `CookieJar` instances automatically expire contained cookies when necessary. Subclasses are also responsible for storing and retrieving cookies from a file or database.

```
class cookielib.FileCookieJar(filename, delayload=None, policy=None)
```

`policy` is an object implementing the `CookiePolicy` interface. For the other arguments, see the documentation for the corresponding attributes.

A `CookieJar` which can load cookies from, and perhaps save cookies to, a file on disk. Cookies are **NOT** loaded from the named file until either the `load()` or `revert()` method is called. Subclasses of this class are documented in section `FileCookieJar subclasses and co-operation with web browsers`.

```
class cookielib.CookiePolicy
```

This class is responsible for deciding whether each cookie should
be accepted from / returned to the server.

```python
class cookielib.DefaultCookiePolicy(blocked_domains=None, allowed_domains=None, netscape=True, rfc2965=False, rfc2109_as_netscape=None, hide_cookie2=False, strict_domain=False, strict_rfc2965_unverifiable=True, strict_ns_unverifiable=False, strict_ns_domain=DefaultCookiePolicy.DomainLiberal, strict_ns_set_initial_dollar=False, strict_ns_set_path=False)
```

Constructor arguments should be passed as keyword arguments only. `blocked_domains` is a sequence of domain names that we never accept cookies from, nor return cookies to. `allowed_domains` if not `None`, this is a sequence of the only domains for which we accept and return cookies. For all other arguments, see the documentation for `CookiePolicy` and `DefaultCookiePolicy` objects.

`DefaultCookiePolicy` implements the standard accept / reject rules for Netscape and RFC 2965 cookies. By default, RFC 2109 cookies (ie. cookies received in a Set-Cookie header with a version cookie-attribute of 1) are treated according to the RFC 2965 rules. However, if RFC 2965 handling is turned off or `rfc2109_as_netscape` is True, RFC 2109 cookies are ‘downgraded’ by the `CookieJar` instance to Netscape cookies, by setting the `version` attribute of the `Cookie` instance to 0. `DefaultCookiePolicy` also provides some parameters to allow some fine-tuning of policy.

```python
class cookielib.Cookie
```

This class represents Netscape, RFC 2109 and RFC 2965 cookies. It is not expected that users of `cookielib` construct their own `Cookie` instances. Instead, if necessary, call `make_cookies()` on a `CookieJar` instance.
See also:

**Module urllib2**
URL opening with automatic cookie handling.

**Module Cookie**
HTTP cookie classes, principally useful for server-side code. The `cookielib` and `Cookie` modules do not depend on each other.

Extensions to this module, including a class for reading Microsoft Internet Explorer cookies on Windows.

The specification of the original Netscape cookie protocol. Though this is still the dominant protocol, the ‘Netscape cookie protocol’ implemented by all the major browsers (and `cookielib`) only bears a passing resemblance to the one sketched out in `cookie_spec.html`.

**RFC 2109 - HTTP State Management Mechanism**
Obsoleted by RFC 2965. Uses `Set-Cookie` with version=1.

**RFC 2965 - HTTP State Management Mechanism**
The Netscape protocol with the bugs fixed. Uses `Set-Cookie2` in place of `Set-Cookie`. Not widely used.

[http://kristol.org/cookie/errata.html](http://kristol.org/cookie/errata.html)
Unfinished errata to RFC 2965.

**RFC 2964 - Use of HTTP State Management**

CookieJar objects support the iterator protocol for iterating over contained Cookie objects.

CookieJar has the following methods:

CookieJar.add_cookie_header(request)
Add correct Cookie header to request.

If policy allows (ie. the rfc2965 and hide_cookie2 attributes of the CookieJar's CookiePolicy instance are true and false respectively), the Cookie2 header is also added when appropriate.

The request object (usually a urllib2.Request instance) must support the methods get_full_url(), get_host(), get_type(), unverifiable(), get_origin_req_host(), has_header(), get_header(), header_items(), and add_unredirected_header(), as documented by urllib2.

CookieJar.extract_cookies(response, request)
Extract cookies from HTTP response and store them in the CookieJar, where allowed by policy.

The CookieJar will look for allowable Set-Cookie and Set-Cookie2 headers in the response argument, and store cookies as appropriate (subject to the CookiePolicy.set_ok() method's approval).

The response object (usually the result of a call to
urllib2.urlopen(), or similar) should support an info() method, which returns an object with a getallmatchingheaders() method (usually a mimetools.Message instance).

The request object (usually a urllib2.Request instance) must support the methods get_full_url(), get_host(), unverifiable(), and get_origin_req_host(), as documented by urllib2. The request is used to set default values for cookie-attributes as well as for checking that the cookie is allowed to be set.

CookieJar.set_policy(policy)
Set the CookiePolicy instance to be used.

CookieJar.make_cookies(response, request)
Return sequence of Cookie objects extracted from response object.

See the documentation for extract_cookies() for the interfaces required of the response and request arguments.

CookieJar.set_cookie_if_ok(cookie, request)
Set a Cookie if policy says it's OK to do so.

CookieJar.set_cookie(cookie)
Set a Cookie, without checking with policy to see whether or not it should be set.

CookieJar.clear([domain[, path[, name]]])
Clear some cookies.

If invoked without arguments, clear all cookies. If given a single argument, only cookies belonging to that domain will be removed. If given two arguments, cookies belonging to the specified
domain and URL path are removed. If given three arguments, then the cookie with the specified domain, path and name is removed.

Raises KeyError if no matching cookie exists.

CookieJar.clear_session_cookies()
Discard all session cookies.

Discards all contained cookies that have a true discard attribute (usually because they had either no max-age or expires cookie-attribute, or an explicit discard cookie-attribute). For interactive browsers, the end of a session usually corresponds to closing the browser window.

Note that the save() method won't save session cookies anyway, unless you ask otherwise by passing a true ignore_discard argument.

FileCookieJar implements the following additional methods:

FileCookieJar.save(filename=None, ignore_discard=False, ignore.expires=False)
Save cookies to a file.

This base class raises NotImplemented. Subclasses may leave this method unimplemented.

filename is the name of file in which to save cookies. If filename is not specified, self.filename is used (whose default is the value passed to the constructor, if any); if self.filename is None, ValueError is raised.

ignore_discard: save even cookies set to be discarded.
ignore_expired: save even cookies that have expired
The file is overwritten if it already exists, thus wiping all the cookies it contains. Saved cookies can be restored later using the `load()` or `revert()` methods.

FileCookieJar.load(filename=None, ignore_discard=False, ignore_expires=False)

Load cookies from a file.

Old cookies are kept unless overwritten by newly loaded ones.

Arguments are as for `save()`.

The named file must be in the format understood by the class, or `LoadError` will be raised. Also, `IOError` may be raised, for example if the file does not exist.

**Note:** For backwards-compatibility with Python 2.4 (which raised an `IOError`), `LoadError` is a subclass of `IOError`.

FileCookieJar.revert(filename=None, ignore_discard=False, ignore_expires=False)

Clear all cookies and reload cookies from a saved file.

`revert()` can raise the same exceptions as `load()`. If there is a failure, the object’s state will not be altered.

FileCookieJar instances have the following public attributes:

FileCookieJar.filename

Filename of default file in which to keep cookies. This attribute may be assigned to.

FileCookieJar.delayload

If true, load cookies lazily from disk. This attribute should not be assigned to. This is only a hint, since this only affects
performance, not behaviour (unless the cookies on disk are changing). A `CookieJar` object may ignore it. None of the `FileCookieJar` classes included in the standard library lazily loads cookies.
20.21.2. FileCookieJar subclasses and cooperation with web browsers

The following `CookieJar` subclasses are provided for reading and writing. Further `CookieJar` subclasses, including one that reads Microsoft Internet Explorer cookies, are available at http://wwwsearch.sourceforge.net/mechanize/.

```python
class cookielib.MozillaCookieJar(filename, delayload=None, policy=None)
```

A `FileCookieJar` that can load from and save cookies to disk in the Mozilla `cookies.txt` file format (which is also used by the Lynx and Netscape browsers).

**Note:** Version 3 of the Firefox web browser no longer writes cookies in the `cookies.txt` file format.

**Note:** This loses information about RFC 2965 cookies, and also about newer or non-standard cookie-attributes such as `port`.

**Warning:** Back up your cookies before saving if you have cookies whose loss / corruption would be inconvenient (there are some subtleties which may lead to slight changes in the file over a load / save round-trip).

Also note that cookies saved while Mozilla is running will get clobbered by Mozilla.

```python
class cookielib.LWPCookieJar(filename, delayload=None, policy=None)
```

A `FileCookieJar` that can load from and save cookies to disk in...
format compatible with the libwww-perl library’s Set-Cookie3 file format. This is convenient if you want to store cookies in a human-readable file.
20.21.3. CookiePolicy Objects

Objects implementing the CookiePolicy interface have the following methods:

CookiePolicy.set_ok(cookie, request)

Return boolean value indicating whether cookie should be accepted from server.

cookie is a cookielib.Cookie instance. request is an object implementing the interface defined by the documentation for CookieJar.extract_cookies().

CookiePolicy.return_ok(cookie, request)

Return boolean value indicating whether cookie should be returned to server.

cookie is a cookielib.Cookie instance. request is an object implementing the interface defined by the documentation for CookieJar.add_cookie_header().

CookiePolicy.domain_return_ok(domain, request)

Return false if cookies should not be returned, given cookie domain.

This method is an optimization. It removes the need for checking every cookie with a particular domain (which might involve reading many files). Returning true from domain_return_ok() and path_return_ok() leaves all the work to return_ok().

If domain_return_ok() returns true for the cookie domain, path_return_ok() is called for the cookie path. Otherwise, path_return_ok() and return_ok() are never called for that
cookie domain. If `path_return_ok()` returns true, `return_ok()` is called with the `Cookie` object itself for a full check. Otherwise, `return_ok()` is never called for that cookie path.

Note that `domain_return_ok()` is called for every `cookie` domain, not just for the `request` domain. For example, the function might be called with both `.example.com` and `www.example.com` if the request domain is `www.example.com`. The same goes for `path_return_ok()`.

The `request` argument is as documented for `return_ok()`.

**CookiePolicy.path_return_ok(path, request)**
Return false if cookies should not be returned, given cookie path.

See the documentation for `domain_return_ok()`.

In addition to implementing the methods above, implementations of the `CookiePolicy` interface must also supply the following attributes, indicating which protocols should be used, and how. All of these attributes may be assigned to.

**CookiePolicy.netscape**
Implement Netscape protocol.

**CookiePolicy.rfc2965**
Implement RFC 2965 protocol.

**CookiePolicy.hide_cookie2**
Don’t add `Cookie2` header to requests (the presence of this header indicates to the server that we understand RFC 2965 cookies).

The most useful way to define a `CookiePolicy` class is by subclassing from `DefaultCookiePolicy` and overriding some or all of
the methods above. CookiePolicy itself may be used as a ‘null policy’
to allow setting and receiving any and all cookies (this is unlikely to
be useful).
20.21.4. DefaultCookiePolicy Objects

Implements the standard rules for accepting and returning cookies.

Both RFC 2965 and Netscape cookies are covered. RFC 2965 handling is switched off by default.

The easiest way to provide your own policy is to override this class and call its methods in your overridden implementations before adding your own additional checks:

```python
import cookielib
class MyCookiePolicy(cookielib.DefaultCookiePolicy):
    def set_ok(self, cookie, request):
        if not cookielib.DefaultCookiePolicy.set_ok(self, cookie, request):
            return False
        if i_dont_want_to_store_this_cookie(cookie):
            return False
        return True
```

In addition to the features required to implement the `CookiePolicy` interface, this class allows you to block and allow domains from setting and receiving cookies. There are also some strictness switches that allow you to tighten up the rather loose Netscape protocol rules a little bit (at the cost of blocking some benign cookies).

A domain blacklist and whitelist is provided (both off by default). Only domains not in the blacklist and present in the whitelist (if the whitelist is active) participate in cookie setting and returning. Use the `blocked_domains` constructor argument, and `blocked_domains()` and `set_blocked_domains()` methods (and the corresponding argument and methods for `allowed_domains`). If you set a whitelist, you can turn it off again by setting it to `None`. 
Domains in block or allow lists that do not start with a dot must equal the cookie domain to be matched. For example, "example.com" matches a blacklist entry of "example.com", but "www.example.com" does not. Domains that do start with a dot are matched by more specific domains too. For example, both "www.example.com" and "www.coyote.example.com" match ".example.com" (but "example.com" itself does not). IP addresses are an exception, and must match exactly. For example, if blocked_domains contains "192.168.1.2" and ".168.1.2", 192.168.1.2 is blocked, but 193.168.1.2 is not.

**DefaultCookiePolicy** implements the following additional methods:

**DefaultCookiePolicy.blocked_domains()**
Return the sequence of blocked domains (as a tuple).

**DefaultCookiePolicy.set_blocked_domains(blocked_domains)**
Set the sequence of blocked domains.

**DefaultCookiePolicy.is_blocked(domain)**
Return whether *domain* is on the blacklist for setting or receiving cookies.

**DefaultCookiePolicy.allowed_domains()**
Return None, or the sequence of allowed domains (as a tuple).

**DefaultCookiePolicy.set_allowed_domains(allowed_domains)**
Set the sequence of allowed domains, or None.

**DefaultCookiePolicy.is_not_allowed(domain)**
Return whether *domain* is not on the whitelist for setting or receiving cookies.

**DefaultCookiePolicy** instances have the following attributes, which are all initialised from the constructor arguments of the same name,
and which may all be assigned to.

DefaultCookiePolicy. `rfc2109_as_netscape`

If true, request that the `CookieJar` instance downgrade RFC 2109 cookies (i.e. cookies received in a `Set-Cookie` header with a version cookie-attribute of 1) to Netscape cookies by setting the version attribute of the `Cookie` instance to 0. The default value is `None`, in which case RFC 2109 cookies are downgraded if and only if RFC 2965 handling is turned off. Therefore, RFC 2109 cookies are downgraded by default.

*New in version 2.5.*

General strictness switches:

DefaultCookiePolicy. `strict_domain`

Don't allow sites to set two-component domains with country-code top-level domains like `.co.uk`, `.gov.uk`, `.co.nz` etc. This is far from perfect and isn't guaranteed to work!

RFC 2965 protocol strictness switches:

DefaultCookiePolicy. `strict_rfc2965_unverifiable`

Follow RFC 2965 rules on unverifiable transactions (usually, an unverifiable transaction is one resulting from a redirect or a request for an image hosted on another site). If this is false, cookies are *never* blocked on the basis of verifiability.

Netscape protocol strictness switches:

DefaultCookiePolicy. `strict_ns_unverifiable`

apply RFC 2965 rules on unverifiable transactions even to Netscape cookies

DefaultCookiePolicy. `strict_ns_domain`

Flags indicating how strict to be with domain-matching rules for
Netscape cookies. See below for acceptable values.

DefaultCookiePolicy. **strict_ns_set_initial_dollar**

Ignore cookies in Set-Cookie: headers that have names starting with '$'.

DefaultCookiePolicy. **strict_ns_set_path**

Don’t allow setting cookies whose path doesn’t path-match request URI.

**strict_ns_domain** is a collection of flags. Its value is constructed by or-ing together (for example, `DomainStrictNoDots|DomainStrictNonDomain` means both flags are set).

DefaultCookiePolicy. **DomainStrictNoDots**

When setting cookies, the 'host prefix' must not contain a dot (eg. `www.foo.bar.com` can’t set a cookie for `.bar.com`, because `www.foo` contains a dot).

DefaultCookiePolicy. **DomainStrictNonDomain**

Cookies that did not explicitly specify a domain cookie-attribute can only be returned to a domain equal to the domain that set the cookie (eg. `spam.example.com` won’t be returned cookies from `example.com` that had no domain cookie-attribute).

DefaultCookiePolicy. **DomainRFC2965Match**

When setting cookies, require a full RFC 2965 domain-match.

The following attributes are provided for convenience, and are the most useful combinations of the above flags:

DefaultCookiePolicy. **DomainLiberal**

Equivalent to 0 (ie. all of the above Netscape domain strictness flags switched off).
DefaultCookiePolicy. **DomainStrict**

Equivalent to **DomainStrictNoDots|DomainStrictNonDomain**.
20.21.5. Cookie Objects

Cookie instances have Python attributes roughly corresponding to the standard cookie-attributes specified in the various cookie standards. The correspondence is not one-to-one, because there are complicated rules for assigning default values, because the max-age and expires cookie-attributes contain equivalent information, and because RFC 2109 cookies may be ‘downgraded’ by cookielib from version 1 to version 0 (Netscape) cookies.

Assignment to these attributes should not be necessary other than in rare circumstances in a CookiePolicy method. The class does not enforce internal consistency, so you should know what you’re doing if you do that.

Cookie. **version**

Integer or None. Netscape cookies have version 0. RFC 2965 and RFC 2109 cookies have a version cookie-attribute of 1. However, note that cookielib may ‘downgrade’ RFC 2109 cookies to Netscape cookies, in which case version is 0.

Cookie. **name**

Cookie name (a string).

Cookie. **value**

Cookie value (a string), or None.

Cookie. **port**

String representing a port or a set of ports (eg. ‘80’, or ‘80,8080’), or None.

Cookie. **path**

Cookie path (a string, eg. '/acme/rocket_launchers').
Cookie. **secure**
   True if cookie should only be returned over a secure connection.

Cookie. **expires**
   Integer expiry date in seconds since epoch, or **None**. See also the **is_expired()** method.

Cookie. **discard**
   True if this is a session cookie.

Cookie. **comment**
   String comment from the server explaining the function of this cookie, or **None**.

Cookie. **comment_url**
   URL linking to a comment from the server explaining the function of this cookie, or **None**.

Cookie. **rfc2109**
   True if this cookie was received as an RFC 2109 cookie (ie. the cookie arrived in a Set-Cookie header, and the value of the Version cookie-attribute in that header was 1). This attribute is provided because cookielib may ‘downgrade’ RFC 2109 cookies to Netscape cookies, in which case **version** is 0.

   *New in version 2.5.*

Cookie. **port_specified**
   True if a port or set of ports was explicitly specified by the server (in the Set-Cookie / Set-Cookie2 header).

Cookie. **domain_specified**
   True if a domain was explicitly specified by the server.

Cookie. **domain_initial_dot**
   True if the domain explicitly specified by the server began with a
Cookies may have additional non-standard cookie-attributes. These may be accessed using the following methods:

Cookie.\texttt{has\_nonstandard\_attr(name)}

Return true if cookie has the named cookie-attribute.

Cookie.\texttt{get\_nonstandard\_attr(name, default=\text{None})}

If cookie has the named cookie-attribute, return its value. Otherwise, return \text{default}.

Cookie.\texttt{set\_nonstandard\_attr(name, value)}

Set the value of the named cookie-attribute.

The \texttt{Cookie} class also defines the following method:

Cookie.\texttt{is\_expired([now=\text{None}])}

True if cookie has passed the time at which the server requested it should expire. If \textit{now} is given (in seconds since the epoch), return whether the cookie has expired at the specified time.
The first example shows the most common usage of `cookielib`:

```python
import cookielib, urllib2
cj = cookielib.CookieJar()
opener = urllib2.build_opener(urllib2.HTTPCookieProcessor(cj))
r = opener.open("http://example.com/")
```

This example illustrates how to open a URL using your Netscape, Mozilla, or Lynx cookies (assumes Unix/Netscape convention for location of the cookies file):

```python
import os, cookielib, urllib2
cj = cookielib.MozillaCookieJar()
cj.load(os.path.join(os.environ["HOME"], ".netscape/cookies.txt"))
opener = urllib2.build_opener(urllib2.HTTPCookieProcessor(cj))
r = opener.open("http://example.com/")
```

The next example illustrates the use of `DefaultCookiePolicy`. Turn on RFC 2965 cookies, be more strict about domains when setting and returning Netscape cookies, and block some domains from setting cookies or having them returned:

```python
import urllib2
from cookielib import CookieJar, DefaultCookiePolicy
policy = DefaultCookiePolicy(
  rfc2965=True, strict_ns_domain=DefaultCookiePolicy.DomainStrict,
  blocked_domains=["ads.net", ".ads.net"])
cj = CookieJar(policy)
opener = urllib2.build_opener(urllib2.HTTPCookieProcessor(cj))
r = opener.open("http://example.com/")
```

20.22. **Cookie — HTTP state management**

*Note:* The `cookie` module has been renamed to `http.cookies` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

The `Cookie` module defines classes for abstracting the concept of cookies, an HTTP state management mechanism. It supports both simple string-only cookies, and provides an abstraction for having any serializable data-type as cookie value.

The module formerly strictly applied the parsing rules described in the [RFC 2109](https://tools.ietf.org/html/rfc2109) and [RFC 2068](https://tools.ietf.org/html/rfc2068) specifications. It has since been discovered that MSIE 3.0x doesn’t follow the character rules outlined in those specs. As a result, the parsing rules used are a bit less strict.

*Note:* On encountering an invalid cookie, `CookieError` is raised, so if your cookie data comes from a browser you should always prepare for invalid data and catch `CookieError` on parsing.

```python
exception Cookie.CookieError
    Exception failing because of RFC 2109 invalidity: incorrect attributes, incorrect Set-Cookie header, etc.

class Cookie.BaseCookie([input])
    This class is a dictionary-like object whose keys are strings and whose values are `Morsel` instances. Note that upon setting a key to a value, the value is first converted to a `Morsel` containing the key and the value.
```
If *input* is given, it is passed to the `load()` method.

```python
class Cookie.SimpleCookie([input])
```

This class derives from `BaseCookie` and overrides `value_decode()` and `value_encode()` to be the identity and `str()` respectively.

```python
class Cookie.SerialCookie([input])
```

This class derives from `BaseCookie` and overrides `value_decode()` and `value_encode()` to be the `pickle.loads()` and `pickle.dumps()`.

__Deprecated since version 2.3:__ Reading pickled values from untrusted cookie data is a huge security hole, as pickle strings can be crafted to cause arbitrary code to execute on your server. It is supported for backwards compatibility only, and may eventually go away.

```python
class Cookie.SmartCookie([input])
```

This class derives from `BaseCookie`. It overrides `value_decode()` to be `pickle.loads()` if it is a valid pickle, and otherwise the value itself. It overrides `value_encode()` to be `pickle.dumps()` unless it is a string, in which case it returns the value itself.

__Deprecated since version 2.3:__ The same security warning from `SerialCookie` applies here.

A further security note is warranted. For backwards compatibility, the `cookie` module exports a class named `Cookie` which is just an alias for `SmartCookie`. This is probably a mistake and will likely be removed in a future version. You should not use the `Cookie` class in your applications, for the same reason why you should not use the `SerialCookie` class.
See also:

**Module cookielib**  
HTTP cookie handling for web clients. The `cookie` and `Cookie` modules do not depend on each other.

**RFC 2109 - HTTP State Management Mechanism**  
This is the state management specification implemented by this module.
20.22.1. Cookie Objects

BaseCookie. `value_decode(val)`

Return a decoded value from a string representation. Return value can be any type. This method does nothing in BaseCookie — it exists so it can be overridden.

BaseCookie. `value_encode(val)`

Return an encoded value. `val` can be any type, but return value must be a string. This method does nothing in BaseCookie — it exists so it can be overridden.

In general, it should be the case that `value_encode()` and `value_decode()` are inverses on the range of `value_decode`.

BaseCookie. `output([attrs[, header[, sep]]])`

Return a string representation suitable to be sent as HTTP headers. `attrs` and `header` are sent to each Morsel's `output()` method. `sep` is used to join the headers together, and is by default the combination `\r\n` (CRLF).

*Changed in version 2.5:* The default separator has been changed from `\n` to match the cookie specification.

BaseCookie. `js_output([attrs])`

Return an embeddable JavaScript snippet, which, if run on a browser which supports JavaScript, will act the same as if the HTTP headers was sent.

The meaning for `attrs` is the same as in `output()`.

BaseCookie. `load(rawdata)`
If *rawdata* is a string, parse it as an `HTTP_COOKIE` and add the values found there as *Morsels*. If it is a dictionary, it is equivalent to:

```python
for k, v in rawdata.items():
    cookie[k] = v
```
20.22.2. Morsel Objects

class Cookie.Morsel

Abstract a key/value pair, which has some RFC 2109 attributes.

Morsels are dictionary-like objects, whose set of keys is constant — the valid RFC 2109 attributes, which are

- expires
- path
- comment
- domain
- max-age
- secure
- version
- httponly

The attribute httponly specifies that the cookie is only transferred in HTTP requests, and is not accessible through JavaScript. This is intended to mitigate some forms of cross-site scripting.

The keys are case-insensitive.

New in version 2.6: The httponly attribute was added.

Morsel.value

The value of the cookie.

Morsel.coded_value

The encoded value of the cookie — this is what should be sent.

Morsel.key

The name of the cookie.
Morsel.set(key, value, coded_value)
Set the key, value and coded_value members.

Morsel.isReservedKey(K)
Whether K is a member of the set of keys of a Morsel.

Morsel.output([attrs[, header]])
Return a string representation of the Morsel, suitable to be sent as an HTTP header. By default, all the attributes are included, unless attrs is given, in which case it should be a list of attributes to use. header is by default "Set-Cookie:"

Morsel.js_output([attrs])
Return an embeddable JavaScript snippet, which, if run on a browser which supports JavaScript, will act the same as if the HTTP header was sent.

The meaning for attrs is the same as in output().

Morsel.OutputString([attrs])
Return a string representing the Morsel, without any surrounding HTTP or JavaScript.

The meaning for attrs is the same as in output().
20.22.3. Example

The following example demonstrates how to use the `Cookie` module.

```python
>>> import Cookie
>>> C = Cookie.SimpleCookie()
>>> C = Cookie.SerialCookie()
>>> C = Cookie.SmartCookie()
>>> C["fig"] = "newton"
>>> C["sugar"] = "wafer"
>>> print C # generate HTTP headers
Set-Cookie: fig=newton
Set-Cookie: sugar=wafer
>>> print C.output() # same thing
Set-Cookie: fig=newton
Set-Cookie: sugar=wafer
>>> C = Cookie.SmartCookie()
>>> C["rocky"] = "road"
>>> C["rocky"]["path"] = "/cookie"
>>> print C.output(header="Cookie:")
Cookie: rocky=road; Path=/cookie
>>> print C.output(attrs=[], header="Cookie:")
Cookie: rocky=road
>>> C = Cookie.SmartCookie()
>>> C.load("chips=ahoy; vienna=finger") # load from a string (HTTP header)
>>> print C
Set-Cookie: chips=ahoy
Set-Cookie: vienna=finger
>>> C = Cookie.SmartCookie()
>>> C.load('keebler="E=everybody; L="Loves"; fudge=\012;"')
>>> print C
Set-Cookie: keebler=E=everybody; L=Loves; fudge=\012;
>>> C = Cookie.SmartCookie()
>>> C["oreo"] = "doublestuff"
>>> C["oreo"]["path"] = "/"
>>> print C
Set-Cookie: oreo=doublestuff; Path=/
>>> C = Cookie.SmartCookie()
>>> C["twix"] = "none for you"
>>> C["twix"].value
'none for you'
>>> C = Cookie.SimpleCookie()
>>> C["number"] = 7 # equivalent to C["number"] = str(7)
```
C['string'] = "seven"
C['number'].value
'7'
C['string'].value
'seven'
print C
Set-Cookie: number=7
Set-Cookie: string=seven
C = Cookie.SerialCookie()
C['number'] = 7
C['string'] = "seven"
C['number'].value
7
C['string'].value
'seven'
print C
Set-Cookie: number="I7\012." Set-Cookie: string="S\'seven\'\012p1\012." 
C = Cookie.SmartCookie()
C['number'] = 7
C['string'] = "seven"
C['number'].value
7
C['string'].value
'seven'
print C
Set-Cookie: number="I7\012." Set-Cookie: string=seven
Note: The xmlrpclib module has been renamed to xmlrpc.client in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

New in version 2.2.

XML-RPC is a Remote Procedure Call method that uses XML passed via HTTP as a transport. With it, a client can call methods with parameters on a remote server (the server is named by a URI) and get back structured data. This module supports writing XML-RPC client code; it handles all the details of translating between conformable Python objects and XML on the wire.

class xmlrpclib.ServerProxy(uri[, transport[, encoding[, verbose[, allow_none[, use_datetime]]]]])

A ServerProxy instance is an object that manages communication with a remote XML-RPC server. The required first argument is a URI (Uniform Resource Indicator), and will normally be the URL of the server. The optional second argument is a transport factory instance; by default it is an internal SafeTransport instance for https: URLs and an internal HTTP Transport instance otherwise. The optional third argument is an encoding, by default UTF-8. The optional fourth argument is a debugging flag. If allow_none is true, the Python constant None will be translated into XML; the default behaviour is for None to raise a TypeError. This is a commonly-used extension to the XML-RPC specification, but isn’t supported by all clients and servers; see http://ontosys.com/xml-rpc/extensions.php for a description. The use_datetime flag can be used to cause date/time values to be presented as
datetime.datetime objects; this is false by default. datetime.datetime objects may be passed to calls.

Both the HTTP and HTTPS transports support the URL syntax extension for HTTP Basic Authentication: http://user:pass@host:port/path. The user:pass portion will be base64-encoded as an HTTP ‘Authorization’ header, and sent to the remote server as part of the connection process when invoking an XML-RPC method. You only need to use this if the remote server requires a Basic Authentication user and password.

The returned instance is a proxy object with methods that can be used to invoke corresponding RPC calls on the remote server. If the remote server supports the introspection API, the proxy can also be used to query the remote server for the methods it supports (service discovery) and fetch other server-associated metadata.

ServerProxy instance methods take Python basic types and objects as arguments and return Python basic types and classes. Types that are conformable (e.g. that can be marshalled through XML), include the following (and except where noted, they are unmarshalled as the same Python type):

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>boolean</td>
<td>The True and False constants</td>
</tr>
<tr>
<td>integers</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>floating-point numbers</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>strings</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>arrays</td>
<td>Any Python sequence type containing conformable elements. Arrays are returned as lists</td>
</tr>
<tr>
<td></td>
<td>A Python dictionary. Keys must be</td>
</tr>
<tr>
<td>structures</td>
<td>strings, values may be any conformable type. Objects of user-defined classes can be passed in; only their <code>__dict__</code> attribute is transmitted.</td>
</tr>
<tr>
<td>---</td>
<td>---</td>
</tr>
<tr>
<td>dates</td>
<td>in seconds since the epoch (pass in an instance of the <code>DateTime</code> class) or a <code>datetime.datetime</code> instance.</td>
</tr>
<tr>
<td>binary data</td>
<td>pass in an instance of the <code>Binary</code> wrapper class</td>
</tr>
</tbody>
</table>

This is the full set of data types supported by XML-RPC. Method calls may also raise a special `Fault` instance, used to signal XML-RPC server errors, or `ProtocolError` used to signal an error in the HTTP/HTTPS transport layer. Both `Fault` and `ProtocolError` derive from a base class called `Error`. Note that even though starting with Python 2.2 you can subclass built-in types, the `xmlrpclib` module currently does not marshal instances of such subclasses.

When passing strings, characters special to XML such as `<`, `>`, and `&` will be automatically escaped. However, it’s the caller’s responsibility to ensure that the string is free of characters that aren’t allowed in XML, such as the control characters with ASCII values between 0 and 31 (except, of course, tab, newline and carriage return); failing to do this will result in an XML-RPC request that isn’t well-formed XML. If you have to pass arbitrary strings via XML-RPC, use the `Binary` wrapper class described below.

`Server` is retained as an alias for `ServerProxy` for backwards compatibility. New code should use `ServerProxy`.

*Changed in version 2.5:* The `use_datetime` flag was added.
Changed in version 2.6: Instances of new-style classes can be passed in if they have an \_\_dict\_ attribute and don’t have a base class that is marshalled in a special way.

Describes the XML-RPC protocol extension for introspection.

XML-RPC Specification
The official specification.

Unofficial XML-RPC Errata
Fredrik Lundh’s “unofficial errata, intended to clarify certain details in the XML-RPC specification, as well as hint at ‘best practices’ to use when designing your own XML-RPC implementations.”
20.23.1. ServerProxy Objects

A `ServerProxy` instance has a method corresponding to each remote procedure call accepted by the XML-RPC server. Calling the method performs an RPC, dispatched by both name and argument signature (e.g. the same method name can be overloaded with multiple argument signatures). The RPC finishes by returning a value, which may be either returned data in a conformant type or a `Fault` or `ProtocolError` object indicating an error.

Servers that support the XML introspection API support some common methods grouped under the reserved `system` member:

`ServerProxy.system.listMethods()`

This method returns a list of strings, one for each (non-system) method supported by the XML-RPC server.

`ServerProxy.system.methodSignature(name)`

This method takes one parameter, the name of a method implemented by the XML-RPC server. It returns an array of possible signatures for this method. A signature is an array of types. The first of these types is the return type of the method, the rest are parameters.

Because multiple signatures (ie. overloading) is permitted, this method returns a list of signatures rather than a singleton.

Signatures themselves are restricted to the top level parameters expected by a method. For instance if a method expects one array of structs as a parameter, and it returns a string, its signature is simply “string, array”. If it expects three integers and returns a string, its signature is “string, int, int, int”.

If no signature is defined for the method, a non-array value is returned. In Python this means that the type of the returned value will be something other than list.

ServerProxy.system.methodHelp(name)

This method takes one parameter, the name of a method implemented by the XML-RPC server. It returns a documentation string describing the use of that method. If no such string is available, an empty string is returned. The documentation string may contain HTML markup.
20.23.2. Boolean Objects

This class may be initialized from any Python value; the instance returned depends only on its truth value. It supports various Python operators through `__cmp__()`, `__repr__()`, `__int__()`, and `__nonzero__()` methods, all implemented in the obvious ways.

It also has the following method, supported mainly for internal use by the unmarshalling code:

```python
Boolean.encode(out)
```

Write the XML-RPC encoding of this Boolean item to the output stream object.

A working example follows. The server code:

```python
import xmlrpclib
from SimpleXMLRPCServer import SimpleXMLRPCServer

def is_even(n):
    return n%2 == 0

server = SimpleXMLRPCServer(('localhost', 8000))
print "Listening on port 8000..."
server.register_function(is_even, "is_even")
server.serve_forever()
```

The client code for the preceding server:

```python
import xmlrpclib

proxy = xmlrpclib.ServerProxy("http://localhost:8000/")
print "3 is even: %s" % str(proxy.is_even(3))
print "100 is even: %s" % str(proxy.is_even(100))
```
20.23.3. DateTime Objects

This class may be initialized with seconds since the epoch, a time tuple, an ISO 8601 time/date string, or a `datetime.datetime` instance. It has the following methods, supported mainly for internal use by the marshalling/unmarshalling code:

**DateTime.** `decode(string)`
Accept a string as the instance's new time value.

**DateTime.** `encode(out)`
Write the XML-RPC encoding of this `DateTime` item to the `out` stream object.

It also supports certain of Python's built-in operators through `__cmp__()` and `__repr__()` methods.

A working example follows. The server code:

```python
import datetime
from SimpleXMLRPCServer import SimpleXMLRPCServer
import xmlrpclib

def today():
    today = datetime.datetime.today()
    return xmlrpclib.DateTime(today)

server = SimpleXMLRPCServer(("localhost", 8000))
print "Listening on port 8000..."
server.register_function(today, "today")
server.serve_forever()
```

The client code for the preceding server:

```python
import xmlrpclib
import datetime
```
proxy = xmlrpclib.ServerProxy("http://localhost:8000/")

today = proxy.today()
# convert the ISO8601 string to a datetime object
converted = datetime.datetime.strptime(today.value, "%Y%m%dT%H:")
print "Today: %s" % converted.strftime("%d.%m.%Y, %H:%M")
20.23.4. Binary Objects

This class may be initialized from string data (which may include NULs). The primary access to the content of a Binary object is provided by an attribute:

**Binary.data**

The binary data encapsulated by the Binary instance. The data is provided as an 8-bit string.

Binary objects have the following methods, supported mainly for internal use by the marshalling/unmarshalling code:

**Binary.decode(string)**

Accept a base64 string and decode it as the instance's new data.

**Binary.encode(out)**

Write the XML-RPC base 64 encoding of this binary item to the out stream object.

The encoded data will have newlines every 76 characters as per RFC 2045 section 6.8, which was the de facto standard base64 specification when the XML-RPC spec was written.

It also supports certain of Python's built-in operators through a **__cmp__()** method.

Example usage of the binary objects. We're going to transfer an image over XMLRPC:

```python
def python_logo():
    with open("python_logo.jpg", "rb") as handle:
```
The client gets the image and saves it to a file:

```
import xmlrpclib

proxy = xmlrpclib.ServerProxy("http://localhost:8000/")
with open("fetched_python_logo.jpg", "wb") as handle:
    handle.write(proxy.python_logo().data)
```
20.23.5. Fault Objects

A Fault object encapsulates the content of an XML-RPC fault tag. Fault objects have the following members:

Fault. **faultCode**
A string indicating the fault type.

Fault. **faultString**
A string containing a diagnostic message associated with the fault.

In the following example we're going to intentionally cause a Fault by returning a complex type object. The server code:

```python
from SimpleXMLRPCServer import SimpleXMLRPCServer
# A marshalling error is going to occur because we're returning
# complex number
def add(x,y):
    return x+y+0j

server = SimpleXMLRPCServer(("localhost", 8000))
print "Listening on port 8000..."
server.register_function(add, 'add')
server.serve_forever()
```

The client code for the preceding server:

```python
import xmlrpclib

proxy = xmlrpclib.ServerProxy("http://localhost:8000/")
try:
    proxy.add(2, 5)
except xmlrpclib.Fault, err:
    print "A fault occurred"
    print "Fault code: \%d" % err.faultCode
print "Fault string: %s" % err.faultString
20.23.6. ProtocolError Objects

A ProtocolError object describes a protocol error in the underlying transport layer (such as a 404 ‘not found’ error if the server named by the URI does not exist). It has the following members:

ProtocolError.

url

The URI or URL that triggered the error.

ProtocolError.

errcode

The error code.

ProtocolError.

errmsg

The error message or diagnostic string.

ProtocolError.

headers

A string containing the headers of the HTTP/HTTPS request that triggered the error.

In the following example we're going to intentionally cause a ProtocolError by providing an URI that doesn’t point to an XMLRPC server:

```python
import xmlrpclib

# create a ServerProxy with an URI that doesn't respond to XMLR
proxy = xmlrpclib.ServerProxy("http://www.google.com/")

try:
    proxy.some_method()
except xmlrpclib.ProtocolError, err:
    print "A protocol error occurred"
    print "URL: %s" % err.url
    print "HTTP/HTTPS headers: %s" % err.headers
    print "Error code: %d" % err.errcode
    print "Error message: %s" % err.errmsg
```
20.23.7. MultiCall Objects

New in version 2.4.

In http://www.xmlrpc.com/discuss/msgReader%241208, an approach is presented to encapsulate multiple calls to a remote server into a single request.

class xmlrpclib.MultiCall(server)

Create an object used to boxcar method calls. server is the eventual target of the call. Calls can be made to the result object, but they will immediately return None, and only store the call name and parameters in the MultiCall object. Calling the object itself causes all stored calls to be transmitted as a single system.multicall request. The result of this call is a generator; iterating over this generator yields the individual results.

A usage example of this class follows. The server code

```python
from SimpleXMLRPCServer import SimpleXMLRPCServer

def add(x,y):
    return x+y

def subtract(x, y):
    return x-y

def multiply(x, y):
    return x*y

def divide(x, y):
    return x/y

# A simple server with simple arithmetic functions
server = SimpleXMLRPCServer("localhost", 8000)
print "Listening on port 8000..."
server.register_multicall_functions()
s server.register_function(add, 'add')
```
The client code for the preceding server:

```python
import xmlrpclib

proxy = xmlrpclib.ServerProxy("http://localhost:8000/")
multicall = xmlrpclib.MultiCall(proxy)
multicall.add(7,3)
multicall.subtract(7,3)
multicall.multiply(7,3)
multicall.divide(7,3)
result = multicall()

print "7+3=%d, 7-3=%d, 7*3=%d, 7/3=%d" % tuple(result)
```
20.23.8. Convenience Functions

xmlrpclib.boolean(value)
Convert any Python value to one of the XML-RPC Boolean constants, True or False.

xmlrpclib.dumps(params[, methodname[, methodresponse[, encoding[, allow_none]]]])
Convert params into an XML-RPC request. or into a response if methodresponse is true. params can be either a tuple of arguments or an instance of the Fault exception class. If methodresponse is true, only a single value can be returned, meaning that params must be of length 1. encoding, if supplied, is the encoding to use in the generated XML; the default is UTF-8. Python’s None value cannot be used in standard XML-RPC; to allow using it via an extension, provide a true value for allow_none.

xmlrpclib.loads(data[, use_datetime])
Convert an XML-RPC request or response into Python objects, a (params, methodname). params is a tuple of argument; methodname is a string, or None if no method name is present in the packet. If the XML-RPC packet represents a fault condition, this function will raise a Fault exception. The use_datetime flag can be used to cause date/time values to be presented as datetime.datetime objects; this is false by default.

Changed in version 2.5: The use_datetime flag was added.
# simple test program (from the XML-RPC specification)
from xmlrpclib import ServerProxy, Error

# server = ServerProxy("http://localhost:8000") # local server
server = ServerProxy("http://betty.userland.com")

print server

try:
    print server.examples.getStateName(41)
except Error, v:
    print "ERROR", v

To access an XML-RPC server through a proxy, you need to define a custom transport. The following example shows how:

import xmlrpclib, httplib

class ProxiedTransport(xmlrpclib.Transport):
    def set_proxy(self, proxy):
        self.proxy = proxy
    def make_connection(self, host):
        self.realhost = host
        h = httplib.HTTP(self.proxy)
        return h
    def send_request(self, connection, handler, request_body):
        connection.putrequest("POST", 'http://%s%s' % (self.realhost, handler))
    def send_host(self, connection, host):
        connection.putheader('Host', self.realhost)

p = ProxiedTransport()
p.set_proxy('proxy-server:8080')
print server.currentTime.getCurrentTime()
20.23.10. Example of Client and Server Usage

See SimpleXMLRPCServer Example.
20.24. SimpleXMLRPCServer — Basic XML-RPC server

**Note:** The SimpleXMLRPCServer module has been merged into xmlrpc.server in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

*New in version 2.2.*

The SimpleXMLRPCServer module provides a basic server framework for XML-RPC servers written in Python. Servers can either be free standing, using SimpleXMLRPCServer, or embedded in a CGI environment, using CGIXMLRPCRequestHandler.

```
SimpleXMLRPCServer(addr[, requestHandler[, logRequests[, allow_none[, encoding[, bind_and_activate]]]]])
```

Create a new server instance. This class provides methods for registration of functions that can be called by the XML-RPC protocol. The `requestHandler` parameter should be a factory for request handler instances; it defaults to SimpleXMLRPCRequestHandler. The `addr` and `requestHandler` parameters are passed to the `SocketServer.TCPServer` constructor. If `logRequests` is true (the default), requests will be logged; setting this parameter to false will turn off logging. The `allow_none` and `encoding` parameters are passed on to `xmlrpclib` and control the XML-RPC responses that will be returned from the server. The `bind_and_activate` parameter controls whether `server_bind()` and `server_activate()` are called immediately by the constructor; it defaults to true. Setting it to false allows code to manipulate the `allow_reuse_address` class variable before the address is bound.
Changed in version 2.5: The allow_none and encoding parameters were added.

Changed in version 2.6: The bind_and_activate parameter was added.

class SimpleXMLRPCServer.CGIXMLRPCRequestHandler([allow_none,
encoding]])
Create a new instance to handle XML-RPC requests in a CGI environment. The allow_none and encoding parameters are passed on to xmlrpclib and control the XML-RPC responses that will be returned from the server.

New in version 2.3.

Changed in version 2.5: The allow_none and encoding parameters were added.

class SimpleXMLRPCServer.SimpleXMLRPCRequestHandler
Create a new request handler instance. This request handler supports POST requests and modifies logging so that the logRequests parameter to the SimpleXMLRPCServer constructor parameter is honored.
20.24.1. SimpleXMLRPCServer Objects

The SimpleXMLRPCServer class is based on SocketServer.TCPServer and provides a means of creating simple, stand alone XML-RPC servers.

SimpleXMLRPCServer.register_function(function[, name])

Register a function that can respond to XML-RPC requests. If name is given, it will be the method name associated with function, otherwise function.__name__ will be used. name can be either a normal or Unicode string, and may contain characters not legal in Python identifiers, including the period character.

SimpleXMLRPCServer.register_instance(instance[, allow_dotted_names])

Register an object which is used to expose method names which have not been registered using register_function(). If instance contains a _dispatch() method, it is called with the requested method name and the parameters from the request. Its API is def _dispatch(self, method, params) (note that params does not represent a variable argument list). If it calls an underlying function to perform its task, that function is called as func(*params), expanding the parameter list. The return value from _dispatch() is returned to the client as the result. If instance does not have a _dispatch() method, it is searched for an attribute matching the name of the requested method.

If the optional allow_dotted_names argument is true and the instance does not have a _dispatch() method, then if the requested method name contains periods, each component of the method name is searched for individually, with the effect that
a simple hierarchical search is performed. The value found from this search is then called with the parameters from the request, and the return value is passed back to the client.

**Warning:** Enabling the `allow_dotted_names` option allows intruders to access your module's global variables and may allow intruders to execute arbitrary code on your machine. Only use this option on a secure, closed network.

*Changed in version 2.3.5,:* 2.4.1 allow_dotted_names was added to plug a security hole; prior versions are insecure.

**SimpleXMLRPCServer.** `register_introspection_functions()`  
Registers the XML-RPC introspection functions `system.listMethods`, `system.methodHelp` and `system.methodSignature`.

*New in version 2.3.*

**SimpleXMLRPCServer.** `register_multicall_functions()`  
Registers the XML-RPC multicall function `system.multicall`.

**SimpleXMLRPCRequestHandler.** `rpc_paths`  
An attribute value that must be a tuple listing valid path portions of the URL for receiving XML-RPC requests. Requests posted to other paths will result in a 404 “no such page” HTTP error. If this tuple is empty, all paths will be considered valid. The default value is (`'/'`, `'RPC2'`).

*New in version 2.5.*

**SimpleXMLRPCRequestHandler.** `encode_threshold`  
If this attribute is not `None`, responses larger than this value will be encoded using the `gzip` transfer encoding, if permitted by the client. The default is `1400` which corresponds roughly to a single
TCP packet.

New in version 2.7.

20.24.1.1. SimpleXMLRPCServer Example

Server code:

```python
from SimpleXMLRPCServer import SimpleXMLRPCServer
from SimpleXMLRPCServer import SimpleXMLRPCRequestHandler

# Restrict to a particular path.
class RequestHandler(SimpleXMLRPCRequestHandler):
    rpc_paths = ('/RPC2',)

# Create server
server = SimpleXMLRPCServer(("localhost", 8000),
                             requestHandler=RequestHandler)
server.register_introspection_functions()

# Register pow() function; this will use the value of
# pow.__name__ as the name, which is just 'pow'.
server.register_function(pow)

# Register a function under a different name
def adder_function(x,y):
    return x + y
server.register_function(adder_function, 'add')

# Register an instance; all the methods of the instance are
# published as XML-RPC methods (in this case, just 'div').
class MyFuncs:
    def div(self, x, y):
        return x // y
server.register_instance(MyFuncs())

# Run the server's main loop
server.serve_forever()
```

The following client code will call the methods made available by the preceding server:
import xmlrpclib

s = xmlrpclib.ServerProxy('http://localhost:8000')
print s.pow(2, 3)  # Returns $2^3 = 8$
print s.add(2, 3)  # Returns 5
print s.div(5, 2)  # Returns $5/2 = 2$

# Print list of available methods
print s.system.listMethods()
20.24.2. CGIXMLRPCRequestHandler

The CGIXMLRPCRequestHandler class can be used to handle XML-RPC requests sent to Python CGI scripts.

CGIXMLRPCRequestHandler.register_function(function[, name])

Register a function that can respond to XML-RPC requests. If name is given, it will be the method name associated with function, otherwise function.__name__ will be used. name can be either a normal or Unicode string, and may contain characters not legal in Python identifiers, including the period character.

CGIXMLRPCRequestHandler.register_instance(instance)

Register an object which is used to expose method names which have not been registered using register_function(). If instance contains a _dispatch() method, it is called with the requested method name and the parameters from the request; the return value is returned to the client as the result. If instance does not have a _dispatch() method, it is searched for an attribute matching the name of the requested method; if the requested method name contains periods, each component of the method name is searched for individually, with the effect that a simple hierarchical search is performed. The value found from this search is then called with the parameters from the request, and the return value is passed back to the client.

CGIXMLRPCRequestHandler.register_introspection_functions()

Register the XML-RPC introspection functions system.listMethods, system.methodHelp and system.methodSignature.

CGIXMLRPCRequestHandler.register_multicall_functions()
Register the XML-RPC multicall function `system.multicall`.

```python
CGIXMLRPCRequestHandler. handle_request([request_text = None])
```

Handle a XML-RPC request. If `request_text` is given, it should be the POST data provided by the HTTP server, otherwise the contents of stdin will be used.

Example:

```python
class MyFuncs:  
    def div(self, x, y): return x // y

handler = CGIXMLRPCRequestHandler()  
handler.register_function(pow)  
handler.register_function(lambda x,y: x+y, 'add')  
handler.register_introspection_functions()  
handler.register_instance(MyFuncs())  
handler.handle_request()
```
20.25. DocXMLRPCServer — Self-documenting XML-RPC server

**Note:** The DocXMLRPCServer module has been merged into xmlrpc.server in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

*New in version 2.3.*

The DocXMLRPCServer module extends the classes found in SimpleXMLRPCServer to serve HTML documentation in response to HTTP GET requests. Servers can either be free standing, using DocXMLRPCServer, or embedded in a CGI environment, using DocCGIXMLRPCRequestHandler.

```python
class DocXMLRPCServer(DocXMLRPCServer(addr[, requestHandler[, logRequests[, allow_none[, encoding[, bind_and_activate]]]]]]))
    Create a new server instance. All parameters have the same meaning as for SimpleXMLRPCServer.SimpleXMLRPCServer; requestHandler defaults to DocXMLRPCRequestHandler.

class DocXMLRPCServer.DocCGIXMLRPCRequestHandler
    Create a new instance to handle XML-RPC requests in a CGI environment.

class DocXMLRPCServer.DocXMLRPCRequestHandler
    Create a new request handler instance. This request handler supports XML-RPC POST requests, documentation GET requests, and modifies logging so that the logRequests parameter to the DocXMLRPCServer constructor parameter is honored.
```
20.25.1. DocXMLRPCServer Objects

The `DocXMLRPCServer` class is derived from `SimpleXMLRPCServer.SimpleXMLRPCServer` and provides a means of creating self-documenting, stand alone XML-RPC servers. HTTP POST requests are handled as XML-RPC method calls. HTTP GET requests are handled by generating pydoc-style HTML documentation. This allows a server to provide its own web-based documentation.

DocXMLRPCServer.\texttt{set\_server\_title}(\texttt{server\_title})

Set the title used in the generated HTML documentation. This title will be used inside the HTML “title” element.

DocXMLRPCServer.\texttt{set\_server\_name}(\texttt{server\_name})

Set the name used in the generated HTML documentation. This name will appear at the top of the generated documentation inside a “h1” element.

DocXMLRPCServer.\texttt{set\_server\_documentation}(\texttt{server\_documentation})

Set the description used in the generated HTML documentation. This description will appear as a paragraph, below the server name, in the documentation.
20.25.2. DocCGIXMLRPCRequestHandler

The `DocCGIXMLRPCRequestHandler` class is derived from `SimpleXMLRPCServer.CGIXMLRPCRequestHandler` and provides a means of creating self-documenting, XML-RPC CGI scripts. HTTP POST requests are handled as XML-RPC method calls. HTTP GET requests are handled by generating pydoc-style HTML documentation. This allows a server to provide its own web-based documentation.

`DocCGIXMLRPCRequestHandler.set_server_title(server_title)`
Set the title used in the generated HTML documentation. This title will be used inside the HTML “title” element.

`DocCGIXMLRPCRequestHandler.set_server_name(server_name)`
Set the name used in the generated HTML documentation. This name will appear at the top of the generated documentation inside a “h1” element.

`DocCGIXMLRPCRequestHandler.set_server_documentation(server_doc)`
Set the description used in the generated HTML documentation. This description will appear as a paragraph, below the server name, in the documentation.
21. Multimedia Services

The modules described in this chapter implement various algorithms or interfaces that are mainly useful for multimedia applications. They are available at the discretion of the installation. Here’s an overview:

- **21.1. audioop** — Manipulate raw audio data
- **21.2. imageop** — Manipulate raw image data
- **21.3. aifc** — Read and write AIFF and AIFC files
- **21.4. sunau** — Read and write Sun AU files
  - **21.4.1. AU_read Objects**
  - **21.4.2. AU_write Objects**
- **21.5. wave** — Read and write WAV files
  - **21.5.1. Wave_read Objects**
  - **21.5.2. Wave_write Objects**
- **21.6. chunk** — Read IFF chunked data
- **21.7. colorsys** — Conversions between color systems
- **21.8. imghdr** — Determine the type of an image
- **21.9. sndhdr** — Determine type of sound file
21.1. audioop — Manipulate raw audio data

The `audioop` module contains some useful operations on sound fragments. It operates on sound fragments consisting of signed integer samples 8, 16 or 32 bits wide, stored in Python strings. This is the same format as used by the `al` and `sunaudiodev` modules. All scalar items are integers, unless specified otherwise.

This module provides support for a-LAW, u-LAW and Intel/DVI ADPCM encodings.

A few of the more complicated operations only take 16-bit samples, otherwise the sample size (in bytes) is always a parameter of the operation.

The module defines the following variables and functions:

* `exception audioop.error`  
  This exception is raised on all errors, such as unknown number of bytes per sample, etc.

* `audioop.add(fragment1, fragment2, width)`  
  Return a fragment which is the addition of the two samples passed as parameters. `width` is the sample width in bytes, either 1, 2 or 4. Both fragments should have the same length.

* `audioop.adpcm2lin(adpcmfragment, width, state)`  
  Decode an Intel/DVI ADPCM coded fragment to a linear fragment. See the description of `lin2adpcm()` for details on ADPCM coding. Return a tuple `(sample, newstate)` where the sample has the width specified in `width`. 
audioop. **alaw2lin** *(fragment, width)*

Convert sound fragments in a-LAW encoding to linearly encoded sound fragments. a-LAW encoding always uses 8 bits samples, so *width* refers only to the sample width of the output fragment here.

*New in version 2.5.*

audioop. **avg** *(fragment, width)*

Return the average over all samples in the fragment.

audioop. **avgpp** *(fragment, width)*

Return the average peak-peak value over all samples in the fragment. No filtering is done, so the usefulness of this routine is questionable.

audioop. **bias** *(fragment, width, bias)*

Return a fragment that is the original fragment with a bias added to each sample.

audioop. **cross** *(fragment, width)*

Return the number of zero crossings in the fragment passed as an argument.

audioop. **findfactor** *(fragment, reference)*

Return a factor *F* such that \( \text{rms}(\text{add(fragment, mul(reference, -F)))} \) is minimal, i.e., return the factor with which you should multiply *reference* to make it match as well as possible to *fragment*. The fragments should both contain 2-byte samples.

The time taken by this routine is proportional to \( \text{len(fragment)} \).

audioop. **findfit** *(fragment, reference)*

Try to match *reference* as well as possible to a portion of *fragment* (which should be the longer fragment). This is
(conceptually) done by taking slices out of $\text{fragment}$, using $\text{findfactor()}$ to compute the best match, and minimizing the result. The fragments should both contain 2-byte samples. Return a tuple $(offset, factor)$ where $offset$ is the (integer) offset into $\text{fragment}$ where the optimal match started and $factor$ is the (floating-point) factor as per $\text{findfactor()}$.

\begin{verbatim}
audioop.\textbf{findmax}(\text{fragment, length})
\end{verbatim}

Search $\text{fragment}$ for a slice of length $length$ samples (not bytes!) with maximum energy, i.e., return $i$ for which $\text{rms}(\text{fragment}[i*2: (i+\text{length})*2])$ is maximal. The fragments should both contain 2-byte samples.

The routine takes time proportional to $\text{len}(\text{fragment})$.

\begin{verbatim}
audioop.\textbf{getsample}(\text{fragment, width, index})
\end{verbatim}

Return the value of sample $index$ from the fragment.

\begin{verbatim}
audioop.\textbf{lin2adpcm}(\text{fragment, width, state})
\end{verbatim}

Convert samples to 4 bit Intel/DVI ADPCM encoding. ADPCM coding is an adaptive coding scheme, whereby each 4 bit number is the difference between one sample and the next, divided by a (varying) step. The Intel/DVI ADPCM algorithm has been selected for use by the IMA, so it may well become a standard.

$state$ is a tuple containing the state of the coder. The coder returns a tuple $(\text{adpcmfrag, newstate})$, and the $\text{newstate}$ should be passed to the next call of $\text{lin2adpcm()}$. In the initial call, $\text{None}$ can be passed as the state. $\text{adpcmfrag}$ is the ADPCM coded fragment packed 2 4-bit values per byte.

\begin{verbatim}
audioop.\textbf{lin2alaw}(\text{fragment, width})
\end{verbatim}

Convert samples in the audio fragment to a-LAW encoding and return this as a Python string. a-LAW is an audio encoding format
whereby you get a dynamic range of about 13 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

*New in version 2.5.*

**audioop.\texttt{lin2lin}(\texttt{fragment, width, newwidth})**

Convert samples between 1-, 2- and 4-byte formats.

\begin{verbatim}
new_frames = audioop.lin2lin(frames, old_width, 1)
new_frames = audioop.bias(new_frames, 1, 128)
\end{verbatim}

The same, in reverse, has to be applied when converting from 8 to 16 or 32 bit width samples.

**audioop.\texttt{lin2ulaw}(\texttt{fragment, width})**

Convert samples in the audio fragment to u-LAW encoding and return this as a Python string. u-LAW is an audio encoding format whereby you get a dynamic range of about 14 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

**audioop.\texttt{minmax}(\texttt{fragment, width})**

Return a tuple consisting of the minimum and maximum values of all samples in the sound fragment.

**audioop.\texttt{max}(\texttt{fragment, width})**

Return the maximum of the absolute value of all samples in a fragment.

**audioop.\texttt{maxpp}(\texttt{fragment, width})**
Return the maximum peak-peak value in the sound fragment.

audioop.\texttt{mul}(\texttt{fragment}, \texttt{width}, \texttt{factor})

Return a fragment that has all samples in the original fragment multiplied by the floating-point value \texttt{factor}. Overflow is silently ignored.

audioop.\texttt{ratecv}(\texttt{fragment}, \texttt{width}, \texttt{nchannels}, \texttt{inrate}, \texttt{outrate}, \texttt{state}[, \texttt{weightA}[, \texttt{weightB}]])

Convert the frame rate of the input fragment.

\texttt{state} is a tuple containing the state of the converter. The converter returns a tuple (\texttt{newfragment}, \texttt{newstate}), and \texttt{newstate} should be passed to the next call of \texttt{ratecv()}. The initial call should pass \texttt{None} as the state.

The \texttt{weightA} and \texttt{weightB} arguments are parameters for a simple digital filter and default to 1 and 0 respectively.

audioop.\texttt{reverse}(\texttt{fragment}, \texttt{width})

Reverse the samples in a fragment and returns the modified fragment.

audioop.\texttt{rms}(\texttt{fragment}, \texttt{width})

Return the root-mean-square of the fragment, i.e. \texttt{sqrt(sum(S_i^2)/n)}.

This is a measure of the power in an audio signal.

audioop.\texttt{tomono}(\texttt{fragment}, \texttt{width}, \texttt{lfactor}, \texttt{rfactor})

Convert a stereo fragment to a mono fragment. The left channel is multiplied by \texttt{lfactor} and the right channel by \texttt{rfactor} before adding the two channels to give a mono signal.
audioop.\texttt{tostereo}(fragment, width, lfactor, rfactor)

Generate a stereo fragment from a mono fragment. Each pair of samples in the stereo fragment are computed from the mono sample, whereby left channel samples are multiplied by \textit{lfactor} and right channel samples by \textit{rfactor}.

audioop.\texttt{ulaw2lin}(fragment, width)

Convert sound fragments in u-LAW encoding to linearly encoded sound fragments. u-LAW encoding always uses 8 bits samples, so \textit{width} refers only to the sample width of the output fragment here.

Note that operations such as \texttt{mul()} or \texttt{max()} make no distinction between mono and stereo fragments, i.e. all samples are treated equal. If this is a problem the stereo fragment should be split into two mono fragments first and recombined later. Here is an example of how to do that:

```python
def mul_stereo(sample, width, lfactor, rfactor):
    lsample = audioop.tomono(sample, width, 1, 0)
    rsample = audioop.tomono(sample, width, 0, 1)
    lsample = audioop.mul(sample, width, lfactor)
    rsample = audioop.mul(sample, width, rfactor)
    lsample = audioop.tostereo(lsample, width, 1, 0)
    rsample = audioop.tostereo(rsample, width, 0, 1)
    return audioop.add(lsample, rsample, width)
```

If you use the ADPCM coder to build network packets and you want your protocol to be stateless (i.e. to be able to tolerate packet loss) you should not only transmit the data but also the state. Note that you should send the \textit{initial} state (the one you passed to \texttt{lin2adpcm()}) along to the decoder, not the final state (as returned by the coder). If you want to use \texttt{struct.struct()} to store the state in binary you can code the first element (the predicted value) in 16 bits and the second (the delta index) in 8.
The ADPCM coders have never been tried against other ADPCM coders, only against themselves. It could well be that I misinterpreted the standards in which case they will not be interoperable with the respective standards.

The `find*()` routines might look a bit funny at first sight. They are primarily meant to do echo cancellation. A reasonably fast way to do this is to pick the most energetic piece of the output sample, locate that in the input sample and subtract the whole output sample from the input sample:

```python
def echocancel(outputdata, inputdata):
    pos = audioop.findmax(outputdata, 800)  # one tenth second
    out_test = outputdata[pos*2:]
    in_test = inputdata[pos*2:]
    ipos, factor = audioop.findfit(in_test, out_test)
    # Optional (for better cancellation):
    # factor = audioop.findfactor(in_test[ipos*2:ipos*2+len(out_test)],
    # out_test)
    prefill = '\0'*(pos+ipos)*2
    postfill = '\0'*(len(inputdata)-len(prefill)-len(outputdata))
    outputdata = prefill + audioop.mul(outputdata, 2, -factor) + postfill
    return audioop.add(inputdata, outputdata, 2)
```
Standard Library » 21. Multimedia Services »
21.2. imageop — Manipulate raw image data

*Deprecated since version 2.6:* The `imageop` module has been removed in Python 3.0.

The `imageop` module contains some useful operations on images. It operates on images consisting of 8 or 32 bit pixels stored in Python strings. This is the same format as used by `gl.lrectwrite()` and the `imgfile` module.

The module defines the following variables and functions:

`exception imageop.error`
This exception is raised on all errors, such as unknown number of bits per pixel, etc.

`imageop.crop(image, psize, width, height, x0, y0, x1, y1)`
Return the selected part of `image`, which should be `width` by `height` in size and consist of pixels of `psize` bytes. `x0`, `y0`, `x1` and `y1` are like the `gl.lrectread()` parameters, i.e. the boundary is included in the new image. The new boundaries need not be inside the picture. Pixels that fall outside the old image will have their value set to zero. If `x0` is bigger than `x1` the new image is mirrored. The same holds for the y coordinates.

`imageop.scale(image, psize, width, height, newwidth, newheight)`
Return `image` scaled to size `newwidth` by `newheight`. No interpolation is done, scaling is done by simple-minded pixel duplication or removal. Therefore, computer-generated images or dithered images will not look nice after scaling.
imageop. **tovideo**(*image*, *psize*, *width*, *height*)

Run a vertical low-pass filter over an image. It does so by computing each destination pixel as the average of two vertically-aligned source pixels. The main use of this routine is to forestall excessive flicker if the image is displayed on a video device that uses interlacing, hence the name.

imageop. **grey2mono**(*image*, *width*, *height*, *threshold*)

Convert a 8-bit deep greyscale image to a 1-bit deep image by thresholding all the pixels. The resulting image is tightly packed and is probably only useful as an argument to **mono2grey**().

imageop. **dither2mono**(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 1-bit monochrome image using a (simple-minded) dithering algorithm.

imageop. **mono2grey**(*image*, *width*, *height*, *p0*, *p1*)

Convert a 1-bit monochrome image to an 8 bit greyscale or color image. All pixels that are zero-valued on input get value *p0* on output and all one-value input pixels get value *p1* on output. To convert a monochrome black-and-white image to greyscale pass the values 0 and 255 respectively.

imageop. **grey2grey4**(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 4-bit greyscale image without dithering.

imageop. **grey2grey2**(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 2-bit greyscale image without dithering.

imageop. **dither2grey2**(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 2-bit greyscale image with dithering. As for **dither2mono**(), the dithering algorithm is
currently very simple.

```
imageop. grey42grey(image, width, height)
Convert a 4-bit greyscale image to an 8-bit greyscale image.
```

```
imageop. grey22grey(image, width, height)
Convert a 2-bit greyscale image to an 8-bit greyscale image.
```

```
imageop. backward_compatible
If set to 0, the functions in this module use a non-backward
compatible way of representing multi-byte pixels on little-endian
systems. The SGI for which this module was originally written is a
big-endian system, so setting this variable will have no effect.
However, the code wasn't originally intended to run on anything
else, so it made assumptions about byte order which are not
universal. Setting this variable to 0 will cause the byte order to be
reversed on little-endian systems, so that it then is the same as
on big-endian systems.
```
21.3. aifc — Read and write AIFF and AIFC files

This module provides support for reading and writing AIFF and AIFF-C files. AIFF is Audio Interchange File Format, a format for storing digital audio samples in a file. AIFF-C is a newer version of the format that includes the ability to compress the audio data.

**Note:** Some operations may only work under IRIX; these will raise `ImportError` when attempting to import the `cl` module, which is only available on IRIX.

Audio files have a number of parameters that describe the audio data. The sampling rate or frame rate is the number of times per second the sound is sampled. The number of channels indicate if the audio is mono, stereo, or quadro. Each frame consists of one sample per channel. The sample size is the size in bytes of each sample. Thus a frame consists of `nchannels`**samplesize` bytes, and a second’s worth of audio consists of `nchannels`**samplesize`**framerate` bytes.

For example, CD quality audio has a sample size of two bytes (16 bits), uses two channels (stereo) and has a frame rate of 44,100 frames/second. This gives a frame size of 4 bytes (2*2), and a second’s worth occupies 2*2*44100 bytes (176,400 bytes).

Module `aifc` defines the following function:

```python
aifc.open(file[, mode])
```

Open an AIFF or AIFF-C file and return an object instance with methods that are described below. The argument `file` is either a string naming a file or a file object. `mode` must be `'r'` or `'rb'`
when the file must be opened for reading, or 'w' or 'wb' when
the file must be opened for writing. If omitted, file.mode is used if
it exists, otherwise 'rb' is used. When used for writing, the file
object should be seekable, unless you know ahead of time how
many samples you are going to write in total and use
writeframesraw() and setnframes()

Objects returned by open() when a file is opened for reading have
the following methods:

aifc.getnchannels()
    Return the number of audio channels (1 for mono, 2 for stereo).

aifc.getsampwidth()
    Return the size in bytes of individual samples.

aifc.getframerate()
    Return the sampling rate (number of audio frames per second).

aifc.getnframes()
    Return the number of audio frames in the file.

aifc.getcomptype()
    Return a four-character string describing the type of compression
used in the audio file. For AIFF files, the returned value is 'NONE'.

aifc.getcompname()
    Return a human-readable description of the type of compression
used in the audio file. For AIFF files, the returned value is 'not
compressed'.

aifc.getparams()
    Return a tuple consisting of all of the above values in the above
order.
aifc.\texttt{getmarkers()} 
Return a list of markers in the audio file. A marker consists of a tuple of three elements. The first is the mark ID (an integer), the second is the mark position in frames from the beginning of the data (an integer), the third is the name of the mark (a string).

aifc.\texttt{getmark(id)}
Return the tuple as described in \texttt{getmarkers()} for the mark with the given \textit{id}.

aifc.\texttt{readframes(nframes)}
Read and return the next \textit{nframes} frames from the audio file. The returned data is a string containing for each frame the uncompressed samples of all channels.

aifc.\texttt{rewind()}
Rewind the read pointer. The next \texttt{readframes()} will start from the beginning.

aifc.\texttt{setpos(pos)}
Seek to the specified frame number.

aifc.\texttt{tell()}
Return the current frame number.

aifc.\texttt{close()}
Close the AIFF file. After calling this method, the object can no longer be used.

Objects returned by \texttt{open()} when a file is opened for writing have all the above methods, except for \texttt{readframes()} and \texttt{setpos()}. In addition the following methods exist. The \texttt{get*()} methods can only be called after the corresponding \texttt{set*()} methods have been called. Before the first \texttt{writeframes()} or \texttt{writeframesraw()}, all parameters
except for the number of frames must be filled in.

\texttt{aifc.aiff()}

Create an AIFF file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

\texttt{aifc.aifc()}

Create an AIFF-C file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

\texttt{aifc.setnchannels(nchannels)}

Specify the number of channels in the audio file.

\texttt{aifc.setsampwidth(width)}

Specify the size in bytes of audio samples.

\texttt{aifc.setframerate(rate)}

Specify the sampling frequency in frames per second.

\texttt{aifc.setnframes(nframes)}

Specify the number of frames that are to be written to the audio file. If this parameter is not set, or not set correctly, the file needs to support seeking.

\texttt{aifc.setcomptype(type, name)}

Specify the compression type. If not specified, the audio data will not be compressed. In AIFF files, compression is not possible. The name parameter should be a human-readable description of the compression type, the type parameter should be a four-character string. Currently the following compression types are supported: NONE, ULAW, ALAW, G722.

\texttt{aifc.setparams(nchannels, sampwidth, framerate, comptype,}
Set all the above parameters at once. The argument is a tuple consisting of the various parameters. This means that it is possible to use the result of a `getparams()` call as argument to `setparams()`.

setmark(id, pos, name)
Add a mark with the given id (larger than 0), and the given name at the given position. This method can be called at any time before `close()`.

tell()
Return the current write position in the output file. Useful in combination with `setmark()`.

writeframes(data)
Write data to the output file. This method can only be called after the audio file parameters have been set.

writeframesraw(data)
Like `writeframes()`, except that the header of the audio file is not updated.

close()
Close the AIFF file. The header of the file is updated to reflect the actual size of the audio data. After calling this method, the object can no longer be used.
21.4. *sunau* — Read and write Sun AU files

The *sunau* module provides a convenient interface to the Sun AU sound format. Note that this module is interface-compatible with the modules *aifc* and *wave*.

An audio file consists of a header followed by the data. The fields of the header are:

<table>
<thead>
<tr>
<th>Field</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>magic word</td>
<td>The four bytes <code>.snd</code></td>
</tr>
<tr>
<td>header size</td>
<td>Size of the header, including info, in bytes.</td>
</tr>
<tr>
<td>data size</td>
<td>Physical size of the data, in bytes.</td>
</tr>
<tr>
<td>encoding</td>
<td>Indicates how the audio samples are encoded.</td>
</tr>
<tr>
<td>sample rate</td>
<td>The sampling rate.</td>
</tr>
<tr>
<td># of channels</td>
<td>The number of channels in the samples.</td>
</tr>
<tr>
<td>info</td>
<td>ASCII string giving a description of the audio file (padded with null bytes).</td>
</tr>
</tbody>
</table>

Apart from the info field, all header fields are 4 bytes in size. They are all 32-bit unsigned integers encoded in big-endian byte order.

The *sunau* module defines the following functions:

sunau.*open*(file, mode)

If *file* is a string, open the file by that name, otherwise treat it as a seekable file-like object. *mode* can be any of

```python
'r'
```

Read only mode.

```python
'w'
```

Write mode.
Write only mode.

Note that it does not allow read/write files.

A `mode` of `'r'` returns a `AU_read` object, while a `mode` of `'w'` or `'wb'` returns a `AU_write` object.

```python
sunau.openfp(file, mode)
```

A synonym for `open()`, maintained for backwards compatibility.

The `sunau` module defines the following exception:

```python
exception sunau.Error
```

An error raised when something is impossible because of Sun AU specs or implementation deficiency.

The `sunau` module defines the following data items:

```python
sunau.AUDIO_FILE_MAGIC
```

An integer every valid Sun AU file begins with, stored in big-endian form. This is the string `.snd` interpreted as an integer.

```python
sunau.AUDIO_FILE_ENCODING_MULAW_8
sunau.AUDIO_FILE_ENCODING_LINEAR_8
sunau.AUDIO_FILE_ENCODING_LINEAR_16
sunau.AUDIO_FILE_ENCODING_LINEAR_24
sunau.AUDIO_FILE_ENCODING_LINEAR_32
sunau.AUDIO_FILE_ENCODING_ALAW_8
```

Values of the encoding field from the AU header which are supported by this module.

```python
sunau.AUDIO_FILE_ENCODING_FLOAT
sunau.AUDIO_FILE_ENCODING_DOUBLE
sunau.AUDIO_FILE_ENCODING_ADPCM_G721
sunau.AUDIO_FILE_ENCODING_ADPCM_G722
sunau.AUDIO_FILE_ENCODING_ADPCM_G723_3
sunau.AUDIO_FILE_ENCODING_ADPCM_G723_5
```

Additional known values of the encoding field from the AU
header, but which are not supported by this module.
21.4.1. AU_read Objects

AU_read objects, as returned by `open()` above, have the following methods:

**AU_read.close()**
Close the stream, and make the instance unusable. (This is called automatically on deletion.)

**AU_read.getnchannels()**
Returns number of audio channels (1 for mono, 2 for stereo).

**AU_read.getsampwidth()**
Returns sample width in bytes.

**AU_read.getframerate()**
Returns sampling frequency.

**AU_read.getnframes()**
Returns number of audio frames.

**AU_read.getcomptype()**
Returns compression type. Supported compression types are 'ULAW', 'ALAW' and 'NONE'.

**AU_read.getcompname()**
Human-readable version of `getcomptype()`. The supported types have the respective names 'CCITT G.711 u-law', 'CCITT G.711 A-law' and 'not compressed'.

**AU_read.getparams()**
Returns a tuple `(nchannels, sampwidth, framerate, nframes, comptype, compname)`, equivalent to output of the `get*()` methods.
`AU_read.readframes(n)`
Reads and returns at most `n` frames of audio, as a string of bytes. The data will be returned in linear format. If the original data is in u-LAW format, it will be converted.

`AU_read.rewind()`
Rewind the file pointer to the beginning of the audio stream.

The following two methods define a term “position” which is compatible between them, and is otherwise implementation dependent.

`AU_read.setpos(pos)`
Set the file pointer to the specified position. Only values returned from `tell()` should be used for `pos`.

`AU_read.tell()`
Return current file pointer position. Note that the returned value has nothing to do with the actual position in the file.

The following two functions are defined for compatibility with the `aifc`, and don’t do anything interesting.

`AU_read.getmarkers()`
Returns `None`.

`AU_read.getmark(id)`
Raise an error.
21.4.2. AU_write Objects

AU_write objects, as returned by `open()` above, have the following methods:

- **AU_write.setnchannels(n)**
  Set the number of channels.

- **AU_write.setsampwidth(n)**
  Set the sample width (in bytes.)

- **AU_write.setframerate(n)**
  Set the frame rate.

- **AU_write.setnframes(n)**
  Set the number of frames. This can be later changed, when and if more frames are written.

- **AU_write.setcomptype(type, name)**
  Set the compression type and description. Only 'NONE' and 'ULAW' are supported on output.

- **AU_write.setparams(tuple)**
  The `tuple` should be `(nchannels, sampwidth, framerate, nframes, comptype, compname)`, with values valid for the `set*()` methods. Set all parameters.

- **AU_write.tell()**
  Return current position in the file, with the same disclaimer for the `AU_read.tell()` and `AU_read.setpos()` methods.

- **AU_write.writeframesraw(data)**
  Write audio frames, without correcting `nframes`. 
AU_write.writeframes(data)
Write audio frames and make sure nframes is correct.

AU_write.close()
Make sure nframes is correct, and close the file.

This method is called upon deletion.

Note that it is invalid to set any parameters after calling writeframes() or writeframesraw().
21. Multimedia Services
The `wave` module provides a convenient interface to the WAV sound format. It does not support compression/decompression, but it does support mono/stereo.

The `wave` module defines the following function and exception:

```python
wave.open(file[, mode])
```

If `file` is a string, open the file by that name, other treat it as a seekable file-like object. `mode` can be any of

- `'r', 'rb'`
  
  Read only mode.

- `'w', 'wb'`
  
  Write only mode.

Note that it does not allow read/write WAV files.

A `mode` of `'r'` or `'rb'` returns a `Wave_read` object, while a `mode` of `'w'` or `'wb'` returns a `Wave_write` object. If `mode` is omitted and a file-like object is passed as `file`, `file.mode` is used as the default value for `mode` (the `'b'` flag is still added if necessary).

```python
wave.openfp(file, mode)
```

A synonym for `open()`, maintained for backwards compatibility.

```python
exception wave.Error
```

An error raised when something is impossible because it violates the WAV specification or hits an implementation deficiency.
21.5.1. Wave_read Objects

Wave_read objects, as returned by `open()`, have the following methods:

Wave_read.close()
Close the stream, and make the instance unusable. This is called automatically on object collection.

Wave_read.getnchannels()
Returns number of audio channels (1 for mono, 2 for stereo).

Wave_read.getsampwidth()
Returns sample width in bytes.

Wave_read.getframerate()
Returns sampling frequency.

Wave_read.getnframes()
Returns number of audio frames.

Wave_read.getcomptype()
Returns compression type ('NONE' is the only supported type).

Wave_read.getcompname()
Human-readable version of getcomptype(). Usually 'not compressed' parallels 'NONE'.

Wave_read.getparams()
Returns a tuple (nchannels, sampwidth, framerate, nframes, comptype, compname), equivalent to output of the get*() methods.

Wave_read.readframes(n)
Reads and returns at most $n$ frames of audio, as a string of bytes.

`Wave_read.rewind()`
Rewind the file pointer to the beginning of the audio stream.

The following two methods are defined for compatibility with the `aifc` module, and don’t do anything interesting.

`Wave_read.getmarkers()`
Returns `None`.

`Wave_read.getmark(id)`
Raise an error.

The following two methods define a term “position” which is compatible between them, and is otherwise implementation dependent.

`Wave_read.setpos(pos)`
Set the file pointer to the specified position.

`Wave_read.tell()`
Return current file pointer position.
21.5.2. Wave_write Objects

Wave_write objects, as returned by `open()`, have the following methods:

Wave_write.close()
Make sure `nframes` is correct, and close the file. This method is called upon deletion.

Wave_write.setnchannels(n)
Set the number of channels.

Wave_write.setsampwidth(n)
Set the sample width to `n` bytes.

Wave_write.setframerate(n)
Set the frame rate to `n`.

Wave_write.setnframes(n)
Set the number of frames to `n`. This will be changed later if more frames are written.

Wave_write.setcomptype(type, name)
Set the compression type and description. At the moment, only compression type `NONE` is supported, meaning no compression.

Wave_write.setparams(tuple)
The `tuple` should be `(nchannels, sampwidth, framerate, nframes, comptype, compname)`, with values valid for the `set*()` methods. Sets all parameters.

Wave_write.tell()
Return current position in the file, with the same disclaimer for the
Wave_read.tell() and Wave_read.setpos() methods.

Wave_write.writeframesraw(data)
Write audio frames, without correcting nframes.

Wave_write.writeframes(data)
Write audio frames and make sure nframes is correct.

Note that it is invalid to set any parameters after calling writeframes() or writeframesraw(), and any attempt to do so will raise wave.Error.
This module provides an interface for reading files that use EA IFF 85 chunks. [1] This format is used in at least the Audio Interchange File Format (AIFF/AIFF-C) and the Real Media File Format (RMFF). The WAVE audio file format is closely related and can also be read using this module.

A chunk has the following structure:

<table>
<thead>
<tr>
<th>Offset</th>
<th>Length</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>4</td>
<td>Chunk ID</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>Size of chunk in big-endian byte order, not including the header</td>
</tr>
<tr>
<td>8</td>
<td>n</td>
<td>Data bytes, where n is the size given in the preceding field</td>
</tr>
<tr>
<td>8 + n</td>
<td>0 or 1</td>
<td>Pad byte needed if n is odd and chunk alignment is used</td>
</tr>
</tbody>
</table>

The ID is a 4-byte string which identifies the type of chunk.

The size field (a 32-bit value, encoded using big-endian byte order) gives the size of the chunk data, not including the 8-byte header.

Usually an IFF-type file consists of one or more chunks. The proposed usage of the `Chunk` class defined here is to instantiate an instance at the start of each chunk and read from the instance until it reaches the end, after which a new instance can be instantiated. At the end of the file, creating a new instance will fail with a `EOFError` exception.

```python
class chunk:
    Chunk(file[, align, bigendian, inclheader])
```
Class which represents a chunk. The file argument is expected to be a file-like object. An instance of this class is specifically allowed. The only method that is needed is read(). If the methods seek() and tell() are present and don’t raise an exception, they are also used. If these methods are present and raise an exception, they are expected to not have altered the object. If the optional argument align is true, chunks are assumed to be aligned on 2-byte boundaries. If align is false, no alignment is assumed. The default value is true. If the optional argument bigendian is false, the chunk size is assumed to be in little-endian order. This is needed for WAVE audio files. The default value is true. If the optional argument inclheader is true, the size given in the chunk header includes the size of the header. The default value is false.

A Chunk object supports the following methods:

getname()

Returns the name (ID) of the chunk. This is the first 4 bytes of the chunk.

getsize()

Returns the size of the chunk.

close()

Close and skip to the end of the chunk. This does not close the underlying file.

The remaining methods will raise IOError if called after the close() method has been called.

isatty()

Returns False.

seek(pos[, whence])
Set the chunk’s current position. The *whence* argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file’s end). There is no return value. If the underlying file does not allow seek, only forward seeks are allowed.

**tell()**

Return the current position into the chunk.

**read([size])**

Read at most size bytes from the chunk (less if the read hits the end of the chunk before obtaining size bytes). If the size argument is negative or omitted, read all data until the end of the chunk. The bytes are returned as a string object. An empty string is returned when the end of the chunk is encountered immediately.

**skip()**

Skip to the end of the chunk. All further calls to **read()** for the chunk will return ‘’. If you are not interested in the contents of the chunk, this method should be called so that the file points to the start of the next chunk.

**Footnotes**

21.7. colorsys — Conversions between color systems

The colorsys module defines bidirectional conversions of color values between colors expressed in the RGB (Red Green Blue) color space used in computer monitors and three other coordinate systems: YIQ, HLS (Hue Lightness Saturation) and HSV (Hue Saturation Value). Coordinates in all of these color spaces are floating point values. In the YIQ space, the Y coordinate is between 0 and 1, but the I and Q coordinates can be positive or negative. In all other spaces, the coordinates are all between 0 and 1.

The colorsys module defines the following functions:

colorsys.\texttt{rgb\_to\_yiq}(r, g, b)

Convert the color from RGB coordinates to YIQ coordinates.

colorsys.\texttt{yiq\_to\_rgb}(y, i, q)

Convert the color from YIQ coordinates to RGB coordinates.

colorsys.\texttt{rgb\_to\_hls}(r, g, b)

Convert the color from RGB coordinates to HLS coordinates.

colorsys.\texttt{hls\_to\_rgb}(h, l, s)

Convert the color from HLS coordinates to RGB coordinates.

colorsys.\texttt{rgb\_to\_hsv}(r, g, b)

Convert the color from RGB coordinates to HSV coordinates.
colorsyst.hsv_to_rgb(h, s, v)

Convert the color from HSV coordinates to RGB coordinates.

Example:

```python
>>> import colorsys
>>> colorsys.rgb_to_hsv(.3, .4, .2)
(0.25, 0.5, 0.4)
>>> colorsys.hsv_to_rgb(0.25, 0.5, 0.4)
(0.3, 0.4, 0.2)
```
21.8. imghdr — Determine the type of an image

The `imghdr` module determines the type of image contained in a file or byte stream.

The `imghdr` module defines the following function:

```python
imghdr.what(filename[, h])
```

Tests the image data contained in the file named by `filename`, and returns a string describing the image type. If optional `h` is provided, the `filename` is ignored and `h` is assumed to contain the byte stream to test.

The following image types are recognized, as listed below with the return value from `what()`:

<table>
<thead>
<tr>
<th>Value</th>
<th>Image format</th>
</tr>
</thead>
<tbody>
<tr>
<td>'rgb'</td>
<td>SGI ImgLib Files</td>
</tr>
<tr>
<td>'gif'</td>
<td>GIF 87a and 89a Files</td>
</tr>
<tr>
<td>'pbm'</td>
<td>Portable Bitmap Files</td>
</tr>
<tr>
<td>'pgm'</td>
<td>Portable Graymap Files</td>
</tr>
<tr>
<td>'ppm'</td>
<td>Portable Pixmap Files</td>
</tr>
<tr>
<td>'tiff'</td>
<td>TIFF Files</td>
</tr>
<tr>
<td>'rast'</td>
<td>Sun Raster Files</td>
</tr>
<tr>
<td>'xbm'</td>
<td>X Bitmap Files</td>
</tr>
<tr>
<td>'jpeg'</td>
<td>JPEG data in JFIF or Exif formats</td>
</tr>
<tr>
<td>'bmp'</td>
<td>BMP files</td>
</tr>
<tr>
<td>'png'</td>
<td>Portable Network Graphics</td>
</tr>
</tbody>
</table>

*New in version 2.5:* Exif detection.
You can extend the list of file types `imghdr` can recognize by appending to this variable:

```python
imghdr.tests
```

A list of functions performing the individual tests. Each function takes two arguments: the byte-stream and an open file-like object. When `what()` is called with a byte-stream, the file-like object will be `None`.

The test function should return a string describing the image type if the test succeeded, or `None` if it failed.

Example:

```python
>>> import imghdr
>>> imghdr.what('/tmp/bass.gif')
'gif'
```
21.9. sndhdr — Determine type of sound file

The `sndhdr` provides utility functions which attempt to determine the type of sound data which is in a file. When these functions are able to determine what type of sound data is stored in a file, they return a tuple `(type, sampling_rate, channels, frames, bits_per_sample)`. The value for `type` indicates the data type and will be one of the strings 'aifc', 'aiff', 'au', 'hcom', 'sndr', 'sndt', 'voc', 'wav', '8svx', 'sb', 'ub', or 'ul'. The `sampling_rate` will be either the actual value or 0 if unknown or difficult to decode. Similarly, `channels` will be either the number of channels or 0 if it cannot be determined or if the value is difficult to decode. The value for `frames` will be either the number of frames or -1. The last item in the tuple, `bits_per_sample`, will either be the sample size in bits or 'A' for A-LAW or 'U' for u-LAW.

`sndhdr.whathdr(filename)`

Determines the type of sound data stored in the file `filename` using `whathdr()`. If it succeeds, returns a tuple as described above, otherwise `None` is returned.

`sndhdr.whathdr(filename)`

Determines the type of sound data stored in a file based on the file header. The name of the file is given by `filename`. This function returns a tuple as described above on success, or `None`. 
22. Internationalization

The modules described in this chapter help you write software that is independent of language and locale by providing mechanisms for selecting a language to be used in program messages or by tailoring output to match local conventions.

The list of modules described in this chapter is:

- **22.1. gettext — Multilingual internationalization services**
  - 22.1.1. GNU gettext API
  - 22.1.2. Class-based API
    - 22.1.2.1. The NullTranslations class
    - 22.1.2.2. The GNUTranslations class
    - 22.1.2.3. Solaris message catalog support
    - 22.1.2.4. The Catalog constructor
  - 22.1.3. Internationalizing your programs and modules
    - 22.1.3.1. Localizing your module
    - 22.1.3.2. Localizing your application
    - 22.1.3.3. Changing languages on the fly
    - 22.1.3.4. Deferred translations
    - 22.1.3.5. gettext() vs. lgettext()
  - 22.1.4. Acknowledgements
- **22.2. locale — Internationalization services**
  - 22.2.1. Background, details, hints, tips and caveats
  - 22.2.2. For extension writers and programs that embed Python
  - 22.2.3. Access to message catalogs
The gettext module provides internationalization (I18N) and localization (L10N) services for your Python modules and applications. It supports both the GNU gettext message catalog API and a higher level, class-based API that may be more appropriate for Python files. The interface described below allows you to write your module and application messages in one natural language, and provide a catalog of translated messages for running under different natural languages.

Some hints on localizing your Python modules and applications are also given.
22.1.1. GNU gettext API

The gettext module defines the following API, which is very similar to the GNU gettext API. If you use this API you will affect the translation of your entire application globally. Often this is what you want if your application is monolingual, with the choice of language dependent on the locale of your user. If you are localizing a Python module, or if your application needs to switch languages on the fly, you probably want to use the class-based API instead.

gettext.bindtextdomain(domain[, localedir])

Bind the domain to the locale directory localedir. More concretely, gettext will look for binary .mo files for the given domain using the path (on Unix): localedir/language/LC_MESSAGES/domain.mo, where languages is searched for in the environment variables LANGUAGE, LC_ALL, LC_MESSAGES, and LANG respectively.

If localedir is omitted or None, then the current binding for domain is returned. [1]

gettext.bind_textdomain_codeset(domain[, codeset])

Bind the domain to codeset, changing the encoding of strings returned by the gettext() family of functions. If codeset is omitted, then the current binding is returned.

New in version 2.4.

gettext.textdomain([domain])

Change or query the current global domain. If domain is None, then the current global domain is returned, otherwise the global domain is set to domain, which is returned.
gettext. **gettext**(message)

Return the localized translation of *message*, based on the current global domain, language, and locale directory. This function is usually aliased as `_()` in the local namespace (see examples below).

gettext. **lgettext**(message)

Equivalent to `gettext()`, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with `bind_textdomain_codeset()`.

*New in version 2.4.*

gettext. **dgettext**(domain, message)

Like `gettext()`, but look the message up in the specified *domain*.

gettext. **ldgettext**(domain, message)

Equivalent to `dgettext()`, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with `bind_textdomain_codeset()`.

*New in version 2.4.*

gettext. **ngettext**(singular, plural, n)

Like `gettext()`, but consider plural forms. If a translation is found, apply the plural formula to *n*, and return the resulting message (some languages have more than two plural forms). If no translation is found, return *singular* if *n* is 1; return *plural* otherwise.

The Plural formula is taken from the catalog header. It is a C or Python expression that has a free variable *n*; the expression evaluates to the index of the plural in the catalog. See the GNU gettext documentation for the precise syntax to be used in `.po`
files and the formulas for a variety of languages.

New in version 2.3.

gettext. **lngettext** *(singular, plural, n)*  
Equivalent to **ngettext()**, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with **bind_textdomain_codeset()**.

New in version 2.4.

gettext. **dngettext** *(domain, singular, plural, n)*  
Like **ngettext()**, but look the message up in the specified domain.

New in version 2.3.

gettext. **ldngettext** *(domain, singular, plural, n)*  
Equivalent to **dngettext()**, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with **bind_textdomain_codeset()**.

New in version 2.4.

Note that GNU gettext also defines a **dcgettext()** method, but this was deemed not useful and so it is currently unimplemented.

Here’s an example of typical usage for this API:

```python
import gettext
gettext.bindtextdomain('myapplication', '/path/to/my/language/directory')
ggettext.textdomain('myapplication')
_
= gettext.gettext
# ...
print _("This is a translatable string.")
```
22.1.2. Class-based API

The class-based API of the gettext module gives you more flexibility and greater convenience than the GNU gettext API. It is the recommended way of localizing your Python applications and modules. gettext defines a “translations” class which implements the parsing of GNU .mo format files, and has methods for returning either standard 8-bit strings or Unicode strings. Instances of this “translations” class can also install themselves in the built-in namespace as the function _().

```python
gettext.find(domain[, localedir[, languages[, all]]])
```

This function implements the standard .mo file search algorithm. It takes a `domain`, identical to what `textdomain()` takes. Optional `localedir` is as in `bindtextdomain()`. Optional `languages` is a list of strings, where each string is a language code.

If `localedir` is not given, then the default system locale directory is used. [2] If `languages` is not given, then the following environment variables are searched: `LANGUAGE`, `LC_ALL`, `LC_MESSAGES`, and `LANG`. The first one returning a non-empty value is used for the `languages` variable. The environment variables should contain a colon separated list of languages, which will be split on the colon to produce the expected list of language code strings.

`find()` then expands and normalizes the languages, and then iterates through them, searching for an existing file built of these components:

```python
localedir/language/LC_MESSAGES/domain.mo
```

The first such file name that exists is returned by `find()`. If no
such file is found, then None is returned. If all is given, it returns a list of all file names, in the order in which they appear in the languages list or the environment variables.

gettext.translation(domain[, localedir[, languages[, class_[, fallback[, codeset]]]]])

Return a Translations instance based on the domain, localedir, and languages, which are first passed to find() to get a list of the associated .mo file paths. Instances with identical .mo file names are cached. The actual class instantiated is either class_ if provided, otherwise GNUTranslations. The class's constructor must take a single file object argument. If provided, codeset will change the charset used to encode translated strings.

If multiple files are found, later files are used as fallbacks for earlier ones. To allow setting the fallback, copy.copy() is used to clone each translation object from the cache; the actual instance data is still shared with the cache.

If no .mo file is found, this function raises IOError if fallback is false (which is the default), and returns a NullTranslations instance if fallback is true.

Changed in version 2.4: Added the codeset parameter.

gettext.install(domain[, localedir[, unicode[, codeset[, names]]]])

This installs the function _() in Python’s builtins namespace, based on domain, localedir, and codeset which are passed to the function translation(). The unicode flag is passed to the resulting translation object’s install() method.

For the names parameter, please see the description of the
translation object’s \texttt{install()} method.

As seen below, you usually mark the strings in your application that are candidates for translation, by wrapping them in a call to the \texttt{\textunderscore{}()} function, like this:

\begin{verbatim}
print \textunderscore{}('This string will be translated.')
\end{verbatim}

For convenience, you want the \texttt{\textunderscore{}()} function to be installed in Python’s builtins namespace, so it is easily accessible in all modules of your application.

\emph{Changed in version 2.4:} Added the \texttt{codeset} parameter.

\emph{Changed in version 2.5:} Added the \texttt{names} parameter.

\section*{22.1.2.1. The \texttt{NullTranslations} class}

Translation classes are what actually implement the translation of original source file message strings to translated message strings. The base class used by all translation classes is \texttt{NullTranslations}; this provides the basic interface you can use to write your own specialized translation classes. Here are the methods of \texttt{NullTranslations}:

\begin{verbatim}
class gettext.\texttt{NullTranslations}([fp])
  Takes an optional file object \texttt{fp}, which is ignored by the base class. Initializes “protected” instance variables \texttt{\_info} and \texttt{\_charset} which are set by derived classes, as well as \texttt{\_fallback}, which is set through \texttt{add\_fallback()}. It then calls \texttt{self._parse(fp)} if \texttt{fp} is not \texttt{None}.

  \_parse(fp)
  No-op’d in the base class, this method takes file object \texttt{fp}, and
\end{verbatim}
reads the data from the file, initializing its message catalog. If you have an unsupported message catalog file format, you should override this method to parse your format.

**add_translation(fallback)**
Add *fallback* as the fallback object for the current translation object. A translation object should consult the fallback if it cannot provide a translation for a given message.

**gettext(message)**
If a fallback has been set, forward `gettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

**lgettext(message)**
If a fallback has been set, forward `lgettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

*New in version 2.4.*

**ugettext(message)**
If a fallback has been set, forward `ugettext()` to the fallback. Otherwise, return the translated message as a Unicode string. Overridden in derived classes.

**ngettext(singular, plural, n)**
If a fallback has been set, forward `ngettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

*New in version 2.3.*

**lngettext(singular, plural, n)**
If a fallback has been set, forward `lngettext()` to the fallback.
Otherwise, return the translated message. Overridden in derived classes.

*New in version 2.4.*

**ungettext**(singular, plural, n)
If a fallback has been set, forward `ungettext()` to the fallback. Otherwise, return the translated message as a Unicode string. Overridden in derived classes.

*New in version 2.3.*

**info()**
Return the “protected” `_info` variable.

**charset()**
Return the “protected” `_charset` variable.

**output_charset()**
Return the “protected” `_output_charset` variable, which defines the encoding used to return translated messages.

*New in version 2.4.*

**set_output_charset**(charset)
Change the “protected” `_output_charset` variable, which defines the encoding used to return translated messages.

*New in version 2.4.*

**install**(unicode[, names])
If the `unicode` flag is false, this method installs `self.gettext()` into the built-in namespace, binding it to `_`. If `unicode` is true, it binds `self.ugettext()` instead. By default, `unicode` is false.
If the *names* parameter is given, it must be a sequence containing the names of functions you want to install in the builtins namespace in addition to *()*. Supported names are 'gettext' (bound to `self.gettext()` or `self.ugettext()` according to the *unicode* flag), 'ngettext' (bound to `self.ngettext()` or `self.ungettext()` according to the *unicode* flag), 'lgettext' and 'lngettext'.

Note that this is only one way, albeit the most convenient way, to make the *()* function available to your application. Because it affects the entire application globally, and specifically the built-in namespace, localized modules should never install *()*. Instead, they should use this code to make *()* available to their module:

```python
import gettext
t = gettext.translation('mymodule', ...)
_ = t.gettext
```

This puts *()* only in the module’s global namespace and so only affects calls within this module.

*Changed in version 2.5:* Added the *names* parameter.

### 22.1.2.2. The GNUTranslations class

The *gettext* module provides one additional class derived from *NullTranslations*: **GNUTranslations**. This class overrides *parse()* to enable reading GNU *gettext* format .mo files in both big-endian and little-endian format. It also coerces both message ids and message strings to Unicode.

**GNUTranslations** parses optional meta-data out of the translation catalog. It is convention with GNU *gettext* to include meta-data as
the translation for the empty string. This meta-data is in RFC 822-
style **key: value** pairs, and should contain the **Project-Id-Version**
key. If the key **Content-Type** is found, then the **charset** property is
used to initialize the “protected” **_charset** instance variable,
defaulting to **None** if not found. If the charset encoding is specified,
then all message ids and message strings read from the catalog are
converted to Unicode using this encoding. The **ugettext()** method
always returns a Unicode, while the **gettext()** returns an encoded 8-
bit string. For the message id arguments of both methods, either
Unicode strings or 8-bit strings containing only US-ASCII characters
are acceptable. Note that the Unicode version of the methods (i.e.
**ugettext()** and **ungettext()**) are the recommended interface to use
for internationalized Python programs.

The entire set of key/value pairs are placed into a dictionary and set
as the “protected” **_info** instance variable.

If the **.mo** file’s magic number is invalid, or if other problems occur
while reading the file, instantiating a **GNUTranslations** class can raise
**IOError**.

The following methods are overridden from the base class implementation:

**GNUTranslations.gettext**(message)
Look up the **message** id in the catalog and return the corresponding message string, as an 8-bit string encoded with
the catalog’s charset encoding, if known. If there is no entry in the
catalog for the **message** id, and a fallback has been set, the look up is forwarded to the fallback’s **gettext()** method. Otherwise,
the **message** id is returned.

**GNUTranslations.lgettext**(message)
Equivalent to `gettext()`, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with `set_output_charset()`.

*New in version 2.4.*

**GNUTranslations. gettext**\(\textit{message}\)

Look up the `message` id in the catalog and return the corresponding message string, as a Unicode string. If there is no entry in the catalog for the `message` id, and a fallback has been set, the look up is forwarded to the fallback's `gettext()` method. Otherwise, the `message` id is returned.

**GNUTranslations. ngettext**\(\textit{singular, plural, n}\)

Do a plural-forms lookup of a message id. `singular` is used as the message id for purposes of lookup in the catalog, while `n` is used to determine which plural form to use. The returned message string is an 8-bit string encoded with the catalog's charset encoding, if known.

If the message id is not found in the catalog, and a fallback is specified, the request is forwarded to the fallback's `ngettext()` method. Otherwise, when \(n = 1\) `singular` is returned, and `plural` is returned in all other cases.

*New in version 2.3.*

**GNUTranslations. lngettext**\(\textit{singular, plural, n}\)

Equivalent to `gettext()`, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with `set_output_charset()`.

*New in version 2.4.*

**GNUTranslations. ungettext**\(\textit{singular, plural, n}\)
Do a plural-forms lookup of a message id. *singular* is used as the message id for purposes of lookup in the catalog, while *n* is used to determine which plural form to use. The returned message string is a Unicode string.

If the message id is not found in the catalog, and a fallback is specified, the request is forwarded to the fallback’s `ungettext()` method. Otherwise, when *n* is 1 *singular* is returned, and *plural* is returned in all other cases.

Here is an example:

```python
n = len(os.listdir('.'))
cat = GNUTranslations(somefile)
message = cat.ungettext(
    'There is %(num)d file in this directory',
    'There are %(num)d files in this directory',
    n) % {'num': n}
```

*New in version 2.3.*

### 22.1.2.3. Solaris message catalog support

The Solaris operating system defines its own binary `.mo` file format, but since no documentation can be found on this format, it is not supported at this time.

### 22.1.2.4. The Catalog constructor

GNOME uses a version of the `gettext` module by James Henstridge, but this version has a slightly different API. Its documented usage was:

```python
import gettext
cat = gettext.Catalog(domain, localedir)
_ = cat.gettext
print _('hello world')
```
For compatibility with this older module, the function `catalog()` is an alias for the `translation()` function described above.

One difference between this module and Henstridge’s: his catalog objects supported access through a mapping API, but this appears to be unused and so is not currently supported.
22.1.3. Internationalizing your programs and modules

Internationalization (I18N) refers to the operation by which a program is made aware of multiple languages. Localization (L10N) refers to the adaptation of your program, once internationalized, to the local language and cultural habits. In order to provide multilingual messages for your Python programs, you need to take the following steps:

1. prepare your program or module by specially marking translatable strings
2. run a suite of tools over your marked files to generate raw messages catalogs
3. create language specific translations of the message catalogs
4. use the gettext module so that message strings are properly translated

In order to prepare your code for I18N, you need to look at all the strings in your files. Any string that needs to be translated should be marked by wrapping it in `_('...')` — that is, a call to the function `_()`. For example:

```python
filename = 'mylog.txt'
message = _('writing a log message')
fp = open(filename, 'w')
fp.write(message)
fp.close()
```

In this example, the string 'writing a log message' is marked as a candidate for translation, while the strings 'mylog.txt' and 'w' are not.

The Python distribution comes with two tools which help you
generate the message catalogs once you’ve prepared your source code. These may or may not be available from a binary distribution, but they can be found in a source distribution, in the Tools/i18n directory.

The **pygettext** [3] program scans all your Python source code looking for the strings you previously marked as translatable. It is similar to the GNU **gettext** program except that it understands all the intricacies of Python source code, but knows nothing about C or C++ source code. You don’t need GNU **gettext** unless you’re also going to be translating C code (such as C extension modules).

**pygettext** generates textual Uniforum-style human readable message catalog `.pot` files, essentially structured human readable files which contain every marked string in the source code, along with a placeholder for the translation strings. **pygettext** is a command line script that supports a similar command line interface as **xgettext**; for details on its use, run:

```
pygettext.py --help
```

Copies of these `.pot` files are then handed over to the individual human translators who write language-specific versions for every supported natural language. They send you back the filled in language-specific versions as a `.po` file. Using the **msgfmt.py** [4] program (in the Tools/i18n directory), you take the `.po` files from your translators and generate the machine-readable `.mo` binary catalog files. The `.mo` files are what the **gettext** module uses for the actual translation processing during run-time.

How you use the **gettext** module in your code depends on whether you are internationalizing a single module or your entire application. The next two sections will discuss each case.
22.1.3.1. Localizing your module

If you are localizing your module, you must take care not to make global changes, e.g. to the built-in namespace. You should not use the GNU gettext API but instead the class-based API.

Let’s say your module is called “spam” and the module’s various natural language translation .mo files reside in /usr/share/locale in GNU gettext format. Here’s what you would put at the top of your module:

```python
import gettext
t = gettext.translation('spam', '/usr/share/locale')
_ = t.lgettext
```

If your translators were providing you with Unicode strings in their .po files, you’d instead do:

```python
import gettext
t = gettext.translation('spam', '/usr/share/locale')
_ = t.ugettext
```

22.1.3.2. Localizing your application

If you are localizing your application, you can install the _( ) function globally into the built-in namespace, usually in the main driver file of your application. This will let all your application-specific files just use _(‘...’) without having to explicitly install it in each file.

In the simple case then, you need only add the following bit of code to the main driver file of your application:

```python
import gettext
gettext.install('myapplication')
```

If you need to set the locale directory or the unicode flag, you can
pass these into the **install()** function:

```python
import gettext
ggettext.install('myapplication', '/usr/share/locale', unicode=1)
```

### 22.1.3.3. Changing languages on the fly

If your program needs to support many languages at the same time, you may want to create multiple translation instances and then switch between them explicitly, like so:

```python
import gettext

lang1 = gettext.translation('myapplication', languages=['en'])
lang2 = gettext.translation('myapplication', languages=['fr'])
lang3 = gettext.translation('myapplication', languages=['de'])

# start by using language 1
lang1.install()

# ... time goes by, user selects language 2
lang2.install()

# ... more time goes by, user selects language 3
lang3.install()
```

### 22.1.3.4. Deferred translations

In most coding situations, strings are translated where they are coded. Occasionally however, you need to mark strings for translation, but defer actual translation until later. A classic example is:

```python
animals = ['mollusk',
          'albatross',
          'rat',
          'penguin',
          'python',]

# ...
```
Here, you want to mark the strings in the `animals` list as being translatable, but you don’t actually want to translate them until they are printed.

Here is one way you can handle this situation:

```python
def _(message): return message
animals = [_('mollusk'),
           _('albatross'),
           _('rat'),
           _('penguin'),
           _('python'),]
del _

# ...
for a in animals:
    print _(a)
```

This works because the dummy definition of `()` simply returns the string unchanged. And this dummy definition will temporarily override any definition of `()` in the built-in namespace (until the `del` command). Take care, though if you have a previous definition of `()` in the local namespace.

Note that the second use of `()` will not identify “a” as being translatable to the `pygettext` program, since it is not a string.

Another way to handle this is with the following example:

```python
def N_(message): return message
animals = [N_('mollusk'),
           N_('albatross'),
           N_('rat'),
           N_('penguin'),
           N_('python'),]
```
In this case, you are marking translatable strings with the function `N_()`, [5] which won’t conflict with any definition of `_()`. However, you will need to teach your message extraction program to look for translatable strings marked with `N_()`. `pygettext` and `xpot` both support this through the use of command line switches.

### 22.1.3.5. gettext() vs. lgettext()

In Python 2.4 the `lgettext()` family of functions were introduced. The intention of these functions is to provide an alternative which is more compliant with the current implementation of GNU gettext. Unlike `gettext()`, which returns strings encoded with the same codeset used in the translation file, `lgettext()` will return strings encoded with the preferred system encoding, as returned by `locale.getpreferredencoding()`. Also notice that Python 2.4 introduces new functions to explicitly choose the codeset used in translated strings. If a codeset is explicitly set, even `lgettext()` will return translated strings in the requested codeset, as would be expected in the GNU gettext implementation.
22.1.4. Acknowledgements

The following people contributed code, feedback, design suggestions, previous implementations, and valuable experience to the creation of this module:

- Peter Funk
- James Henstridge
- Juan David Ibáñez Palomar
- Marc-André Lemburg
- Martin von Löwis
- François Pinard
- Barry Warsaw
- Gustavo Niemeyer

Footnotes

The default locale directory is system dependent; for example, on RedHat Linux it is /usr/share/locale, but on Solaris it is /usr/lib/locale. The gettext module does not try to support these system dependent defaults; instead its default is sys.prefix/share/locale. For this reason, it is always best to call bindtextdomain() with an explicit absolute path at the start of your application.

[1] See the footnote for bindtextdomain() above.

François Pinard has written a program called xpot which does a similar job. It is available as part of his po-utils package at http://po-utils.progiciels-bpi.ca/.

msgfmt.py is binary compatible with GNU msgfmt except that it provides a simpler, all-Python implementation. With this and pygettext.py, you generally won’t need to install the GNU gettext package to internationalize your Python applications.

[3] msgfmt.py is binary compatible with GNU msgfmt except that it provides a simpler, all-Python implementation. With this and pygettext.py, you generally won’t need to install the GNU gettext package to internationalize your Python applications.

[4] The choice of n_() here is totally arbitrary; it could have just as easily been MarkThisStringForTranslation().

[5] The choice of n_() here is totally arbitrary; it could have just as easily been MarkThisStringForTranslation().
22.2. `locale` — Internationalization services

The `locale` module opens access to the POSIX locale database and functionality. The POSIX locale mechanism allows programmers to deal with certain cultural issues in an application, without requiring the programmer to know all the specifics of each country where the software is executed.

The `locale` module is implemented on top of the `_locale` module, which in turn uses an ANSI C locale implementation if available.

The `locale` module defines the following exception and functions:

`exception locale.Error`

Exception raised when `setlocale()` fails.

`locale.setlocale(category[, locale])`

If `locale` is specified, it may be a string, a tuple of the form `(language code, encoding)`, or `None`. If it is a tuple, it is converted to a string using the locale aliasing engine. If `locale` is given and not `None`, `setlocale()` modifies the locale setting for the `category`. The available categories are listed in the data description below. The value is the name of a locale. An empty string specifies the user's default settings. If the modification of the locale fails, the exception `Error` is raised. If successful, the new locale setting is returned.

If `locale` is omitted or `None`, the current setting for `category` is returned.

`setlocale()` is not thread safe on most systems. Applications
typically start with a call of

```python
import locale
locale.setlocale(locale.LC_ALL, '')
```

This sets the locale for all categories to the user’s default setting (typically specified in the `LANG` environment variable). If the locale is not changed thereafter, using multithreading should not cause problems.

*Changed in version 2.0:* Added support for tuple values of the `locale` parameter.

`locale.localeconv()`

Returns the database of the local conventions as a dictionary. This dictionary has the following strings as keys:

<table>
<thead>
<tr>
<th>Category</th>
<th>Key</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>LC_NUMERIC</strong></td>
<td>'decimal_point'</td>
<td>Decimal point character.</td>
</tr>
<tr>
<td></td>
<td>'grouping'</td>
<td>Sequence of numbers specifying which relative positions the 'thousands_sep' is expected. If the sequence is terminated with <code>CHAR_MAX</code>, no further grouping is performed. If the sequence terminates with a <code>0</code>, the last group size is repeatedly...</td>
</tr>
<tr>
<td><strong>LC_MONETARY</strong></td>
<td><strong>'int_curr_symbol'</strong></td>
<td>International currency symbol.</td>
</tr>
<tr>
<td>-------------------</td>
<td>-----------------------</td>
<td>--------------------------------</td>
</tr>
<tr>
<td>'currency_symbol'</td>
<td></td>
<td>Local currency symbol.</td>
</tr>
<tr>
<td>'thousands_sep'</td>
<td></td>
<td>Character used between groups.</td>
</tr>
<tr>
<td>'p_cs_precedes/n_cs_precedes'</td>
<td>Whether the currency symbol precedes the value (for positive resp. negative values).</td>
<td></td>
</tr>
<tr>
<td>'p_sep_by_space/n_sep_by_space'</td>
<td>Whether the currency symbol is separated from the value by a space (for positive resp. negative values).</td>
<td></td>
</tr>
<tr>
<td>'mon_decimal_point'</td>
<td></td>
<td>Decimal point used for monetary values.</td>
</tr>
<tr>
<td>'frac_digits'</td>
<td></td>
<td>Number of fractional digits used in local formatting of monetary values.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Number of fractional digits used in</td>
</tr>
<tr>
<td>'int_frac_digits'</td>
<td>international formatting of monetary values.</td>
<td></td>
</tr>
<tr>
<td>'mon_thousands_sep'</td>
<td>Group separator used for monetary values.</td>
<td></td>
</tr>
<tr>
<td>'mon_grouping'</td>
<td>Equivalent to 'grouping', used for monetary values.</td>
<td></td>
</tr>
<tr>
<td>'positive_sign'</td>
<td>Symbol used to annotate a positive monetary value.</td>
<td></td>
</tr>
<tr>
<td>'negative_sign'</td>
<td>Symbol used to annotate a negative monetary value.</td>
<td></td>
</tr>
<tr>
<td>'p_sign_posn/n_sign_posn'</td>
<td>The position of the sign (for positive resp. negative values), see below.</td>
<td></td>
</tr>
</tbody>
</table>

All numeric values can be set to **CHAR_MAX** to indicate that there is no value specified in this locale.

The possible values for 'p_sign_posn' and 'n_sign_posn' are given below.

<table>
<thead>
<tr>
<th>Value</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Currency and value are surrounded by parentheses.</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>---</td>
<td>---</td>
</tr>
<tr>
<td>1</td>
<td>The sign should precede the value and currency symbol.</td>
</tr>
<tr>
<td>2</td>
<td>The sign should follow the value and currency symbol.</td>
</tr>
<tr>
<td>3</td>
<td>The sign should immediately precede the value.</td>
</tr>
<tr>
<td>4</td>
<td>The sign should immediately follow the value.</td>
</tr>
<tr>
<td>CHAR_MAX</td>
<td>Nothing is specified in this locale.</td>
</tr>
</tbody>
</table>

**locale.**`nl_langinfo(option)`

Return some locale-specific information as a string. This function is not available on all systems, and the set of possible options might also vary across platforms. The possible argument values are numbers, for which symbolic constants are available in the locale module.

The `nl_langinfo()` function accepts one of the following keys. Most descriptions are taken from the corresponding description in the GNU C library.

**locale.**`CODESET`

Get a string with the name of the character encoding used in the selected locale.

**locale.**`D_T_FMT`

Get a string that can be used as a format string for `strftime()` to represent time and date in a locale-specific way.

**locale.**`D_FMT`

Get a string that can be used as a format string for `strftime()` to represent a date in a locale-specific way.

**locale.**`T_FMT`

Get a string that can be used as a format string for `strftime()` to represent a time in a locale-specific way.
locale. **T_FMT_AMPM**
Get a format string for `strftime()` to represent time in the am/pm format.

**DAY_1 . . . DAY_7**
Get the name of the n-th day of the week.

**Note:** This follows the US convention of **DAY_1** being Sunday, not the international convention (ISO 8601) that Monday is the first day of the week.

**ABDAY_1 . . . ABDAY_7**
Get the abbreviated name of the n-th day of the week.

**MON_1 . . . MON_12**
Get the name of the n-th month.

**ABMON_1 . . . ABMON_12**
Get the abbreviated name of the n-th month.

locale. **RADIXCHAR**
Get the radix character (decimal dot, decimal comma, etc.)

locale. **THOUSEP**
Get the separator character for thousands (groups of three digits).

locale. **YESEXPR**
Get a regular expression that can be used with the `regex()` function to recognize a positive response to a yes/no question.

**Note:** The expression is in the syntax suitable for the `regex()` function from the C library, which might differ from the syntax used in re.
locale. **NOEXPR**

Get a regular expression that can be used with the **regex(3)** function to recognize a negative response to a yes/no question.

locale. **CRNCYSTR**

Get the currency symbol, preceded by “-” if the symbol should appear before the value, “+” if the symbol should appear after the value, or “.” if the symbol should replace the radix character.

locale. **ERA**

Get a string that represents the era used in the current locale.

Most locales do not define this value. An example of a locale which does define this value is the Japanese one. In Japan, the traditional representation of dates includes the name of the era corresponding to the then-emperor’s reign.

Normally it should not be necessary to use this value directly. Specifying the **e** modifier in their format strings causes the **strftime()** function to use this information. The format of the returned string is not specified, and therefore you should not assume knowledge of it on different systems.

locale. **ERA_YEAR**

Get the year in the relevant era of the locale.

locale. **ERA_D_T_FMT**

Get a format string for **strftime()** to represent dates and times in a locale-specific era-based way.

locale. **ERA_D_FMT**

Get a format string for **strftime()** to represent time in a locale-specific era-based way.
locale. **ALT_DIGITS**

Get a representation of up to 100 values used to represent the values 0 to 99.

locale. **getdefaultlocale([envvars])**

Tries to determine the default locale settings and returns them as a tuple of the form `(language code, encoding)`.

According to POSIX, a program which has not called `setlocale(LC_ALL, '')` runs using the portable `C` locale. Calling `setlocale(LC_ALL, '')` lets it use the default locale as defined by the `LANG` variable. Since we do not want to interfere with the current locale setting we thus emulate the behavior in the way described above.

To maintain compatibility with other platforms, not only the `LANG` variable is tested, but a list of variables given as envvars parameter. The first found to be defined will be used. `envvars` defaults to the search path used in GNU gettext; it must always contain the variable name `LANG`. The GNU gettext search path contains `'LANGUAGE'`, `'LC_ALL'`, `'LC_CTYPE'`, and `'LANG'`, in that order.

Except for the code `C`, the language code corresponds to RFC 1766. `language code` and `encoding` may be `None` if their values cannot be determined.

New in version 2.0.

locale. **getlocale([category])**

Returns the current setting for the given locale category as sequence containing `language code, encoding`. `category` may be one of the `LC_*` values except `LC_ALL`. It defaults to `LC_CTYPE`. 
Except for the code `'c'`, the language code corresponds to RFC 1766. *language code* and *encoding* may be *None* if their values cannot be determined.

*New in version 2.0.*

```python
locale.getpreferredencoding([do_setlocale])
```

Return the encoding used for text data, according to user preferences. User preferences are expressed differently on different systems, and might not be available programatically on some systems, so this function only returns a guess.

On some systems, it is necessary to invoke `setlocale()` to obtain the user preferences, so this function is not thread-safe. If invoking setlocale is not necessary or desired, `do_setlocale` should be set to `False`.

*New in version 2.3.*

```python
locale.normalize(localename)
```

Returns a normalized locale code for the given locale name. The returned locale code is formatted for use with `setlocale()`. If normalization fails, the original name is returned unchanged.

If the given encoding is not known, the function defaults to the default encoding for the locale code just like `setlocale()`.

*New in version 2.0.*

```python
locale.resetlocale([category])
```

Sets the locale for `category` to the default setting.

The default setting is determined by calling `getdefaultlocale()`. `category` defaults to `LC_ALL`. 
New in version 2.0.

locale.strcoll(string1, string2)

Compares two strings according to the current LC_COLLATE setting. As any other compare function, returns a negative, or a positive value, or 0, depending on whether string1 collates before or after string2 or is equal to it.

locale.strxfrm(string)

Transforms a string to one that can be used for the built-in function cmp(), and still returns locale-aware results. This function can be used when the same string is compared repeatedly, e.g. when collating a sequence of strings.

locale.format(format, val[, grouping[, monetary]])

Formats a number val according to the current LC_NUMERIC setting. The format follows the conventions of the % operator. For floating point values, the decimal point is modified if appropriate. If grouping is true, also takes the grouping into account.

If monetary is true, the conversion uses monetary thousands separator and grouping strings.

Please note that this function will only work for exactly one %char specifier. For whole format strings, use format_string().

Changed in version 2.5: Added the monetary parameter.

locale.format_string(format, val[, grouping])

Processes formatting specifiers as in format % val, but takes the current locale settings into account.

New in version 2.5.
locale.\texttt{currency}(val[, \texttt{symbol}[, \texttt{grouping}[, \texttt{international}]])

Formats a number \texttt{val} according to the current \texttt{LC_MONETARY} settings.

The returned string includes the currency symbol if \texttt{symbol} is true, which is the default. If \texttt{grouping} is true (which is not the default), grouping is done with the value. If \texttt{international} is true (which is not the default), the international currency symbol is used.

Note that this function will not work with the ‘C’ locale, so you have to set a locale via \texttt{setlocale()} first.

\textit{New in version 2.5.}

locale.\texttt{str}(float)

Formats a floating point number using the same format as the built-in function \texttt{str(float)}, but takes the decimal point into account.

locale.\texttt{atof}(string)

Converts a string to a floating point number, following the \texttt{LC_NUMERIC} settings.

locale.\texttt{atoi}(string)

Converts a string to an integer, following the \texttt{LC_NUMERIC} conventions.

locale.\texttt{LC_CTYPE}

Locale category for the character type functions. Depending on the settings of this category, the functions of module \texttt{string} dealing with case change their behaviour.

locale.\texttt{LC_COLLATE}
Locale category for sorting strings. The functions `strcoll()` and `strxfrm()` of the `locale` module are affected.

locale. **LC_TIME**
Locale category for the formatting of time. The function `time.strftime()` follows these conventions.

locale. **LC_MONETARY**
Locale category for formatting of monetary values. The available options are available from the `localeconv()` function.

locale. **LC_MESSAGES**
Locale category for message display. Python currently does not support application specific locale-aware messages. Messages displayed by the operating system, like those returned by `os.strerror()` might be affected by this category.

locale. **LC_NUMERIC**
Locale category for formatting numbers. The functions `format()`, `atoi()`, `atof()` and `str()` of the `locale` module are affected by that category. All other numeric formatting operations are not affected.

locale. **LC_ALL**
Combination of all locale settings. If this flag is used when the locale is changed, setting the locale for all categories is attempted. If that fails for any category, no category is changed at all. When the locale is retrieved using this flag, a string indicating the setting for all categories is returned. This string can be later used to restore the settings.

locale. **CHAR_MAX**
This is a symbolic constant used for different values returned by `localeconv()`.
Example:

```python
>>> import locale
>>> loc = locale.getlocale() # get current locale
# use German locale; name might vary with platform
>>> locale.setlocale(locale.LC_ALL, 'de_DE')
>>> locale.strcoll('f\xe4n', 'foo') # compare a string containi
>>> locale.setlocale(locale.LC_ALL, '') # use user's preferred
>>> locale.setlocale(locale.LC_ALL, 'C') # use default (C) loca
>>> locale.setlocale(locale.LC_ALL, loc) # restore saved locale
```
22.2.1. Background, details, hints, tips and caveats

The C standard defines the locale as a program-wide property that may be relatively expensive to change. On top of that, some implementation are broken in such a way that frequent locale changes may cause core dumps. This makes the locale somewhat painful to use correctly.

Initially, when a program is started, the locale is the C locale, no matter what the user’s preferred locale is. The program must explicitly say that it wants the user’s preferred locale settings by calling `setlocale(LC_ALL, '')`.

It is generally a bad idea to call `setlocale()` in some library routine, since as a side effect it affects the entire program. Saving and restoring it is almost as bad: it is expensive and affects other threads that happen to run before the settings have been restored.

If, when coding a module for general use, you need a locale independent version of an operation that is affected by the locale (such as `string.lower()`, or certain formats used with `time.strftime()`), you will have to find a way to do it without using the standard library routine. Even better is convincing yourself that using locale settings is okay. Only as a last resort should you document that your module is not compatible with non-C locale settings.

The case conversion functions in the `string` module are affected by the locale settings. When a call to the `setlocale()` function changes the `LC_CTYPE` settings, the variables `string.lowercase`, `string.uppercase` and `string.letters` are recalculated. Note that
code that uses these variable through 'from ... import ...', e.g. from string import letters, is not affected by subsequent setlocale() calls.

The only way to perform numeric operations according to the locale is to use the special functions defined by this module: atof(), atoi(), format(), str().
Extension modules should never call `setlocale()`, except to find out what the current locale is. But since the return value can only be used portably to restore it, that is not very useful (except perhaps to find out whether or not the locale is C).

When Python code uses the `locale` module to change the locale, this also affects the embedding application. If the embedding application doesn’t want this to happen, it should remove the `_locale` extension module (which does all the work) from the table of built-in modules in the `config.c` file, and make sure that the `_locale` module is not accessible as a shared library.
22.2.3. Access to message catalogs

The locale module exposes the C library's gettext interface on systems that provide this interface. It consists of the functions `gettext()`, `dgettext()`, `dcgettext()`, `textdomain()`, `bindtextdomain()`, and `bind_textdomain_codeset()`. These are similar to the same functions in the `gettext` module, but use the C library's binary format for message catalogs, and the C library's search algorithms for locating message catalogs.

Python applications should normally find no need to invoke these functions, and should use `gettext` instead. A known exception to this rule are applications that link use additional C libraries which internally invoke `gettext()` or `dcgettext()`. For these applications, it may be necessary to bind the text domain, so that the libraries can properly locate their message catalogs.
23. Program Frameworks

The modules described in this chapter are frameworks that will largely dictate the structure of your program. Currently the modules described here are all oriented toward writing command-line interfaces.

The full list of modules described in this chapter is:

- 23.1. cmd — Support for line-oriented command interpreters
  - 23.1.1. Cmd Objects
- 23.2. shlex — Simple lexical analysis
  - 23.2.1. shlex Objects
  - 23.2.2. Parsing Rules
23.1. `cmd` — Support for line-oriented command interpreters

The `cmd` class provides a simple framework for writing line-oriented command interpreters. These are often useful for test harnesses, administrative tools, and prototypes that will later be wrapped in a more sophisticated interface.

```python
class cmd.Cmd([completekey[, stdin[, stdout]]])
```

A `Cmd` instance or subclass instance is a line-oriented interpreter framework. There is no good reason to instantiate `Cmd` itself; rather, it’s useful as a superclass of an interpreter class you define yourself in order to inherit `Cmd`’s methods and encapsulate action methods.

The optional argument `completekey` is the `readline` name of a completion key; it defaults to `Tab`. If `completekey` is not `None` and `readline` is available, command completion is done automatically.

The optional arguments `stdin` and `stdout` specify the input and output file objects that the `Cmd` instance or subclass instance will use for input and output. If not specified, they will default to `sys.stdin` and `sys.stdout`.

If you want a given `stdin` to be used, make sure to set the instance’s `use_rawinput` attribute to `False`, otherwise `stdin` will be ignored.

*Changed in version 2.3:* The `stdin` and `stdout` parameters were added.
23.1.1. Cmd Objects

A `Cmd` instance has the following methods:

`Cmd.cmdloop([intro])`

Repeatedly issue a prompt, accept input, parse an initial prefix off the received input, and dispatch to action methods, passing them the remainder of the line as argument.

The optional argument is a banner or intro string to be issued before the first prompt (this overrides the `intro` class member).

If the `readline` module is loaded, input will automatically inherit `bash`-like history-list editing (e.g. `Control-P` scrolls back to the last command, `Control-N` forward to the next one, `Control-F` moves the cursor to the right non-destructively, `Control-B` moves the cursor to the left non-destructively, etc.).

An end-of-file on input is passed back as the string `EOF`.

An interpreter instance will recognize a command name `foo` if and only if it has a method `do_foo()`. As a special case, a line beginning with the character `?` is dispatched to the method `do_help()`. As another special case, a line beginning with the character `!` is dispatched to the method `do_shell()` (if such a method is defined).

This method will return when the `postcmd()` method returns a true value. The `stop` argument to `postcmd()` is the return value from the command’s corresponding `do_*()` method.

If completion is enabled, completing commands will be done
automatically, and completing of commands args is done by
calling complete_foo() with arguments text, line, begidx, and
endidx. text is the string prefix we are attempting to match: all
returned matches must begin with it. line is the current input line
with leading whitespace removed, begidx and endidx are the
beginning and ending indexes of the prefix text, which could be
used to provide different completion depending upon which
position the argument is in.

All subclasses of Cmd inherit a predefined do_help(). This
method, called with an argument 'bar', invokes the
corresponding method help_bar(). With no argument, do_help()
lists all available help topics (that is, all commands with
corresponding help_*() methods), and also lists any
undocumented commands.

Cmd. onecmd(str)
Interpret the argument as though it had been typed in response
to the prompt. This may be overridden, but should not normally
need to be; see the precmd() and postcmd() methods for useful
execution hooks. The return value is a flag indicating whether
interpretation of commands by the interpreter should stop. If there
is a do_*() method for the command str, the return value of that
method is returned, otherwise the return value from the
default() method is returned.

Cmd. emptyline()
Method called when an empty line is entered in response to the
prompt. If this method is not overridden, it repeats the last
nonempty command entered.

Cmd. default(line)
Method called on an input line when the command prefix is not
recognized. If this method is not overridden, it prints an error
message and returns.

**Cmd. completedefault(text, line, begidx, endidx)**
Method called to complete an input line when no command-specific `complete_*()` method is available. By default, it returns an empty list.

**Cmd. precmd(line)**
Hook method executed just before the command line `line` is interpreted, but after the input prompt is generated and issued. This method is a stub in `Cmd`; it exists to be overridden by subclasses. The return value is used as the command which will be executed by the `onecmd()` method; the `precmd()` implementation may re-write the command or simply return `line` unchanged.

**Cmd. postcmd(stop, line)**
Hook method executed just after a command dispatch is finished. This method is a stub in `Cmd`; it exists to be overridden by subclasses. `line` is the command line which was executed, and `stop` is a flag which indicates whether execution will be terminated after the call to `postcmd()`; this will be the return value of the `onecmd()` method. The return value of this method will be used as the new value for the internal flag which corresponds to `stop`; returning false will cause interpretation to continue.

**Cmd. preloop()**
Hook method executed once when `cmdloop()` is called. This method is a stub in `Cmd`; it exists to be overridden by subclasses.

**Cmd. postloop()**
Hook method executed once when `cmdloop()` is about to return. This method is a stub in `Cmd`; it exists to be overridden by
Instances of \texttt{Cmd} subclasses have some public instance variables:

\texttt{Cmd.\ prompt}  
The prompt issued to solicit input.

\texttt{Cmd.\ identchars}  
The string of characters accepted for the command prefix.

\texttt{Cmd.\ lastcmd}  
The last nonempty command prefix seen.

\texttt{Cmd.\ intro}  
A string to issue as an intro or banner. May be overridden by giving the \texttt{cmdloop()} method an argument.

\texttt{Cmd.\ doc_header}  
The header to issue if the help output has a section for documented commands.

\texttt{Cmd.\ misc_header}  
The header to issue if the help output has a section for miscellaneous help topics (that is, there are \texttt{help_*()} methods without corresponding \texttt{do_*()} methods).

\texttt{Cmd.\ undoc_header}  
The header to issue if the help output has a section for undocumented commands (that is, there are \texttt{do_*()} methods without corresponding \texttt{help_*()} methods).

\texttt{Cmd.\ ruler}  
The character used to draw separator lines under the help-message headers. If empty, no ruler line is drawn. It defaults to \\
"==".
Cmd. **use_rawinput**

A flag, defaulting to true. If true, `cmdloop()` uses `raw_input()` to display a prompt and read the next command; if false, `sys.stdout.write()` and `sys.stdin.readline()` are used. (This means that by importing `readline`, on systems that support it, the interpreter will automatically support **Emacs**-like line editing and command-history keystrokes.)
23.2. shlex — Simple lexical analysis

New in version 1.5.2.

The shlex class makes it easy to write lexical analyzers for simple syntaxes resembling that of the Unix shell. This will often be useful for writing minilanguages, (for example, in run control files for Python applications) or for parsing quoted strings.

Note: The shlex module currently does not support Unicode input.

The shlex module defines the following functions:

shlex.split(s[, comments[, posix]])

Split the string s using shell-like syntax. If comments is False (the default), the parsing of comments in the given string will be disabled (setting the commenters member of the shlex instance to the empty string). This function operates in shlex instance mode by default, but uses non-POSIX mode if the posix argument is false.

New in version 2.3.

Changed in version 2.6: Added the posix parameter.

Note: Since the split() function instantiates a shlex instance, passing None for s will read the string to split from standard input.

The shlex module defines the following class:
class shlex.shlex([instream[, infile[, posix]]])

A shlex instance or subclass instance is a lexical analyzer object. The initialization argument, if present, specifies where to read characters from. It must be a file-/stream-like object with read() and readline() methods, or a string (strings are accepted since Python 2.3). If no argument is given, input will be taken from `sys.stdin`. The second optional argument is a filename string, which sets the initial value of the infile member. If the instream argument is omitted or equal to `sys.stdin`, this second argument defaults to “stdin”. The posix argument was introduced in Python 2.3, and defines the operational mode. When posix is not true (default), the shlex instance will operate in compatibility mode. When operating in POSIX mode, shlex will try to be as close as possible to the POSIX shell parsing rules.

See also:

Module ConfigParser
Parser for configuration files similar to the Windows .ini files.
shlex Objects

A shlex instance has the following methods:

shlex.get_token()
   Return a token. If tokens have been stacked using push_token(), pop a token off the stack. Otherwise, read one from the input stream. If reading encounters an immediate end-of-file, self.eof is returned (the empty string ("" in non-POSIX mode, and None in POSIX mode).

shlex.push_token(str)
   Push the argument onto the token stack.

shlex.read_token()
   Read a raw token. Ignore the pushback stack, and do not interpret source requests. (This is not ordinarily a useful entry point, and is documented here only for the sake of completeness.)

shlex.sourcehook(filename)
   When shlex detects a source request (see source below) this method is given the following token as argument, and expected to return a tuple consisting of a filename and an open file-like object.

Normally, this method first strips any quotes off the argument. If the result is an absolute pathname, or there was no previous source request in effect, or the previous source was a stream (such as sys.stdin), the result is left alone. Otherwise, if the result is a relative pathname, the directory part of the name of the file immediately before it on the source inclusion stack is prepended (this behavior is like the way the C preprocessor
handles `#include "file.h"`).

The result of the manipulations is treated as a filename, and returned as the first component of the tuple, with `open()` called on it to yield the second component. (Note: this is the reverse of the order of arguments in instance initialization!)

This hook is exposed so that you can use it to implement directory search paths, addition of file extensions, and other namespace hacks. There is no corresponding ‘close’ hook, but a shlex instance will call the `close()` method of the sourced input stream when it returns EOF.

For more explicit control of source stacking, use the `push_source()` and `pop_source()` methods.

```python
shlex.push_source(stream[, filename])
```

Push an input source stream onto the input stack. If the filename argument is specified it will later be available for use in error messages. This is the same method used internally by the `sourcehook()` method.

*New in version 2.1.*

```python
shlex.pop_source()
```

Pop the last-pushed input source from the input stack. This is the same method used internally when the lexer reaches EOF on a stacked input stream.

*New in version 2.1.*

```python
shlex.error_leader([file[, line]])
```

This method generates an error message leader in the format of a Unix C compiler error label; the format is `"%s", line %d: `,
where the %s is replaced with the name of the current source file and the %d with the current input line number (the optional arguments can be used to override these).

This convenience is provided to encourage shlex users to generate error messages in the standard, parseable format understood by Emacs and other Unix tools.

Instances of shlex subclasses have some public instance variables which either control lexical analysis or can be used for debugging:

shlex.commenters
The string of characters that are recognized as comment beginners. All characters from the comment beginner to end of line are ignored. Includes just '#' by default.

shlex.wordchars
The string of characters that will accumulate into multi-character tokens. By default, includes all ASCII alphanumerics and underscore.

shlex.whitespace
Characters that will be considered whitespace and skipped. Whitespace bounds tokens. By default, includes space, tab, linefeed and carriage-return.

shlex.escape
Characters that will be considered as escape. This will be only used in POSIX mode, and includes just '\' by default.

New in version 2.3.

shlex.quotes
Characters that will be considered string quotes. The token accumulates until the same quote is encountered again (thus, different quote types protect each other as in the shell.) By
default, includes ASCII single and double quotes.

**shlex.escapedquotes**

Characters in quotes that will interpret escape characters defined in escape. This is only used in POSIX mode, and includes just '.STRING' by default.

*New in version 2.3.*

**shlex.whitespace_split**

If True, tokens will only be split in whitespaces. This is useful, for example, for parsing command lines with shlex, getting tokens in a similar way to shell arguments.

*New in version 2.3.*

**shlex.infile**

The name of the current input file, as initially set at class instantiation time or stacked by later source requests. It may be useful to examine this when constructing error messages.

**shlex.instream**

The input stream from which this shlex instance is reading characters.

**shlex.source**

This member is None by default. If you assign a string to it, that string will be recognized as a lexical-level inclusion request similar to the source keyword in various shells. That is, the immediately following token will opened as a filename and input taken from that stream until EOF, at which point the close() method of that stream will be called and the input source will again become the original input stream. Source requests may be stacked any number of levels deep.

**shlex.debug**
If this member is numeric and 1 or more, a `shlex` instance will print verbose progress output on its behavior. If you need to use this, you can read the module source code to learn the details.

`shlex.lineno`

Source line number (count of newlines seen so far plus one).

`shlex.token`

The token buffer. It may be useful to examine this when catching exceptions.

`shlex.eof`

Token used to determine end of file. This will be set to the empty string (`''`), in non-POSIX mode, and to `None` in POSIX mode.

*New in version 2.3.*
23.2.2. Parsing Rules

When operating in non-POSIX mode, shlex will try to obey to the following rules.

- Quote characters are not recognized within words (Do"Not"Separate is parsed as the single word Do"Not"Separate);
- Escape characters are not recognized;
- Enclosing characters in quotes preserve the literal value of all characters within the quotes;
- Closing quotes separate words ("Do"Separate is parsed as "Do" and Separate);
- If whitespace_split is False, any character not declared to be a word character, whitespace, or a quote will be returned as a single-character token. If it is True, shlex will only split words in whitespaces;
- EOF is signaled with an empty string ('');
- It’s not possible to parse empty strings, even if quoted.

When operating in POSIX mode, shlex will try to obey to the following parsing rules.

- Quotes are stripped out, and do not separate words ("Do"Not"Separate" is parsed as the single word DoNotSeparate);
- Non-quoted escape characters (e.g. '\') preserve the literal value of the next character that follows;
- Enclosing characters in quotes which are not part of escapedquotes (e.g. "") preserve the literal value of all characters within the quotes;
- Enclosing characters in quotes which are part of escapedquotes (e.g. "'") preserves the literal value of all characters within the quotes, with the exception of the characters mentioned in
escape. The escape characters retain its special meaning only when followed by the quote in use, or the escape character itself. Otherwise the escape character will be considered a normal character.

- EOF is signaled with a `None` value;
- Quoted empty strings ('') are allowed;
24. Development Tools

The modules described in this chapter help you write software. For example, the **pydoc** module takes a module and generates documentation based on the module’s contents. The **doctest** and **unittest** modules contain frameworks for writing unit tests that automatically exercise code and verify that the expected output is produced. **2to3** can translate Python 2.x source code into valid Python 3.x code.

The list of modules described in this chapter is:

- **24.1. pydoc** — Documentation generator and online help system
- **24.2. doctest** — Test interactive Python examples
  - 24.2.1. Simple Usage: Checking Examples in Docstrings
  - 24.2.2. Simple Usage: Checking Examples in a Text File
  - 24.2.3. How It Works
    - 24.2.3.1. Which Docstrings Are Examined?
    - 24.2.3.2. How are Docstring Examples Recognized?
    - 24.2.3.3. What’s the Execution Context?
    - 24.2.3.4. What About Exceptions?
    - 24.2.3.5. Option Flags and Directives
    - 24.2.3.6. Warnings
  - 24.2.4. Basic API
  - 24.2.5. Unittest API
  - 24.2.6. Advanced API
    - 24.2.6.1. DocTest Objects
    - 24.2.6.2. Example Objects
    - 24.2.6.3. DocTestFinder objects
    - 24.2.6.4. DocTestParser objects
    - 24.2.6.5. DocTestRunner objects
    - 24.2.6.6. OutputChecker objects
  - 24.2.7. Debugging
24.2.8. Soapbox

- 24.3. unittest — Unit testing framework
  - 24.3.1. Basic example
  - 24.3.2. Command Line Interface
    - 24.3.2.1. failfast, catch and buffer command line options
  - 24.3.3. Test Discovery
  - 24.3.4. Organizing test code
  - 24.3.5. Re-using old test code
  - 24.3.6. Skipping tests and expected failures
  - 24.3.7. Classes and functions
    - 24.3.7.1. Test cases
    - 24.3.7.2. Grouping tests
    - 24.3.7.3. Loading and running tests
      - 24.3.7.3.1. load_tests Protocol
  - 24.3.8. Class and Module Fixtures
    - 24.3.8.1. setUpClass and tearDownClass
    - 24.3.8.2. setUpModule and tearDownModule
  - 24.3.9. Signal Handling
- 24.4. 2to3 - Automated Python 2 to 3 code translation
  - 24.4.1. Using 2to3
  - 24.4.2. Fixers
  - 24.4.3. lib2to3 - 2to3’s library
- 24.5. test — Regression tests package for Python
  - 24.5.1. Writing Unit Tests for the test package
  - 24.5.2. Running tests using test.regrtest
- 24.6. test.test_support — Utility functions for tests
New in version 2.1.

The `pydoc` module automatically generates documentation from Python modules. The documentation can be presented as pages of text on the console, served to a Web browser, or saved to HTML files.

The built-in function `help()` invokes the online help system in the interactive interpreter, which uses `pydoc` to generate its documentation as text on the console. The same text documentation can also be viewed from outside the Python interpreter by running `pydoc` as a script at the operating system’s command prompt. For example, running

```
pydoc sys
```

at a shell prompt will display documentation on the `sys` module, in a style similar to the manual pages shown by the Unix `man` command. The argument to `pydoc` can be the name of a function, module, or package, or a dotted reference to a class, method, or function within a module or module in a package. If the argument to `pydoc` looks like a path (that is, it contains the path separator for your operating system, such as a slash in Unix), and refers to an existing Python source file, then documentation is produced for that file.

**Note:** In order to find objects and their documentation, `pydoc` imports the module(s) to be documented. Therefore, any code on module level will be executed on that occasion. Use an `if __name__ == '__main__':` guard to only execute code when a file is
invoked as a script and not just imported.

Specifying a -w flag before the argument will cause HTML documentation to be written out to a file in the current directory, instead of displaying text on the console.

Specifying a -k flag before the argument will search the synopsis lines of all available modules for the keyword given as the argument, again in a manner similar to the Unix man command. The synopsis line of a module is the first line of its documentation string.

You can also use pydoc to start an HTTP server on the local machine that will serve documentation to visiting Web browsers. pydoc -p 1234 will start a HTTP server on port 1234, allowing you to browse the documentation at http://localhost:1234/ in your preferred Web browser. pydoc -g will start the server and additionally bring up a small Tkinter-based graphical interface to help you search for documentation pages.

When pydoc generates documentation, it uses the current environment and path to locate modules. Thus, invoking pydoc spam documents precisely the version of the module you would get if you started the Python interpreter and typed import spam.

Module docs for core modules are assumed to reside in http://docs.python.org/library/. This can be overridden by setting the PYTHONDOCS environment variable to a different URL or to a local directory containing the Library Reference Manual pages.
24.2. doctest — Test interactive Python examples

The doctest module searches for pieces of text that look like interactive Python sessions, and then executes those sessions to verify that they work exactly as shown. There are several common ways to use doctest:

- To check that a module’s docstrings are up-to-date by verifying that all interactive examples still work as documented.
- To perform regression testing by verifying that interactive examples from a test file or a test object work as expected.
- To write tutorial documentation for a package, liberally illustrated with input-output examples. Depending on whether the examples or the expository text are emphasized, this has the flavor of “literate testing” or “executable documentation”.

Here’s a complete but small example module:

```python
"""
This is the "example" module.

The example module supplies one function, factorial(). For example:

>>> factorial(5)
120
"""

def factorial(n):
    """Return the factorial of n, an exact integer >= 0.
    If the result is small enough to fit in an int, return an int.
    Else return a long.
   "
    return [factorial(n) for n in range(6)]
    [1, 1, 2, 6, 24, 120]
>>> [factorial(long(n)) for n in range(6)]
[1, 1, 2, 6, 24, 120]
```
>>> factorial(30)
265252859812191058636308480000000L
>>> factorial(30L)
265252859812191058636308480000000L
>>> factorial(-1)
Traceback (most recent call last):
...
ValueError: n must be >= 0

Factorials of floats are OK, but the float must be an exact
>>> factorial(30.1)
Traceback (most recent call last):
...
ValueError: n must be exact integer
>>> factorial(30.0)
265252859812191058636308480000000L

It must also not be ridiculously large:
>>> factorial(1e100)
Traceback (most recent call last):
...
OverflowError: n too large

""

import math
if not n >= 0:
    raise ValueError("n must be >= 0")
if math.floor(n) != n:
    raise ValueError("n must be exact integer")
if n+1 == n:  # catch a value like 1e300
    raise OverflowError("n too large")
result = 1
factor = 2
while factor <= n:
    result *= factor
    factor += 1
return result

if __name__ == "__main__":
    import doctest
doctest.testmod()

If you run example.py directly from the command line, doctest works its magic:
There’s no output! That’s normal, and it means all the examples worked. Pass `-v` to the script, and `doctest` prints a detailed log of what it’s trying, and prints a summary at the end:

```
$ python example.py -v
Trying:
    factorial(5)
Expecting:
    120
ok
Trying:
    [factorial(n) for n in range(6)]
Expecting:
    [1, 1, 2, 6, 24, 120]
ok
Trying:
    [factorial(long(n)) for n in range(6)]
Expecting:
    [1, 1, 2, 6, 24, 120]
ok

And so on, eventually ending with:

```
Trying:
    factorial(1e100)
Expecting:
    Traceback (most recent call last):
      ...
        OverflowError: n too large
ok
2 items passed all tests:
  1 tests in __main__
  8 tests in __main__.factorial
9 tests in 2 items.
9 passed and 0 failed.
Test passed.
$```

That’s all you need to know to start making productive use of
doctest! Jump in. The following sections provide full details. Note that there are many examples of doctests in the standard Python test suite and libraries. Especially useful examples can be found in the standard test file Lib/test/test_doctest.py.
24.2.1. Simple Usage: Checking Examples in Docstrings

The simplest way to start using doctest (but not necessarily the way you'll continue to do it) is to end each module \texttt{M} with:

```python
if \_\_name\_ == "\_\_main\_":
    import doctest
doctest.testmod()
```

\texttt{doctest} then examines docstrings in module \texttt{M}.

Running the module as a script causes the examples in the docstrings to get executed and verified:

```python
python M.py
```

This won't display anything unless an example fails, in which case the failing example(s) and the cause(s) of the failure(s) are printed to stdout, and the final line of output is \texttt{***Test Failed*** N failures.}, where \texttt{N} is the number of examples that failed.

Run it with the \texttt{-v} switch instead:

```python
python M.py -v
```

and a detailed report of all examples tried is printed to standard output, along with assorted summaries at the end.

You can force verbose mode by passing \texttt{verbose=True} to \texttt{testmod()}, or prohibit it by passing \texttt{verbose=False}. In either of those cases, \texttt{sys.argv} is not examined by \texttt{testmod()} (so passing \texttt{-v} or not has no effect).
Since Python 2.6, there is also a command line shortcut for running `testmod()`. You can instruct the Python interpreter to run the doctest module directly from the standard library and pass the module name(s) on the command line:

```
python -m doctest -v example.py
```

This will import `example.py` as a standalone module and run `testmod()` on it. Note that this may not work correctly if the file is part of a package and imports other submodules from that package.

For more information on `testmod()`, see section `Basic API`. 
Another simple application of doctest is testing interactive examples in a text file. This can be done with the `testfile()` function:

```python
import doctest
doctest.testfile("example.txt")
```

That short script executes and verifies any interactive Python examples contained in the file `example.txt`. The file content is treated as if it were a single giant docstring; the file doesn't need to contain a Python program! For example, perhaps `example.txt` contains this:

```rst
The ``example`` module
======================

Using ``factorial``
-----------------

This is an example text file in reStructuredText format. First ``factorial`` from the ``example`` module:

```python
>>> from example import factorial
```

Now use it:

```python
>>> factorial(6)
120
```

Running `doctest.testfile("example.txt")` then finds the error in this documentation:

```
File "./example.txt", line 14, in example.txt
Failed example:
    factorial(6)
```
As with `testmod()`, `testfile()` won't display anything unless an example fails. If an example does fail, then the failing example(s) and the cause(s) of the failure(s) are printed to stdout, using the same format as `testmod()`.

By default, `testfile()` looks for files in the calling module's directory. See section *Basic API* for a description of the optional arguments that can be used to tell it to look for files in other locations.

Like `testmod()`, `testfile()`'s verbosity can be set with the `-v` command-line switch or with the optional keyword argument `verbose`.

Since Python 2.6, there is also a command line shortcut for running `testfile()`. You can instruct the Python interpreter to run the doctest module directly from the standard library and pass the file name(s) on the command line:

```
python -m doctest -v example.txt
```

Because the file name does not end with `.py`, `doctest` infers that it must be run with `testfile()`, not `testmod()`.

For more information on `testfile()`, see section *Basic API*. 
24.2.3. How It Works

This section examines in detail how doctest works: which docstrings it looks at, how it finds interactive examples, what execution context it uses, how it handles exceptions, and how option flags can be used to control its behavior. This is the information that you need to know to write doctest examples; for information about actually running doctest on these examples, see the following sections.

24.2.3.1. Which Docstrings Are Examined?

The module docstring, and all function, class and method docstrings are searched. Objects imported into the module are not searched.

In addition, if \_\_test\_\_ exists and “is true”, it must be a dict, and each entry maps a (string) name to a function object, class object, or string. Function and class object docstrings found from \_\_test\_\_ are searched, and strings are treated as if they were docstrings. In output, a key K in \_\_test\_\_ appears with name

<name of M>.__test__.K

Any classes found are recursively searched similarly, to test docstrings in their contained methods and nested classes.

*Changed in version 2.4:* A “private name” concept is deprecated and no longer documented.

24.2.3.2. How are Docstring Examples Recognized?

In most cases a copy-and-paste of an interactive console session works fine, but doctest isn’t trying to do an exact emulation of any
specific Python shell.

```python
>>> # comments are ignored
>>> x = 12
>>> x
12
>>> if x == 13:
...   print "yes"
... else:
...   print "no"
...   print "NO"
...   print "NO!!"
no
NO
NO!!!
```

Any expected output must immediately follow the final `'''` or `...` line containing the code, and the expected output (if any) extends to the next `'''` or all-whitespace line.

The fine print:

- Expected output cannot contain an all-whitespace line, since such a line is taken to signal the end of expected output. If expected output does contain a blank line, put `<BLANKLINE>` in your doctest example each place a blank line is expected.

  *New in version 2.4:* `<BLANKLINE>` was added; there was no way to use expected output containing empty lines in previous versions.

- All hard tab characters are expanded to spaces, using 8-column tab stops. Tabs in output generated by the tested code are not modified. Because any hard tabs in the sample output are expanded, this means that if the code output includes hard tabs, the only way the doctest can pass is if the `NORMALIZE_WHITESPACE`
option or directive is in effect. Alternatively, the test can be rewritten to capture the output and compare it to an expected value as part of the test. This handling of tabs in the source was arrived at through trial and error, and has proven to be the least error prone way of handling them. It is possible to use a different algorithm for handling tabs by writing a custom `DocTestParser` class.

*Changed in version 2.4:* Expanding tabs to spaces is new; previous versions tried to preserve hard tabs, with confusing results.

- Output to stdout is captured, but not output to stderr (exception tracebacks are captured via a different means).

- If you continue a line via backslashing in an interactive session, or for any other reason use a backslash, you should use a raw docstring, which will preserve your backslashes exactly as you type them:

  ```
  >>> def f(x):
  ...     r'''Backslashes in a raw docstring: m\n'''
  >>> print f.__doc__
  Backslashes in a raw docstring: m\n
  Otherwise, the backslash will be interpreted as part of the string. For example, the "\" above would be interpreted as a newline character. Alternatively, you can double each backslash in the doctest version (and not use a raw string):
  ```
  >>> def f(x):
  ...     '''Backslashes in a raw docstring: m\\n'''
  >>> print f.__doc__
  Backslashes in a raw docstring: m\\n
  - The starting column doesn't matter:
and as many leading whitespace characters are stripped from the expected output as appeared in the initial `>>>` line that started the example.

### 24.2.3.3. What’s the Execution Context?

By default, each time doctest finds a docstring to test, it uses a *shallow copy* of M's globals, so that running tests doesn't change the module's real globals, and so that one test in M can't leave behind crumbs that accidentally allow another test to work. This means examples can freely use any names defined at top-level in M, and names defined earlier in the docstring being run. Examples cannot see names defined in other docstrings.

You can force use of your own dict as the execution context by passing `globs=your_dict` to `testmod()` or `testfile()` instead.

### 24.2.3.4. What About Exceptions?

No problem, provided that the traceback is the only output produced by the example: just paste in the traceback. [1] Since tracebacks contain details that are likely to change rapidly (for example, exact file paths and line numbers), this is one case where doctest works hard to be flexible in what it accepts.

Simple example:

```python
>>> [1, 2, 3].remove(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: list.remove(x): x not in list
```
That doctest succeeds if `ValueError` is raised, with the
`list.remove(x): x not in list` detail as shown.

The expected output for an exception must start with a traceback
header, which may be either of the following two lines, indented the
same as the first line of the example:

```
Traceback (most recent call last):
Traceback (innermost last):
```

The traceback header is followed by an optional traceback stack,
whose contents are ignored by doctest. The traceback stack is
typically omitted, or copied verbatim from an interactive session.

The traceback stack is followed by the most interesting part: the
line(s) containing the exception type and detail. This is usually the
last line of a traceback, but can extend across multiple lines if the
exception has a multi-line detail:

```
>>> raise ValueError('multi
    line
detail')
Traceback (most recent call last):
    File "<stdin>", line 1, in ?
ValueError: multi
    line
detail
```

The last three lines (starting with `ValueError`) are compared against
the exception’s type and detail, and the rest are ignored.

*Changed in version 2.4:* Previous versions were unable to handle
multi-line exception details.

Best practice is to omit the traceback stack, unless it adds significant
documentation value to the example. So the last example is probably
better as:
Note that tracebacks are treated very specially. In particular, in the rewritten example, the use of ... is independent of doctest's ELLIPSIS option. The ellipsis in that example could be left out, or could just as well be three (or three hundred) commas or digits, or an indented transcript of a Monty Python skit.

Some details you should read once, but won’t need to remember:

- Doctest can’t guess whether your expected output came from an exception traceback or from ordinary printing. So, e.g., an example that expects ValueError: 42 is prime will pass whether ValueError is actually raised or if the example merely prints that traceback text. In practice, ordinary output rarely begins with a traceback header line, so this doesn’t create real problems.

- Each line of the traceback stack (if present) must be indented further than the first line of the example, or start with a non-alphanumeric character. The first line following the traceback header indented the same and starting with an alphanumeric is taken to be the start of the exception detail. Of course this does the right thing for genuine tracebacks.

- When the IGNORE_EXCEPTION_DETAIL doctest option is specified, everything following the leftmost colon and any module information in the exception name is ignored.

- The interactive shell omits the traceback header line for some SyntaxErrors. But doctest uses the traceback header line to
distinguish exceptions from non-exceptions. So in the rare case where you need to test a `SyntaxError` that omits the traceback header, you will need to manually add the traceback header line to your test example.

- For some `SyntaxError`s, Python displays the character position of the syntax error, using a `^` marker:

```python
>>> 1 1
    File "<stdin>", line 1
 1 1
    ^
SyntaxError: invalid syntax
```

Since the lines showing the position of the error come before the exception type and detail, they are not checked by doctest. For example, the following test would pass, even though it puts the `^` marker in the wrong location:

```python
>>> 1 1
    Traceback (most recent call last):
    File "<stdin>", line 1
 1 1
    ^
SyntaxError: invalid syntax
```

24.2.3.5. Option Flags and Directives

A number of option flags control various aspects of doctest's behavior. Symbolic names for the flags are supplied as module constants, which can be or'ed together and passed to various functions. The names can also be used in doctest directives (see below).

The first group of options define test semantics, controlling aspects of how doctest decides whether actual output matches an example's expected output:
By default, if an expected output block contains just 1, an actual output block containing just 1 or just True is considered to be a match, and similarly for 0 versus False. When DONT_ACCEPT_TRUE_FOR_1 is specified, neither substitution is allowed. The default behavior caters to that Python changed the return type of many functions from integer to boolean; doctests expecting “little integer” output still work in these cases. This option will probably go away, but not for several years.

By default, if an expected output block contains a line containing only the string <BLANKLINE>, then that line will match a blank line in the actual output. Because a genuinely blank line delimits the expected output, this is the only way to communicate that a blank line is expected. When DONT_ACCEPT_BLANKLINE is specified, this substitution is not allowed.

When specified, all sequences of whitespace (blanks and newlines) are treated as equal. Any sequence of whitespace within the expected output will match any sequence of whitespace within the actual output. By default, whitespace must match exactly. NORMALIZE_WHITESPACE is especially useful when a line of expected output is very long, and you want to wrap it across multiple lines in your source.

When specified, an ellipsis marker (...) in the expected output can match any substring in the actual output. This includes substrings that span line boundaries, and empty substrings, so it’s best to keep usage of this simple. Complicated uses can lead to the same kinds of “oops, it matched too much!” surprises that .* is prone to in regular expressions.
doctest. **IGNORE_EXCEPTION_DETAIL**

When specified, an example that expects an exception passes if an exception of the expected type is raised, even if the exception detail does not match. For example, an example expecting `ValueError: 42` will pass if the actual exception raised is `ValueError: 3*14`, but will fail, e.g., if `TypeError` is raised.

It will also ignore the module name used in Python 3 doctest reports. Hence both these variations will work regardless of whether the test is run under Python 2.7 or Python 3.2 (or later versions):

```python
>>> raise CustomError('message')  # doctest: +IGNORE_EXCEPTION_DETAIL
Traceback (most recent call last):
  CustomError: message
```

Note that **ELLIPSIS** can also be used to ignore the details of the exception message, but such a test may still fail based on whether or not the module details are printed as part of the exception name. Using **IGNORE_EXCEPTION_DETAIL** and the details from Python 2.3 is also the only clear way to write a doctest that doesn't care about the exception detail yet continues to pass under Python 2.3 or earlier (those releases do not support doctest directives and ignore them as irrelevant comments). For example,

```python
>>> (1, 2)[3] = 'moo'  # doctest: +IGNORE_EXCEPTION_DETAIL
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  TypeError: object doesn't support item assignment
```

passes under Python 2.3 and later Python versions, even though
the detail changed in Python 2.4 to say “does not” instead of “doesn't”.

**Changed in version 2.7:** `IGNORE_EXCEPTION_DETAIL` now also ignores any information relating to the module containing the exception under test

**doctest.SKIP**
When specified, do not run the example at all. This can be useful in contexts where doctest examples serve as both documentation and test cases, and an example should be included for documentation purposes, but should not be checked. E.g., the example's output might be random; or the example might depend on resources which would be unavailable to the test driver.

The SKIP flag can also be used for temporarily “commenting out” examples.

**New in version 2.5.**

**doctest.COMPARISON_FLAGS**
A bitmask or’ing together all the comparison flags above.

The second group of options controls how test failures are reported:

**doctest.REPORT_UDIFF**
When specified, failures that involve multi-line expected and actual outputs are displayed using a unified diff.

**doctest.REPORT_CDIFF**
When specified, failures that involve multi-line expected and actual outputs will be displayed using a context diff.

**doctest.REPORT_NDIFF**
When specified, differences are computed by `difflib.Differ`, using the same algorithm as the popular `ndiff.py` utility. This is
the only method that marks differences within lines as well as across lines. For example, if a line of expected output contains digit 1 where actual output contains letter l, a line is inserted with a caret marking the mismatching column positions.

**doctest. REPORT_ONLY_FIRST_FAILURE**

When specified, display the first failing example in each doctest, but suppress output for all remaining examples. This will prevent doctest from reporting correct examples that break because of earlier failures; but it might also hide incorrect examples that fail independently of the first failure. When **REPORT_ONLY_FIRST_FAILURE** is specified, the remaining examples are still run, and still count towards the total number of failures reported; only the output is suppressed.

**doctest. REPORTING_FLAGS**

A bitmask or’ing together all the reporting flags above.

“Doctest directives” may be used to modify the option flags for individual examples. Doctest directives are expressed as a special Python comment following an example’s source code:

```
directive ::= "#" "doctest:" directive_options
directive_options ::= directive_option ("," directive_option)*
directive_option ::= on_or_off directive_option_name
on_or_off ::= "+" | "-"
directive_option_name ::= "DONT_ACCEPT_BLANKLINE" | "NORMALIZE_WHITESPACE"
```

Whitespace is not allowed between the + or - and the directive option name. The directive option name can be any of the option flag names explained above.

An example’s doctest directives modify doctest’s behavior for that single example. Use + to enable the named behavior, or - to disable it.
For example, this test passes:

```python
>>> print range(20) # doctest: +NORMALIZE_WHITESPACE
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9,
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19]
```

Without the directive it would fail, both because the actual output doesn’t have two blanks before the single-digit list elements, and because the actual output is on a single line. This test also passes, and also requires a directive to do so:

```python
>>> print range(20) # doctest:+ELLIPSIS
[0, 1, ..., 18, 19]
```

Multiple directives can be used on a single physical line, separated by commas:

```python
>>> print range(20) # doctest: +ELLIPSIS, +NORMALIZE_WHITESPACE
[0, 1, ..., 18, 19]
```

If multiple directive comments are used for a single example, then they are combined:

```python
>>> print range(20) # doctest: +ELLIPSIS
... # doctest: +NORMALIZE_WHITESPACE
[0, 1, ..., 18, 19]
```

As the previous example shows, you can add `...` lines to your example containing only directives. This can be useful when an example is too long for a directive to comfortably fit on the same line:

```python
>>> print range(5) + range(10,20) + range(30,40) + range(50,60)
... # doctest: +ELLIPSIS
[0, ..., 4, 10, ..., 19, 30, ..., 39, 50, ..., 59]
```

Note that since all options are disabled by default, and directives
apply only to the example they appear in, enabling options (via `+` in a directive) is usually the only meaningful choice. However, option flags can also be passed to functions that run doctests, establishing different defaults. In such cases, disabling an option via `-` in a directive can be useful.

**New in version 2.4:** Doctest directives and the associated constants `DONT_ACCEPT_BLANKLINE`, `NORMALIZE_WHITESPACE`, `ELLIPSIS`, `IGNORE_EXCEPTION_DETAIL`, `REPORT_UDIFF`, `REPORT_CDIFF`, `REPORT_NDIFF`, `REPORT_ONLY_FIRST_FAILURE`, `COMPARISON_FLAGS` and `REPORTING_FLAGS` were added.

There's also a way to register new option flag names, although this isn't useful unless you intend to extend doctest internals via subclassing:

```python
doctest.register_optionflag(name)
```

Create a new option flag with a given name, and return the new flag's integer value. `register_optionflag()` can be used when subclassing `OutputChecker` or `DocTestRunner` to create new options that are supported by your subclasses. `register_optionflag()` should always be called using the following idiom:

```python
MY_FLAG = register_optionflag('MY_FLAG')
```

**New in version 2.4.**

### 24.2.3.6. Warnings

`doctest` is serious about requiring exact matches in expected output. If even a single character doesn't match, the test fails. This will probably surprise you a few times, as you learn exactly what Python does and doesn't guarantee about output. For example, when
printing a dict, Python doesn’t guarantee that the key-value pairs will be printed in any particular order, so a test like

```python
>>> foo()
{'Hermione': 'hippogryph', 'Harry': 'broomstick'}
```

is vulnerable! One workaround is to do

```python
>>> foo() == {'Hermione': 'hippogryph', 'Harry': 'broomstick'}
True
```

instead. Another is to do

```python
>>> d = foo().items()
>>> d.sort()
>>> d
[('Harry', 'broomstick'), ('Hermione', 'hippogryph')]
```

There are others, but you get the idea.

Another bad idea is to print things that embed an object address, like

```python
>>> id(1.0)  # certain to fail some of the time
7948648
>>> class C: pass
>>> C()  # the default repr() for instances embeds an address
<__main__.C instance at 0x00AC18F0>
```

The `ELLIPSIS` directive gives a nice approach for the last example:

```python
>>> C()  # doctest: +ELLIPSIS
<__main__.C instance at 0x...>
```

Floating-point numbers are also subject to small output variations across platforms, because Python defers to the platform C library for float formatting, and C libraries vary widely in quality here.

```python
>>> 1./7  # risky
0.14285714285714285
```
Numbers of the form $1/2.**J$ are safe across all platforms, and I often contrive doctest examples to produce numbers of that form:

```
>>> print 1./7 # safer
0.142857142857
>>> print round(1./7, 6) # much safer
0.142857
```

Simple fractions are also easier for people to understand, and that makes for better documentation.
24.2.4. Basic API

The functions `testmod()` and `testfile()` provide a simple interface to doctest that should be sufficient for most basic uses. For a less formal introduction to these two functions, see sections *Simple Usage: Checking Examples in Docstrings* and *Simple Usage: Checking Examples in a Text File*.

```python
import doctest

doctest.testfile(filename[, module_relative][, name][, package][, globs][, verbose][, report][, optionflags][, extraglobs][, raise_on_error][, parser][, encoding])
```

All arguments except `filename` are optional, and should be specified in keyword form.

Test examples in the file named `filename`. Return `(failure_count, test_count)`.

Optional argument `module_relative` specifies how the `filename` should be interpreted:

- If `module_relative` is `True` (the default), then `filename` specifies an OS-independent module-relative path. By default, this path is relative to the calling module’s directory; but if the `package` argument is specified, then it is relative to that package. To ensure OS-independence, `filename` should use `/` characters to separate path segments, and may not be an absolute path (i.e., it may not begin with `/`).
- If `module_relative` is `False`, then `filename` specifies an OS-specific path. The path may be absolute or relative; relative paths are resolved with respect to the current working directory.

Optional argument `name` gives the name of the test; by default,
or if None, os.path.basename(filename) is used.

Optional argument package is a Python package or the name of a Python package whose directory should be used as the base directory for a module-relative filename. If no package is specified, then the calling module’s directory is used as the base directory for module-relative filenames. It is an error to specify package if module_relative is False.

Optional argument globs gives a dict to be used as the globals when executing examples. A new shallow copy of this dict is created for the doctest, so its examples start with a clean slate. By default, or if None, a new empty dict is used.

Optional argument extraglobs gives a dict merged into the globals used to execute examples. This works like dict.update(): if globs and extraglobs have a common key, the associated value in extraglobs appears in the combined dict. By default, or if None, no extra globals are used. This is an advanced feature that allows parameterization of doctests. For example, a doctest can be written for a base class, using a generic name for the class, then reused to test any number of subclasses by passing an extraglobs dict mapping the generic name to the subclass to be tested.

Optional argument verbose prints lots of stuff if true, and prints only failures if false; by default, or if None, it's true if and only if '-v' is in sys.argv.

Optional argument report prints a summary at the end when true, else prints nothing at the end. In verbose mode, the summary is detailed, else the summary is very brief (in fact, empty if all tests passed).

Optional argument optionflags or's together option flags. See
section *Option Flags and Directives.*

Optional argument `raise_on_error` defaults to false. If true, an exception is raised upon the first failure or unexpected exception in an example. This allows failures to be post-mortem debugged. Default behavior is to continue running examples.

Optional argument `parser` specifies a `DocTestParser` (or subclass) that should be used to extract tests from the files. It defaults to a normal parser (i.e., `DocTestParser()`).

Optional argument `encoding` specifies an encoding that should be used to convert the file to unicode.

*New in version 2.4.*

*Changed in version 2.5:* The parameter `encoding` was added.

```
doctest.testmod([m], name=[], globs=[], verbose=[], report=[],
optionflags=[], extraglobs=[], raise_on_error=[], exclude_empty)
```

All arguments are optional, and all except for `m` should be specified in keyword form.

Test examples in docstrings in functions and classes reachable from module `m` (or module `__main__` if `m` is not supplied or is `None`), starting with `m.__doc__`.

Also test examples reachable from dict `m.__test__`, if it exists and is not `None`. `m.__test__` maps names (strings) to functions, classes and strings; function and class docstrings are searched for examples; strings are searched directly, as if they were docstrings.

Only docstrings attached to objects belonging to module `m` are searched.
Return \((\text{failure\_count}, \text{test\_count})\).

Optional argument \textit{name} gives the name of the module; by default, or if \texttt{None}, \texttt{m.__name__} is used.

Optional argument \textit{exclude\_empty} defaults to false. If true, objects for which no doctests are found are excluded from consideration. The default is a backward compatibility hack, so that code still using \texttt{doctest.master.summarize()} in conjunction with \texttt{testmod()} continues to get output for objects with no tests. The \textit{exclude\_empty} argument to the newer \texttt{DocTestFinder} constructor defaults to true.

Optional arguments \textit{extraglobs}, \textit{verbose}, \textit{report}, \textit{optionflags}, \textit{raise\_on\_error}, and \textit{globs} are the same as for function \texttt{testfile()} above, except that \textit{globs} defaults to \texttt{m.__dict__}.

\textit{Changed in version 2.3:} The parameter \textit{optionflags} was added.

\textit{Changed in version 2.4:} The parameters \textit{extraglobs}, \textit{raise\_on\_error} and \textit{exclude\_empty} were added.

\textit{Changed in version 2.5:} The optional argument \textit{isprivate}, deprecated in 2.4, was removed.

There's also a function to run the doctests associated with a single object. This function is provided for backward compatibility. There are no plans to deprecate it, but it's rarely useful:

\texttt{doctest.run\_docstring\_examples(f, globs[, verbose][, name][, compileflags][, optionflags])}

Test examples associated with object \textit{f}; for example, \textit{f} may be a module, function, or class object.

A shallow copy of dictionary argument \textit{globs} is used for the
execution context.

Optional argument *name* is used in failure messages, and defaults to "NoName".

If optional argument *verbose* is true, output is generated even if there are no failures. By default, output is generated only in case of an example failure.

Optional argument *compileflags* gives the set of flags that should be used by the Python compiler when running the examples. By default, or if *None*, flags are deduced corresponding to the set of future features found in *globs*.

Optional argument *optionflags* works as for function *testfile()* above.
24.2.5. Unittest API

As your collection of doctest'ed modules grows, you’ll want a way to run all their doctests systematically. Prior to Python 2.4, doctest had a barely documented Tester class that supplied a rudimentary way to combine doctests from multiple modules. Tester was feeble, and in practice most serious Python testing frameworks build on the unittest module, which supplies many flexible ways to combine tests from multiple sources. So, in Python 2.4, doctest's Tester class is deprecated, and doctest provides two functions that can be used to create unittest test suites from modules and text files containing doctests. These test suites can then be run using unittest test runners:

```python
import unittest
import doctest
import my_module_with_doctests, and_another

suite = unittest.TestSuite()
for mod in my_module_with_doctests, and_another:
    suite.addTest(doctest.DocTestSuite(mod))
runner = unittest.TextTestRunner()
runner.run(suite)
```

There are two main functions for creating unittest.TestSuite instances from text files and modules with doctests:

```python
doctest.DocFileSuite(*paths[, module_relative][, package][, setUp][, tearDown][, globs][, optionflags][, parser][, encoding])
```

Convert doctest tests from one or more text files to a unittest.TestSuite.

The returned unittest.TestSuite is to be run by the unittest framework and runs the interactive examples in each file. If an
example in any file fails, then the synthesized unit test fails, and a \texttt{failureException} exception is raised showing the name of the file containing the test and a (sometimes approximate) line number.

Pass one or more paths (as strings) to text files to be examined.

Options may be provided as keyword arguments:

Optional argument \texttt{module\_relative} specifies how the filenames in \texttt{paths} should be interpreted:

- If \texttt{module\_relative} is \texttt{True} (the default), then each filename in \texttt{paths} specifies an OS-independent module-relative path. By default, this path is relative to the calling module’s directory; but if the \texttt{package} argument is specified, then it is relative to that package. To ensure OS-independence, each filename should use / characters to separate path segments, and may not be an absolute path (i.e., it may not begin with /).
- If \texttt{module\_relative} is \texttt{False}, then each filename in \texttt{paths} specifies an OS-specific path. The path may be absolute or relative; relative paths are resolved with respect to the current working directory.

Optional argument \texttt{package} is a Python package or the name of a Python package whose directory should be used as the base directory for module-relative filenames in \texttt{paths}. If no package is specified, then the calling module’s directory is used as the base directory for module-relative filenames. It is an error to specify \texttt{package} if \texttt{module\_relative} is \texttt{False}.

Optional argument \texttt{setUp} specifies a set-up function for the test suite. This is called before running the tests in each file. The \texttt{setUp} function will be passed a \texttt{DocTest} object. The setUp function can access the test globals as the \texttt{globals} attribute of the
test passed.

Optional argument `tearDown` specifies a tear-down function for the test suite. This is called after running the tests in each file. The `tearDown` function will be passed a `DocTest` object. The `setUp` function can access the test globals as the `globs` attribute of the test passed.

Optional argument `globs` is a dictionary containing the initial global variables for the tests. A new copy of this dictionary is created for each test. By default, `globs` is a new empty dictionary.

Optional argument `optionflags` specifies the default doctest options for the tests, created by or-ing together individual option flags. See section `Option Flags and Directives`. See function `set_unittest_reportflags()` below for a better way to set reporting options.

Optional argument `parser` specifies a `DocTestParser` (or subclass) that should be used to extract tests from the files. It defaults to a normal parser (i.e., `DocTestParser()`).

Optional argument `encoding` specifies an encoding that should be used to convert the file to unicode.

*New in version 2.4.*

*Changed in version 2.5:* The global `__file__` was added to the globals provided to doctests loaded from a text file using `DocFileSuite()`.

*Changed in version 2.5:* The parameter `encoding` was added.

```python
doctest.DocTestSuite([module][, globs][, extraglobs][, test_finder][, setUp][, tearDown][, checker])```
Convert doctest tests for a module to a `unittest.TestSuite`.

The returned `unittest.TestSuite` is to be run by the unittest framework and runs each doctest in the module. If any of the doctests fail, then the synthesized unit test fails, and a `failureException` exception is raised showing the name of the file containing the test and a (sometimes approximate) line number.

Optional argument `module` provides the module to be tested. It can be a module object or a (possibly dotted) module name. If not specified, the module calling this function is used.

Optional argument `globs` is a dictionary containing the initial global variables for the tests. A new copy of this dictionary is created for each test. By default, `globs` is a new empty dictionary.

Optional argument `extraglobs` specifies an extra set of global variables, which is merged into `globs`. By default, no extra globals are used.

Optional argument `test_finder` is the `DocTestFinder` object (or a drop-in replacement) that is used to extract doctests from the module.

Optional arguments `setUp`, `tearDown`, and `optionflags` are the same as for function `DocFileSuite()` above.

*New in version 2.3.*

*Changed in version 2.4:* The parameters `globs`, `extraglobs`, `test_finder`, `setUp`, `tearDown`, and `optionflags` were added; this function now uses the same search technique as `testmod()`.

Under the covers, `DocTestSuite()` creates a `unittest.TestSuite` out
of doctest.DocTestCase instances, and DocTestCase is a subclass of unittest.TestCase. DocTestCase isn’t documented here (it’s an internal detail), but studying its code can answer questions about the exact details of unittest integration.

Similarly, DocFileSuite() creates a unittest.TestSuite out of doctest.DocFileCase instances, and DocFileCase is a subclass of DocTestCase.

So both ways of creating a unittest.TestSuite run instances of DocTestCase. This is important for a subtle reason: when you run doctest functions yourself, you can control the doctest options in use directly, by passing option flags to doctest functions. However, if you’re writing a unittest framework, unittest ultimately controls when and how tests get run. The framework author typically wants to control doctest reporting options (perhaps, e.g., specified by command line options), but there’s no way to pass options through unittest to doctest test runners.

For this reason, doctest also supports a notion of doctest reporting flags specific to unittest support, via this function:

doctest.set_unittest_reportflags(flags)

Set the doctest reporting flags to use.

Argument flags or’s together option flags. See section Option Flags and Directives. Only “reporting flags” can be used.

This is a module-global setting, and affects all future doctests run by module unittest: the runTest() method of DocTestCase looks at the option flags specified for the test case when the DocTestCase instance was constructed. If no reporting flags were specified (which is the typical and expected case), doctest’s
unittest reporting flags are or’ed into the option flags, and the option flags so augmented are passed to the DocTestRunner instance created to run the doctest. If any reporting flags were specified when the DocTestCase instance was constructed, doctest's unittest reporting flags are ignored.

The value of the unittest reporting flags in effect before the function was called is returned by the function.

New in version 2.4.
24.2.6. Advanced API

The basic API is a simple wrapper that's intended to make doctest easy to use. It is fairly flexible, and should meet most users’ needs; however, if you require more fine-grained control over testing, or wish to extend doctest’s capabilities, then you should use the advanced API.

The advanced API revolves around two container classes, which are used to store the interactive examples extracted from doctest cases:

- **Example**: A single Python `statement`, paired with its expected output.
- **DocTest**: A collection of `Examples`, typically extracted from a single docstring or text file.

Additional processing classes are defined to find, parse, and run, and check doctest examples:

- **DocTestFinder**: Finds all docstrings in a given module, and uses a `DocTestParser` to create a `DocTest` from every docstring that contains interactive examples.
- **DocTestParser**: Creates a `DocTest` object from a string (such as an object's docstring).
- **DocTestRunner**: Executes the examples in a `DocTest`, and uses an `OutputChecker` to verify their output.
- **OutputChecker**: Compares the actual output from a doctest example with the expected output, and decides whether they match.

The relationships among these processing classes are summarized in the following diagram:
24.2.6.1. DocTest Objects

class doctest.DocTest(examples, globs, name, filename, lineno, docstring)

A collection of doctest examples that should be run in a single namespace. The constructor arguments are used to initialize the member variables of the same names.

New in version 2.4.

DocTest defines the following member variables. They are initialized by the constructor, and should not be modified directly.

docstring

A string name identifying the DocTest. Typically, this is the name of the object or file that the test was extracted from.
filename
    The name of the file that this `DocTest` was extracted from; or `None` if the filename is unknown, or if the `DocTest` was not extracted from a file.

lineno
    The line number within `filename` where this `DocTest` begins, or `None` if the line number is unavailable. This line number is zero-based with respect to the beginning of the file.

docstring
    The string that the test was extracted from, or ‘None’ if the string is unavailable, or if the test was not extracted from a string.

### 24.2.6.2. Example Objects

```python
class doctest.Example(source, want[, exc_msg][, lineno][, indent][, options])
```

A single interactive example, consisting of a Python statement and its expected output. The constructor arguments are used to initialize the member variables of the same names.

*New in version 2.4.*

`Example` defines the following member variables. They are initialized by the constructor, and should not be modified directly.

source
    A string containing the example's source code. This source code consists of a single Python statement, and always ends with a newline; the constructor adds a newline when necessary.

want
The expected output from running the example's source code (either from stdout, or a traceback in case of exception). \texttt{want} ends with a newline unless no output is expected, in which case it's an empty string. The constructor adds a newline when necessary.

\texttt{exc_msg}

The exception message generated by the example, if the example is expected to generate an exception; or \texttt{None} if it is not expected to generate an exception. This exception message is compared against the return value of \texttt{traceback.format_exception_only()}. \texttt{exc_msg} ends with a newline unless it's \texttt{None}. The constructor adds a newline if needed.

\texttt{lineno}

The line number within the string containing this example where the example begins. This line number is zero-based with respect to the beginning of the containing string.

\texttt{indent}

The example's indentation in the containing string, i.e., the number of space characters that precede the example's first prompt.

\texttt{options}

A dictionary mapping from option flags to \texttt{True} or \texttt{False}, which is used to override default options for this example. Any option flags not contained in this dictionary are left at their default value (as specified by the \texttt{DocTestRunner}'s \texttt{optionflags}). By default, no options are set.

\textbf{24.2.6.3. DocTestFinder objects}

\texttt{class doctest.\texttt{DocTestFinder}([\texttt{verbose}][, \texttt{parser}][, \texttt{recurse}][, \texttt{...}])}
A processing class used to extract the `DocTest`s that are relevant to a given object, from its docstring and the docstrings of its contained objects. `DocTest`s can currently be extracted from the following object types: modules, functions, classes, methods, staticmethods, classmethods, and properties.

The optional argument `verbose` can be used to display the objects searched by the finder. It defaults to `False` (no output).

The optional argument `parser` specifies the `DocTestParser` object (or a drop-in replacement) that is used to extract doctests from docstrings.

If the optional argument `recurse` is false, then `DocTestFinder.find()` will only examine the given object, and not any contained objects.

If the optional argument `exclude_empty` is false, then `DocTestFinder.find()` will include tests for objects with empty docstrings.

*New in version 2.4.*

`DocTestFinder` defines the following method:

```python
find(obj[, name][, module][, globs][, extraglobs])
```

Return a list of the `DocTest`s that are defined by `obj`'s docstring, or by any of its contained objects' docstrings.

The optional argument `name` specifies the object's name; this name will be used to construct names for the returned `DocTest`s. If `name` is not specified, then `obj.__name__` is used.
The optional parameter *module* is the module that contains the given object. If the module is not specified or is None, then the test finder will attempt to automatically determine the correct module. The object's module is used:

- As a default namespace, if *globs* is not specified.
- To prevent the DocTestFinder from extracting DocTests from objects that are imported from other modules. (Contained objects with modules other than *module* are ignored.)
- To find the name of the file containing the object.
- To help find the line number of the object within its file.

If *module* is *False*, no attempt to find the module will be made. This is obscure, of use mostly in testing doctest itself: if *module* is *False*, or is *None* but cannot be found automatically, then all objects are considered to belong to the (non-existent) module, so all contained objects will (recursively) be searched for doctests.

The globals for each *DocTest* is formed by combining *globs* and *extraglobs* (bindings in *extraglobs* override bindings in *globs*). A new shallow copy of the globals dictionary is created for each *DocTest*. If *globs* is not specified, then it defaults to the module's *__dict__*, if specified, or *{}* otherwise. If *extraglobs* is not specified, then it defaults to *{}*. 

### 24.2.6.4. DocTestParser objects

*class* doctest.**DocTestParser**

A processing class used to extract interactive examples from a string, and use them to create a *DocTest* object.

*New in version 2.4.*
**DocTestParser** defines the following methods:

**get_doctest**(string, globs, name, filename, lineno)
Extract all doctest examples from the given string, and collect them into a *DocTest* object.

*globs, name, filename*, and *lineno* are attributes for the new *DocTest* object. See the documentation for *DocTest* for more information.

**get_examples**(string[, name])
Extract all doctest examples from the given string, and return them as a list of *Example* objects. Line numbers are 0-based. The optional argument *name* is a name identifying this string, and is only used for error messages.

**parse**(string[, name])
Divide the given string into examples and intervening text, and return them as a list of alternating *Examples* and strings. Line numbers for the *Examples* are 0-based. The optional argument *name* is a name identifying this string, and is only used for error messages.

### 24.2.6.5. DocTestRunner objects

**class** doctest.**DocTestRunner**([checker][, verbose][, optionflags])
A processing class used to execute and verify the interactive examples in a *DocTest*.

The comparison between expected outputs and actual outputs is done by an *OutputChecker*. This comparison may be customized with a number of option flags; see section *Option Flags and Directives* for more information. If the option flags are insufficient,
then the comparison may also be customized by passing a subclass of `OutputChecker` to the constructor.

The test runner’s display output can be controlled in two ways. First, an output function can be passed to `TestRunner.run()`; this function will be called with strings that should be displayed. It defaults to `sys.stdout.write`. If capturing the output is not sufficient, then the display output can be also customized by subclassing `DocTestRunner`, and overriding the methods `report_start()`, `report_success()`, `report_unexpected_exception()`, and `report_failure()`.

The optional keyword argument `checker` specifies the `OutputChecker` object (or drop-in replacement) that should be used to compare the expected outputs to the actual outputs of doctest examples.

The optional keyword argument `verbose` controls the `DocTestRunner`’s verbosity. If `verbose` is `True`, then information is printed about each example, as it is run. If `verbose` is `False`, then only failures are printed. If `verbose` is unspecified, or `None`, then verbose output is used iff the command-line switch `-v` is used.

The optional keyword argument `optionflags` can be used to control how the test runner compares expected output to actual output, and how it displays failures. For more information, see section `Option Flags and Directives`.

*New in version 2.4.*

`DocTestParser` defines the following methods:

```python
report_start(out, test, example)
```

Report that the test runner is about to process the given
example. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. test is the test containing example. out is the output function that was passed to DocTestRunner.run().

**report_success(out, test, example, got)**
Report that the given example ran successfully. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. got is the actual output from the example. test is the test containing example. out is the output function that was passed to DocTestRunner.run().

**report_failure(out, test, example, got)**
Report that the given example failed. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. got is the actual output from the example. test is the test containing example. out is the output function that was passed to DocTestRunner.run().

**report_unexpected_exception(out, test, example, exc_info)**
Report that the given example raised an unexpected exception. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.
example is the example about to be processed. exc_info is a tuple containing information about the unexpected exception (as returned by sys.exc_info()). test is the test containing example. out is the output function that was passed to DocTestRunner.run().

run(test[, compileflags][, out][, clear_globs])
Run the examples in test (a DocTest object), and display the results using the writer function out.

The examples are run in the namespace test.globs. If clear_globs is true (the default), then this namespace will be cleared after the test runs, to help with garbage collection. If you would like to examine the namespace after the test completes, then use clear_globs=False.

compileflags gives the set of flags that should be used by the Python compiler when running the examples. If not specified, then it will default to the set of future-import flags that apply to globs.

The output of each example is checked using the DocTestRunner's output checker, and the results are formatted by the DocTestRunner.report_*() methods.

summarize([verbose])
Print a summary of all the test cases that have been run by this DocTestRunner, and return a named tuple TestResults(failed, attempted).

The optional verbose argument controls how detailed the summary is. If the verbosity is not specified, then the DocTestRunner's verbosity is used.
Changed in version 2.6: Use a named tuple.

24.2.6.6. OutputChecker objects

class doctest.OutputChecker

A class used to check whether the actual output from a doctest example matches the expected output. OutputChecker defines two methods: `check_output()`, which compares a given pair of outputs, and returns true if they match; and `output_difference()`, which returns a string describing the differences between two outputs.

New in version 2.4.

OutputChecker defines the following methods:

`check_output(want, got, optionflags)`

Return `True` iff the actual output from an example (`got`) matches the expected output (`want`). These strings are always considered to match if they are identical; but depending on what option flags the test runner is using, several non-exact match types are also possible. See section Option Flags and Directives for more information about option flags.

`output_difference(example, got, optionflags)`

Return a string describing the differences between the expected output for a given example (`example`) and the actual output (`got`). `optionflags` is the set of option flags used to compare `want` and `got`. 
24.2.7. Debugging
Doctest provides several mechanisms for debugging doctest
examples:
Several functions convert doctests to executable Python
programs, which can be run under the Python debugger, pdb .
The DebugRunner class is a subclass of DocTestRunner that
raises an exception for the first failing example, containing
information about that example. This information can be used to
perform post-mortem debugging on the example.
The

cases generated by DocTestSuite() support the
method defined by unittest.TestCase .

unittest

debug()

You can add a call to pdb.set_trace() in a doctest example, and
you’ll drop into the Python debugger when that line is executed.
Then you can inspect current values of variables, and so on. For
example, suppose a.py contains just this module docstring:
"""
>>> def f(x):
...
g(x*2)
>>> def g(x):
...
print x+3
...
import pdb; pdb.set_trace()
>>> f(3)
9
"""

Then an interactive Python session may look like this:
>>> import a, doctest
>>> doctest.testmod(a)
--Return-> <doctest a[1]>(3)g()->None


import pdb; pdb.set_trace()

(Pdb) list
  1    def g(x):
  2        print x+3
  3    ->   import pdb; pdb.set_trace()

[EOF]

(Pdb) print x
  6

(Pdb) step
--Return--
> <doctest a[0]>(2)f()--None
-> g(x*2)

(Pdb) list
  1    def f(x):
  2    ->   g(x*2)

[EOF]

(Pdb) print x
  3

(Pdb) step
--Return--
> <doctest a[2]>(1)?()--None
-> f(3)

(Pdb) cont
(0, 3)

>>> 

Changed in version 2.4: The ability to use `pdb.set_trace()` usefully inside doctests was added.

Functions that convert doctests to Python code, and possibly run the synthesized code under the debugger:

doctest.script_from_examples(s)

    Convert text with examples to a script.

Argument `s` is a string containing doctest examples. The string is converted to a Python script, where doctest examples in `s` are converted to regular code, and everything else is converted to Python comments. The generated script is returned as a string. For example,

```
import doctest
```
print doctest.script_from_examples(r""
    Set x and y to 1 and 2.
    >>> x, y = 1, 2

    Print their sum:
    >>> print x+y
    3
""
)

display:

# Set x and y to 1 and 2.
x, y = 1, 2
#
# Print their sum:
print x+y
# Expected:
## 3

This function is used internally by other functions (see below), but can also be useful when you want to transform an interactive Python session into a Python script.

*New in version 2.4.*

doctest.**testsource**(module, name)

Convert the doctest for an object to a script.

Argument *module* is a module object, or dotted name of a module, containing the object whose doctests are of interest. Argument *name* is the name (within the module) of the object with the doctests of interest. The result is a string, containing the object’s docstring converted to a Python script, as described for `script_from_examples()` above. For example, if module *a.py* contains a top-level function *f()* , then

import a, doctest
print doctest.testsource(a, "a.f")
prints a script version of function \( f() \)'s docstring, with doctests converted to code, and the rest placed in comments.

*New in version 2.3.*

doctest.\texttt{debug} (\texttt{module}, \texttt{name}[, \texttt{pm}])

Debug the doctests for an object.

The \texttt{module} and \texttt{name} arguments are the same as for function \texttt{testsource()} above. The synthesized Python script for the named object's docstring is written to a temporary file, and then that file is run under the control of the Python debugger, \texttt{pdb}.

A shallow copy of \texttt{module.__dict__} is used for both local and global execution context.

Optional argument \texttt{pm} controls whether post-mortem debugging is used. If \texttt{pm} has a true value, the script file is run directly, and the debugger gets involved only if the script terminates via raising an unhandled exception. If it does, then post-mortem debugging is invoked, via \texttt{pdb.post_mortem()}, passing the traceback object from the unhandled exception. If \texttt{pm} is not specified, or is false, the script is run under the debugger from the start, via passing an appropriate \texttt{execfile()} call to \texttt{pdb.run()}.

*New in version 2.3.*

*Changed in version 2.4:* The \texttt{pm} argument was added.

doctest.\texttt{debug_src} (\texttt{src}[, \texttt{pm}][, \texttt{globs}])

Debug the doctests in a string.

This is like function \texttt{debug()} above, except that a string containing doctest examples is specified directly, via the \texttt{src} argument.
Optional argument \textit{pm} has the same meaning as in function \texttt{debug()} above.

Optional argument \textit{globals} gives a dictionary to use as both local and global execution context. If not specified, or \texttt{None}, an empty dictionary is used. If specified, a shallow copy of the dictionary is used.

\textit{New in version 2.4.}\texttt{\textbackslash n}

The \texttt{DebugRunner} class, and the special exceptions it may raise, are of most interest to testing framework authors, and will only be sketched here. See the source code, and especially \texttt{DebugRunner}'s docstring (which is a doctest!) for more details:

\lstinputlisting{doctest.py}

A subclass of \texttt{DocTestRunner} that raises an exception as soon as a failure is encountered. If an unexpected exception occurs, an \texttt{UnexpectedException} exception is raised, containing the test, the example, and the original exception. If the output doesn’t match, then a \texttt{DocTestFailure} exception is raised, containing the test, the example, and the actual output.

For information about the constructor parameters and methods, see the documentation for \texttt{DocTestRunner} in section \textit{Advanced API}.

There are two exceptions that may be raised by \texttt{DebugRunner} instances:

\texttt{exception doctest.\texttt{DocTestFailure}(test, example, got)}

An exception thrown by \texttt{DocTestRunner} to signal that a doctest example's actual output did not match its expected output. The constructor arguments are used to initialize the member variables
of the same names.

**DocTestFailure** defines the following member variables:

*DocTestFailure.* **test**
  The **DocTest** object that was being run when the example failed.

*DocTestFailure.* **example**
  The **Example** that failed.

*DocTestFailure.* **got**
  The example’s actual output.

*exception doctest.* **UnexpectedException**(*test, example, exc_info*)
  An exception thrown by **DocTestRunner** to signal that a doctest example raised an unexpected exception. The constructor arguments are used to initialize the member variables of the same names.

**UnexpectedException** defines the following member variables:

*UnexpectedException.* **test**
  The **DocTest** object that was being run when the example failed.

*UnexpectedException.* **example**
  The **Example** that failed.

*UnexpectedException.* **exc_info**
  A tuple containing information about the unexpected exception, as returned by *sys.exc_info()*.
As mentioned in the introduction, `doctest` has grown to have three primary uses:

1. Checking examples in docstrings.
2. Regression testing.
3. Executable documentation / literate testing.

These uses have different requirements, and it is important to distinguish them. In particular, filling your docstrings with obscure test cases makes for bad documentation.

When writing a docstring, choose docstring examples with care. There's an art to this that needs to be learned—it may not be natural at first. Examples should add genuine value to the documentation. A good example can often be worth many words. If done with care, the examples will be invaluable for your users, and will pay back the time it takes to collect them many times over as the years go by and things change. I'm still amazed at how often one of my `doctest` examples stops working after a “harmless” change.

Doctest also makes an excellent tool for regression testing, especially if you don’t skimp on explanatory text. By interleaving prose and examples, it becomes much easier to keep track of what’s actually being tested, and why. When a test fails, good prose can make it much easier to figure out what the problem is, and how it should be fixed. It’s true that you could write extensive comments in code-based testing, but few programmers do. Many have found that using doctest approaches instead leads to much clearer tests. Perhaps this is simply because doctest makes writing prose a little easier than writing code, while writing comments in code is a little harder. I think it goes deeper than just that: the natural attitude when writing a doctest-based test is that you want to explain the fine points
of your software, and illustrate them with examples. This in turn naturally leads to test files that start with the simplest features, and logically progress to complications and edge cases. A coherent narrative is the result, instead of a collection of isolated functions that test isolated bits of functionality seemingly at random. It’s a different attitude, and produces different results, blurring the distinction between testing and explaining.

Regression testing is best confined to dedicated objects or files. There are several options for organizing tests:

- Write text files containing test cases as interactive examples, and test the files using `testfile()` or `DocFileSuite()`. This is recommended, although is easiest to do for new projects, designed from the start to use `doctest`.
- Define functions named `_regrtest_topic` that consist of single docstrings, containing test cases for the named topics. These functions can be included in the same file as the module, or separated out into a separate test file.
- Define a `__test__` dictionary mapping from regression test topics to docstrings containing test cases.

**Footnotes**

[1] Examples containing both expected output and an exception are not supported. Trying to guess where one ends and the other begins is too error-prone, and that also makes for a confusing test.
24.3. unittest — Unit testing framework

New in version 2.1.

The Python unit testing framework, sometimes referred to as “PyUnit,” is a Python language version of JUnit, by Kent Beck and Erich Gamma. JUnit is, in turn, a Java version of Kent’s Smalltalk testing framework. Each is the de facto standard unit testing framework for its respective language.

unittest supports test automation, sharing of setup and shutdown code for tests, aggregation of tests into collections, and independence of the tests from the reporting framework. The unittest module provides classes that make it easy to support these qualities for a set of tests.

To achieve this, unittest supports some important concepts:

- **test fixture**
  A test fixture represents the preparation needed to perform one or more tests, and any associate cleanup actions. This may involve, for example, creating temporary or proxy databases, directories, or starting a server process.

- **test case**
  A test case is the smallest unit of testing. It checks for a specific response to a particular set of inputs. unittest provides a base class, **TestCase**, which may be used to create new test cases.

- **test suite**
  A test suite is a collection of test cases, test suites, or both. It is used to aggregate tests that should be executed together.

- **test runner**
A test runner is a component which orchestrates the execution of tests and provides the outcome to the user. The runner may use a graphical interface, a textual interface, or return a special value to indicate the results of executing the tests.

The test case and test fixture concepts are supported through the `TestCase` and `FunctionTestCase` classes; the former should be used when creating new tests, and the latter can be used when integrating existing test code with a `unittest`-driven framework. When building test fixtures using `TestCase`, the `setUp()` and `tearDown()` methods can be overridden to provide initialization and cleanup for the fixture. With `FunctionTestCase`, existing functions can be passed to the constructor for these purposes. When the test is run, the fixture initialization is run first; if it succeeds, the cleanup method is run after the test has been executed, regardless of the outcome of the test. Each instance of the `TestCase` will only be used to run a single test method, so a new fixture is created for each test.

Test suites are implemented by the `TestSuite` class. This class allows individual tests and test suites to be aggregated; when the suite is executed, all tests added directly to the suite and in “child” test suites are run.

A test runner is an object that provides a single method, `run()`, which accepts a `TestCase` or `TestSuite` object as a parameter, and returns a result object. The class `TestResult` is provided for use as the result object. `unittest` provides the `TextTestRunner` as an example test runner which reports test results on the standard error stream by default. Alternate runners can be implemented for other environments (such as graphical environments) without any need to derive from a specific class.

A special-interest-group for discussion of testing, and testing tools, in Python.
24.3.1. Basic example

The `unittest` module provides a rich set of tools for constructing and running tests. This section demonstrates that a small subset of the tools suffice to meet the needs of most users.

Here is a short script to test three functions from the `random` module:

```python
import random
import unittest

class TestSequenceFunctions(unittest.TestCase):
    def setUp(self):
        self.seq = range(10)
    
    def test_shuffle(self):
        # make sure the shuffled sequence does not lose any elements
        random.shuffle(self.seq)
        self.seq.sort()
        self.assertEqual(self.seq, range(10))

        # should raise an exception for an immutable sequence
        self.assertRaises(TypeError, random.shuffle, (1,2,3))
    
    def test_choice(self):
        element = random.choice(self.seq)
        self.assertTrue(element in self.seq)
    
    def test_sample(self):
        with self.assertRaises(ValueError):
            random.sample(self.seq, 20)
        for element in random.sample(self.seq, 5):
            self.assertTrue(element in self.seq)

if __name__ == '__main__':
    unittest.main()
```

A testcase is created by subclassing `unittest.TestCase`. The three individual tests are defined with methods whose names start with the
letters \texttt{test}. This naming convention informs the test runner about which methods represent tests.

The crux of each test is a call to \texttt{assertEqual()} to check for an expected result; \texttt{assertTrue()} to verify a condition; or \texttt{assertRaises()} to verify that an expected exception gets raised. These methods are used instead of the \texttt{assert} statement so the test runner can accumulate all test results and produce a report.

When a \texttt{setUp()} method is defined, the test runner will run that method prior to each test. Likewise, if a \texttt{tearDown()} method is defined, the test runner will invoke that method after each test. In the example, \texttt{setUp()} was used to create a fresh sequence for each test.

The final block shows a simple way to run the tests. \texttt{unittest.main()} provides a command line interface to the test script. When run from the command line, the above script produces an output that looks like this:

\begin{verbatim}
...
Ran 3 tests in 0.000s
OK
\end{verbatim}

Instead of \texttt{unittest.main()}, there are other ways to run the tests with a finer level of control, less terse output, and no requirement to be run from the command line. For example, the last two lines may be replaced with:

\begin{verbatim}
suite = unittest.TestLoader().loadTestsFromTestCase(TestSequenceFunctions)
suite = unittest.TextTestRunner(verbosity=2).run(suite)
\end{verbatim}

Running the revised script from the interpreter or another script
produces the following output:

```python

test_choice (__main__.TestSequenceFunctions) ... ok
test_sample (__main__.TestSequenceFunctions) ... ok
test_shuffle (__main__.TestSequenceFunctions) ... ok

Ran 3 tests in 0.110s
OK
```

The above examples show the most commonly used unittest features which are sufficient to meet many everyday testing needs. The remainder of the documentation explores the full feature set from first principles.
24.3.2. Command Line Interface

The unittest module can be used from the command line to run tests from modules, classes or even individual test methods:

```
python -m unittest test_module1 test_module2
python -m unittest test_module.TestClass
python -m unittest test_module.TestClass.test_method
```

You can pass in a list with any combination of module names, and fully qualified class or method names.

You can run tests with more detail (higher verbosity) by passing in the `-v` flag:

```
python -m unittest -v test_module
```

For a list of all the command line options:

```
python -m unittest -h
```

*Changed in version 2.7:* In earlier versions it was only possible to run individual test methods and not modules or classes.

24.3.2.1. failfast, catch and buffer command line options

unittest supports three command options.

- `-b / --buffer`

  The standard output and standard error streams are buffered during the test run. Output during a passing test is discarded. Output is echoed normally on test fail or error and is added to the failure messages.
- **-c / --catch**

  Control-C during the test run waits for the current test to end and then reports all the results so far. A second control-C raises the normal `KeyboardInterrupt` exception.

  See [Signal Handling](#) for the functions that provide this functionality.

- **-f / --failfast**

  Stop the test run on the first error or failure.

  *New in version 2.7:* The command line options `-c`, `-b` and `-f` were added.

  The command line can also be used for test discovery, for running all of the tests in a project or just a subset.
24.3.3. Test Discovery

New in version 2.7.

Unittest supports simple test discovery. For a project's tests to be compatible with test discovery they must all be importable from the top level directory of the project (in other words, they must all be in Python packages).

Test discovery is implemented in `TestLoader.discover()`, but can also be used from the command line. The basic command line usage is:

```
cd project_directory
python -m unittest discover
```

The `discover` sub-command has the following options:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>-v, --verbose</td>
<td>Verbose output</td>
</tr>
<tr>
<td>-s directory</td>
<td>Directory to start discovery (‘.’ default)</td>
</tr>
<tr>
<td>-p pattern</td>
<td>Pattern to match test files (‘test*.py’ default)</td>
</tr>
<tr>
<td>-t directory</td>
<td>Top level directory of project (default to start directory)</td>
</tr>
</tbody>
</table>

The `-s`, `-p`, and `-t` options can be passed in as positional arguments in that order. The following two command lines are equivalent:

```
python -m unittest discover -s project_directory -p '*_test.py'
python -m unittest discover project_directory '*_test.py'
```

As well as being a path it is possible to pass a package name, for example `myproject.subpackage.test`, as the start directory. The package name you supply will then be imported and its location on
the filesystem will be used as the start directory.

**Caution:** Test discovery loads tests by importing them. Once test discovery has found all the test files from the start directory you specify it turns the paths into package names to import. For example `foo/bar/baz.py` will be imported as `foo.bar.baz`.

If you have a package installed globally and attempt test discovery on a different copy of the package then the import *could* happen from the wrong place. If this happens test discovery will warn you and exit.

If you supply the start directory as a package name rather than a path to a directory then discover assumes that whichever location it imports from is the location you intended, so you will not get the warning.

Test modules and packages can customize test loading and discovery by through the `load_tests` protocol.
24.3.4. Organizing test code

The basic building blocks of unit testing are test cases — single scenarios that must be set up and checked for correctness. In unittest, test cases are represented by instances of unittest's TestCase class. To make your own test cases you must write subclasses of TestCase, or use FunctionTestCase.

An instance of a TestCase-derived class is an object that can completely run a single test method, together with optional set-up and tidy-up code.

The testing code of a TestCase instance should be entirely self contained, such that it can be run either in isolation or in arbitrary combination with any number of other test cases.

The simplest TestCase subclass will simply override the runTest() method in order to perform specific testing code:

```python
import unittest

class DefaultWidgetSizeTestCase(unittest.TestCase):
    def runTest(self):
        widget = Widget('The widget')
        self.assertEqual(widget.size(), (50, 50), 'incorrect default size')
```

Note that in order to test something, we use the one of the assert*() methods provided by the TestCase base class. If the test fails, an exception will be raised, and unittest will identify the test case as a failure. Any other exceptions will be treated as errors. This helps you identify where the problem is: failures are caused by incorrect results - a 5 where you expected a 6. Errors are caused by incorrect code - e.g., a TypeError caused by an incorrect function call.
The way to run a test case will be described later. For now, note that to construct an instance of such a test case, we call its constructor without arguments:

```python
testCase = DefaultWidgetSizeTestCase()
```

Now, such test cases can be numerous, and their set-up can be repetitive. In the above case, constructing a `Widget` in each of 100 `Widget` test case subclasses would mean unsightly duplication.

Luckily, we can factor out such set-up code by implementing a method called `setUp()`, which the testing framework will automatically call for us when we run the test:

```python
import unittest
class SimpleWidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget('The widget')
class DefaultWidgetSizeTestCase(SimpleWidgetTestCase):
    def runTest(self):
        self.assertEqual(self.widget.size(), (50,50), 'incorrect default size')
class WidgetResizeTestCase(SimpleWidgetTestCase):
    def runTest(self):
        self.widget.resize(100,150)
        self.assertEqual(self.widget.size(), (100,150), 'wrong size after resize')
```

If the `setUp()` method raises an exception while the test is running, the framework will consider the test to have suffered an error, and the `runTest()` method will not be executed.

Similarly, we can provide a `tearDown()` method that tidies up after the `runTest()` method has been run:

```python
import unittest
```
class SimpleWidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget('The widget')

    def tearDown(self):
        self.widget.dispose()
        self.widget = None

If `setUp()` succeeded, the `tearDown()` method will be run whether `runTest()` succeeded or not.

Such a working environment for the testing code is called a *fixture*.

Often, many small test cases will use the same fixture. In this case, we would end up subclassing `SimpleWidgetTestCase` into many small one-method classes such as `DefaultWidgetSizeTestCase`. This is time-consuming and discouraging, so in the same vein as JUnit, `unittest` provides a simpler mechanism:

```python
import unittest

class WidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget('The widget')

    def tearDown(self):
        self.widget.dispose()
        self.widget = None

    def test_default_size(self):
        self.assertEqual(self.widget.size(), (50, 50),
                         'incorrect default size')

    def test_resize(self):
        self.widget.resize(100, 150)
        self.assertEqual(self.widget.size(), (100, 150),
                         'wrong size after resize')
```

Here we have not provided a `runTest()` method, but have instead provided two different test methods. Class instances will now each
run one of the test_*() methods, with self.widget created and destroyed separately for each instance. When creating an instance we must specify the test method it is to run. We do this by passing the method name in the constructor:

```python
defaultSizeTestCase = WidgetTestCase('test_default_size')
resizeTestCase = WidgetTestCase('test_resize')
```

Test case instances are grouped together according to the features they test. unittest provides a mechanism for this: the test suite, represented by unittest's TestSuite class:

```python
widgetTestSuite = unittest.TestSuite()  
widgetTestSuite.addTest(WidgetTestCase('test_default_size'))
widgetTestSuite.addTest(WidgetTestCase('test_resize'))
```

For the ease of running tests, as we will see later, it is a good idea to provide in each test module a callable object that returns a pre-built test suite:

```python
def suite():
    suite = unittest.TestSuite()  
suite.addTest(WidgetTestCase('test_default_size'))
    suite.addTest(WidgetTestCase('test_resize'))
    return suite
```

or even:

```python
def suite():
    tests = ['test_default_size', 'test_resize']
    return unittest.TestSuite(map(WidgetTestCase, tests))
```

Since it is a common pattern to create a TestCase subclass with many similarly named test functions, unittest provides a TestLoader class that can be used to automate the process of creating a test suite and populating it with individual tests. For example,
suite = unittest.TestLoader().loadTestsFromTestCase(WidgetTestCase)

will create a test suite that will run
WidgetTestCase.test_default_size() and
WidgetTestCase.test_resize. TestLoader uses the 'test' method
name prefix to identify test methods automatically.

Note that the order in which the various test cases will be run is
determined by sorting the test function names with the built-in cmp() function.

Often it is desirable to group suites of test cases together, so as to run tests for the whole system at once. This is easy, since TestSuite instances can be added to a TestSuite just as TestCase instances can be added to a TestSuite:

```
suite1 = module1.TheTestSuite()
suite2 = module2.TheTestSuite()
alltests = unittest.TestSuite([suite1, suite2])
```

You can place the definitions of test cases and test suites in the same modules as the code they are to test (such as widget.py), but there are several advantages to placing the test code in a separate module, such as test_widget.py:

- The test module can be run standalone from the command line.
- The test code can more easily be separated from shipped code.
- There is less temptation to change test code to fit the code it tests without a good reason.
- Test code should be modified much less frequently than the code it tests.
- Tested code can be refactored more easily.
- Tests for modules written in C must be in separate modules anyway, so why not be consistent?
• If the testing strategy changes, there is no need to change the source code.
24.3.5. Re-using old test code

Some users will find that they have existing test code that they would like to run from unittest, without converting every old test function to a TestCase subclass.

For this reason, unittest provides a FunctionTestCase class. This subclass of TestCase can be used to wrap an existing test function. Set-up and tear-down functions can also be provided.

Given the following test function:

```python
def testSomething():
    something = makeSomething()
    assert something.name is not None
    # ...
```

one can create an equivalent test case instance as follows:

```python
testcase = unittest.FunctionTestCase(testSomething)
```

If there are additional set-up and tear-down methods that should be called as part of the test case’s operation, they can also be provided like so:

```python
testcase = unittest.FunctionTestCase(testSomething,
    setUp=makeSomethingDB,
    tearDown=deleteSomethingDB)
```

To make migrating existing test suites easier, unittest supports tests raising AssertionError to indicate test failure. However, it is recommended that you use the explicit TestCase.fail*() and TestCase.assert*() methods instead, as future versions of unittest may treat AssertionError differently.
**Note:** Even though `FunctionTestCase` can be used to quickly convert an existing test base over to a `unittest`-based system, this approach is not recommended. Taking the time to set up proper `TestCase` subclasses will make future test refactorings infinitely easier.

In some cases, the existing tests may have been written using the `doctest` module. If so, `doctest` provides a `DocTestSuite` class that can automatically build `unittest.TestSuite` instances from the existing `doctest`-based tests.
24.3.6. Skipping tests and expected failures

*New in version 2.7.*

Unittest supports skipping individual test methods and even whole classes of tests. In addition, it supports marking a test as a “expected failure,” a test that is broken and will fail, but shouldn't be counted as a failure on a `TestResult`.

Skipping a test is simply a matter of using the `skip()` decorator or one of its conditional variants.

Basic skipping looks like this:

```python
class MyTestCase(unittest.TestCase):
    @unittest.skip("demonstrating skipping")
    def test_nothing(self):
        self.fail("shouldn't happen")

    @unittest.skipIf(mylib.__version__ < (1, 3),
                     "not supported in this library version")
    def test_format(self):
        # Tests that work for only a certain version of the lib
        pass

    @unittest.skipUnless(sys.platform.startswith("win"),
                         "requires Windows")
    def test_windows_support(self):
        # windows specific testing code
        pass
```

This is the output of running the example above in verbose mode:

```
test_format (__main__.MyTestCase) ... skipped 'not supported in
test_nothing (__main__.MyTestCase) ... skipped 'demonstrating s
test_windows_support (__main__.MyTestCase) ... skipped 'require
```

Ran 3 tests in 0.005s
Classes can be skipped just like methods:

```python
@skip("showing class skipping")
class MySkippedTestCase(unittest.TestCase):
    def test_not_run(self):
        pass
```

`TestCase.setUp()` can also skip the test. This is useful when a resource that needs to be set up is not available.

Expected failures use the `expectedFailure()` decorator.

```python
class ExpectedFailureTestCase(unittest.TestCase):
    @unittest.expectedFailure
    def test_fail(self):
        self.assertEqual(1, 0, "broken")
```

It's easy to roll your own skipping decorators by making a decorator that calls `skip()` on the test when it wants it to be skipped. This decorator skips the test unless the passed object has a certain attribute:

```python
def skipUnlessHasattr(obj, attr):
    if hasattr(obj, attr):
        return lambda func: func
    return unittest.skip("{0!r} doesn't have {1!r}".format(obj,
```

The following decorators implement test skipping and expected failures:

```python
unittest.skip(reason)
```

Unconditionally skip the decorated test. `reason` should describe why the test is being skipped.
unittest. **skipIf**(*condition*, *reason*)

Skip the decorated test if *condition* is true.

unittest. **skipUnless**(*condition*, *reason*)

Skip the decorated test unless *condition* is true.

unittest. **expectedFailure**()

Mark the test as an expected failure. If the test fails when run, the test is not counted as a failure.

Skipped tests will not have *setUp()* or *tearDown()* run around them. Skipped classes will not have *setUpClass()* or *tearDownClass()* run.
This section describes in depth the API of `unittest`.

### 24.3.7.1. Test cases

```python
class unittest.TestCase([methodName])
```

Instances of the `TestCase` class represent the smallest testable units in the `unittest` universe. This class is intended to be used as a base class, with specific tests being implemented by concrete subclasses. This class implements the interface needed by the test runner to allow it to drive the test, and methods that the test code can use to check for and report various kinds of failure.

Each instance of `TestCase` will run a single test method: the method named `methodName`. If you remember, we had an earlier example that went something like this:

```python
def suite():
    suite = unittest.TestSuite()
    suite.addTest(WidgetTestCase('test_default_size'))
    suite.addTest(WidgetTestCase('test_resize'))
    return suite
```

Here, we create two instances of `WidgetTestCase`, each of which runs a single test.

`methodName` defaults to `runTest()`.

`TestCase` instances provide three groups of methods: one group used to run the test, another used by the test implementation to check conditions and report failures, and some inquiry methods allowing information about the test itself to be gathered.
Methods in the first group (running the test) are:

**setUp()**
Method called to prepare the test fixture. This is called immediately before calling the test method; any exception raised by this method will be considered an error rather than a test failure. The default implementation does nothing.

**tearDown()**
Method called immediately after the test method has been called and the result recorded. This is called even if the test method raised an exception, so the implementation in subclasses may need to be particularly careful about checking internal state. Any exception raised by this method will be considered an error rather than a test failure. This method will only be called if the **setUp()** succeeds, regardless of the outcome of the test method. The default implementation does nothing.

**setUpClass()**
A class method called before tests in an individual class run. **setUpClass** is called with the class as the only argument and must be decorated as a **classmethod()**:

```python
@classmethod
def setUpClass(cls):
    ...
```

See [Class and Module Fixtures](#) for more details.

*New in version 2.7.*

**tearDownClass()**
A class method called after tests in an individual class have run. **tearDownClass** is called with the class as the only
argument and must be decorated as a `classmethod()`:

```python
@classmethod
def tearDownClass(cls):
    ...
```

See [Class and Module Fixtures](#) for more details.

*New in version 2.7.*

**run([[result]])**

Run the test, collecting the result into the test result object passed as `result`. If `result` is omitted or `None`, a temporary result object is created (by calling the `defaultTestResult()` method) and used. The result object is not returned to `run()`'s caller.

The same effect may be had by simply calling the `TestCase` instance.

**skipTest(reason)**

Calling this during a test method or `setUp()` skips the current test. See [Skipping tests and expected failures](#) for more information.

*New in version 2.7.*

**debug()**

Run the test without collecting the result. This allows exceptions raised by the test to be propagated to the caller, and can be used to support running tests under a debugger.

The test code can use any of the following methods to check for and report failures.
assertTrue(expr[, msg])
assert_(expr[, msg])
failUnless(expr[, msg])

Signal a test failure if expr is false; the explanation for the failure will be msg if given, otherwise it will be None.

Deprecated since version 2.7: failUnless() and assert_(); use assertTrue().

assertEqual(first, second[, msg])
failUnlessEqual(first, second[, msg])

Test that first and second are equal. If the values do not compare equal, the test will fail with the explanation given by msg, or None. Note that using assertEqual() improves upon doing the comparison as the first parameter to assertTrue(): the default value for msg include representations of both first and second.

In addition, if first and second are the exact same type and one of list, tuple, dict, set, frozenset or unicode or any type that a subclass registers with addTypeEqualityFunc() the type specific equality function will be called in order to generate a more useful default error message.

Changed in version 2.7: Added the automatic calling of type specific equality function.

Deprecated since version 2.7: failUnlessEqual(); use assertEqual().

assertNotEqual(first, second[, msg])
failIfEqual(first, second[, msg])

Test that first and second are not equal. If the values do compare equal, the test will fail with the explanation given by msg, or None. Note that using assertFalse() improves upon doing the comparison as the first parameter to assertTrue() is that the default value for msg can be computed to include representations of both first and second.

Deprecated since version 2.7: failIfEqual(); use assertNotEqual().

assertAlmostEqual(first, second[, places[, msg[, delta]]]])

Test that first and second are approximately equal by computing the difference, rounding to the given number of decimal places (default 7), and comparing to zero.

Note that comparing a given number of decimal places is not the same as comparing a given number of significant digits. If the values do not compare equal, the test will fail with the explanation given by msg, or None.

If delta is supplied instead of places then the difference between first and second must be less than delta.

Supplying both delta and places raises a TypeError.

Changed in version 2.7: Objects that compare equal are automatically almost equal. Added the delta keyword argument.

Deprecated since version 2.7: failUnlessAlmostEqual(); use assertAlmostEqual().
assertNotAlmostEqual(first, second[, places[, msg[, delta]]]])
failIfAlmostEqual(first, second[, places[, msg[, delta]]])

Test that first and second are not approximately equal by computing the difference, rounding to the given number of decimal places (default 7), and comparing to zero.

Note that comparing a given number of decimal places is not the same as comparing a given number of significant digits. If the values do not compare equal, the test will fail with the explanation given by msg, or None.

If delta is supplied instead of places then the difference between first and second must be more than delta.

Supplying both delta and places raises a TypeError.

Changed in version 2.7: Objects that compare equal automatically fail. Added the delta keyword argument.

Deprecated since version 2.7: failIfAlmostEqual(); use assertNotAlmostEqual().

assertGreater(first, second, msg=None)
assertGreaterEqual(first, second, msg=None)
assertLess(first, second, msg=None)
assertLessEqual(first, second, msg=None)

Test that first is respectively >, >=, < or <= than second depending on the method name. If not, the test will fail with an explanation or with the explanation given by msg:

```python
greater = self.assertGreaterEqual(3, 4)
AssertionError: "3" unexpectedly not greater than or equal to "4"
```
**New in version 2.7.**

**assertMultiLineEqual** *(self, first, second, msg=None)*

Test that the multiline string *first* is equal to the string *second*. When not equal a diff of the two strings highlighting the differences will be included in the error message. This method is used by default when comparing Unicode strings with **assertEqual()**.

If specified, *msg* will be used as the error message on failure.

**New in version 2.7.**

**assertRegexpMatches** *(text, regexp, msg=None)*

Verifies that a *regexp* search matches *text*. Fails with an error message including the pattern and the *text*. *regexp* may be a regular expression object or a string containing a regular expression suitable for use by **re.search()**.

**New in version 2.7.**

**assertNotRegexpMatches** *(text, regexp, msg=None)*

Verifies that a *regexp* search does not match *text*. Fails with an error message including the pattern and the part of *text* that matches. *regexp* may be a regular expression object or a string containing a regular expression suitable for use by **re.search()**.

**New in version 2.7.**

**assertIn** *(first, second, msg=None)*

**assertNotIn** *(first, second, msg=None)*

Tests that *first* is or is not in *second* with an explanatory error message as appropriate.
If specified, *msg* will be used as the error message on failure.

*New in version 2.7.*

**assertItemsEqual(actual, expected, msg=None)**

Test that sequence *expected* contains the same elements as *actual*, regardless of their order. When they don’t, an error message listing the differences between the sequences will be generated.

Duplicate elements are *not* ignored when comparing *actual* and *expected*. It verifies if each element has the same count in both sequences. It is the equivalent of `assertEqual(sorted(expected), sorted(actual))` but it works with sequences of unhashable objects as well.

If specified, *msg* will be used as the error message on failure.

*New in version 2.7.*

**assertSetEqual(set1, set2, msg=None)**

Tests that two sets are equal. If not, an error message is constructed that lists the differences between the sets. This method is used by default when comparing sets or frozensets with `assertEqual()`.

Fails if either of *set1* or *set2* does not have a `set.difference()` method.

If specified, *msg* will be used as the error message on failure.

*New in version 2.7.*

**assertDictEqual(expected, actual, msg=None)**

Test that two dictionaries are equal. If not, an error message is constructed that shows the differences in the dictionaries.
This method will be used by default to compare dictionaries in calls to `assertEqual()`.

If specified, `msg` will be used as the error message on failure.

*New in version 2.7.*

`assertDictContainsSubset(expected, actual, msg=None)`

Tests whether the key/value pairs in dictionary `actual` are a superset of those in `expected`. If not, an error message listing the missing keys and mismatched values is generated.

If specified, `msg` will be used as the error message on failure.

*New in version 2.7.*

`assertListEqual(list1, list2, msg=None)`

`assertTupleEqual(tuple1, tuple2, msg=None)`

Tests that two lists or tuples are equal. If not an error message is constructed that shows only the differences between the two. An error is also raised if either of the parameters are of the wrong type. These methods are used by default when comparing lists or tuples with `assertEqual()`.

If specified, `msg` will be used as the error message on failure.

*New in version 2.7.*

`assertSequenceEqual(seq1, seq2, msg=None, seq_type=None)`

Tests that two sequences are equal. If a `seq_type` is supplied, both `seq1` and `seq2` must be instances of `seq_type` or a failure will be raised. If the sequences are different an error message is constructed that shows the difference between the two.
If specified, msg will be used as the error message on failure.

This method is used to implement assertListEqual() and assertTupleEqual().

*New in version 2.7.*

assertRaises(exception[, callable, ...])

failUnlessRaises(exception[, callable, ...])

Test that an exception is raised when callable is called with any positional or keyword arguments that are also passed to assertRaises(). The test passes if exception is raised, is an error if another exception is raised, or fails if no exception is raised. To catch any of a group of exceptions, a tuple containing the exception classes may be passed as exception.

If callable is omitted or None, returns a context manager so that the code under test can be written inline rather than as a function:

```python
with self.assertRaises(SomeException):
    do_something()
```

The context manager will store the caught exception object in its exception attribute. This can be useful if the intention is to perform additional checks on the exception raised:

```python
with self.assertRaises(SomeException) as cm:
    do_something()

the_exception = cm.exception
self.assertEqual(the_exception.error_code, 3)
```

*Change in version 2.7:* Added the ability to use assertRaises() as a context manager.
assertRaisesRegexp(exception, regexp[, callable, ...])
Like assertRaises() but also tests that regexp matches on the string representation of the raised exception. regexp may be a regular expression object or a string containing a regular expression suitable for use by re.search(). Examples:

```python
def test_correct_value(self):
    self.assertRaisesRegexp(ValueError, 'invalid literal for.*XYZ$', int, 'XYZ')

    with self.assertRaisesRegexp(ValueError, 'literal'):
        int('XYZ')
```

*New in version 2.7.*

assertIsNone(expr[, msg])
This signals a test failure if expr is not None.

*New in version 2.7.*

assertIsNotNone(expr[, msg])
The inverse of the assertIsNone() method. This signals a test failure if expr is None.

*New in version 2.7.*

assertIs(expr1, expr2[, msg])
This signals a test failure if expr1 and expr2 don’t evaluate to the same object.
New in version 2.7.

`assertIsNot(expr1, expr2[, msg])`

The inverse of the `assertIs()` method. This signals a test failure if `expr1` and `expr2` evaluate to the same object.

New in version 2.7.

`assertIsInstance(obj, cls[, msg])`

This signals a test failure if `obj` is not an instance of `cls` (which can be a class or a tuple of classes, as supported by `isinstance()`).

New in version 2.7.

`assertNotIsInstance(obj, cls[, msg])`

The inverse of the `assertIsInstance()` method. This signals a test failure if `obj` is an instance of `cls`.

New in version 2.7.

`assertFalse(expr[, msg])`

`failIf(expr[, msg])`

The inverse of the `assertTrue()` method is the `assertFalse()` method. This signals a test failure if `expr` is true, with `msg` or `None` for the error message.

*Deprecated since version 2.7: `failIf()`; use `assertFalse()`.*

`fail([msg])`

Signals a test failure unconditionally, with `msg` or `None` for the error message.
failureException
This class attribute gives the exception raised by the test method. If a test framework needs to use a specialized exception, possibly to carry additional information, it must subclass this exception in order to “play fair” with the framework. The initial value of this attribute is `AssertionError`.

longMessage
If set to True then any explicit failure message you pass in to the assert methods will be appended to the end of the normal failure message. The normal messages contain useful information about the objects involved, for example the message from assertEqual shows you the repr of the two unequal objects. Setting this attribute to True allows you to have a custom error message in addition to the normal one.

This attribute defaults to False, meaning that a custom message passed to an assert method will silence the normal message.

The class setting can be overridden in individual tests by assigning an instance attribute to True or False before calling the assert methods.

New in version 2.7.

maxDiff
This attribute controls the maximum length of diffs output by assert methods that report diffs on failure. It defaults to 80*8 characters. Assert methods affected by this attribute are `assertSequenceEqual()` (including all the sequence comparison methods that delegate to it), `assertDictEqual()` and `assertMultiLineEqual()`.

Setting `maxDiff` to None means that there is no maximum
length of diffs.

*New in version 2.7.*

Testing frameworks can use the following methods to collect information on the test:

**countTestCases()**

Return the number of tests represented by this test object. For *TestCase* instances, this will always be 1.

**defaultTestResult()**

Return an instance of the test result class that should be used for this test case class (if no other result instance is provided to the *run()* method).

For *TestCase* instances, this will always be an instance of *TestResult*; subclasses of *TestCase* should override this as necessary.

**id()**

Return a string identifying the specific test case. This is usually the full name of the test method, including the module and class name.

**shortDescription()**

Returns a description of the test, or *None* if no description has been provided. The default implementation of this method returns the first line of the test method’s docstring, if available, or *None*.

**addTypeEqualityFunc(typeobj, function)**

Registers a type specific *assertEqual()* equality checking function to be called by *assertEqual()* when both objects it has been asked to compare are exactly *typeobj* (not
subclasses). \textit{function} must take two positional arguments and a third \texttt{msg=None} keyword argument just as \texttt{assertEquals()} does. It must raise \texttt{self.failureException} when inequality between the first two parameters is detected.

One good use of custom equality checking functions for a type is to raise \texttt{self.failureException} with an error message useful for debugging the problem by explaining the inequalities in detail.

\textit{New in version 2.7.}

\texttt{addCleanup(function[, \*args[, **kwargs]])}

Add a function to be called after \texttt{tearDown()} to cleanup resources used during the test. Functions will be called in reverse order to the order they are added (LIFO). They are called with any arguments and keyword arguments passed into \texttt{addCleanup()} when they are added.

If \texttt{setUp()} fails, meaning that \texttt{tearDown()} is not called, then any cleanup functions added will still be called.

\textit{New in version 2.7.}

\texttt{doCleanups()}

This method is called unconditionally after \texttt{tearDown()}, or after \texttt{setUp()} if \texttt{setUp()} raises an exception.

It is responsible for calling all the cleanup functions added by \texttt{addCleanup()}. If you need cleanup functions to be called \textit{prior} to \texttt{tearDown()} then you can call \texttt{doCleanups()} yourself.

\texttt{doCleanups()} pops methods off the stack of cleanup functions one at a time, so it can be called at any time.
New in version 2.7.

class unittest.FunctionTestCase(testFunc, setUp, tearDown, description)

This class implements the portion of the TestCase interface which allows the test runner to drive the test, but does not provide the methods which test code can use to check and report errors. This is used to create test cases using legacy test code, allowing it to be integrated into a unittest-based test framework.

24.3.7.2. Grouping tests

class unittest.TestSuite([tests])

This class represents an aggregation of individual tests cases and test suites. The class presents the interface needed by the test runner to allow it to be run as any other test case. Running a TestSuite instance is the same as iterating over the suite, running each test individually.

If tests is given, it must be an iterable of individual test cases or other test suites that will be used to build the suite initially. Additional methods are provided to add test cases and suites to the collection later on.

TestSuite objects behave much like TestCase objects, except they do not actually implement a test. Instead, they are used to aggregate tests into groups of tests that should be run together. Some additional methods are available to add tests to TestSuite instances:

addTest(test)

Add a TestCase or TestSuite to the suite.
addTests(tests)
Add all the tests from an iterable of testCase and TestSuite instances to this test suite.

This is equivalent to iterating over tests, calling addTest() for each element.

TestSuite shares the following methods with TestCase:

run(result)
Run the tests associated with this suite, collecting the result into the test result object passed as result. Note that unlike testCase.run(), TestSuite.run() requires the result object to be passed in.

debug()
Run the tests associated with this suite without collecting the result. This allows exceptions raised by the test to be propagated to the caller and can be used to support running tests under a debugger.

countTestCases()
Return the number of tests represented by this test object, including all individual tests and sub-suites.

__iter__()
Tests grouped by a TestSuite are always accessed by iteration. Subclasses can lazily provide tests by overriding __iter__(). Note that this method maybe called several times on a single suite (for example when counting tests or comparing for equality) so the tests returned must be the same for repeated iterations.

Changed in version 2.7: In earlier versions the TestSuite accessed tests directly rather than through iteration, so
overriding __iter__() wasn't sufficient for providing tests.

In the typical usage of a TestSuite object, the run() method is invoked by a TestRunner rather than by the end-user test harness.

24.3.7.3. Loading and running tests

class unittest.TestLoader

The TestLoader class is used to create test suites from classes and modules. Normally, there is no need to create an instance of this class; the unittest module provides an instance that can be shared as unittest.defaultTestLoader. Using a subclass or instance, however, allows customization of some configurable properties.

TestLoader objects have the following methods:

loadTestsFromTestCase(testCaseClass)

Return a suite of all tests cases contained in the TestCase-derived testCaseClass.

loadTestsFromModule(module)

Return a suite of all tests cases contained in the given module. This method searches module for classes derived from TestCase and creates an instance of the class for each test method defined for the class.

Note: While using a hierarchy of TestCase-derived classes can be convenient in sharing fixtures and helper functions, defining test methods on base classes that are not intended to be instantiated directly does not play well with this method. Doing so, however, can be useful when the fixtures
are different and defined in subclasses.

If a module provides a `load_tests` function it will be called to load the tests. This allows modules to customize test loading. This is the `load_tests` protocol.

*Changed in version 2.7:* Support for `load_tests` added.

`loadTestsFromName(name[, module])`

Return a suite of all tests cases given a string specifier.

The specifier `name` is a “dotted name” that may resolve either to a module, a test case class, a test method within a test case class, a `TestSuite` instance, or a callable object which returns a `TestCase` or `TestSuite` instance. These checks are applied in the order listed here; that is, a method on a possible test case class will be picked up as “a test method within a test case class”, rather than “a callable object”.

For example, if you have a module `SampleTests` containing a `TestCase`-derived class `SampleTestCase` with three test methods (`test_one()`, `test_two()`, and `test_three()`), the specifier `'SampleTests.SampleTestCase'` would cause this method to return a suite which will run all three test methods. Using the specifier `'SampleTests.SampleTestCase.test_two'` would cause it to return a test suite which will run only the `test_two()` test method. The specifier can refer to modules and packages which have not been imported; they will be imported as a side-effect.

The method optionally resolves `name` relative to the given `module`.

`loadTestsFromNames(names[, module])`
Similar to `loadTestsFromName()`, but takes a sequence of names rather than a single name. The return value is a test suite which supports all the tests defined for each name.

**getTestCaseNames(testCaseClass)**

Return a sorted sequence of method names found within `testCaseClass`; this should be a subclass of `TestCase`.

**discover(start_dir, pattern='test*.py', top_level_dir=None)**

Find and return all test modules from the specified start directory, recursing into subdirectories to find them. Only test files that match `pattern` will be loaded. (Using shell style pattern matching.) Only module names that are importable (i.e. are valid Python identifiers) will be loaded.

All test modules must be importable from the top level of the project. If the start directory is not the top level directory then the top level directory must be specified separately.

If importing a module fails, for example due to a syntax error, then this will be recorded as a single error and discovery will continue.

If a test package name (directory with `__init__.py`) matches the pattern then the package will be checked for a `load_tests` function. If this exists then it will be called with `loader, tests, pattern`.

If `load_tests` exists then discovery does *not* recurse into the package, `load_tests` is responsible for loading all tests in the package.

The pattern is deliberately not stored as a loader attribute so that packages can continue discovery themselves. `top_level_dir` is stored so `load_tests` does not need to pass
this argument in to `loader.discover()`.

`start_dir` can be a dotted module name as well as a directory.

*New in version 2.7.*

The following attributes of a `TestLoader` can be configured either by subclassing or assignment on an instance:

**testMethodPrefix**
String giving the prefix of method names which will be interpreted as test methods. The default value is `test'.

This affects `getTestCaseNames()` and all the `loadTestsFrom*()` methods.

**sortTestMethodsUsing**
Function to be used to compare method names when sorting them in `getTestCaseNames()` and all the `loadTestsFrom*()` methods. The default value is the built-in `cmp()` function; the attribute can also be set to `None` to disable the sort.

**suiteClass**
Callable object that constructs a test suite from a list of tests. No methods on the resulting object are needed. The default value is the `TestSuite` class.

This affects all the `loadTestsFrom*()` methods.

```python
class unittest.TestResult
```

This class is used to compile information about which tests have succeeded and which have failed.

A `TestResult` object stores the results of a set of tests. The `TestCase` and `TestSuite` classes ensure that results are properly recorded; test authors do not need to worry about recording the
outcome of tests.

Testing frameworks built on top of unittest may want access to the TestResult object generated by running a set of tests for reporting purposes; a TestResult instance is returned by the TestRunner.run() method for this purpose.

TestResult instances have the following attributes that will be of interest when inspecting the results of running a set of tests:

**errors**
A list containing 2-tuples of TestCase instances and strings holding formatted tracebacks. Each tuple represents a test which raised an unexpected exception.

*Changed in version 2.2:* Contains formatted tracebacks instead of sys.exc_info() results.

**failures**
A list containing 2-tuples of TestCase instances and strings holding formatted tracebacks. Each tuple represents a test where a failure was explicitly signalled using the TestCase.fail*() or TestCase.assert*() methods.

*Changed in version 2.2:* Contains formatted tracebacks instead of sys.exc_info() results.

**skipped**
A list containing 2-tuples of TestCase instances and strings holding the reason for skipping the test.

*New in version 2.7.*

**expectedFailures**
A list containing 2-tuples of TestCase instances and strings
holding formatted tracebacks. Each tuple represents a expected failures of the test case.

unexpectedSuccesses
A list containing `TestCase` instances that were marked as expected failures, but succeeded.

shouldStop
Set to `True` when the execution of tests should stop by `stop()`.

testsRun
The total number of tests run so far.

buffer
If set to true, `sys.stdout` and `sys.stderr` will be buffered in between `startTest()` and `stopTest()` being called. Collected output will only be echoed onto the real `sys.stdout` and `sys.stderr` if the test fails or errors. Any output is also attached to the failure / error message.

*New in version 2.7.*

failfast
If set to true `stop()` will be called on the first failure or error, halting the test run.

*New in version 2.7.*

wasSuccessful()
Return `True` if all tests run so far have passed, otherwise returns `False`.

stop()
This method can be called to signal that the set of tests being run should be aborted by setting the `shouldStop` attribute to
True. **TestRunner** objects should respect this flag and return without running any additional tests.

For example, this feature is used by the **TextTestRunner** class to stop the test framework when the user signals an interrupt from the keyboard. Interactive tools which provide **TestRunner** implementations can use this in a similar manner.

The following methods of the **TestResult** class are used to maintain the internal data structures, and may be extended in subclasses to support additional reporting requirements. This is particularly useful in building tools which support interactive reporting while tests are being run.

**startTest**(test)
   Called when the test case test is about to be run.

**stopTest**(test)
   Called after the test case test has been executed, regardless of the outcome.

**startTestRun**(test)
   Called once before any tests are executed.

   *New in version 2.7.*

**stopTestRun**(test)
   Called once after all tests are executed.

   *New in version 2.7.*

**addError**(test, err)
   Called when the test case test raises an unexpected exception err is a tuple of the form returned by `sys.exc_info()`:(type, value, traceback).
The default implementation appends a tuple \((test, \text{formatted}_{err})\) to the instance's \texttt{errors} attribute, where \texttt{formatted}_{err} is a formatted traceback derived from \texttt{err}.

\texttt{addFailure(test, err)}

Called when the test case \texttt{test} signals a failure. \texttt{err} is a tuple of the form returned by \texttt{sys.exc_info()}: \((\text{type, value, traceback})\).

The default implementation appends a tuple \((test, \text{formatted}_{err})\) to the instance's \texttt{failures} attribute, where \texttt{formatted}_{err} is a formatted traceback derived from \texttt{err}.

\texttt{addSuccess(test)}

Called when the test case \texttt{test} succeeds.

The default implementation does nothing.

\texttt{addSkip(test, reason)}

Called when the test case \texttt{test} is skipped. \texttt{reason} is the reason the test gave for skipping.

The default implementation appends a tuple \((test, reason)\) to the instance's \texttt{skipped} attribute.

\texttt{addExpectedFailure(test, err)}

Called when the test case \texttt{test} fails, but was marked with the \texttt{expectedFailure()} decorator.

The default implementation appends a tuple \((test, \text{formatted}_{err})\) to the instance's \texttt{expectedFailures} attribute, where \texttt{formatted}_{err} is a formatted traceback derived from \texttt{err}.
addUnexpectedSuccess(test)
   Called when the test case test was marked with the expectedFailure() decorator, but succeeded.

   The default implementation appends the test to the instance's unexpectedSuccesses attribute.

class unittest.TextTestResult(stream, descriptions, verbosity)
   A concrete implementation of TestResult used by the TextTestRunner.

   New in version 2.7: This class was previously named _TextTestResult. The old name still exists as an alias but is deprecated.

unittest.defaultTestLoader
   Instance of the TestLoader class intended to be shared. If no customization of the TestLoader is needed, this instance can be used instead of repeatedly creating new instances.

class unittest.TextTestRunner([stream[, descriptions[, verbosity][, resultclass]]])
   A basic test runner implementation which prints results on standard error. It has a few configurable parameters, but is essentially very simple. Graphical applications which run test suites should provide alternate implementations.

_makeResult()
   This method returns the instance of TestResult used by run(). It is not intended to be called directly, but can be overridden in subclasses to provide a custom TestResult.

_makeResult() instantiates the class or callable passed in the
**TextTestRunner** constructor as the `resultclass` argument. It defaults to **TextTestResult** if no `resultclass` is provided. The result class is instantiated with the following arguments:

```python
stream, descriptions, verbosity
```

```python
unittest.main([module[, defaultTest[, argv[, testRunner[, testLoader[, exit[, verbosity[, failfast[, catchbreak[, buffer]]]]]]]]]])
```

A command-line program that runs a set of tests; this is primarily for making test modules conveniently executable. The simplest use for this function is to include the following line at the end of a test script:

```python
if __name__ == '__main__':
    unittest.main()
```

You can run tests with more detailed information by passing in the `verbosity` argument:

```python
if __name__ == '__main__':
    unittest.main(verbosity=2)
```

The `testRunner` argument can either be a test runner class or an already created instance of it. By default `main` calls `sys.exit()` with an exit code indicating success or failure of the tests run.

`main` supports being used from the interactive interpreter by passing in the argument `exit=False`. This displays the result on standard output without calling `sys.exit()`:

```python
>>> from unittest import main
>>> main(module='test_module', exit=False)
```

The `failfast`, `catchbreak` and `buffer` parameters have the same effect as the `failfast`, `catch` and `buffer` command line options.
Calling `main` actually returns an instance of the `TestProgram` class. This stores the result of the tests run as the `result` attribute.

*Changed in version 2.7:* The `exit`, `verbosity`, `failfast`, `catchbreak` and `buffer` parameters were added.

## 24.3.7.3.1. load_tests Protocol

*New in version 2.7.*

Modules or packages can customize how tests are loaded from them during normal test runs or test discovery by implementing a function called `load_tests`.

If a test module defines `load_tests` it will be called by `TestLoader.loadTestsFromModule()` with the following arguments:

```python
load_tests(loader, standard_tests, None)
```

It should return a `TestSuite`.

`loader` is the instance of `TestLoader` doing the loading. `standard_tests` are the tests that would be loaded by default from the module. It is common for test modules to only want to add or remove tests from the standard set of tests. The third argument is used when loading packages as part of test discovery.

A typical `load_tests` function that loads tests from a specific set of `TestCase` classes may look like:

```python
test_cases = (TestCase1, TestCase2, TestCase3)

def load_tests(loader, tests, pattern):
    suite = TestSuite()
    for test_class in test_cases:
```
If discovery is started, either from the command line or by calling `TestLoader.discover()`, with a pattern that matches a package name then the package `__init__.py` will be checked for `load_tests`.

**Note:** The default pattern is ‘test*.py’. This matches all Python files that start with ‘test’ but won’t match any test directories.

A pattern like ‘test*’ will match test packages as well as modules.

If the package `__init__.py` defines `load_tests` then it will be called and discovery not continued into the package. `load_tests` is called with the following arguments:

```python
def load_tests(loader, standard_tests, pattern):
    # top level directory cached on loader instance
    this_dir = os.path.dirname(__file__)
    package_tests = loader.discover(start_dir=this_dir, pattern=pattern)
    standard_tests.addTests(package_tests)
    return standard_tests
```

This should return a `TestSuite` representing all the tests from the package. (standard_tests will only contain tests collected from `__init__.py`.)

Because the pattern is passed into `load_tests` the package is free to continue (and potentially modify) test discovery. A ‘do nothing’ `load_tests` function for a test package would look like:
24.3.8. Class and Module Fixtures

Class and module level fixtures are implemented in `TestSuite`. When the test suite encounters a test from a new class then `tearDownClass()` from the previous class (if there is one) is called, followed by `setUpClass()` from the new class.

Similarly if a test is from a different module from the previous test then `tearDownModule` from the previous module is run, followed by `setUpModule` from the new module.

After all the tests have run the final `tearDownClass` and `tearDownModule` are run.

Note that shared fixtures do not play well with [potential] features like test parallelization and they break test isolation. They should be used with care.

The default ordering of tests created by the unittest test loaders is to group all tests from the same modules and classes together. This will lead to `setUpClass` / `setUpModule` (etc) being called exactly once per class and module. If you randomize the order, so that tests from different modules and classes are adjacent to each other, then these shared fixture functions may be called multiple times in a single test run.

Shared fixtures are not intended to work with suites with non-standard ordering. A `BaseTestSuite` still exists for frameworks that don’t want to support shared fixtures.

If there are any exceptions raised during one of the shared fixture functions the test is reported as an error. Because there is no corresponding test instance an `ErrorHandler` object (that has the
same interface as a `TestCase`) is created to represent the error. If you are just using the standard unittest test runner then this detail doesn’t matter, but if you are a framework author it may be relevant.

24.3.8.1. `setUpClass` and `tearDownClass`

These must be implemented as class methods:

```python
import unittest

class Test(unittest.TestCase):
    @classmethod
    def setUpClass(cls):
        cls._connection = createExpensiveConnectionObject()

    @classmethod
    def tearDownClass(cls):
        cls._connection.destroy()
```

If you want the `setUpClass` and `tearDownClass` on base classes called then you must call up to them yourself. The implementations in `TestCase` are empty.

If an exception is raised during a `setUpClass` then the tests in the class are not run and the `tearDownClass` is not run. Skipped classes will not have `setUpClass` or `tearDownClass` run. If the exception is a `SkipTest` exception then the class will be reported as having been skipped instead of as an error.

24.3.8.2. `setUpModule` and `tearDownModule`

These should be implemented as functions:

```python
def setUpModule():
    createConnection()

def tearDownModule():
```
If an exception is raised in a `setUpModule` then none of the tests in the module will be run and the `tearDownModule` will not be run. If the exception is a `SkipTest` exception then the module will be reported as having been skipped instead of as an error.
24.3.9. Signal Handling

The `-c/--catch` command line option to unittest, along with the `catchbreak` parameter to `unittest.main()`, provide more friendly handling of control-C during a test run. With catch break behavior enabled control-C will allow the currently running test to complete, and the test run will then end and report all the results so far. A second control-c will raise a `KeyboardInterrupt` in the usual way.

The control-c handling signal handler attempts to remain compatible with code or tests that install their own `signal.SIGINT` handler. If the `unittest` handler is called but isn't the installed `signal.SIGINT` handler, i.e. it has been replaced by the system under test and delegated to, then it calls the default handler. This will normally be the expected behavior by code that replaces an installed handler and delegates to it. For individual tests that need `unittest` control-c handling disabled the `removeHandler()` decorator can be used.

There are a few utility functions for framework authors to enable control-c handling functionality within test frameworks.

`unittest.installHandler()`

Install the control-c handler. When a `signal.SIGINT` is received (usually in response to the user pressing control-c) all registered results have `stop()` called.

*New in version 2.7.*

`unittest.registerResult(result)`

Register a `TestResult` object for control-c handling. Registering a result stores a weak reference to it, so it doesn't prevent the result from being garbage collected.
Registering a `TestResult` object has no side-effects if control-c handling is not enabled, so test frameworks can unconditionally register all results they create independently of whether or not handling is enabled.

*New in version 2.7.*

```python
unittest.removeResult(result)
```

Remove a registered result. Once a result has been removed then `stop()` will no longer be called on that result object in response to a control-c.

*New in version 2.7.*

```python
unittest.removeHandler(function=None)
```

When called without arguments this function removes the control-c handler if it has been installed. This function can also be used as a test decorator to temporarily remove the handler whilst the test is being executed:

```python
@unittest.removeHandler
def test_signal_handling(self):
    ...
```

*New in version 2.7.*
2to3 is a Python program that reads Python 2.x source code and applies a series of fixers to transform it into valid Python 3.x code. The standard library contains a rich set of fixers that will handle almost all code. 2to3 supporting library `lib2to3` is, however, a flexible and generic library, so it is possible to write your own fixers for 2to3. `lib2to3` could also be adapted to custom applications in which Python code needs to be edited automatically.
24.4.1. Using 2to3

2to3 will usually be installed with the Python interpreter as a script. It is also located in the \texttt{Tools/scripts} directory of the Python root.

2to3’s basic arguments are a list of files or directories to transform. The directories are to recursively traversed for Python sources.

Here is a sample Python 2.x source file, \texttt{example.py}:

```python
def greet(name):
    print "Hello, {0}!".format(name)
print "What's your name?"
nname = raw_input()
greet(name)
```

It can be converted to Python 3.x code via 2to3 on the command line:

```
$ 2to3 example.py
```

A diff against the original source file is printed. 2to3 can also write the needed modifications right back to the source file. (A backup of the original file is made unless \texttt{-n} is also given.) Writing the changes back is enabled with the \texttt{-w} flag:

```
$ 2to3 -w example.py
```

After transformation, \texttt{example.py} looks like this:

```python
def greet(name):
    print("Hello, {0}!".format(name))
print("What's your name?")
nname = input()
greet(name)
```
Comments and exact indentation are preserved throughout the translation process.

By default, 2to3 runs a set of *predefined fixers*. The `-l` flag lists all available fixers. An explicit set of fixers to run can be given with `-f`. Likewise the `-x` explicitly disables a fixer. The following example runs only the `imports` and `has_key` fixers:

```
$ 2to3 -f imports -f has_key example.py
```

This command runs every fixer except the `apply` fixer:

```
$ 2to3 -x apply example.py
```

Some fixers are *explicit*, meaning they aren’t run by default and must be listed on the command line to be run. Here, in addition to the default fixers, the `idioms` fixer is run:

```
$ 2to3 -f all -f idioms example.py
```

Notice how passing `all` enables all default fixers.

Sometimes 2to3 will find a place in your source code that needs to be changed, but 2to3 cannot fix automatically. In this case, 2to3 will print a warning beneath the diff for a file. You should address the warning in order to have compliant 3.x code.

2to3 can also refactor doctests. To enable this mode, use the `-d` flag. Note that *only* doctests will be refactored. This also doesn’t require the module to be valid Python. For example, doctest like examples in a reST document could also be refactored with this option.

The `-v` option enables output of more information on the translation process.

Since some print statements can be parsed as function calls or
statements, 2to3 cannot always read files containing the print function. When 2to3 detects the presence of the `from __future__
import print_function` compiler directive, it modifies its internal grammar to interpret `print()` as a function. This change can also be enabled manually with the `-p` flag. Use `-p` to run fixers on code that already has had its print statements converted.
24.4.2. Fixers

Each step of transforming code is encapsulated in a fixer. The command `2to3 -l` lists them. As documented above, each can be turned on and off individually. They are described here in more detail.

**apply**
Removes usage of `apply()`. For example `apply(function, *args, **kwargs)` is converted to `function(*args, **kwargs)`.

**basestring**
Converts `basestring` to `str`.

**buffer**
Converts `buffer` to `memoryview`. This fixer is optional because the `memoryview` API is similar but not exactly the same as that of `buffer`.

**callable**
Converts `callable(x)` to `isinstance(x, collections.Callable)`, adding an import to `collections` if needed.

**dict**
Fixes dictionary iteration methods. `dict.iteritems()` is converted to `dict.items()`, `dict.iterkeys()` to `dict.keys()`, and `dict.itervalues()` to `dict.values()`. Similarly, `dict.viewitems()`, `dict.viewkeys()` and `dict.viewvalues()` are converted respectively to `dict.items()`, `dict.keys()` and `dict.values()`. It also wraps existing usages of `dict.items()`, `dict.keys()`, and `dict.values()` in a call to `list`.

**except**
Converts `except X, T` to `except X as T`.

**exec**
Converts the `exec` statement to the `exec()` function.

**execfile**
Removes usage of `execfile()`. The argument to `execfile()` is wrapped in calls to `open()`, `compile()`, and `exec()`.

**exitfunc**
Changes assignment of `sys.exitfunc` to use of the `atexit` module.

**filter**
Wraps `filter()` usage in a `list` call.

**funcattrs**
Fixes function attributes that have been renamed. For example, `my_function.func_closure` is converted to `my_function.__closure__`.

**future**
Removes `from __future__ import new_feature` statements.

**getcwdu**
Renames `os.getcwdu()` to `os.getcwd()`.

**has_key**
Changes `dict.has_key(key)` to `key in dict`.

**idioms**
This optional fixer performs several transformations that make Python code more idiomatic. Type comparisons like `type(x) is SomeClass` and `type(x) == SomeClass` are converted to `isinstance(x, SomeClass)`. while `1` becomes `while True`. This
fixer also tries to make use of `sorted()` in appropriate places. For example, this block

```python
L = list(some_iterable)
L.sort()
```

is changed to

```python
L = sorted(some_iterable)
```

`import`

Detects sibling imports and converts them to relative imports.

`imports`

Handles module renames in the standard library.

`imports2`

Handles other modules renames in the standard library. It is separate from the `imports` fixer only because of technical limitations.

`input`

Converts `input(prompt)` to `eval(input(prompt))`

`intern`

Converts `intern()` to `sys.intern()`.

`isinstance`

Fixes duplicate types in the second argument of `isinstance()`. For example, `isinstance(x, (int, int))` is converted to `isinstance(x, (int))`.

`itertools_imports`

Removes imports of `itertools.ifilter()`, `itertools.izip()`, and `itertools.imap()`. Imports of `itertools.ifilterfalse()` are also changed to `itertools.filterfalse()`.
**itertools**
Changes usage of `itertools.ifilter()`, `itertools.izip()`, and `itertools.imap()` to their built-in equivalents. `itertools.ifilterfalse()` is changed to `itertools.filterfalse()`.

**long**
Strips the `L` prefix on long literals and renames `long` to `int`.

**map**
Wraps `map()` in a `list` call. It also changes `map(None, x)` to `list(x)`. Using `from future_builtins import map` disables this fixer.

**metaclass**
Converts the old metaclass syntax (`__metaclass__ = Meta` in the class body) to the new (`class X(metaclass=Meta)`).

**methodattrs**
Fixes old method attribute names. For example, `meth.im_func` is converted to `meth.__func__`.

**ne**
Converts the old not-equal syntax, `<>`, to `!=`.

**next**
Converts the use of iterator’s `next()` methods to the `next()` function. It also renames `next()` methods to `__next__()`.

**nonzero**
Renames `__nonzero__()` to `__bool__()`.

**numliterals**
Converts octal literals into the new syntax.
paren
Add extra parenthesis where they are required in list comprehensions. For example, \([x \text{ for } x \text{ in } 1, 2]\) becomes \([x \text{ for } x \text{ in } (1, 2)]\).

print
Converts the `print` statement to the `print()` function.

raise
Converts `raise E, V` to `raise E(V)`, and `raise E, V, T` to `raise E(V).with_traceback(T)`. If `E` is a tuple, the translation will be incorrect because substituting tuples for exceptions has been removed in 3.0.

raw_input
Converts `raw_input()` to `input()`.

reduce
Handles the move of `reduce()` to `functools.reduce()`.

renames
Changes `sys.maxint` to `sys.maxsize`.

repr
Replaces backtick repr with the `repr()` function.

set_literal
Replaces use of the `set` constructor with set literals. This fixer is optional.

standard_error
Renames `StandardError` to `Exception`.

sys_exc
Changes the deprecated `sys.exc_value`, `sys.exc_type`,
`sys.exc_traceback` to use `sys.exc_info()`.

**throw**
Fixes the API change in generator's `throw()` method.

**tuple_params**
Removes implicit tuple parameter unpacking. This fixer inserts temporary variables.

**types**
Fixes code broken from the removal of some members in the `types` module.

**unicode**
Renames `unicode` to `str`.

**urllib**
Handles the rename of `urllib` and `urllib2` to the `urllib` package.

**ws_comma**
Removes excess whitespace from comma separated items. This fixer is optional.

**xrange**
Renames `xrange()` to `range()` and wraps existing `range()` calls with `list`.

**xreadlines**
Changes `for x in file.xreadlines()` to `for x in file`.

**zip**
Wraps `zip()` usage in a `list` call. This is disabled when `from future_builtins import zip` appears.
24.4.3. lib2to3 - 2to3’s library

**Note:** The `lib2to3` API should be considered unstable and may change drastically in the future.
24.5. test — Regression tests package for Python

The test package contains all regression tests for Python as well as the modules test.test_support and test.regrtest. test.test_support is used to enhance your tests while test.regrtest drives the testing suite.

Each module in the test package whose name starts with test_ is a testing suite for a specific module or feature. All new tests should be written using the unittest or doctest module. Some older tests are written using a “traditional” testing style that compares output printed to sys.stdout; this style of test is considered deprecated.

See also:

Module unittest
  Writing PyUnit regression tests.

Module doctest
  Tests embedded in documentation strings.
24.5.1. Writing Unit Tests for the test package

It is preferred that tests that use the unittest module follow a few guidelines. One is to name the test module by starting it with test_ and end it with the name of the module being tested. The test methods in the test module should start with test_ and end with a description of what the method is testing. This is needed so that the methods are recognized by the test driver as test methods. Also, no documentation string for the method should be included. A comment (such as # Tests function returns only True or False) should be used to provide documentation for test methods. This is done because documentation strings get printed out if they exist and thus what test is being run is not stated.

A basic boilerplate is often used:

```python
import unittest
from test import test_support

class MyTestCase1(unittest.TestCase):

    # Only use setUp() and tearDown() if necessary

def setUp(self):
    ... code to execute in preparation for tests ...

def tearDown(self):
    ... code to execute to clean up after tests ...

def test_feature_one(self):
    # Test feature one.
    ... testing code ...

def test_feature_two(self):
    # Test feature two.
    ... testing code ...
```
... more test methods ...

class MyTestCase2(unittest.TestCase):
    ... same structure as MyTestCase1 ...

... more test classes ...

def test_main():
    test_support.run_unittest(MyTestCase1,
        MyTestCase2,
        ... list other tests ...
    )

if __name__ == '__main__':
    test_main()

This boilerplate code allows the testing suite to be run by `test.regrtest` as well as on its own as a script.

The goal for regression testing is to try to break code. This leads to a few guidelines to be followed:

- The testing suite should exercise all classes, functions, and constants. This includes not just the external API that is to be presented to the outside world but also “private” code.

- Whitebox testing (examining the code being tested when the tests are being written) is preferred. Blackbox testing (testing only the published user interface) is not complete enough to make sure all boundary and edge cases are tested.

- Make sure all possible values are tested including invalid ones. This makes sure that not only all valid values are acceptable but also that improper values are handled correctly.

- Exhaust as many code paths as possible. Test where branching occurs and thus tailor input to make sure as many different paths through the code are taken.
• Add an explicit test for any bugs discovered for the tested code. This will make sure that the error does not crop up again if the code is changed in the future.

• Make sure to clean up after your tests (such as close and remove all temporary files).

• If a test is dependent on a specific condition of the operating system then verify the condition already exists before attempting the test.

• Import as few modules as possible and do it as soon as possible. This minimizes external dependencies of tests and also minimizes possible anomalous behavior from side-effects of importing a module.

• Try to maximize code reuse. On occasion, tests will vary by something as small as what type of input is used. Minimize code duplication by subclassing a basic test class with a class that specifies the input:

```python
class TestFuncAcceptsSequences(unittest.TestCase):
    func = mySuperWhammyFunction

def test_func(self):
    self.func(self.arg)

class AcceptLists(TestFuncAcceptsSequences):
    arg = [1, 2, 3]

class AcceptStrings(TestFuncAcceptsSequences):
    arg = 'abc'

class AcceptTuples(TestFuncAcceptsSequences):
    arg = (1, 2, 3)
```

See also:
Test Driven Development
A book by Kent Beck on writing tests before code.
24.5.2. Running tests using \texttt{test.regrtest}

\texttt{test.regrtest} can be used as a script to drive Python's regression test suite. Running the script by itself automatically starts running all regression tests in the \texttt{test} package. It does this by finding all modules in the package whose name starts with \texttt{test_}, importing them, and executing the function \texttt{test\_main()} if present. The names of tests to execute may also be passed to the script. Specifying a single regression test (\texttt{python regrtest.py test\_spam.py}) will minimize output and only print whether the test passed or failed and thus minimize output.

Running \texttt{test.regrtest} directly allows what resources are available for tests to use to be set. You do this by using the \texttt{-u} command-line option. Run \texttt{python regrtest.py -u all} to turn on all resources; specifying \texttt{all} as an option for \texttt{-u} enables all possible resources. If all but one resource is desired (a more common case), a comma-separated list of resources that are not desired may be listed after \texttt{all}. The command \texttt{python regrtest.py -u all,-audio,-largefile} will run \texttt{test.regrtest} with all resources except the \texttt{audio} and \texttt{largefile} resources. For a list of all resources and more command-line options, run \texttt{python regrtest.py -h}.

Some other ways to execute the regression tests depend on what platform the tests are being executed on. On Unix, you can run \texttt{make test} at the top-level directory where Python was built. On Windows, executing \texttt{rt.bat} from your \texttt{PCBuild} directory will run all regression tests.
24.6. test.test_support — Utility functions for tests

**Note:** The `test.test_support` module has been renamed to `test.support` in Python 3.x.

The `test.test_support` module provides support for Python's regression tests.

This module defines the following exceptions:

*exception* `test.test_support.TestFailed`

  Exception to be raised when a test fails. This is deprecated in favor of `unittest`-based tests and `unittest.TestCase`'s assertion methods.

*exception* `test.test_support.ResourceDenied`

  Subclass of `unittest.SkipTest`. Raised when a resource (such as a network connection) is not available. Raised by the `requires()` function.

The `test.test_support` module defines the following constants:

`test.test_support.verbose`

  *True* when verbose output is enabled. Should be checked when more detailed information is desired about a running test. `verbose` is set by `test.regrtest`.

`test.test_support.have_unicode`

  *True* when Unicode support is available.

`test.test_support.is_jython`

  *True* if the running interpreter is Jython.
test.test_support.TESTFN
Set to a name that is safe to use as the name of a temporary file. Any temporary file that is created should be closed and unlinked (removed).

The test.test_support module defines the following functions:

test.test_support.forget(module_name)
Remove the module named module_name from sys.modules and delete any byte-compiled files of the module.

test.test_support.is_resource_enabled(resource)
Return True if resource is enabled and available. The list of available resources is only set when test.regrtest is executing the tests.

test.test_support.requires(resource[, msg])
Raise ResourceDenied if resource is not available. msg is the argument to ResourceDenied if it is raised. Always returns True if called by a function whose __name__ is '__main__'. Used when tests are executed by test.regrtest.

test.test_support.findfile(filename)
Return the path to the file named filename. If no match is found filename is returned. This does not equal a failure since it could be the path to the file.

test.test_support.run_unittest(*classes)
Execute unittest.TestCase subclasses passed to the function. The function scans the classes for methods starting with the prefix test_ and executes the tests individually.

It is also legal to pass strings as parameters; these should be keys in sys.modules. Each associated module will be scanned by
unittest.TestLoader.loadTestsFromModule(). This is usually seen in the following `test_main()` function:

```python
def test_main():
    test_support.run_unittest(__name__)
```

This will run all tests defined in the named module.

test.test_support.check_warnings(*filters, quiet=True)

A convenience wrapper for `warnings.catch_warnings()` that makes it easier to test that a warning was correctly raised. It is approximately equivalent to calling `warnings.catch_warnings(record=True)` with `warnings.simplefilter()` set to `always` and with the option to automatically validate the results that are recorded.

check_warnings accepts 2-tuples of the form ("message regexp", WarningCategory) as positional arguments. If one or more `filters` are provided, or if the optional keyword argument `quiet` is `False`, it checks to make sure the warnings are as expected: each specified filter must match at least one of the warnings raised by the enclosed code or the test fails, and if any warnings are raised that do not match any of the specified filters the test fails. To disable the first of these checks, set `quiet` to `True`.

If no arguments are specified, it defaults to:

```python
check_warnings('', Warning, quiet=True)
```

In this case all warnings are caught and no errors are raised.

On entry to the context manager, a `WarningRecorder` instance is returned. The underlying warnings list from `catch_warnings()` is available via the recorder object’s `warnings` attribute. As a convenience, the attributes of the object representing the most
recent warning can also be accessed directly through the recorder object (see example below). If no warning has been raised, then any of the attributes that would otherwise be expected on an object representing a warning will return None.

The recorder object also has a reset() method, which clears the warnings list.

The context manager is designed to be used like this:

```python
with check_warnings(("assertion is always true", SyntaxWarning), 
    
    exec('assert(False, "Hey!")

warnings.warn(UserWarning("Hide me!")))"
```

In this case if either warning was not raised, or some other warning was raised, check_warnings() would raise an error.

When a test needs to look more deeply into the warnings, rather than just checking whether or not they occurred, code like this can be used:

```python
with check_warnings(quiet=True) as w:
    warnings.warn("foo")
    assert str(w.args[0]) == "foo"
    warnings.warn("bar")
    assert str(w.args[0]) == "bar"
    assert str(w.warnings[0].args[0]) == "foo"
    assert str(w.warnings[1].args[0]) == "bar"
    w.reset()
    assert len(w.warnings) == 0
```

Here all warnings will be caught, and the test code tests the captured warnings directly.

New in version 2.6.

Changed in version 2.7: New optional arguments filters and quiet.
test.test_support.**check_py3k_warnings**(*filters, quiet=False*)

Similar to **check_warnings()**, but for Python 3 compatibility warnings. If `sys.py3kwarning == 1`, it checks if the warning is effectively raised. If `sys.py3kwarning == 0`, it checks that no warning is raised. It accepts 2-tuples of the form ("message regexp", `WarningCategory`) as positional arguments. When the optional keyword argument `quiet` is **True**, it does not fail if a filter catches nothing. Without arguments, it defaults to:

```python
check_py3k_warnings(("", DeprecationWarning), quiet=False)
```

*New in version 2.7.*

test.test_support.**captured_stdout**()

This is a context manager that runs the `with` statement body using a `StringIO.StringIO` object as `sys.stdout`. That object can be retrieved using the `as` clause of the `with` statement.

Example use:

```python
with captured_stdout() as s:
    print "hello"
assert s.getvalue() == "hello"
```

*New in version 2.6.*

test.test_support.**import_module**(*name, deprecated=False*)

This function imports and returns the named module. Unlike a normal import, this function raises `unittest.SkipTest` if the module cannot be imported.

Module and package deprecation messages are suppressed during this import if `deprecated` is **True**.

*New in version 2.7.*
test.test_support.import_fresh_module(name, fresh=(), blocked=(), deprecated=False)

This function imports and returns a fresh copy of the named Python module by removing the named module from sys.modules before doing the import. Note that unlike reload(), the original module is not affected by this operation.

fresh is an iterable of additional module names that are also removed from the sys.modules cache before doing the import.

blocked is an iterable of module names that are replaced with θ in the module cache during the import to ensure that attempts to import them raise ImportError.

The named module and any modules named in the fresh and blocked parameters are saved before starting the import and then reinserted into sys.modules when the fresh import is complete.

Module and package deprecation messages are suppressed during this import if deprecated is True.

This function will raise unittest.SkipTest is the named module cannot be imported.

Example use:

```
# Get copies of the warnings module for testing without
# affecting the version being used by the rest of the test s
# One copy uses the C implementation, the other is forced to
# the pure Python fallback implementation
py_warnings = import_fresh_module('warnings', blocked=['_warnings'])
c_warnings = import_fresh_module('warnings', fresh=['_warnings'])
```

New in version 2.7.

The test.test_support module defines the following classes:
class test.test_support.TransientResource(exc[, **kwargs])

Instances are a context manager that raises ResourceDenied if the specified exception type is raised. Any keyword arguments are treated as attribute/value pairs to be compared against any exception raised within the with statement. Only if all pairs match properly against attributes on the exception is ResourceDenied raised.

New in version 2.6.

class test.test_support.EnvironmentVarGuard

Class used to temporarily set or unset environment variables. Instances can be used as a context manager and have a complete dictionary interface for querying/modifying the underlying os.environ. After exit from the context manager all changes to environment variables done through this instance will be rolled back.

New in version 2.6.

Changed in version 2.7: Added dictionary interface.

EnvironmentVarGuard.set(envvar, value)

Temporarily set the environment variable envvar to the value of value.

EnvironmentVarGuard.unset(envvar)

Temporarily unset the environment variable envvar.

class test.test_support.WarningsRecorder

Class used to record warnings for unit tests. See documentation of check_warnings() above for more details.

New in version 2.6.
25. Debugging and Profiling

These libraries help you with Python development: the debugger enables you to step through code, analyze stack frames and set breakpoints etc., and the profilers run code and give you a detailed breakdown of execution times, allowing you to identify bottlenecks in your programs.

  - 25.7.1. Command Line Usage
  - 25.7.2. Programming Interface
25.1. *bdb* — Debugger framework

The *bdb* module handles basic debugger functions, like setting breakpoints or managing execution via the debugger.

The following exception is defined:

```python
exception bdb.BdbQuit
    Exception raised by the Bdb class for quitting the debugger.
```

The *bdb* module also defines two classes:

```python
class bdb.Breakpoint(self, file, line[, temporary=0[, cond=0[, funcname=None]]]]]
    This class implements temporary breakpoints, ignore counts, disabling and (re-)enabling, and conditionals.

    Breakpoints are indexed by number through a list called bpbynumber and by (file, line) pairs through bplist. The former points to a single instance of class Breakpoint. The latter points to a list of such instances since there may be more than one breakpoint per line.

    When creating a breakpoint, its associated filename should be in canonical form. If a *funcname* is defined, a breakpoint hit will be counted when the first line of that function is executed. A conditional breakpoint always counts a hit.

    Breakpoint instances have the following methods:

    `deleteMe()`
    Delete the breakpoint from the list associated to a file/line. If it is the last breakpoint in that position, it also deletes the entry for the file/line.
```
enable()
Mark the breakpoint as enabled.

disable()
Mark the breakpoint as disabled.

pprint([out])
Print all the information about the breakpoint:

- The breakpoint number.
- If it is temporary or not.
- Its file, line position.
- The condition that causes a break.
- If it must be ignored the next N times.
- The breakpoint hit count.

class bdb. Bdb(skip=None)
The Bdb class acts as a generic Python debugger base class.

This class takes care of the details of the trace facility; a derived
class should implement user interaction. The standard debugger
class (pdb.Pdb) is an example.

The skip argument, if given, must be an iterable of glob-style
module name patterns. The debugger will not step into frames
that originate in a module that matches one of these patterns.
Whether a frame is considered to originate in a certain module is
determined by the __name__ in the frame globals.

New in version 2.7: The skip argument.

The following methods of Bdb normally don’t need to be
overridden.

canonic(filename)
Auxiliary method for getting a filename in a canonical form, that is, as a case-normalized (on case-insensitive filesystems) absolute path, stripped of surrounding angle brackets.

reset()

Set the botframe, stopframe, returnframe and quitting attributes with values ready to start debugging.

trace_dispatch(frame, event, arg)

This function is installed as the trace function of debugged frames. Its return value is the new trace function (in most cases, that is, itself).

The default implementation decides how to dispatch a frame, depending on the type of event (passed as a string) that is about to be executed. event can be one of the following:

- "line": A new line of code is going to be executed.
- "call": A function is about to be called, or another code block entered.
- "return": A function or other code block is about to return.
- "exception": An exception has occurred.
- "c_call": A C function is about to be called.
- "c_return": A C function has returned.
- "c_exception": A C function has thrown an exception.

For the Python events, specialized functions (see below) are called. For the C events, no action is taken.

The arg parameter depends on the previous event.

See the documentation for sys.settrace() for more information on the trace function. For more information on code and frame objects, refer to The standard type hierarchy.
**dispatch_line**(frame)
If the debugger should stop on the current line, invoke the user_line() method (which should be overridden in subclasses). Raise a BdbQuit exception if the Bdb. quitting flag is set (which can be set from user_line()). Return a reference to the trace_dispatch() method for further tracing in that scope.

**dispatch_call**(frame, arg)
If the debugger should stop on this function call, invoke the user_call() method (which should be overridden in subclasses). Raise a BdbQuit exception if the Bdb. quitting flag is set (which can be set from user_call()). Return a reference to the trace_dispatch() method for further tracing in that scope.

**dispatch_return**(frame, arg)
If the debugger should stop on this function return, invoke the user_return() method (which should be overridden in subclasses). Raise a BdbQuit exception if the Bdb. quitting flag is set (which can be set from user_return()). Return a reference to the trace_dispatch() method for further tracing in that scope.

**dispatch_exception**(frame, arg)
If the debugger should stop at this exception, invokes the user_exception() method (which should be overridden in subclasses). Raise a BdbQuit exception if the Bdb. quitting flag is set (which can be set from user_exception()). Return a reference to the trace_dispatch() method for further tracing in that scope.

Normally derived classes don’t override the following methods,
but they may if they want to redefine the definition of stopping and breakpoints.

**stop_here(frame)**
This method checks if the frame is somewhere below botframe in the call stack. botframe is the frame in which debugging started.

**break_here(frame)**
This method checks if there is a breakpoint in the filename and line belonging to frame or, at least, in the current function. If the breakpoint is a temporary one, this method deletes it.

**break_anywhere(frame)**
This method checks if there is a breakpoint in the filename of the current frame.

Derived classes should override these methods to gain control over debugger operation.

**user_call(frame, argument_list)**
This method is called from dispatch_call() when there is the possibility that a break might be necessary anywhere inside the called function.

**user_line(frame)**
This method is called from dispatch_line() when either stop_here() or break_here() yields True.

**user_return(frame, return_value)**
This method is called from dispatch_return() when stop_here() yields True.

**user_exception(frame, exc_info)**
This method is called from dispatch_exception() when
stop_here() yields True.

do_clear(arg)
    Handle how a breakpoint must be removed when it is a temporary one.

    This method must be implemented by derived classes.

Derived classes and clients can call the following methods to affect the stepping state.

set_step()
    Stop after one line of code.

set_next(frame)
    Stop on the next line in or below the given frame.

set_return(frame)
    Stop when returning from the given frame.

set_until(frame)
    Stop when the line with the line no greater than the current one is reached or when returning from current frame

set_trace([frame])
    Start debugging from frame. If frame is not specified, debugging starts from caller’s frame.

set_continue()
    Stop only at breakpoints or when finished. If there are no breakpoints, set the system trace function to None.

set_quit()
    Set the quitting attribute to True. This raises BdbQuit in the next call to one of the dispatch_*() methods.
Derived classes and clients can call the following methods to manipulate breakpoints. These methods return a string containing an error message if something went wrong, or None if all is well.

**set_break(filename, lineno[, temporary=0[, cond[, funcname]]]])**
Set a new breakpoint. If the lineno line doesn't exist for the filename passed as argument, return an error message. The filename should be in canonical form, as described in the canonic() method.

**clear_break(filename, lineno)**
Delete the breakpoints in filename and lineno. If none were set, an error message is returned.

**clear_bpbynumber(arg)**
Delete the breakpoint which has the index arg in the Breakpoint.bpbynumber. If arg is not numeric or out of range, return an error message.

**clear_all_file_breaks(filename)**
Delete all breakpoints in filename. If none were set, an error message is returned.

**clear_all_breaks()**
Delete all existing breakpoints.

**get_break(filename, lineno)**
Check if there is a breakpoint for lineno of filename.

**get_breaks(filename, lineno)**
Return all breakpoints for lineno in filename, or an empty list if none are set.

**get_file_breaks(filename)**
Return all breakpoints in filename, or an empty list if none are
get_all_breaks()

Return all breakpoints that are set.

Derived classes and clients can call the following methods to get a data structure representing a stack trace.

get_stack(f, t)

Get a list of records for a frame and all higher (calling) and lower frames, and the size of the higher part.

format_stack_entry(frame_lineno[, lprefix=': '])

Return a string with information about a stack entry, identified by a (frame, lineno) tuple:

- The canonical form of the filename which contains the frame.
- The function name, or "<lambda>".
- The input arguments.
- The return value.
- The line of code (if it exists).

The following two methods can be called by clients to use a debugger to debug a statement, given as a string.

run(cmd[, globals[, locals]])

Debug a statement executed via the `exec` statement. `globals` defaults to `__main__.__dict__`, `locals` defaults to `globals`.

runeval(expr[, globals[, locals]])

Debug an expression executed via the `eval()` function. `globals` and `locals` have the same meaning as in `run()`.

runcxt(cmd, globals, locals)
For backwards compatibility. Calls the \texttt{run()} method.

\texttt{runcall(func, *args, **kwds)}

Debug a single function call, and return its result.

Finally, the module defines the following functions:

\texttt{bdb.checkfuncname(b, frame)}

Check whether we should break here, depending on the way the breakpoint \texttt{b} was set.

If it was set via line number, it checks if \texttt{b.line} is the same as the one in the frame also passed as argument. If the breakpoint was set via function name, we have to check we are in the right frame (the right function) and if we are in its first executable line.

\texttt{bdb.effective(file, line, frame)}

Determine if there is an effective (active) breakpoint at this line of code. Return breakpoint number or 0 if none.

Called only if we know there is a breakpoint at this location. Returns the breakpoint that was triggered and a flag that indicates if it is ok to delete a temporary breakpoint.

\texttt{bdb.set_trace()}

Starts debugging with a \texttt{Bdb} instance from caller's frame.
25.2. \texttt{pdb} — The Python Debugger

The module \texttt{pdb} defines an interactive source code debugger for Python programs. It supports setting (conditional) breakpoints and single stepping at the source line level, inspection of stack frames, source code listing, and evaluation of arbitrary Python code in the context of any stack frame. It also supports post-mortem debugging and can be called under program control.

The debugger is extensible — it is actually defined as the class \texttt{Pdb}. This is currently undocumented but easily understood by reading the source. The extension interface uses the modules \texttt{bdb} and \texttt{cmd}.

The debugger’s prompt is \texttt{(Pdb)}. Typical usage to run a program under control of the debugger is:

```python
>>> import pdb
>>> import mymodule
>>> pdb.run('mymodule.test()')
> <string>(0)?()
(Pdb) continue
> <string>(1)?()
(Pdb) continue
NameError: 'spam'
> <string>(1)?()
(Pdb)
```

\texttt{pdb.py} can also be invoked as a script to debug other scripts. For example:

```bash
python -m pdb myscript.py
```

When invoked as a script, \texttt{pdb} will automatically enter post-mortem debugging if the program being debugged exits abnormally. After post-mortem debugging (or after normal exit of the program), \texttt{pdb} will restart the program. Automatic restarting preserves \texttt{pdb}'s state (such
as breakpoints) and in most cases is more useful than quitting the debugger upon program's exit.

New in version 2.4: Restarting post-mortem behavior added.

The typical usage to break into the debugger from a running program is to insert

```python
import pdb; pdb.set_trace()
```

at the location you want to break into the debugger. You can then step through the code following this statement, and continue running without the debugger using the `c` command.

The typical usage to inspect a crashed program is:

```python
>>> import pdb
>>> import mymodule
>>> mymodule.test()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "./mymodule.py", line 4, in test
    test2()
  File "./mymodule.py", line 3, in test2
    print spam
NameError: spam
>>> pdb.pm()
> ./mymodule.py(3)test2()
-> print spam
(Pdb)
```

The module defines the following functions; each enters the debugger in a slightly different way:

```
pdb.run(statement[, globals[, locals]]])
```

Execute the `statement` (given as a string) under debugger control. The debugger prompt appears before any code is executed; you can set breakpoints and type `continue`, or you can
step through the statement using `step` or `next` (all these commands are explained below). The optional `globals` and `locals` arguments specify the environment in which the code is executed; by default the dictionary of the module `__main__` is used. (See the explanation of the `exec` statement or the `eval()` built-in function.)

```
pdb. `runeval`(*expression*, `[globals]`, `[locals]`)  
```
Evaluate the `expression` (given as a string) under debugger control. When `runeval()` returns, it returns the value of the expression. Otherwise this function is similar to `run()`.

```
pdb. `runcall`(*function*, `[argument]`, ...)  
```
Call the `function` (a function or method object, not a string) with the given arguments. When `runcall()` returns, it returns whatever the function call returned. The debugger prompt appears as soon as the function is entered.

```
pdb. `set_trace`()  
```
Enter the debugger at the calling stack frame. This is useful to hard-code a breakpoint at a given point in a program, even if the code is not otherwise being debugged (e.g. when an assertion fails).

```
pdb. `post_mortem`([`traceback`])  
```
Enter post-mortem debugging of the given `traceback` object. If no `traceback` is given, it uses the one of the exception that is currently being handled (an exception must be being handled if the default is to be used).

```
pdb. `pm`()  
```
Enter post-mortem debugging of the traceback found in `sys.last_traceback`.  

The `run_*` functions and `set_trace()` are aliases for instantiating the `Pdb` class and calling the method of the same name. If you want to access further features, you have to do this yourself:

```python
class pdb.Pdb(completekey='tab', stdin=None, stdout=None, skip=None)
```

`Pdb` is the debugger class.

The `completekey`, `stdin` and `stdout` arguments are passed to the underlying `cmd.Cmd` class; see the description there.

The `skip` argument, if given, must be an iterable of glob-style module name patterns. The debugger will not step into frames that originate in a module that matches one of these patterns. [1]

Example call to enable tracing with `skip`:

```python
import pdb; pdb.Pdb(skip=['django.*']).set_trace()
```

*New in version 2.7:* The `skip` argument.

```python
run(statement[, globals[, locals]])
runeval(expression[, globals[, locals]])
runcall(function[, argument, ...])
set_trace()
```

See the documentation for the functions explained above.
25.3. Debugger Commands

The debugger recognizes the following commands. Most commands can be abbreviated to one or two letters; e.g. `h(e1p)` means that either `h` or `help` can be used to enter the help command (but not `he` or `hel`, nor `H` or `Help` or `HELP`). Arguments to commands must be separated by whitespace (spaces or tabs). Optional arguments are enclosed in square brackets ([ ]) in the command syntax; the square brackets must not be typed. Alternatives in the command syntax are separated by a vertical bar (|).

Entering a blank line repeats the last command entered. Exception: if the last command was a `list` command, the next 11 lines are listed.

Commands that the debugger doesn’t recognize are assumed to be Python statements and are executed in the context of the program being debugged. Python statements can also be prefixed with an exclamation point (!). This is a powerful way to inspect the program being debugged; it is even possible to change a variable or call a function. When an exception occurs in such a statement, the exception name is printed but the debugger’s state is not changed.

Multiple commands may be entered on a single line, separated by `;`. (A single ; is not used as it is the separator for multiple commands in a line that is passed to the Python parser.) No intelligence is applied to separating the commands; the input is split at the first ;; pair, even if it is in the middle of a quoted string.

The debugger supports aliases. Aliases can have parameters which allows one a certain level of adaptability to the context under examination.

If a file `.pdbrc` exists in the user’s home directory or in the current
directory, it is read in and executed as if it had been typed at the debugger prompt. This is particularly useful for aliases. If both files exist, the one in the home directory is read first and aliases defined there can be overridden by the local file.

**h(elp) [command]**

Without argument, print the list of available commands. With a *command* as argument, print help about that command. `help pdb` displays the full documentation file; if the environment variable `PAGER` is defined, the file is piped through that command instead. Since the *command* argument must be an identifier, `help exec` must be entered to get help on the `!` command.

**w(here)**

Print a stack trace, with the most recent frame at the bottom. An arrow indicates the current frame, which determines the context of most commands.

**d(own)**

Move the current frame one level down in the stack trace (to a newer frame).

**u(p)**

Move the current frame one level up in the stack trace (to an older frame).

**b(reak) [[filename:]lineno | function[, condition]]**

With a *lineno* argument, set a break there in the current file. With a *function* argument, set a break at the first executable statement within that function. The line number may be prefixed with a filename and a colon, to specify a breakpoint in another file (probably one that hasn’t been loaded yet). The file is searched on `sys.path`. Note that each breakpoint is assigned a number to which all the other breakpoint commands refer.

If a second argument is present, it is an expression which must evaluate to true before the breakpoint is honored.
Without argument, list all breaks, including for each breakpoint, the number of times that breakpoint has been hit, the current ignore count, and the associated condition if any.

tbreak [[filename:]lineno | function[, condition]]
Temporary breakpoint, which is removed automatically when it is first hit. The arguments are the same as break.

clear [bpnumber [bpnumber ...]]
With a space separated list of breakpoint numbers, clear those breakpoints. Without argument, clear all breaks (but first ask confirmation).

disable [bpnumber [bpnumber ...]]
Disables the breakpoints given as a space separated list of breakpoint numbers. Disabling a breakpoint means it cannot cause the program to stop execution, but unlike clearing a breakpoint, it remains in the list of breakpoints and can be (re-)enabled.

enable [bpnumber [bpnumber ...]]
Enables the breakpoints specified.

ignore bpnumber [count]
Sets the ignore count for the given breakpoint number. If count is omitted, the ignore count is set to 0. A breakpoint becomes active when the ignore count is zero. When non-zero, the count is decremented each time the breakpoint is reached and the breakpoint is not disabled and any associated condition evaluates to true.

condition bpnumber [condition]
Condition is an expression which must evaluate to true before the breakpoint is honored. If condition is absent, any existing condition is removed; i.e., the breakpoint is made unconditional.

commands [bpnumber]
Specify a list of commands for breakpoint number bpnumber. The
commands themselves appear on the following lines. Type a line containing just ‘end’ to terminate the commands. An example:

```
(Pdb) commands 1
(com) print some_variable
(com) end
(Pdb)
```

To remove all commands from a breakpoint, type commands and follow it immediately with end; that is, give no commands.

With no bpnumber argument, commands refers to the last breakpoint set.

You can use breakpoint commands to start your program up again. Simply use the continue command, or step, or any other command that resumes execution.

Specifying any command resuming execution (currently continue, step, next, return, jump, quit and their abbreviations) terminates the command list (as if that command was immediately followed by end). This is because any time you resume execution (even with a simple next or step), you may encounter another breakpoint—which could have its own command list, leading to ambiguities about which list to execute.

If you use the ‘silent’ command in the command list, the usual message about stopping at a breakpoint is not printed. This may be desirable for breakpoints that are to print a specific message and then continue. If none of the other commands print anything, you see no sign that the breakpoint was reached.

*New in version 2.5.*

s(tep)

Execute the current line, stop at the first possible occasion (either in a function that is called or on the next line in the current
function).

next
Continue execution until the next line in the current function is reached or it returns. (The difference between next and step is that step stops inside a called function, while next executes called functions at (nearly) full speed, only stopping at the next line in the current function.)

until
Continue execution until the line with the line number greater than the current one is reached or when returning from current frame.

New in version 2.6.

return
Continue execution until the current function returns.

continue
Continue execution, only stop when a breakpoint is encountered.

jump lineno
Set the next line that will be executed. Only available in the bottom-most frame. This lets you jump back and execute code again, or jump forward to skip code that you don’t want to run.

It should be noted that not all jumps are allowed — for instance it is not possible to jump into the middle of a for loop or out of a finally clause.

list [first[, last]]
List source code for the current file. Without arguments, list 11 lines around the current line or continue the previous listing. With one argument, list 11 lines around at that line. With two arguments, list the given range; if the second argument is less than the first, it is interpreted as a count.
a(rgs)
Print the argument list of the current function.

p expression
Evaluate the expression in the current context and print its value.

**Note:** print can also be used, but is not a debugger command — this executes the Python `print` statement.

pp expression
Like the p command, except the value of the expression is pretty-printed using the `pprint` module.

alias [name [command]]
Creates an alias called name that executes command. The command must not be enclosed in quotes. Replaceable parameters can be indicated by %1, %2, and so on, while %* is replaced by all the parameters. If no command is given, the current alias for name is shown. If no arguments are given, all aliases are listed.

Aliases may be nested and can contain anything that can be legally typed at the `pdb` prompt. Note that internal `pdb` commands can be overridden by aliases. Such a command is then hidden until the alias is removed. Aliasing is recursively applied to the first word of the command line; all other words in the line are left alone.

As an example, here are two useful aliases (especially when placed in the `.pdbrc` file):

```python
#Print instance variables (usage "pi classInst")
alias pi for k in %1.__dict__.keys(): print "%1."k,"=",%1.
#Print instance variables in self
alias ps pi self
```
unalias name
   Deletes the specified alias.

[!]statement
   Execute the (one-line) statement in the context of the current stack frame. The exclamation point can be omitted unless the first word of the statement resembles a debugger command. To set a global variable, you can prefix the assignment command with a global command on the same line, e.g.:

```
(Pdb) global list_options; list_options = ['-l']
(Pdb)
```

run [args ...]
   Restart the debugged Python program. If an argument is supplied, it is split with “shlex” and the result is used as the new sys.argv. History, breakpoints, actions and debugger options are preserved. “restart” is an alias for “run”.

   New in version 2.6.

q(uit)
   Quit from the debugger. The program being executed is aborted.

Footnotes

[1] Whether a frame is considered to originate in a certain module is determined by the __name__ in the frame globals.

25.4.1. Introduction to the profilers

A profiler is a program that describes the run time performance of a program, providing a variety of statistics. This documentation describes the profiler functionality provided in the modules `cProfile`, `profile` and `pstats`. This profiler provides deterministic profiling of Python programs. It also provides a series of report generation tools to allow users to rapidly examine the results of a profile operation.

The Python standard library provides three different profilers:

1. `cProfile` is recommended for most users; it’s a C extension with reasonable overhead that makes it suitable for profiling long-running programs. Based on `lsprof`, contributed by Brett Rosen and Ted Czotter.

   *New in version 2.5.*

2. `profile`, a pure Python module whose interface is imitated by `cProfile`. Adds significant overhead to profiled programs. If you're trying to extend the profiler in some way, the task might be easier with this module. Copyright © 1994, by InfoSeek Corporation.

   *Changed in version 2.4:* Now also reports the time spent in calls to built-in functions and methods.

3. `hotshot` was an experimental C module that focused on minimizing the overhead of profiling, at the expense of longer data post-processing times. It is no longer maintained and may be dropped in a future version of Python.

   *Changed in version 2.5:* The results should be more meaningful than in the past: the timing core contained a critical bug.
The `profile` and `cProfile` modules export the same interface, so they are mostly interchangeable; `cProfile` has a much lower overhead but is newer and might not be available on all systems. `cProfile` is really a compatibility layer on top of the internal `_lsprof` module. The `hotshot` module is reserved for specialized usage.
This section is provided for users that “don’t want to read the manual.” It provides a very brief overview, and allows a user to rapidly perform profiling on an existing application.

To profile an application with a main entry point of `foo()`, you would add the following to your module:

```python
import cProfile
cProfile.run('foo()')
```

(Use `profile` instead of `cProfile` if the latter is not available on your system.)

The above action would cause `foo()` to be run, and a series of informative lines (the profile) to be printed. The above approach is most useful when working with the interpreter. If you would like to save the results of a profile into a file for later examination, you can supply a file name as the second argument to the `run()` function:

```python
import cProfile
cProfile.run('foo()', 'fooprof')
```

The file `cProfile.py` can also be invoked as a script to profile another script. For example:

```
python -m cProfile myscript.py
```

cProfile.py accepts two optional arguments on the command line:

```
cProfile.py [-o output_file] [-s sort_order]
```

`-s` only applies to standard output (`-o` is not supplied). Look in the
Stats documentation for valid sort values.

When you wish to review the profile, you should use the methods in the pstats module. Typically you would load the statistics data as follows:

```python
import pstats
p = pstats.Stats('fooprof')
```

The class stats (the above code just created an instance of this class) has a variety of methods for manipulating and printing the data that was just read into `p`. When you ran cProfile.run() above, what was printed was the result of three method calls:

```python
p.strip_dirs().sort_stats(-1).print_stats()
```

The first method removed the extraneous path from all the module names. The second method sorted all the entries according to the standard module/line/name string that is printed. The third method printed out all the statistics. You might try the following sort calls:

```python
p.sort_stats('name')
p.print_stats()
```

The first call will actually sort the list by function name, and the second call will print out the statistics. The following are some interesting calls to experiment with:

```python
p.sort_stats('cumulative').print_stats(10)
```

This sorts the profile by cumulative time in a function, and then only prints the ten most significant lines. If you want to understand what algorithms are taking time, the above line is what you would use.

If you were looking to see what functions were looping a lot, and taking a lot of time, you would do:
p.sort_stats('time').print_stats(10)

to sort according to time spent within each function, and then print the statistics for the top ten functions.

You might also try:

p.sort_stats('file').print_stats('__init__')

This will sort all the statistics by file name, and then print out statistics for only the class init methods (since they are spelled with __init__ in them). As one final example, you could try:

p.sort_stats('time', 'cum').print_stats(.5, 'init')

This line sorts statistics with a primary key of time, and a secondary key of cumulative time, and then prints out some of the statistics. To be specific, the list is first culled down to 50% (re: .5) of its original size, then only lines containing init are maintained, and that sub-sub-list is printed.

If you wondered what functions called the above functions, you could now (p is still sorted according to the last criteria) do:

p.print_callers(.5, 'init')

and you would get a list of callers for each of the listed functions.

If you want more functionality, you’re going to have to read the manual, or guess what the following functions do:

p.print_callees()
p.add('fooprof')

Invoked as a script, the pstats module is a statistics browser for reading and examining profile dumps. It has a simple line-oriented
interface (implemented using \texttt{cmd}) and interactive help.
25.4.3. What Is Deterministic Profiling?

Deterministic profiling is meant to reflect the fact that all function call, function return, and exception events are monitored, and precise timings are made for the intervals between these events (during which time the user’s code is executing). In contrast, statistical profiling (which is not done by this module) randomly samples the effective instruction pointer, and deduces where time is being spent. The latter technique traditionally involves less overhead (as the code does not need to be instrumented), but provides only relative indications of where time is being spent.

In Python, since there is an interpreter active during execution, the presence of instrumented code is not required to do deterministic profiling. Python automatically provides a hook (optional callback) for each event. In addition, the interpreted nature of Python tends to add so much overhead to execution, that deterministic profiling tends to only add small processing overhead in typical applications. The result is that deterministic profiling is not that expensive, yet provides extensive run time statistics about the execution of a Python program.

Call count statistics can be used to identify bugs in code (surprising counts), and to identify possible inline-expansion points (high call counts). Internal time statistics can be used to identify “hot loops” that should be carefully optimized. Cumulative time statistics should be used to identify high level errors in the selection of algorithms. Note that the unusual handling of cumulative times in this profiler allows statistics for recursive implementations of algorithms to be directly compared to iterative implementations.
25.4.4. Reference Manual – profile and cProfile

The primary entry point for the profiler is the global function `profile.run()` (resp. `cProfile.run()`). It is typically used to create any profile information. The reports are formatted and printed using methods of the class `pstats.Stats`. The following is a description of all of these standard entry points and functions. For a more in-depth view of some of the code, consider reading the later section on Profiler Extensions, which includes discussion of how to derive “better” profilers from the classes presented, or reading the source code for these modules.

**cProfile.**`run(command[, filename])`

This function takes a single argument that can be passed to the `exec` statement, and an optional file name. In all cases this routine attempts to `exec` its first argument, and gather profiling statistics from the execution. If no file name is present, then this function automatically prints a simple profiling report, sorted by the standard name string (file/line/function-name) that is presented in each line. The following is a typical output from such a call:

```
2706 function calls (2004 primitive calls) in 4.504 CPU

Ordered by: standard name

     ncalls  tottime  percall  cumtime  percall filename:lineno(function)
              2    0.006    0.003    0.953    0.477 pobject.py:75(save_objects)
         43/3    0.533  0.012    0.749  0.250 pobject.py:99(evaluate)
          ...
```

The first line indicates that 2706 calls were monitored. Of those calls, 2004 were *primitive*. We define *primitive* to mean that the
call was not induced via recursion. The next line: ordered by:
standard name, indicates that the text string in the far right column
was used to sort the output. The column headings include:

ncalls
  for the number of calls,
tottime
  for the total time spent in the given function (and excluding
time made in calls to sub-functions),
percall
  is the quotient of tottime divided by ncalls
cumtime
  is the total time spent in this and all subfunctions (from
  invocation till exit). This figure is accurate even for recursive
functions.
percall
  is the quotient of cumtime divided by primitive calls

filename:lineno(function)
  provides the respective data of each function

When there are two numbers in the first column (for example,
43/3), then the latter is the number of primitive calls, and the
former is the actual number of calls. Note that when the function
does not recurse, these two values are the same, and only the
single figure is printed.

cProfile.runctx(command, globals, locals[, filename])
  This function is similar to run(), with added arguments to supply
  the globals and locals dictionaries for the command string.

Analysis of the profiler data is done using the Stats class.
class pstats.Stats(filename[, stream=sys.stdout[, ...]])

This class constructor creates an instance of a “statistics object” from a filename (or set of filenames). Stats objects are manipulated by methods, in order to print useful reports. You may specify an alternate output stream by giving the keyword argument, stream.

The file selected by the above constructor must have been created by the corresponding version of profile or cProfile. To be specific, there is no file compatibility guaranteed with future versions of this profiler, and there is no compatibility with files produced by other profilers. If several files are provided, all the statistics for identical functions will be coalesced, so that an overall view of several processes can be considered in a single report. If additional files need to be combined with data in an existing Stats object, the add() method can be used.

*Changed in version 2.5:* The stream parameter was added.

25.4.4.1. The Stats Class

Stats objects have the following methods:

Stats.strip_dirs()

This method for the Stats class removes all leading path information from file names. It is very useful in reducing the size of the printout to fit within (close to) 80 columns. This method modifies the object, and the stripped information is lost. After performing a strip operation, the object is considered to have its entries in a “random” order, as it was just after object initialization and loading. If strip_dirs() causes two function names to be
indistinguishable (they are on the same line of the same filename, and have the same function name), then the statistics for these two entries are accumulated into a single entry.

**Stats.add(filename[, ...])**

This method of the Stats class accumulates additional profiling information into the current profiling object. Its arguments should refer to filenames created by the corresponding version of profile.run() or cProfile.run(). Statistics for identically named (re: file, line, name) functions are automatically accumulated into single function statistics.

**Stats.dump_stats(filename)**

Save the data loaded into the Stats object to a file named filename. The file is created if it does not exist, and is overwritten if it already exists. This is equivalent to the method of the same name on the profile.Profile and cProfile.Profile classes.

*New in version 2.3.*

**Stats.sort_stats(key[, ...])**

This method modifies the Stats object by sorting it according to the supplied criteria. The argument is typically a string identifying the basis of a sort (example: 'time' or 'name').

When more than one key is provided, then additional keys are used as secondary criteria when there is equality in all keys selected before them. For example, sort_stats('name', 'file') will sort all the entries according to their function name, and resolve all ties (identical function names) by sorting by file name.

Abbreviations can be used for any key names, as long as the abbreviation is unambiguous. The following are the keys currently defined:
<table>
<thead>
<tr>
<th>Valid Arg</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'calls'</td>
<td>call count</td>
</tr>
<tr>
<td>'cumulative'</td>
<td>cumulative time</td>
</tr>
<tr>
<td>'file'</td>
<td>file name</td>
</tr>
<tr>
<td>'module'</td>
<td>file name</td>
</tr>
<tr>
<td>'pcalls'</td>
<td>primitive call count</td>
</tr>
<tr>
<td>'line'</td>
<td>line number</td>
</tr>
<tr>
<td>'name'</td>
<td>function name</td>
</tr>
<tr>
<td>'nfl'</td>
<td>name/file/line</td>
</tr>
<tr>
<td>'stdname'</td>
<td>standard name</td>
</tr>
<tr>
<td>'time'</td>
<td>internal time</td>
</tr>
</tbody>
</table>

Note that all sorts on statistics are in descending order (placing most time consuming items first), where as name, file, and line number searches are in ascending order (alphabetical). The subtle distinction between 'nfl' and 'stdname' is that the standard name is a sort of the name as printed, which means that the embedded line numbers get compared in an odd way. For example, lines 3, 20, and 40 would (if the file names were the same) appear in the string order 20, 3 and 40. In contrast, 'nfl' does a numeric compare of the line numbers. In fact, `sort_stats('nfl')` is the same as `sort_stats('name', 'file', 'line')`.

For backward-compatibility reasons, the numeric arguments -1, 0, 1, and 2 are permitted. They are interpreted as 'stdname', 'calls', 'time', and 'cumulative' respectively. If this old style format (numeric) is used, only one sort key (the numeric key) will be used, and additional arguments will be silently ignored.

**Stats.reverse_order()**

This method for the Stats class reverses the ordering of the basic list within the object. Note that by default ascending vs
descending order is properly selected based on the sort key of choice.

Stats. print_stats([restriction, ...])

This method for the Stats class prints out a report as described in the profile.run() definition.

The order of the printing is based on the last sort_stats() operation done on the object (subject to caveats in add() and strip_dirs()).

The arguments provided (if any) can be used to limit the list down to the significant entries. Initially, the list is taken to be the complete set of profiled functions. Each restriction is either an integer (to select a count of lines), or a decimal fraction between 0.0 and 1.0 inclusive (to select a percentage of lines), or a regular expression (to pattern match the standard name that is printed; as of Python 1.5b1, this uses the Perl-style regular expression syntax defined by the re module). If several restrictions are provided, then they are applied sequentially. For example:

```
print_stats(.1, 'foo:')
```

would first limit the printing to first 10% of list, and then only print functions that were part of filename .*foo:. In contrast, the command:

```
print_stats('foo:', .1)
```

would limit the list to all functions having file names .*foo:, and then proceed to only print the first 10% of them.

Stats. print_callers([restriction, ...])

This method for the Stats class prints a list of all functions that
called each function in the profiled database. The ordering is identical to that provided by \texttt{print_stats()}, and the definition of the restricting argument is also identical. Each caller is reported on its own line. The format differs slightly depending on the profiler that produced the stats:

- With \texttt{profile}, a number is shown in parentheses after each caller to show how many times this specific call was made. For convenience, a second non-parenthesized number repeats the cumulative time spent in the function at the right.
- With \texttt{cProfile}, each caller is preceded by three numbers: the number of times this specific call was made, and the total and cumulative times spent in the current function while it was invoked by this specific caller.

\texttt{Stats.print_callees([\textit{restriction}, ...])}

This method for the \texttt{Stats} class prints a list of all function that were called by the indicated function. Aside from this reversal of direction of calls (re: called vs was called by), the arguments and ordering are identical to the \texttt{print_callers()} method.
One limitation has to do with accuracy of timing information. There is a fundamental problem with deterministic profilers involving accuracy. The most obvious restriction is that the underlying “clock” is only ticking at a rate (typically) of about .001 seconds. Hence no measurements will be more accurate than the underlying clock. If enough measurements are taken, then the “error” will tend to average out. Unfortunately, removing this first error induces a second source of error.

The second problem is that it “takes a while” from when an event is dispatched until the profiler’s call to get the time actually gets the state of the clock. Similarly, there is a certain lag when exiting the profiler event handler from the time that the clock’s value was obtained (and then squirreled away), until the user’s code is once again executing. As a result, functions that are called many times, or call many functions, will typically accumulate this error. The error that accumulates in this fashion is typically less than the accuracy of the clock (less than one clock tick), but it can accumulate and become very significant.

The problem is more important with profile than with the lower-overhead cProfile. For this reason, profile provides a means of calibrating itself for a given platform so that this error can be probabilistically (on the average) removed. After the profiler is calibrated, it will be more accurate (in a least square sense), but it will sometimes produce negative numbers (when call counts are exceptionally low, and the gods of probability work against you :-). ) Do not be alarmed by negative numbers in the profile. They should only appear if you have calibrated your profiler, and the results are actually better than without calibration.
25.4.6. Calibration

The profiler of the profile module subtracts a constant from each event handling time to compensate for the overhead of calling the time function, and socking away the results. By default, the constant is 0. The following procedure can be used to obtain a better constant for a given platform (see discussion in section Limitations above).

```python
import profile
pr = profile.Profile()
for i in range(5):
    print pr.calibrate(10000)
```

The method executes the number of Python calls given by the argument, directly and again under the profiler, measuring the time for both. It then computes the hidden overhead per profiler event, and returns that as a float. For example, on an 800 MHz Pentium running Windows 2000, and using Python’s time.clock() as the timer, the magical number is about 12.5e-6.

The object of this exercise is to get a fairly consistent result. If your computer is very fast, or your timer function has poor resolution, you might have to pass 100000, or even 1000000, to get consistent results.

When you have a consistent answer, there are three ways you can use it: [2]

```python
import profile

# 1. Apply computed bias to all Profile instances created herea
profile.Profile.bias = your_computed_bias

# 2. Apply computed bias to a specific Profile instance.
pr = profile.Profile()
pr.bias = your_computed_bias
```
# 3. Specify computed bias in instance constructor.
pr = profile.Profile(bias=your_computed_bias)

If you have a choice, you are better off choosing a smaller constant, and then your results will “less often” show up as negative in profile statistics.
25.4.7. Extensions — Deriving Better Profilers

The Profile class of both modules, profile and cProfile, were written so that derived classes could be developed to extend the profiler. The details are not described here, as doing this successfully requires an expert understanding of how the Profile class works internally. Study the source code of the module carefully if you want to pursue this.

If all you want to do is change how current time is determined (for example, to force use of wall-clock time or elapsed process time), pass the timing function you want to the Profile class constructor:

```
pr = profile.Profile(your_time_func)
```

The resulting profiler will then call `your_time_func()`.

Profile.Profile

`your_time_func()` should return a single number, or a list of numbers whose sum is the current time (like what `os.times()` returns). If the function returns a single time number, or the list of returned numbers has length 2, then you will get an especially fast version of the dispatch routine.

Be warned that you should calibrate the profiler class for the timer function that you choose. For most machines, a timer that returns a lone integer value will provide the best results in terms of low overhead during profiling. (`os.times()` is pretty bad, as it returns a tuple of floating point values). If you want to substitute a better timer in the cleanest fashion, derive a class and hardwire a replacement dispatch method that best handles your timer call, along with the appropriate calibration constant.
cProfile.Profile

`your_time_func()` should return a single number. If it returns plain integers, you can also invoke the class constructor with a second argument specifying the real duration of one unit of time. For example, if `your_integer_time_func()` returns times measured in thousands of seconds, you would construct the `Profile` instance as follows:

```python
pr = profile.Profile(your_integer_time_func, 0.001)
```

As the `cProfile.Profile` class cannot be calibrated, custom timer functions should be used with care and should be as fast as possible. For the best results with a custom timer, it might be necessary to hard-code it in the C source of the internal `_lsprof` module.

Footnotes

[1] Updated and converted to LaTeX by Guido van Rossum.
[2] Further updated by Armin Rigo to integrate the documentation for the new `cProfile` module of Python 2.5.

Prior to Python 2.2, it was necessary to edit the profiler source code to embed the bias as a literal number. You still can, but that method is no longer described, because no longer needed.
25.5. **hotshot — High performance logging profiler**

*New in version 2.2.*

This module provides a nicer interface to the `_hotshot` C module. Hotshot is a replacement for the existing `profile` module. As it's written mostly in C, it should result in a much smaller performance impact than the existing `profile` module.

**Note:** The `hotshot` module focuses on minimizing the overhead while profiling, at the expense of long data post-processing times. For common usage it is recommended to use `cProfile` instead. `hotshot` is not maintained and might be removed from the standard library in the future.

*Changed in version 2.5:* The results should be more meaningful than in the past: the timing core contained a critical bug.

**Note:** The `hotshot` profiler does not yet work well with threads. It is useful to use an unthreaded script to run the profiler over the code you’re interested in measuring if at all possible.

```python
class hotshot.Profile(logfile[, lineevents[, linetimings]])
```

The profiler object. The argument `logfile` is the name of a log file to use for logged profile data. The argument `lineevents` specifies whether to generate events for every source line, or just on function call/return. It defaults to `0` (only log function call/return). The argument `linetimings` specifies whether to record timing information. It defaults to `1` (store timing information).
25.5.1. Profile Objects

Profile objects have the following methods:

Profile\texttt{.addinfo}(\textit{key, value})
Add an arbitrary labelled value to the profile output.

Profile\texttt{.close}()
Close the logfile and terminate the profiler.

Profile\texttt{.fileno}()
Return the file descriptor of the profiler's log file.

Profile\texttt{.run}(\textit{cmd})
Profile an \texttt{exec}-compatible string in the script environment. The globals from the \texttt{__main__} module are used as both the globals and locals for the script.

Profile\texttt{.runcall}(\textit{func, *args, **keywords})
Profile a single call of a callable. Additional positional and keyword arguments may be passed along; the result of the call is returned, and exceptions are allowed to propagate cleanly, while ensuring that profiling is disabled on the way out.

Profile\texttt{.runctx}(\textit{cmd, globals, locals})
Evaluate an \texttt{exec}-compatible string in a specific environment. The string is compiled before profiling begins.

Profile\texttt{.start}()
Start the profiler.

Profile\texttt{.stop}()
Stop the profiler.
25.5.2. Using hotshot data

New in version 2.2.

This module loads hotshot profiling data into the standard `pstats` Stats objects.

`hotshot.stats.load(filename)`

Load hotshot data from `filename`. Returns an instance of the `pstats.Stats` class.

See also:

**Module profile**

The `profile` module’s `stats` class
25.5.3. Example Usage

Note that this example runs the Python “benchmark” pystones. It can take some time to run, and will produce large output files.

```python
>>> import hotshot, hotshot.stats, test.pystone
>>> prof = hotshot.Profile("stones.prof")
>>> benchtime, stones = prof.runcall(test.pystone.pystones)
>>> prof.close()
>>> stats = hotshot.stats.load("stones.prof")
>>> stats.strip_dirs()
>>> stats.sort_stats('time', 'calls')
>>> stats.print_stats(20)

850004 function calls in 10.090 CPU seconds

Ordered by: internal time, call count

25.6. timeit — Measure execution time of small code snippets

New in version 2.3.

This module provides a simple way to time small bits of Python code. It has both command line as well as callable interfaces. It avoids a number of common traps for measuring execution times. See also Tim Peters’ introduction to the “Algorithms” chapter in the Python Cookbook, published by O’Reilly.

The module defines the following public class:

```python
class timeit.Timer([stmt='pass', setup='pass', timer=<timer function>])
```

Class for timing execution speed of small code snippets.

The constructor takes a statement to be timed, an additional statement used for setup, and a timer function. Both statements default to 'pass'; the timer function is platform-dependent (see the module doc string). `stmt` and `setup` may also contain multiple statements separated by ; or newlines, as long as they don’t contain multi-line string literals.

To measure the execution time of the first statement, use the `timeit()` method. The `repeat()` method is a convenience to call `timeit()` multiple times and return a list of results.

*Changed in version 2.6:* The `stmt` and `setup` parameters can now also take objects that are callable without arguments. This will embed calls to them in a timer function that will then be executed by `timeit()`. Note that the timing overhead is a little larger in this case because of the extra function calls.
Timer.\texttt{print}\_\texttt{exc}([\texttt{file=\texttt{None}}])

Helper to print a traceback from the timed code.

Typical use:

```python
import time

t = Timer(...)  # outside the try/except
try:
    t.timeit(...)  # or t.repeat(...)
except:
    t.print_exc()
```

The advantage over the standard traceback is that source lines in the compiled template will be displayed. The optional \texttt{file} argument directs where the traceback is sent; it defaults to \texttt{sys.stderr}.

Timer.\texttt{repeat}([\texttt{repeat=3[, number=100000]}])

Call \texttt{timeit()} a few times.

This is a convenience function that calls the \texttt{timeit()} repeatedly, returning a list of results. The first argument specifies how many times to call \texttt{timeit()}. The second argument specifies the \texttt{number} argument for \texttt{timeit()}.

\textbf{Note:} It's tempting to calculate mean and standard deviation from the result vector and report these. However, this is not very useful. In a typical case, the lowest value gives a lower bound for how fast your machine can run the given code snippet; higher values in the result vector are typically not caused by variability in Python's speed, but by other processes interfering with your timing accuracy. So the \texttt{min()} of the result is probably the only number you should be interested in. After that, you should look at the entire vector and apply common sense rather than statistics.
Timer.timeit([number=1000000])

Time number executions of the main statement. This executes the setup statement once, and then returns the time it takes to execute the main statement a number of times, measured in seconds as a float. The argument is the number of times through the loop, defaulting to one million. The main statement, the setup statement and the timer function to be used are passed to the constructor.

Note: By default, timeit() temporarily turns off garbage collection during the timing. The advantage of this approach is that it makes independent timings more comparable. This disadvantage is that GC may be an important component of the performance of the function being measured. If so, GC can be re-enabled as the first statement in the setup string. For example:

```python
timeit.Timer('for i in xrange(10): oct(i)', 'gc.enable()').timeit()
```

Starting with version 2.6, the module also defines two convenience functions:

```python
timeit.repeat(stmt[, setup[, timer[, repeat=3[, number=1000000]]]]))
```
Create a Timer instance with the given statement, setup code and timer function and run its repeat() method with the given repeat count and number executions.

New in version 2.6.

```python
timeit.timeit(stmt[, setup[, timer[, number=1000000]]])
```
Create a Timer instance with the given statement, setup code
and timer function and run its `timeit()` method with `number` executions.

*New in version 2.6.*
25.6.1. Command Line Interface

When called as a program from the command line, the following form is used:

```
python -m timeit [-n N] [-r N] [-s S] [-t] [-c] [-h] [statement ...]
```

where the following options are understood:

- **-n N**/ **--number=N**
  how many times to execute 'statement'

- **-r N**/ **--repeat=N**
  how many times to repeat the timer (default 3)

- **-s S**/ **--setup=S**
  statement to be executed once initially (default 'pass')

- **-t**/ **--time**
  use `time.time()` (default on all platforms but Windows)

- **-c**/ **--clock**
  use `time.clock()` (default on Windows)

- **-v**/ **--verbose**
  print raw timing results; repeat for more digits precision

- **-h**/ **--help**
  print a short usage message and exit

A multi-line statement may be given by specifying each line as a separate statement argument; indented lines are possible by enclosing an argument in quotes and using leading spaces. Multiple `-s` options are treated similarly.

If `-n` is not given, a suitable number of loops is calculated by trying successive powers of 10 until the total time is at least 0.2 seconds.
The default timer function is platform dependent. On Windows, 
\texttt{time.clock()} has microsecond granularity but \texttt{time.time()}'s 
granularity is 1/60th of a second; on Unix, \texttt{time.clock()} has 1/100th 
of a second granularity and \texttt{time.time()} is much more precise. On 
either platform, the default timer functions measure wall clock time, 
not the CPU time. This means that other processes running on the 
same computer may interfere with the timing. The best thing to do 
when accurate timing is necessary is to repeat the timing a few times 
and use the best time. The \texttt{-r} option is good for this; the default of 3 
repetitions is probably enough in most cases. On Unix, you can use 
\texttt{time.clock()} to measure CPU time.

\textbf{Note:} There is a certain baseline overhead associated with 
executing a pass statement. The code here doesn’t try to hide it, 
but you should be aware of it. The baseline overhead can be 
measured by invoking the program without arguments.

The baseline overhead differs between Python versions! Also, to 
fairly compare older Python versions to Python 2.3, you may want to 
use Python’s \texttt{-O} option for the older versions to avoid timing 
\texttt{SET\_LINENO} instructions.
25.6.2. Examples

Here are two example sessions (one using the command line, one using the module interface) that compare the cost of using `hasattr()` vs. `try/except` to test for missing and present object attributes.

```python
% timeit.py 'try:' '		str.__nonzero__'
except AttributeError:
		pass'
100000 loops, best of 3: 15.7 usec per loop

% timeit.py 'if hasattr(str, "__nonzero__"): pass'
100000 loops, best of 3: 4.26 usec per loop

% timeit.py 'try:' '		int.__nonzero__'
except AttributeError:
		pass'
100000 loop, best of 3: 1.43 usec per loop

% timeit.py 'if hasattr(int, "__nonzero__"): pass'
100000 loops, best of 3: 2.23 usec per loop
```

```python
>>> import timeit

>>> s = """
... try:
...     str.__nonzero__
... except AttributeError:
...     pass
... """

>>> t = timeit.Timer(stmt=s)

>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000))
17.09 usec/pass

>>> s = """
... if hasattr(str, '__nonzero__'): pass
... """

>>> t = timeit.Timer(stmt=s)

>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000))
4.85 usec/pass

>>> s = """
... try:
...     int.__nonzero__
... except AttributeError:
...     pass
... """

>>> t = timeit.Timer(stmt=s)

>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000))
1.97 usec/pass

>>> s = """
```
... if hasattr(int, '__nonzero__'): pass
... ""

>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000))
3.15 usec/pass

To give the timeit module access to functions you define, you can pass a setup parameter which contains an import statement:

```python
def test():
    "Stupid test function"
    L = []
    for i in range(100):
        L.append(i)

if __name__ =='__main__':
    from timeit import Timer
    t = Timer("test()", "from __main__ import test")
    print t.timeit()
```

The `trace` module allows you to trace program execution, generate annotated statement coverage listings, print caller/callee relationships and list functions executed during a program run. It can be used in another program or from the command line.
25.7.1. Command Line Usage

The `trace` module can be invoked from the command line. It can be as simple as

```
python -m trace --count somefile.py ...
```

The above will generate annotated listings of all Python modules imported during the execution of `somefile.py`.

The following command-line arguments are supported:

- `--trace`, `-t`
  Display lines as they are executed.

- `--count`, `-c`
  Produce a set of annotated listing files upon program completion that shows how many times each statement was executed.

- `--report`, `-r`
  Produce an annotated list from an earlier program run that used the `--count` and `--file` arguments.

- `--no-report`, `-R`
  Do not generate annotated listings. This is useful if you intend to make several runs with `--count` then produce a single set of annotated listings at the end.

- `--listfuncs`, `-l`
  List the functions executed by running the program.

- `--trackcalls`, `-T`
  Generate calling relationships exposed by running the program.

- `--file`, `-f`
  Name a file containing (or to contain) counts.

- `--coverdir`, `-C`
Name a directory in which to save annotated listing files.

--missing, -m
When generating annotated listings, mark lines which were not executed with ‘>>>>>>’.

--summary, -s
When using --count or --report, write a brief summary to stdout for each file processed.

--ignore-module
Accepts comma separated list of module names. Ignore each of the named module and its submodules (if it is a package). May be given multiple times.

--ignore-dir
Ignore all modules and packages in the named directory and subdirectories (multiple directories can be joined by os.pathsep). May be given multiple times.
25.7.2. Programming Interface

```python
class trace. Trace([count=1[, trace=1[, countfuncs=0[, countcallers=0[, ignoremods=0[, ignoredirs=0[, infile=None[, outfile=None[, timing=False]]]]]]]]])
```

Create an object to trace execution of a single statement or expression. All parameters are optional. `count` enables counting of line numbers. `trace` enables line execution tracing. `countfuncs` enables listing of the functions called during the run. `countcallers` enables call relationship tracking. `ignoremods` is a list of modules or packages to ignore. `ignoredirs` is a list of directories whose modules or packages should be ignored. `infile` is the file from which to read stored count information. `outfile` is a file in which to write updated count information. `timing` enables a timestamp relative to when tracing was started to be displayed.

```python
Trace.run(cmd)
```

Run `cmd` under control of the Trace object with the current tracing parameters.

```python
Trace.runctx(cmd[, globals=None[, locals=None]])
```

Run `cmd` under control of the Trace object with the current tracing parameters in the defined global and local environments. If not defined, `globals` and `locals` default to empty dictionaries.

```python
Trace.runfunc(func, *args, **kwds)
```

Call `func` with the given arguments under control of the Trace object with the current tracing parameters.

This is a simple example showing the use of this module:

```python
import sys
import trace
```
# create a Trace object, telling it what to ignore, and whether
# do tracing or line-counting or both.
tracer = trace.Trace(
    ignoredirs=[sys.prefix, sys.exec_prefix],
    trace=0,
    count=1)

# run the new command using the given tracer
tracer.run('main()')

# make a report, placing output in /tmp
r = tracer.results()
r.write_results(show_missing=True, coverdir="/tmp")
26. Python Runtime Services

The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here’s an overview:

- 26.1. `sys` — System-specific parameters and functions
- 26.2. `sysconfig` — Provide access to Python’s configuration information
  - 26.2.1. Configuration variables
  - 26.2.2. Installation paths
  - 26.2.3. Other functions
- 26.3. `__builtin__` — Built-in objects
- 26.4. `future_builtins` — Python 3 builtins
- 26.5. `__main__` — Top-level script environment
- 26.6. `warnings` — Warning control
  - 26.6.1. Warning Categories
  - 26.6.2. The Warnings Filter
  - 26.6.3. Temporarily Suppressing Warnings
  - 26.6.4. Testing Warnings
  - 26.6.5. Updating Code For New Versions of Python
  - 26.6.6. Available Functions
  - 26.6.7. Available Context Managers
- 26.7. `contextlib` — Utilities for with-statement contexts
- 26.8. `abc` — Abstract Base Classes
- 26.9. `atexit` — Exit handlers
  - 26.9.1. `atexit` Example
- 26.10. `traceback` — Print or retrieve a stack traceback
  - 26.10.1. Traceback Examples
- 26.11. `__future__` — Future statement definitions
- 26.12. `gc` — Garbage Collector interface
- 26.13. `inspect` — Inspect live objects
26.13.1. Types and members
26.13.2. Retrieving source code
26.13.3. Classes and functions
26.13.4. The interpreter stack
• 26.14. site — Site-specific configuration hook
• 26.15. user — User-specific configuration hook
• 26.16. distutils — Building and installing Python modules
26.1. sys — System-specific parameters and functions

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

**sys.argv**

The list of command line arguments passed to a Python script. `argv[0]` is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the `-c` command line option to the interpreter, `argv[0]` is set to the string `-c`. If no script name was passed to the Python interpreter, `argv[0]` is the empty string.

To loop over the standard input, or the list of files given on the command line, see the `fileinput` module.

**sys.byteorder**

An indicator of the native byte order. This will have the value 'big' on big-endian (most-significant byte first) platforms, and 'little' on little-endian (least-significant byte first) platforms.

*New in version 2.0.*

**sys.subversion**

A triple (repo, branch, version) representing the Subversion information of the Python interpreter. `repo` is the name of the repository, 'CPython'. `branch` is a string of one of the forms 'trunk', 'branches/name' or 'tags/name'. `version` is the output of `svnversion`, if the interpreter was built from a Subversion checkout; it contains the revision number (range) and possibly a trailing ‘M’ if there were local modifications. If the tree was
exported (or svnversion was not available), it is the revision of
`Include/patchlevel.h` if the branch is a tag. Otherwise, it is `None`.

*New in version 2.5.*

**sys.** `builtin_module_names`

A tuple of strings giving the names of all modules that are
compiled into this Python interpreter. (This information is not
available in any other way — `modules.keys()` only lists the
imported modules.)

**sys.** `copyright`

A string containing the copyright pertaining to the Python
interpreter.

**sys.** `__clear_type_cache()`

Clear the internal type cache. The type cache is used to speed
up attribute and method lookups. Use the function only to drop
unnecessary references during reference leak debugging.

This function should be used for internal and specialized
purposes only.

*New in version 2.6.*

**sys.** `__current_frames()`

Return a dictionary mapping each thread's identifier to the
topmost stack frame currently active in that thread at the time the
function is called. Note that functions in the `traceback` module
can build the call stack given such a frame.

This is most useful for debugging deadlock: this function does not
require the deadlocked threads’ cooperation, and such threads' call stacks are frozen for as long as they remain deadlocked. The frame returned for a non-deadlocked thread may bear no
relationship to that thread’s current activity by the time calling code examines the frame.

This function should be used for internal and specialized purposes only.

*New in version 2.5.*

**sys.dllhandle**

Integer specifying the handle of the Python DLL. Availability: Windows.

**sys.displayhook(value)**

If `value` is not `None`, this function prints it to `sys.stdout`, and saves it in `__builtin__.__displayhook__`.

`sys.displayhook` is called on the result of evaluating an *expression* entered in an interactive Python session. The display of these values can be customized by assigning another one-argument function to `sys.displayhook`.

**sys.excepthook(type, value, traceback)**

This function prints out a given traceback and exception to `sys.stderr`.

When an exception is raised and uncaught, the interpreter calls `sys.excepthook` with three arguments, the exception class, exception instance, and a traceback object. In an interactive session this happens just before control is returned to the prompt; in a Python program this happens just before the program exits. The handling of such top-level exceptions can be customized by assigning another three-argument function to `sys.excepthook`.

**sys.__displayhook__**

**sys.__excepthook__**
These objects contain the original values of `displayhook` and `excepthook` at the start of the program. They are saved so that `displayhook` and `excepthook` can be restored in case they happen to get replaced with broken objects.

```python
sys.exc_info()
```

This function returns a tuple of three values that give information about the exception that is currently being handled. The information returned is specific both to the current thread and to the current stack frame. If the current stack frame is not handling an exception, the information is taken from the calling stack frame, or its caller, and so on until a stack frame is found that is handling an exception. Here, “handling an exception” is defined as “executing or having executed an except clause.” For any stack frame, only information about the most recently handled exception is accessible.

If no exception is being handled anywhere on the stack, a tuple containing three `None` values is returned. Otherwise, the values returned are `(type, value, traceback)`. Their meaning is: `type` gets the exception type of the exception being handled (a class object); `value` gets the exception parameter (its associated value or the second argument to `raise`, which is always a class instance if the exception type is a class object); `traceback` gets a traceback object (see the Reference Manual) which encapsulates the call stack at the point where the exception originally occurred.

If `exc_clear()` is called, this function will return three `None` values until either another exception is raised in the current thread or the execution stack returns to a frame where another exception is being handled.

**Warning:** Assigning the `traceback` return value to a local variable in a function that is handling an exception will cause a
circular reference. This will prevent anything referenced by a local variable in the same function or by the traceback from being garbage collected. Since most functions don’t need access to the traceback, the best solution is to use something like `exctype, value = sys.exc_info()[2]` to extract only the exception type and value. If you do need the traceback, make sure to delete it after use (best done with a `try ... finally` statement) or to call `exc_info()` in a function that does not itself handle an exception.

**Note:** Beginning with Python 2.2, such cycles are automatically reclaimed when garbage collection is enabled and they become unreachable, but it remains more efficient to avoid creating cycles.

**sys.exc_clear()**

This function clears all information relating to the current or last exception that occurred in the current thread. After calling this function, `exc_info()` will return three `None` values until another exception is raised in the current thread or the execution stack returns to a frame where another exception is being handled.

This function is only needed in only a few obscure situations. These include logging and error handling systems that report information on the last or current exception. This function can also be used to try to free resources and trigger object finalization, though no guarantee is made as to what objects will be freed, if any.

*New in version 2.3.*

**sys.exc_type**  
**sys.exc_value**  
**sys.exc_traceback**
**Deprecated since version 1.5:** Use `exc_info()` instead.

Since they are global variables, they are not specific to the current thread, so their use is not safe in a multi-threaded program. When no exception is being handled, `exc_type` is set to `None` and the other two are undefined.

**sys.exec_prefix**

A string giving the site-specific directory prefix where the platform-dependent Python files are installed; by default, this is also `'/usr/local'`. This can be set at build time with the `--exec-prefix` argument to the `configure` script. Specifically, all configuration files (e.g. the `pyconfig.h` header file) are installed in the directory `exec_prefix + '/lib/pythonversion/config'`, and shared library modules are installed in `exec_prefix + '/lib/pythonversion/lib-dynload'`, where `version` is equal to `version[:3]`.

**sys.executable**

A string giving the name of the executable binary for the Python interpreter, on systems where this makes sense.

**sys.exit([arg])**

Exit from Python. This is implemented by raising the `SystemExit` exception, so cleanup actions specified by finally clauses of `try` statements are honored, and it is possible to intercept the exit attempt at an outer level. The optional argument `arg` can be an integer giving the exit status (defaulting to zero), or another type of object. If it is an integer, zero is considered “successful termination” and any nonzero value is considered “abnormal termination” by shells and the like. Most systems require it to be in the range 0-127, and produce undefined results otherwise. Some systems have a convention for assigning specific
meanings to specific exit codes, but these are generally underdeveloped; Unix programs generally use 2 for command line syntax errors and 1 for all other kind of errors. If another type of object is passed, `None` is equivalent to passing zero, and any other object is printed to `sys.stderr` and results in an exit code of 1. In particular, `sys.exit("some error message")` is a quick way to exit a program when an error occurs.

**sys.exitfunc**

This value is not actually defined by the module, but can be set by the user (or by a program) to specify a clean-up action at program exit. When set, it should be a parameterless function. This function will be called when the interpreter exits. Only one function may be installed in this way; to allow multiple functions which will be called at termination, use the `atexit` module.

**Note:** The exit function is not called when the program is killed by a signal, when a Python fatal internal error is detected, or when `os._exit()` is called.

*Deprecated since version 2.4: Use `atexit` instead.*

**sys.flags**

The struct sequence `flags` exposes the status of command line flags. The attributes are read only.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>
sys. **float_info**

A structseq holding information about the float type. It contains low level information about the precision and internal representation. The values correspond to the various floating-point constants defined in the standard header file `float.h` for the ‘C’ programming language; see section 5.2.4.2.2 of the 1999 ISO/IEC C standard [C99], ‘Characteristics of floating types’, for details.

</tbody>
</table>

The attribute `sys.float_info.dig` needs further explanation. If \( \text{s} \) is any string representing a decimal number with at most `sys.float_info.dig` significant digits, then converting \( \text{s} \) to a float and back again will recover a string representing the same decimal value:

```python
>>> import sys
>>> sys.float_info.dig
15
>>> s = '3.14159265358979'  # decimal string with 15 significant digits
>>> format(float(s), '.15g')  # convert to float and back -> '3.14159265358979'
```

But for strings with more than `sys.float_info.dig` significant digits, this isn't always true:

```python
>>> s = '9876543211234567'  # 16 significant digits is too many!
>>> format(float(s), '.16g')  # conversion changes value
```
New in version 2.6.

**sys. float repr style**
A string indicating how the `repr()` function behaves for floats. If the string has value 'short' then for a finite float \( x \), `repr(x)` aims to produce a short string with the property that `float(repr(x)) == x`. This is the usual behaviour in Python 2.7 and later. Otherwise, `float_repr_style` has value 'legacy' and `repr(x)` behaves in the same way as it did in versions of Python prior to 2.7.

New in version 2.7.

**sys. getcheckinterval()**
Return the interpreter's “check interval”; see `setcheckinterval()`.

New in version 2.3.

**sys. getdefaultencoding()**
Return the name of the current default string encoding used by the Unicode implementation.

New in version 2.0.

**sys. getdlopenflags()**
Return the current value of the flags that are used for `dlopen()` calls. The flag constants are defined in the `dl` and `DLFCN` modules. Availability: Unix.

New in version 2.2.

**sys. getfilesystemencoding()**
Return the name of the encoding used to convert Unicode
filenames into system file names, or `None` if the system default encoding is used. The result value depends on the operating system:

- On Mac OS X, the encoding is `'utf-8'`.
- On Unix, the encoding is the user’s preference according to the result of `nl_langinfo(CODESET)`, or `None` if the `nl_langinfo(CODESET)` failed.
- On Windows NT+, file names are Unicode natively, so no conversion is performed. `getfilesystemencoding()` still returns `'mbcs'`, as this is the encoding that applications should use when they explicitly want to convert Unicode strings to byte strings that are equivalent when used as file names.
- On Windows 9x, the encoding is `'mbcs'`.

*New in version 2.3.*

**sys. getrefcount**(object)

Return the reference count of the `object`. The count returned is generally one higher than you might expect, because it includes the (temporary) reference as an argument to `getrefcount()`.

**sys. getrecursionlimit()**

Return the current value of the recursion limit, the maximum depth of the Python interpreter stack. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python. It can be set by `setrecursionlimit()`.

**sys. getsizeof**(object[, default])

Return the size of an object in bytes. The object can be any type of object. All built-in objects will return correct results, but this does not have to hold true for third-party extensions as it is implementation specific.
If given, *default* will be returned if the object does not provide means to retrieve the size. Otherwise a *TypeError* will be raised.

`getsizeof()` calls the object’s `__sizeof__` method and adds an additional garbage collector overhead if the object is managed by the garbage collector.

*New in version 2.6.*

```python
def sys._getframe([depth])
    Return a frame object from the call stack. If optional integer `depth` is given, return the frame object that many calls below the top of the stack. If that is deeper than the call stack, *ValueError* is raised. The default for `depth` is zero, returning the frame at the top of the call stack.
```

**CPython implementation detail:** This function should be used for internal and specialized purposes only. It is not guaranteed to exist in all implementations of Python.

```python
def sys.getprofile()
    Get the profiler function as set by `setprofile()`.
```

*New in version 2.6.*

```python
def sys.gettrace()
    Get the trace function as set by `settrace()`.
```

**CPython implementation detail:** The `gettrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.
New in version 2.6.

```
sys.getwindowsversion()
```

Return a named tuple describing the Windows version currently running. The named elements are `major`, `minor`, `build`, `platform`, `service_pack`, `service_pack_minor`, `service_pack_major`, `suite_mask`, and `product_type`. `service_pack` contains a string while all other values are integers. The components can also be accessed by name, so `sys.getwindowsversion()[0]` is equivalent to `sys.getwindowsversion().major`. For compatibility with prior versions, only the first 5 elements are retrievable by indexing.

`platform` may be one of the following values:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Platform</th>
</tr>
</thead>
<tbody>
<tr>
<td>0 (VER_PLATFORM_WIN32s)</td>
<td>Win32s on Windows 3.1</td>
</tr>
<tr>
<td>1 (VER_PLATFORM_WIN32_WINDOWS)</td>
<td>Windows 95/98/ME</td>
</tr>
<tr>
<td>2 (VER_PLATFORM_WIN32_NT)</td>
<td>Windows NT/2000/XP/x64</td>
</tr>
<tr>
<td>3 (VER_PLATFORM_WIN32_CE)</td>
<td>Windows CE</td>
</tr>
</tbody>
</table>

`product_type` may be one of the following values:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 (VER_NT_WORKSTATION)</td>
<td>The system is a workstation.</td>
</tr>
<tr>
<td>2 (VER_NT_DOMAIN_CONTROLLER)</td>
<td>The system is a domain controller.</td>
</tr>
<tr>
<td>3 (VER_NT_SERVER)</td>
<td>The system is a server, but not a domain controller.</td>
</tr>
</tbody>
</table>

This function wraps the Win32 `GetVersionEx()` function; see the Microsoft documentation on `OSVERSIONINFOEX()` for more information about these fields.
Availability: Windows.

New in version 2.3.

Changed in version 2.7: Changed to a named tuple and added
`service_pack_minor`, `service_pack_major`, `suite_mask`, and
`product_type`.

**sys.hexversion**

The version number encoded as a single integer. This is
guaranteed to increase with each version, including proper
support for non-production releases. For example, to test that the
Python interpreter is at least version 1.5.2, use:

```python
if sys.hexversion >= 0x010502F0:
    # use some advanced feature
    ...
else:
    # use an alternative implementation or warn the user
    ...
```

This is called `hexversion` since it only really looks meaningful
when viewed as the result of passing it to the built-in `hex()`
function. The `version_info` value may be used for a more
human-friendly encoding of the same information.

New in version 1.5.2.

**sys.long_info**

A struct sequence that holds information about Python's internal
representation of integers. The attributes are read only.

<table>
<thead>
<tr>
<th>attribute</th>
<th>explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>bits_per_digit</code></td>
<td>number of bits held in each digit. Python integers are stored internally in base $2^{\text{long_info.bits_per_digit}}$</td>
</tr>
<tr>
<td><code>sizeof_digit</code></td>
<td>size in bytes of the C type used to</td>
</tr>
</tbody>
</table>
These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error. (Typical use is \texttt{import pdb; pdb.pm()} to enter the post-mortem debugger; see chapter \textit{pdb — The Python Debugger} for more information.)

The meaning of the variables is the same as that of the return values from \texttt{exc_info()} above. (Since there is only one interactive thread, thread-safety is not a concern for these variables, unlike for \texttt{exc_type} etc.)

\texttt{sys.maxint}

The largest positive integer supported by Python’s regular integer type. This is at least $2^{31}-1$. The largest negative integer is $-\text{maxint}-1$ — the asymmetry results from the use of 2's complement binary arithmetic.

\texttt{sys.maxsize}

The largest positive integer supported by the platform's \texttt{Py_ssize_t} type, and thus the maximum size lists, strings, dicts, and many other containers can have.

\texttt{sys.maxunicode}

An integer giving the largest supported code point for a Unicode character. The value of this depends on the configuration option that specifies whether Unicode characters are stored as UCS-2
or UCS-4.

**sys.meta_path**

A list of *finder* objects that have their `find_module()` methods called to see if one of the objects can find the module to be imported. The `find_module()` method is called at least with the absolute name of the module being imported. If the module to be imported is contained in package then the parent package’s `__path__` attribute is passed in as a second argument. The method returns `None` if the module cannot be found, else returns a *loader*.

**sys.meta_path** is searched before any implicit default finders or **sys.path**.

See [PEP 302](https://www.python.org/dev/peps/pep-0302/) for the original specification.

**sys.modules**

This is a dictionary that maps module names to modules which have already been loaded. This can be manipulated to force reloading of modules and other tricks. Note that removing a module from this dictionary is *not* the same as calling `reload()` on the corresponding module object.

**sys.path**

A list of strings that specifies the search path for modules. Initialized from the environment variable `PYTHONPATH`, plus an installation-dependent default.

As initialized upon program startup, the first item of this list, `path[0]`, is the directory containing the script that was used to invoke the Python interpreter. If the script directory is not available (e.g. if the interpreter is invoked interactively or if the script is read from standard input), `path[0]` is the empty string, which directs Python to search modules in the current directory
first. Notice that the script directory is inserted before the entries inserted as a result of PYTHONPATH.

A program is free to modify this list for its own purposes.

*Changed in version 2.3:* Unicode strings are no longer ignored.

**See also:** Module `site` This describes how to use .pth files to extend `sys.path`.

**sys.** `path_hooks`

A list of callables that take a path argument to try to create a *finder* for the path. If a finder can be created, it is to be returned by the callable, else raise `ImportError`.

Originally specified in PEP 302.

**sys.** `path_importer_cache`

A dictionary acting as a cache for *finder* objects. The keys are paths that have been passed to `sys.path_hooks` and the values are the finders that are found. If a path is a valid file system path but no explicit finder is found on `sys.path_hooks` then `None` is stored to represent the implicit default finder should be used. If the path is not an existing path then `imp.NullImporter` is set.

Originally specified in PEP 302.

**sys.** `platform`

This string contains a platform identifier that can be used to append platform-specific components to `sys.path`, for instance.

For Unix systems, this is the lowercased OS name as returned by `uname -s` with the first part of the version as returned by `uname -r` appended, e.g. 'sunos5' or 'linux2', *at the time when Python was built*. For other systems, the values are:
<table>
<thead>
<tr>
<th>System</th>
<th>platform value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Windows</td>
<td>'win32'</td>
</tr>
<tr>
<td>Windows/Cygwin</td>
<td>'cygwin'</td>
</tr>
<tr>
<td>Mac OS X</td>
<td>'darwin'</td>
</tr>
<tr>
<td>OS/2</td>
<td>'os2'</td>
</tr>
<tr>
<td>OS/2 EMX</td>
<td>'os2emx'</td>
</tr>
<tr>
<td>RiscOS</td>
<td>'riscos'</td>
</tr>
<tr>
<td>AtheOS</td>
<td>'atheos'</td>
</tr>
</tbody>
</table>

**sys.prefix**

A string giving the site-specific directory prefix where the platform independent Python files are installed; by default, this is the string '/usr/local'. This can be set at build time with the `--prefix` argument to the `configure` script. The main collection of Python library modules is installed in the directory `prefix + '/lib/pythonversion'` while the platform independent header files (all except `pyconfig.h`) are stored in `prefix + '/include/pythonversion'`, where `version` is equal to `version[:3]`.

**sys.ps1**

**sys.ps2**

Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are '>>> ' and '... '. If a non-string object is assigned to either variable, its `str()` is re-evaluated each time the interpreter prepares to read a new interactive command; this can be used to implement a dynamic prompt.

**sys.py3kwarning**

Bool containing the status of the Python 3.0 warning flag. It's `True` when Python is started with the -3 option. (This should be
considered read-only; setting it to a different value doesn’t have an effect on Python 3.0 warnings.)

*New in version 2.6.*

**sys.** `dont_write_bytecode`

If this is true, Python won’t try to write `.pyc` or `.pyo` files on the import of source modules. This value is initially set to `True` or `False` depending on the `-B` command line option and the `PYTHONDONTWRITEBYTECODE` environment variable, but you can set it yourself to control bytecode file generation.

*New in version 2.6.*

**sys.** `setcheckinterval(interval)`

Set the interpreter’s “check interval”. This integer value determines how often the interpreter checks for periodic things such as thread switches and signal handlers. The default is 100, meaning the check is performed every 100 Python virtual instructions. Setting it to a larger value may increase performance for programs using threads. Setting it to a value $\leq 0$ checks every virtual instruction, maximizing responsiveness as well as overhead.

**sys.** `setdefaultencoding(name)`

Set the current default string encoding used by the Unicode implementation. If `name` does not match any available encoding, `LookupError` is raised. This function is only intended to be used by the `site` module implementation and, where needed, by `sitecustomize`. Once used by the `site` module, it is removed from the `sys` module’s namespace.

*New in version 2.0.*
sys.\texttt{setdlopenflags}(n)

Set the flags used by the interpreter for \texttt{dlopen()} calls, such as when the interpreter loads extension modules. Among other things, this will enable a lazy resolving of symbols when importing a module, if called as \texttt{sys.setdlopenflags(0)}. To share symbols across extension modules, call as \texttt{sys.setdlopenflags(dl.RTLD_NOW | dl.RTLD_GLOBAL)}. Symbolic names for the flag modules can be either found in the \texttt{dl} module, or in the \texttt{DLFCN} module. If \texttt{DLFCN} is not available, it can be generated from \texttt{/usr/include/dlfcn.h} using the \texttt{h2py} script. Availability: Unix.

\textit{New in version 2.2.}

sys.\texttt{setprofile}(profilefunc)

Set the system's profile function, which allows you to implement a Python source code profiler in Python. See chapter \textit{The Python Profilers} for more information on the Python profiler. The system's profile function is called similarly to the system's trace function (see \texttt{settrace()}), but it isn't called for each executed line of code (only on call and return, but the return event is reported even when an exception has been set). The function is thread-specific, but there is no way for the profiler to know about context switches between threads, so it does not make sense to use this in the presence of multiple threads. Also, its return value is not used, so it can simply return \texttt{None}.

sys.\texttt{setrecursionlimit}(limit)

Set the maximum depth of the Python interpreter stack to \texttt{limit}. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python.

The highest possible limit is platform-dependent. A user may need to set the limit higher when she has a program that requires
deep recursion and a platform that supports a higher limit. This should be done with care, because a too-high limit can lead to a crash.

**sys.settrace(tracefunc)**

Set the system’s trace function, which allows you to implement a Python source code debugger in Python. The function is thread-specific; for a debugger to support multiple threads, it must be registered using `settrace()` for each thread being debugged.

Trace functions should have three arguments: `frame`, `event`, and `arg`. `frame` is the current stack frame. `event` is a string: `'call'`, `'line'`, `'return'`, `'exception'`, `'c_call'`, `'c_return'`, or `'c_exception'`. `arg` depends on the event type.

The trace function is invoked (with `event` set to `'call'`) whenever a new local scope is entered; it should return a reference to a local trace function to be used that scope, or `None` if the scope shouldn’t be traced.

The local trace function should return a reference to itself (or to another function for further tracing in that scope), or `None` to turn off tracing in that scope.

The events have the following meaning:

- `'call'`

  A function is called (or some other code block entered). The global trace function is called; `arg` is `None`; the return value specifies the local trace function.

- `'line'`

  The interpreter is about to execute a new line of code or re-execute the condition of a loop. The local trace function is called; `arg` is `None`; the return value specifies the new local
trace function. See objects/lnotab_notes.txt for a detailed explanation of how this works.

'return'

A function (or other code block) is about to return. The local trace function is called; arg is the value that will be returned. The trace function's return value is ignored.

'expection'

An exception has occurred. The local trace function is called; arg is a tuple (exception, value, traceback); the return value specifies the new local trace function.

'c_call'

A C function is about to be called. This may be an extension function or a built-in. arg is the C function object.

'c_return'

A C function has returned. arg is None.

'c_exception'

A C function has thrown an exception. arg is None.

Note that as an exception is propagated down the chain of callers, an 'exception' event is generated at each level.

For more information on code and frame objects, refer to The standard type hierarchy.

**CPython implementation detail:** The settrace() function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

sys.setsccdump(on_flag)
Activate dumping of VM measurements using the Pentium timestamp counter, if `on_flag` is true. Deactivate these dumps if `on_flag` is off. The function is available only if Python was compiled with `--with-tsc`. To understand the output of this dump, read `Python/ceval.c` in the Python sources.

*New in version 2.4.*

**CPython implementation detail:** This function is intimately bound to CPython implementation details and thus not likely to be implemented elsewhere.

```python
sys.stdin
sys.stdout
sys.stderr
```

File objects corresponding to the interpreter's standard input, output and error streams. `stdin` is used for all interpreter input except for scripts but including calls to `input()` and `raw_input()`. `stdout` is used for the output of `print` and `expression` statements and for the prompts of `input()` and `raw_input()`. The interpreter's own prompts and (almost all of) its error messages go to `stderr`. `stdout` and `stderr` needn't be built-in file objects: any object is acceptable as long as it has a `write()` method that takes a string argument. (Changing these objects doesn't affect the standard I/O streams of processes executed by `os.popen()`, `os.system()` or the `exec*()` family of functions in the `os` module.)

```python
sys.__stdin__
sys.__stdout__
sys.__stderr__
```

These objects contain the original values of `stdin`, `stderr` and `stdout` at the start of the program. They are used during finalization, and could be useful to print to the actual standard
stream no matter if the `sys.std*` object has been redirected.

It can also be used to restore the actual files to known working file objects in case they have been overwritten with a broken object. However, the preferred way to do this is to explicitly save the previous stream before replacing it, and restore the saved object.

**sys.tracebacklimit**

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is 1000. When set to 0 or less, all traceback information is suppressed and only the exception type and value are printed.

**sys.version**

A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. It has a value of the form `version (#build_number, build_date, build_time) [compiler]'`. The first three characters are used to identify the version in the installation directories (where appropriate on each platform). An example:

```python
>>> import sys
>>> sys.version
'1.5.2 (#0 Apr 13 1999, 10:51:12) [MSC 32 bit (Intel)]'
```

**sys.api_version**

The C API version for this interpreter. Always zero in IronPython. Provided for compatibility with CPython.

*New in version 2.3.*

**sys.version_info**

A tuple containing the five components of the version number: `major, minor, micro, releaselevel, and serial`. All values except
releaselevel are integers; the release level is 'alpha', 'beta', 'candidate', or 'final'. The version_info value corresponding to the Python version 2.0 is (2, 0, 0, 'final', 0). The components can also be accessed by name, so sys.version_info[0] is equivalent to sys.version_info.major and so on.

New in version 2.0.

Changed in version 2.7: Added named component attributes

sys.warnoptions
This is an implementation detail of the warnings framework; do not modify this value. Refer to the warnings module for more information on the warnings framework.

sys.winver
The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python DLL. The value is normally the first three characters of version. It is provided in the sys module for informational purposes; modifying this value has no effect on the registry keys used by Python. Availability: Windows.

26.2. sysconfig — Provide access to Python’s configuration information

*New in version 2.7.*

The `sysconfig` module provides access to Python's configuration information like the list of installation paths and the configuration variables relevant for the current platform.
26.2.1. Configuration variables

A Python distribution contains a `Makefile` and a `pyconfig.h` header file that are necessary to build both the Python binary itself and third-party C extensions compiled using `distutils`.

`sysconfig` puts all variables found in these files in a dictionary that can be accessed using `get_config_vars()` or `get_config_var()`.

Notice that on Windows, it's a much smaller set.

```python
sysconfig.get_config_vars(*args)
```

With no arguments, return a dictionary of all configuration variables relevant for the current platform.

With arguments, return a list of values that result from looking up each argument in the configuration variable dictionary.

For each argument, if the value is not found, return `None`.

```python
sysconfig.get_config_var(name)
```

Return the value of a single variable `name`. Equivalent to `get_config_vars().get(name)`.

If `name` is not found, return `None`.

Example of usage:

```python
>>> import sysconfig
>>> sysconfig.get_config_var('Py_ENABLE_SHARED')
0
>>> sysconfig.get_config_var('LIBDIR')
'/usr/local/lib'
>>> sysconfig.get_config_vars('AR', 'CXX')
['ar', 'g++']
```
26.2.2. Installation paths

Python uses an installation scheme that differs depending on the platform and on the installation options. These schemes are stored in `sysconfig` under unique identifiers based on the value returned by `os.name`.

Every new component that is installed using `distutils` or a Distutils-based system will follow the same scheme to copy its file in the right places.

Python currently supports seven schemes:

- `posix_prefix`: scheme for Posix platforms like Linux or Mac OS X. This is the default scheme used when Python or a component is installed.
- `posix_home`: scheme for Posix platforms used when a `home` option is used upon installation. This scheme is used when a component is installed through Distutils with a specific home prefix.
- `posix_user`: scheme for Posix platforms used when a component is installed through Distutils and the `user` option is used. This scheme defines paths located under the user home directory.
- `nt`: scheme for NT platforms like Windows.
- `nt_user`: scheme for NT platforms, when the `user` option is used.
- `os2`: scheme for OS/2 platforms.
- `os2_home`: scheme for OS/2 platforms, when the `user` option is used.

Each scheme is itself composed of a series of paths and each path has a unique identifier. Python currently uses eight paths:

- `stdlib`: directory containing the standard Python library files that
are not platform-specific.

- **platstdlib**: directory containing the standard Python library files that are platform-specific.
- **platlib**: directory for site-specific, platform-specific files.
- **purelib**: directory for site-specific, non-platform-specific files.
- **include**: directory for non-platform-specific header files.
- **platininclude**: directory for platform-specific header files.
- **scripts**: directory for script files.
- **data**: directory for data files.

**sysconfig** provides some functions to determine these paths.

**sysconfig.get_scheme_names()**

Return a tuple containing all schemes currently supported in **sysconfig**.

**sysconfig.get_path_names()**

Return a tuple containing all path names currently supported in **sysconfig**.

**sysconfig.get_path(name[, scheme[, vars[, expand]]])**

Return an installation path corresponding to the path name, from the install scheme named scheme.

name has to be a value from the list returned by **get_path_names()**.

**sysconfig** stores installation paths corresponding to each path name, for each platform, with variables to be expanded. For instance the stdlib path for the nt scheme is: {base}/Lib.

**get_path()** will use the variables returned by **get_config_vars()** to expand the path. All variables have default values for each platform so one may call this function and get the default value.
If `scheme` is provided, it must be a value from the list returned by `get_path_names()`. Otherwise, the default scheme for the current platform is used.

If `vars` is provided, it must be a dictionary of variables that will update the dictionary return by `get_config_vars()`.

If `expand` is set to `False`, the path will not be expanded using the variables.

If `name` is not found, return `None`.

```python
sysconfig.get_paths([scheme, vars, expand])
```

Return a dictionary containing all installation paths corresponding to an installation scheme. See `get_path()` for more information.

If `scheme` is not provided, will use the default scheme for the current platform.

If `vars` is provided, it must be a dictionary of variables that will update the dictionary used to expand the paths.

If `expand` is set to `False`, the paths will not be expanded.

If `scheme` is not an existing scheme, `get_paths()` will raise a `KeyError`.
26.2.3. Other functions

sysconfig.get_python_version()

Return the MAJOR.MINOR Python version number as a string. Similar to sys.version[:3].

sysconfig.get_platform()

Return a string that identifies the current platform.

This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by os.uname()), although the exact information included depends on the OS; e.g. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn’t particularly important.

Examples of returned values:

- linux-i586
- linux-alpha (?)
- solaris-2.6-sun4u
- irix-5.3
- irix64-6.2

Windows will return one of:

- win-amd64 (64bit Windows on AMD64 (aka x86_64, Intel64, EM64T, etc)
- win-ia64 (64bit Windows on Itanium)
- win32 (all others - specifically, sys.platform is returned)

Mac OS X can return:

- macosx-10.6-ppc
• macOSx-10.4-ppc64
• macOSx-10.3-i386
• macOSx-10.4-fat

For other non-POSIX platforms, currently just returns `sys.platform`.

`sysconfig.is_python_build()`  
Return `True` if the current Python installation was built from source.

`sysconfig.parse_config_h(fp[, vars])`  
Parse a `config.h`-style file.

`fp` is a file-like object pointing to the `config.h`-like file.

A dictionary containing name/value pairs is returned. If an optional dictionary is passed in as the second argument, it is used instead of a new dictionary, and updated with the values read in the file.

`sysconfig.get_config_h_filename()`  
Return the path of `pyconfig.h`.
26.3. __builtin__ — Built-in objects

This module provides direct access to all ‘built-in’ identifiers of Python; for example, __builtin__.open is the full name for the built-in function open().

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an open() function that wraps the built-in open(), this module can be used directly:

```python
import __builtin__

def open(path):
    f = __builtin__.open(path, 'r')
    return UpperCaser(f)

class UpperCaser:
    '''Wrapper around a file that converts output to upper-case.'''

    def __init__(self, f):
        self._f = f

    def read(self, count=-1):
        return self._f.read(count).upper()

# ...
```

**CPython implementation detail:** Most modules have the name __builtins__ (note the 's') made available as part of their globals. The value of __builtins__ is normally either this module or the value of this module's __dict__ attribute. Since this is an implementation detail, it may not be used by alternate implementations of Python.
26.4. future_builtins — Python 3 builtins

New in version 2.6.

This module provides functions that exist in 2.x, but have different behavior in Python 3, so they cannot be put into the 2.x builtins namespace.

Instead, if you want to write code compatible with Python 3 builtins, import them from this module, like this:

```python
from future_builtins import map, filter
...
```

The 2to3 tool that ports Python 2 code to Python 3 will recognize this usage and leave the new builtins alone.

**Note:** The Python 3 `print()` function is already in the builtins, but cannot be accessed from Python 2 code unless you use the appropriate future statement:

```python
from __future__ import print_function
```

Available builtins are:

- `future_builtins.ascii(object)`
  - Returns the same as `repr()`. In Python 3, `repr()` will return printable Unicode characters unescaped, while `ascii()` will always backslash-escape them. Using `future_builtins.ascii()` instead of `repr()` in 2.6 code makes it clear that you need a pure ASCII return value.
future_builtins. **filter**(function, iterable)
   Works like *itertools.ifilter*().

future_builtins. **hex**(object)
   Works like the built-in hex(), but instead of **__hex__()** it will use the **__index__()** method on its argument to get an integer that is then converted to hexadecimal.

future_builtins. **map**(function, iterable, ...)
   Works like *itertools.imap*().

future_builtins. **oct**(object)
   Works like the built-in oct(), but instead of **__oct__()** it will use the **__index__()** method on its argument to get an integer that is then converted to octal.

future_builtins. **zip**(\*iterables)
   Works like *itertools.izip*().
This module represents the (otherwise anonymous) scope in which the interpreter’s main program executes — commands read either from standard input, from a script file, or from an interactive prompt. It is this environment in which the idiomatic “conditional script” stanza causes a script to run:

```python
if __name__ == "__main__":
    main()
```
26.6. warnings — Warning control

New in version 2.1.

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn’t warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module.

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the warning category (see below), the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the warning filter, which is a sequence of matching rules and actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`, which may be overridden; the default implementation of this function formats the message by calling `formatwarning()`, which is also
available for use by custom implementations.
26.6.1. Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings. The following warnings category classes are currently defined:

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Warning</td>
<td>This is the base class of all warning category classes. It is a subclass of Exception.</td>
</tr>
<tr>
<td>UserWarning</td>
<td>The default category for warn().</td>
</tr>
<tr>
<td>DeprecationWarning</td>
<td>Base category for warnings about deprecated features (ignored by default).</td>
</tr>
<tr>
<td>SyntaxWarning</td>
<td>Base category for warnings about dubious syntactic features.</td>
</tr>
<tr>
<td>RuntimeWarning</td>
<td>Base category for warnings about dubious runtime features.</td>
</tr>
<tr>
<td>FutureWarning</td>
<td>Base category for warnings about constructs that will changesemantically in the future.</td>
</tr>
<tr>
<td>PendingDeprecationWarning</td>
<td>Base category for warnings about features that will be deprecated in the future (ignored by default).</td>
</tr>
<tr>
<td>ImportWarning</td>
<td>Base category for warnings triggered during the process of importing a module (ignored by default).</td>
</tr>
<tr>
<td>UnicodeWarning</td>
<td>Base category for warnings related to Unicode.</td>
</tr>
</tbody>
</table>

While these are technically built-in exceptions, they are documented here, because conceptually they belong to the warnings mechanism.
User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the `Warning` class.

*Changed in version 2.7:* `DeprecationWarning` is ignored by default.
26.6.2. The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the match determines the disposition of the match. Each entry is a tuple of the form (action, message, category, module, lineno), where:

- action is one of the following strings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Disposition</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;error&quot;</td>
<td>turn matching warnings into exceptions</td>
</tr>
<tr>
<td>&quot;ignore&quot;</td>
<td>never print matching warnings</td>
</tr>
<tr>
<td>&quot;always&quot;</td>
<td>always print matching warnings</td>
</tr>
<tr>
<td>&quot;default&quot;</td>
<td>print the first occurrence of matching warnings for each location where the warning is issued</td>
</tr>
<tr>
<td>&quot;module&quot;</td>
<td>print the first occurrence of matching warnings for each module where the warning is issued</td>
</tr>
<tr>
<td>&quot;once&quot;</td>
<td>print only the first occurrence of matching warnings, regardless of location</td>
</tr>
</tbody>
</table>

- message is a string containing a regular expression that the warning message must match (the match is compiled to always be case-insensitive).
- **category** is a class (a subclass of **Warning**) of which the warning category must be a subclass in order to match.

- **module** is a string containing a regular expression that the module name must match (the match is compiled to be case-sensitive).

- **lineno** is an integer that the line number where the warning occurred must match, or 0 to match all line numbers.

Since the **Warning** class is derived from the built-in **Exception** class, to turn a warning into an error we simply raise `category(message)`.

The warnings filter is initialized by `-W` options passed to the Python interpreter command line. The interpreter saves the arguments for all `-W` options without interpretation in `sys.warnoptions`; the **warnings** module parses these when it is first imported (invalid options are ignored, after printing a message to `sys.stderr`).
26.6.3. Temporarily Suppressing Warnings

If you are using code that you know will raise a warning, such as a deprecated function, but do not want to see the warning, then it is possible to suppress the warning using the `catch_warnings` context manager:

```python
import warnings
def fxn():
    warnings.warn("deprecated", DeprecationWarning)
with warnings.catch_warnings():
    warnings.simplefilter("ignore")
    fxn()
```

While within the context manager all warnings will simply be ignored. This allows you to use known-deprecated code without having to see the warning while not suppressing the warning for other code that might not be aware of its use of deprecated code. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.
26.6.4. Testing Warnings

To test warnings raised by code, use the \texttt{catchWarnings} context manager. With it you can temporarily mutate the warnings filter to facilitate your testing. For instance, do the following to capture all raised warnings to check:

\begin{verbatim}
import warnings
def fxn():
    warnings.warn("deprecated", DeprecationWarning)
with warnings.catch_warnings(record=True) as w:
    # Cause all warnings to always be triggered.
    warnings.simplefilter("always")
    # Trigger a warning.
    fxn()
    # Verify some things
    assert len(w) == 1
    assert issubclass(w[-1].category, DeprecationWarning)
    assert "deprecated" in str(w[-1].message)
\end{verbatim}

One can also cause all warnings to be exceptions by using \texttt{error} instead of \texttt{always}. One thing to be aware of is that if a warning has already been raised because of a \texttt{once/default} rule, then no matter what filters are set the warning will not be seen again unless the warnings registry related to the warning has been cleared.

Once the context manager exits, the warnings filter is restored to its state when the context was entered. This prevents tests from changing the warnings filter in unexpected ways between tests and leading to indeterminate test results. The \texttt{showwarning()} function in the module is also restored to its original value. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the \texttt{catchWarnings} context manager at the same time, the behavior is undefined.
When testing multiple operations that raise the same kind of warning, it is important to test them in a manner that confirms each operation is raising a new warning (e.g. set warnings to be raised as exceptions and check the operations raise exceptions, check that the length of the warning list continues to increase after each operation, or else delete the previous entries from the warnings list before each new operation).
26.6.5. Updating Code For New Versions of Python

Warnings that are only of interest to the developer are ignored by default. As such you should make sure to test your code with typically ignored warnings made visible. You can do this from the command-line by passing `-Wd` to the interpreter (this is shorthand for `-W default`). This enables default handling for all warnings, including those that are ignored by default. To change what action is taken for encountered warnings you simply change what argument is passed to `-W`, e.g. `-W error`. See the `-W` flag for more details on what is possible.

To programmatically do the same as `-Wd`, use:

```python
warnings.simplefilter('default')
```

Make sure to execute this code as soon as possible. This prevents the registering of what warnings have been raised from unexpectedly influencing how future warnings are treated.

Having certain warnings ignored by default is done to prevent a user from seeing warnings that are only of interest to the developer. As you do not necessarily have control over what interpreter a user uses to run their code, it is possible that a new version of Python will be released between your release cycles. The new interpreter release could trigger new warnings in your code that were not there in an older interpreter, e.g. `DeprecationWarning` for a module that you are using. While you as a developer want to be notified that your code is using a deprecated module, to a user this information is essentially noise and provides no benefit to them.
26.6.6. Available Functions

```
warnings.warn(message[, category[, stacklevel]])

Issue a warning, or maybe ignore it or raise an exception. The category argument, if given, must be a warning category class (see above); it defaults to UserWarning. Alternatively message can be a Warning instance, in which case category will be ignored and message.__class__ will be used. In this case the message text will be str(message). This function raises an exception if the particular warning issued is changed into an error by the warnings filter see above. The stacklevel argument can be used by wrapper functions written in Python, like this:

```
def deprecation(message):
    warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to deprecation()'s caller, rather than to the source of deprecation() itself (since the latter would defeat the purpose of the warning message).

```
warnings.warn_explicit(message, category, filename, lineno[, module[, registry[, module_globals]]])
```

This is a low-level interface to the functionality of warn(), passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the __warningregistry__ dictionary of the module). The module name defaults to the filename with .py stripped; if no registry is passed, the warning is never suppressed. message must be a string and category a subclass of Warning or message may be a Warning instance, in which case category will be ignored.
module_globals, if supplied, should be the global namespace in use by the code for which the warning is issued. (This argument is used to support displaying source for modules found in zipfiles or other non-filesystem import sources).

*Changed in version 2.5:* Added the module_globals parameter.

```
warnings.warnpy3k(message[, category[, stacklevel]])
```

Issue a warning related to Python 3.x deprecation. Warnings are only shown when Python is started with the -3 option. Like `warn()` `message` must be a string and `category` a subclass of `Warning`. `warnpy3k()` is using `DeprecationWarning` as default warning class.

*New in version 2.6.*

```
warnings.showwarning(message, category, filename, lineno[, file[, line]])
```

Write a warning to a file. The default implementation calls `formatwarning(message, category, filename, lineno, line)` and writes the resulting string to `file`, which defaults to `sys.stderr`. You may replace this function with an alternative implementation by assigning to `warnings.showwarning`. `line` is a line of source code to be included in the warning message; if `line` is not supplied, `showwarning()` will try to read the line specified by `filename` and `lineno`.

*Changed in version 2.7:* The `line` argument is required to be supported.

```
warnings.formatwarning(message, category, filename, lineno[, line])
```

Format a warning the standard way. This returns a string which may contain embedded newlines and ends in a newline. `line` is a
line of source code to be included in the warning message; if line is not supplied, `formatwarning()` will try to read the line specified by `filename` and `lineno`.

*Changed in version 2.6:* Added the `line` argument.

```python
warnings.filterwarnings(action[, message[, category[, module[, lineno[, append]]]]])
```
Insert an entry into the list of *warnings filter specifications*. The entry is inserted at the front by default; if `append` is true, it is inserted at the end. This checks the types of the arguments, compiles the `message` and `module` regular expressions, and inserts them as a tuple in the list of warnings filters. Entries closer to the front of the list override entries later in the list, if both match a particular warning. Omitted arguments default to a value that matches everything.

```python
warnings.simplefilter(action[, category[, lineno[, append]]])
```
Insert a simple entry into the list of *warnings filter specifications*. The meaning of the function parameters is as for `filterwarnings()`, but regular expressions are not needed as the filter inserted always matches any message in any module as long as the category and line number match.

```python
warnings.resetwarnings()
```
Reset the warnings filter. This discards the effect of all previous calls to `filterwarnings()`, including that of the `-W` command line options and calls to `simplefilter()`. 
26.6.7. Available Context Managers

```python
class warnings.catch_warnings([*, record=False, module=None])
```

A context manager that copies and, upon exit, restores the warnings filter and the `showwarning()` function. If the `record` argument is `False` (the default) the context manager returns `None` on entry. If `record` is `True`, a list is returned that is progressively populated with objects as seen by a custom `showwarning()` function (which also suppresses output to `sys.stdout`). Each object in the list has attributes with the same names as the arguments to `showwarning()`.

The `module` argument takes a module that will be used instead of the module returned when you import `warnings` whose filter will be protected. This argument exists primarily for testing the `warnings` module itself.

**Note:** The `catch_warnings` manager works by replacing and then later restoring the module’s `showwarning()` function and internal list of filter specifications. This means the context manager is modifying global state and therefore is not thread-safe.

**Note:** In Python 3.0, the arguments to the constructor for `catch_warnings` are keyword-only arguments.

*New in version 2.6.*
26.7. `contextlib` — Utilities for `with`-statement contexts

*New in version 2.5.*

This module provides utilities for common tasks involving the `with` statement. For more information see also *Context Manager Types* and *With Statement Context Managers*.

Functions provided:

```python
contextlib.contextmanager(func)
```

This function is a *decorator* that can be used to define a factory function for `with` statement context managers, without needing to create a class or separate `__enter__()` and `__exit__()` methods.

A simple example (this is not recommended as a real way of generating HTML!):

```python
from contextlib import contextmanager

class contextmanager:
    @contextmanager
    def tag(name):
        print '<%s>' % name
        yield
        print '</%s>' % name

>>> with tag("h1"): ...
    print "foo"
...
<h1>
foo
</h1>
```

The function being decorated must return a *generator*-iterator when called. This iterator must yield exactly one value, which will be bound to the targets in the `with` statement's `as` clause, if any.
At the point where the generator yields, the block nested in the `with` statement is executed. The generator is then resumed after the block is exited. If an unhandled exception occurs in the block, it is reraised inside the generator at the point where the yield occurred. Thus, you can use a `try...except...finally` statement to trap the error (if any), or ensure that some cleanup takes place. If an exception is trapped merely in order to log it or to perform some action (rather than to suppress it entirely), the generator must reraise that exception. Otherwise the generator context manager will indicate to the `with` statement that the exception has been handled, and execution will resume with the statement immediately following the `with` statement.

```python
from contextlib import nested

with nested(*managers):
    do_something()
```

Note that if the `__exit__()` method of one of the nested context managers indicates an exception should be suppressed, no exception information will be passed to any remaining outer context managers. Similarly, if the `__exit__()` method of one of the nested managers raises an exception, any previous exception state will be lost; the new exception will be passed to
the **exit**() methods of any remaining outer context managers. In general, **exit**() methods should avoid raising exceptions, and in particular they should not re-raise a passed-in exception.

This function has two major quirks that have led to it being deprecated. Firstly, as the context managers are all constructed before the function is invoked, the **new**() and **init**() methods of the inner context managers are not actually covered by the scope of the outer context managers. That means, for example, that using **nested()** to open two files is a programming error as the first file will not be closed promptly if an exception is thrown when opening the second file.

Secondly, if the **enter**() method of one of the inner context managers raises an exception that is caught and suppressed by the **exit**() method of one of the outer context managers, this construct will raise **RuntimeError** rather than skipping the body of the **with** statement.

Developers that need to support nesting of a variable number of context managers can either use the **warnings** module to suppress the DeprecationWarning raised by this function or else use this function as a model for an application specific implementation.

**Deprecated since version 2.7:** The with-statement now supports this functionality directly (without the confusing error prone quirks).

```python
contextlib.closing(thing)
```

Return a context manager that closes `thing` upon completion of the block. This is basically equivalent to:
from contextlib import contextmanager

@contextmanager
def closing(thing):
    try:
        yield thing
    finally:
        thing.close()

And lets you write code like this:

```python
from contextlib import closing
import urllib

with closing(urllib.urlopen('http://www.python.org')) as page:
    for line in page:
        print line
```

without needing to explicitly close `page`. Even if an error occurs, `page.close()` will be called when the `with` block is exited.

The specification, background, and examples for the Python `with` statement.
26.8. abc — Abstract Base Classes

New in version 2.6.

This module provides the infrastructure for defining an abstract base class (ABCs) in Python, as outlined in PEP 3119; see the PEP for why this was added to Python. (See also PEP 3141 and the numbers module regarding a type hierarchy for numbers based on ABCs.)

The collections module has some concrete classes that derive from ABCs; these can, of course, be further derived. In addition the collections module has some ABCs that can be used to test whether a class or instance provides a particular interface, for example, is it hashable or a mapping.

This module provides the following class:

class abc. ABCMeta
    Metaclass for defining Abstract Base Classes (ABCs).

    Use this metaclass to create an ABC. An ABC can be subclassed directly, and then acts as a mix-in class. You can also register unrelated concrete classes (even built-in classes) and unrelated ABCs as “virtual subclasses” – these and their descendants will be considered subclasses of the registering ABC by the built-in issubclass() function, but the registering ABC won’t show up in their MRO (Method Resolution Order) nor will method implementations defined by the registering ABC be callable (not even via super()). [1]

    Classes created with a metaclass of ABCMeta have the following method:

    register(subclass)
Register *subclass* as a “virtual subclass” of this ABC. For example:

```python
from abc import ABCMeta

class MyABC:
    __metaclass__ = ABCMeta

MyABC.register(tuple)

assert issubclass(tuple, MyABC)
assert isinstance((), MyABC)
```

You can also override this method in an abstract base class:

```python
__subclasshook__(subclass)
```

(Must be defined as a class method.)

Check whether *subclass* is considered a subclass of this ABC. This means that you can customize the behavior of `issubclass` further without the need to call `register()` on every class you want to consider a subclass of the ABC. (This class method is called from the `__subclasscheck__()` method of the ABC.)

This method should return `True`, `False` or `NotImplemented`. If it returns `True`, the *subclass* is considered a subclass of this ABC. If it returns `False`, the *subclass* is not considered a subclass of this ABC, even if it would normally be one. If it returns `NotImplemented`, the subclass check is continued with the usual mechanism.

For a demonstration of these concepts, look at this example ABC definition:

```python
class Foo(object):
    def __getitem__(self, index):
        ...
```
def __len__(self):
    ...
def get_iterator(self):
    return iter(self)

class MyIterable:
    __metaclass__ = ABCMeta

    @abstractmethod
def __iter__(self):
        while False:
            yield None

def get_iterator(self):
    return self.__iter__()

    @classmethod
def __subclasshook__(cls, C):
        if cls is MyIterable:
            if any("__iter__" in B.__dict__ for B in C.__mro__):
                return True
            return NotImplemented

MyIterable.register(Foo)

The ABC **MyIterable** defines the standard iterable method, __iter__(), as an abstract method. The implementation given here can still be called from subclasses. The get_iterator() method is also part of the MyIterable abstract base class, but it does not have to be overridden in non-abstract derived classes.

The __subclasshook__() class method defined here says that any class that has an __iter__() method in its __dict__ (or in that of one of its base classes, accessed via the __mro__ list) is considered a MyIterable too.

Finally, the last line makes Foo a virtual subclass of MyIterable, even though it does not define an __iter__() method (it uses the old-style iterable protocol, defined in terms of __len__() and
__getitem__()). Note that this will not make get_iterator available as a method of Foo, so it is provided separately.

It also provides the following decorators:

abc.abstractmethod(function)

A decorator indicating abstract methods.

Using this decorator requires that the class’s metaclass is ABCMeta or is derived from it. A class that has a metaclass derived from ABCMeta cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract methods can be called using any of the normal ‘super’ call mechanisms.

Dynamically adding abstract methods to a class, or attempting to modify the abstraction status of a method or class once it is created, are not supported. The abstractmethod() only affects subclasses derived using regular inheritance; “virtual subclasses” registered with the ABC’s register() method are not affected.

Usage:

class C:
    __metaclass__ = ABCMeta
    @abstractmethod
    def my_abstract_method(self, ...):
        ...

Note: Unlike Java abstract methods, these abstract methods may have an implementation. This implementation can be called via the super() mechanism from the class that overrides it. This could be useful as an end-point for a super-call in a framework that uses cooperative multiple-inheritance.

abc.abstractproperty([fget[, fset[, fdel[, doc]]]]))
A subclass of the built-in `property()`, indicating an abstract property.

Using this function requires that the class’s metaclass is `ABCMeta` or is derived from it. A class that has a metaclass derived from `ABCMeta` cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract properties can be called using any of the normal ‘super’ call mechanisms.

Usage:

```python
class C:
    __metaclass__ = ABCMeta
    @abstractproperty
    def my_abstract_property(self):
        ...
```

This defines a read-only property; you can also define a read-write abstract property using the ‘long’ form of property declaration:

```python
class C:
    __metaclass__ = ABCMeta
    def getx(self): ...
    def setx(self, value): ...
    x = abstractproperty(getx, setx)
```

Footnotes

[1] C++ programmers should note that Python’s virtual base class concept is not the same as C++’s.
26.9. atexit — Exit handlers

New in version 2.0.

The atexit module defines a single function to register cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination.

Note: the functions registered via this module are not called when the program is killed by a signal, when a Python fatal internal error is detected, or when os._exit() is called.

This is an alternate interface to the functionality provided by the sys.exitfunc variable.

Note: This module is unlikely to work correctly when used with other code that sets sys.exitfunc. In particular, other core Python modules are free to use atexit without the programmer’s knowledge. Authors who use sys.exitfunc should convert their code to use atexit instead. The simplest way to convert code that sets sys.exitfunc is to import atexit and register the function that had been bound to sys.exitfunc.

atexit.register(func[, *args[, **kargs]])

Register func as a function to be executed at termination. Any optional arguments that are to be passed to func must be passed as arguments to register().

At normal program termination (for instance, if sys.exit() is called or the main module’s execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.
If an exception is raised during execution of the exit handlers, a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run the last exception to be raised is re-raised.

*Changed in version 2.6:* This function now returns `func` which makes it possible to use it as a decorator without binding the original name to `None`.

**See also:**

**Module `readline`**

Useful example of `atexit` to read and write `readline` history files.
26.9.1. atexit Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter's updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```python
try:
    _count = int(open("/tmp/counter").read())
except IOError:
    _count = 0

def incrcounter(n):
    global _count
    _count = _count + n

def savecounter():
    open("/tmp/counter", "w").write("%d" % _count)

import atexit
atexit.register(savecounter)
```

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

```python
def goodbye(name, adjective):
    print 'Goodbye, %s, it was %s to meet you.' % (name, adjective)

import atexit
atexit.register(goodbye, 'Donny', 'nice')

# or:
atexit.register(goodbye, adjective='nice', name='Donny')
```

Usage as a `decorator`:
import atexit

@atexit.register
def goodbye():
    print "You are now leaving the Python sector."

This obviously only works with functions that don’t take arguments.
26.10. traceback — Print or retrieve a stack traceback

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a “wrapper” around the interpreter.

The module uses traceback objects — this is the object type that is stored in the variables `sys.exc_traceback` (deprecated) and `sys.last_traceback` and returned as the third item from `sys.exc_info()`.

The module defines the following functions:

```
traceback.print_tb(traceback[, limit[, file]])
```

Print up to `limit` stack trace entries from `traceback`. If `limit` is omitted or `None`, all entries are printed. If `file` is omitted or `None`, the output goes to `sys.stderr`; otherwise it should be an open file or file-like object to receive the output.

```
traceback.print_exception(type, value, traceback[, limit[, file]])
```

Print exception information and up to `limit` stack trace entries from `traceback` to `file`. This differs from `print_tb()` in the following ways: (1) if `traceback` is not `None`, it prints a header `Traceback (most recent call last)`:; (2) it prints the exception `type` and `value` after the stack trace; (3) if `type` is `SyntaxError` and `value` has the appropriate format, it prints the line where the syntax error occurred with a caret indicating the approximate position of the error.
traceback.print_exc([limit[, file]])

This is a shorthand for print_exception(sys.exc_type, sys.exc_value, sys.exc_traceback, limit, file). (In fact, it uses sys.exc_info() to retrieve the same information in a thread-safe way instead of using the deprecated variables.)

traceback.format_exc([limit])

This is like print_exc(limit) but returns a string instead of printing to a file.

New in version 2.4.

traceback.print_last([limit[, file]])

This is a shorthand for print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file). In general it will work only after an exception has reached an interactive prompt (see sys.last_type).

traceback.print_stack([f[, limit[, file]]])

This function prints a stack trace from its invocation point. The optional f argument can be used to specify an alternate stack frame to start. The optional limit and file arguments have the same meaning as for print_exception().

traceback.extract_tb(traceback[, limit])

Return a list of up to limit “pre-processed” stack trace entries extracted from the traceback object traceback. It is useful for alternate formatting of stack traces. If limit is omitted or None, all entries are extracted. A “pre-processed” stack trace entry is a quadruple (filename, line number, function name, text) representing the information that is usually printed for a stack trace. The text is a string with leading and trailing whitespace.
stripped; if the source is not available it is `None`.

```
traceback.extract_stack([f[, limit]])
```

Extract the raw traceback from the current stack frame. The return value has the same format as for `extract_tb()`. The optional `f` and `limit` arguments have the same meaning as for `print_stack()`.

```
traceback.format_list(list)
```

Given a list of tuples as returned by `extract_tb()` or `extract_stack()`, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not `None`.

```
traceback.format_exception_only(type, value)
```

Format the exception part of a traceback. The arguments are the exception type and value such as given by `sys.last_type` and `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

```
traceback.format_exception(type, value, tb[, limit])
```

Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`. The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.
traceback.format_tb(tb[, limit])
   A shorthand for format_list(extract_tb(tb, limit)).

traceback.format_stack([f[, limit]])
   A shorthand for format_list(extract_stack(f, limit)).

traceback.tb_lineno(tb)
   This function returns the current line number set in the traceback object. This function was necessary because in versions of Python prior to 2.3 when the -O flag was passed to Python the tb.tb_lineno was not updated correctly. This function has no use in versions past 2.3.
This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the code module.

```python
import sys, traceback

def run_user_code(envdir):
    source = raw_input(">>> ")
    try:
        exec source in envdir
    except:
        print "Exception in user code:"
        print '-'*60
        traceback.print_exc(file=sys.stdout)
        print '-'*60

envdir = {}
while 1:
    run_user_code(envdir)
```

The following example demonstrates the different ways to print and format the exception and traceback:

```python
import sys, traceback

def lumberjack():
    bright_side_of_death()

def bright_side_of_death():
    return tuple()[0]

try:
    lumberjack()
except IndexError:
    exc_type, exc_value, exc_traceback = sys.exc_info()
    print "*** print_tb:"
    traceback.print_tb(exc_traceback, limit=1, file=sys.stdout)
    print "*** print_exception:"
traceback.print_exception(exc_type, exc_value, exc_traceback, limit=2, file=sys.stdout)
print "*** print_exc:
traceback.print_exc()
print "*** format_exc, first and last line:
formatted_lines = traceback.format_exc().splitlines()
print formatted_lines[0]
print formatted_lines[-1]
print "*** format_exception:
print repr(traceback.format_exception(exc_type, exc_value, exc_traceback))
print "*** extract_tb:
print repr(traceback.extract_tb(exc_traceback))
print "*** format_tb:
print repr(traceback.format_tb(exc_traceback))
print "*** tb_lineno:
print exc_traceback.tb_lineno

The output for the example would look similar to this:

*** print_tb:
  File "<doctest...>", line 10, in <module>
    lumberjack()
*** print_exception:
Traceback (most recent call last):
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
IndexError: tuple index out of range
*** print_exc:
Traceback (most recent call last):
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
IndexError: tuple index out of range
*** format_exc, first and last line:
Traceback (most recent call last):
IndexError: tuple index out of range
*** format_exception:
['Traceback (most recent call last):
', '  File "<doctest...>", line 10, in <module>
    lumberjack()
', '  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
', '  File "<doctest...>", line 7, in bright_side_of_death
  IndexError: tuple index out of range']
The following example shows the different ways to print and format the stack:

```python
>>> import traceback
>>> def another_function():
...    lumberstack()
... >>> def lumberstack():
...    traceback.print_stack()
...    print repr(traceback.extract_stack())
...    print repr(traceback.format_stack())
... >>> another_function()
File "<doctest>", line 10, in <module>
    another_function()
File "<doctest>", line 3, in another_function
    lumberstack()
File "<doctest>", line 6, in lumberstack
    traceback.print_stack()
['<doctest>', 10, '<module>', 'another_function()'),
 ('<doctest>', 3, 'another_function', 'lumberstack()'),
 ('<doctest>', 7, 'lumberstack', 'print repr(traceback.extract_]
 [' File "<doctest>", line 10, in <module>\n    another_function()\n File "<doctest>", line 3, in another_function\n    lumberstack\n File "<doctest>", line 8, in lumberstack\n    print repr(tr
```

This last example demonstrates the final few formatting functions:

```python
>>> import traceback
>>> traceback.format_list([('spam.py', 3, '<module>', 'spam.eggs()'),
('eggs.py', 42, 'eggs', 'return "bacon"')])
['File "spam.py", line 3, in <module>\n    spam.eggs()\n', 'File "eggs.py", line 42, in eggs\n    return "bacon"\n']```
```python
>>> an_error = IndexError('tuple index out of range')
>>> traceback.format_exception_only(type(an_error), an_error)
['IndexError: tuple index out of range\n']
```
26.11. __future__ — Future statement definitions

__future__ is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they're importing.
- To ensure that future statements run under releases prior to 2.1 at least yield runtime exceptions (the import of __future__ will fail, because there was no module of that name prior to 2.1).
- To document when incompatible changes were introduced, and when they will be — or were — made mandatory. This is a form of executable documentation, and can be inspected programmatically via importing __future__ and examining its contents.

Each statement in __future__.py is of the form:

```
FeatureName = _Feature(OptionalRelease, MandatoryRelease, CompilerFlag)
```

where, normally, OptionalRelease is less than MandatoryRelease, and both are 5-tuples of the same form as sys.version_info:

```
(PY_MAJOR_VERSION, # the 2 in 2.1.0a3; an int
 PY_MINOR_VERSION, # the 1; an int
 PY_MICRO_VERSION, # the 0; an int
 PY_RELEASE_LEVEL, # "alpha", "beta", "candidate" or "final"; s
 PY_RELEASE_SERIAL # the 3; an int
)
```

OptionalRelease records the first release in which the feature was accepted.
In the case of a *MandatoryRelease* that has not yet occurred, *MandatoryRelease* predicts the release in which the feature will become part of the language.

Else *MandatoryRelease* records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

*MandatoryRelease* may also be *None*, meaning that a planned feature got dropped.

Instances of class *_Feature* have two corresponding methods, *getOptionalRelease()* and *getMandatoryRelease()*.

*CompilerFlag* is the (bitfield) flag that should be passed in the fourth argument to the built-in function *compile()* to enable the feature in dynamically compiled code. This flag is stored in the *compiler_flag* attribute on *_Feature* instances.

No feature description will ever be deleted from *__future__*. Since its introduction in Python 2.1 the following features have found their way into the language using this mechanism:

<table>
<thead>
<tr>
<th>feature</th>

How the compiler treats future imports.
26.12. gc — Garbage Collector interface

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling `gc.disable()`. To debug a leaking program call `gc.set_debug(gc.DEBUG_LEAK)`. Notice that this includes `gc.DEBUG_SAVEALL`, causing garbage-collected objects to be saved in `gc.garbage` for inspection.

The `gc` module provides the following functions:

- `gc.enable()`  
  Enable automatic garbage collection.

- `gc.disable()`  
  Disable automatic garbage collection.

- `gc.isenabled()`  
  Returns true if automatic collection is enabled.

- `gc.collect([generation])`  
  With no arguments, run a full collection. The optional argument `generation` may be an integer specifying which generation to collect (from 0 to 2). A `ValueError` is raised if the generation number is invalid. The number of unreachable objects found is returned.
Changed in version 2.5: The optional generation argument was added.

Changed in version 2.6: The free lists maintained for a number of built-in types are cleared whenever a full collection or collection of the highest generation (2) is run. Not all items in some free lists may be freed due to the particular implementation, in particular \texttt{int} and \texttt{float}.

\texttt{gc.set\_debug(flags)}
Set the garbage collection debugging flags. Debugging information will be written to \texttt{sys.stderr}. See below for a list of debugging flags which can be combined using bit operations to control debugging.

\texttt{gc.get\_debug()}
Return the debugging flags currently set.

\texttt{gc.get\_objects()}
Returns a list of all objects tracked by the collector, excluding the list returned.

\textit{New in version 2.2.}

\texttt{gc.set\_threshold(threshold0[, threshold1[, threshold2]])}
Set the garbage collection thresholds (the collection frequency). Setting \texttt{threshold0} to zero disables collection.

The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide
when to run, the collector keeps track of the number object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds \(\text{threshold0}\), collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than \(\text{threshold1}\) times since generation 1 has been examined, then generation 1 is examined as well. Similarly, \(\text{threshold2}\) controls the number of collections of generation 1 before collecting generation 2.

\[
gc.\, \text{get\_count}() \\
\text{Return the current collection counts as a tuple of } (\text{count0}, \text{count1}, \text{count2}).
\]

\textit{New in version 2.5.}

\[
gc.\, \text{get\_threshold}() \\
\text{Return the current collection thresholds as a tuple of } (\text{threshold0}, \text{threshold1}, \text{threshold2}).
\]

\[
gc.\, \text{get\_referrers}(*\text{objs}) \\
\text{Return the list of objects that directly refer to any of } \text{objs}. \text{This function will only locate those containers which support garbage collection; extension types which do refer to other objects but do not support garbage collection will not be found.}
\]

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referrers. To get only currently live objects, call \texttt{collect()} before calling \texttt{get\_referrers()}.

Care must be taken when using objects returned by \texttt{get\_referrers()} because some of them could still be under
construction and hence in a temporarily invalid state. Avoid using `get_referrers()` for any purpose other than debugging.

*New in version 2.2.*

`gc.getReferents(*objs)`  
Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments' C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable. `tp_traverse` methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

*New in version 2.3.*

`gc.is_tracked(obj)`  
Returns True if the object is currently tracked by the garbage collector, False otherwise. As a general rule, instances of atomic types aren't tracked and instances of non-atomic types (containers, user-defined objects...) are. However, some type-specific optimizations can be present in order to suppress the garbage collector footprint of simple instances (e.g. dicts containing only atomic keys and values):

```python
>>> gc.is_tracked(0)
False
>>> gc.is_tracked("a")
False
>>> gc.is_tracked([])
True
>>> gc.is_tracked({})
False
>>> gc.is_tracked({"a": 1})
False
```
New in version 2.7.

The following variable is provided for read-only access (you can mutate its value but should not rebind it):

```
gc.garbage
```

A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). By default, this list contains only objects with `__del__() `methods. [1] Objects that have `__del__() `methods and are part of a reference cycle cause the entire reference cycle to be uncollectable, including objects not necessarily in the cycle but reachable only from it. Python doesn't collect such cycles automatically because, in general, it isn't possible for Python to guess a safe order in which to run the `__del__() `methods. If you know a safe order, you can force the issue by examining the `garbage `list, and explicitly breaking cycles due to your objects within the list. Note that these objects are kept alive even so by virtue of being in the `garbage `list, so they should be removed from `garbage `too. For example, after breaking cycles, do `del gc.garbage[:] `to empty the list. It's generally better to avoid the issue by not creating cycles containing objects with `__del__() `methods, and `garbage `can be examined in that case to verify that no such cycles are being created.

If `DEBUG_SAVEALL `is set, then all unreachable objects will be added to this list rather than freed.

The following constants are provided for use with `set_debug() `:

```
gc.DEBUG_STATS
```

Print statistics during collection. This information can be useful
when tuning the collection frequency.

gc. **DEBUG_COLLECTABLE**
Print information on collectable objects found.

gc. **DEBUG_UNCOLLECTABLE**
Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These objects will be added to the garbage list.

gc. **DEBUG_INSTANCES**
When **DEBUG_COLLECTABLE** or **DEBUG_UNCOLLECTABLE** is set, print information about instance objects found.

gc. **DEBUG_OBJECTS**
When **DEBUG_COLLECTABLE** or **DEBUG_UNCOLLECTABLE** is set, print information about objects other than instance objects found.

gc. **DEBUG_SAVEALL**
When set, all unreachable objects found will be appended to garbage rather than being freed. This can be useful for debugging a leaking program.

gc. **DEBUG_LEAK**
The debugging flags necessary for the collector to print information about a leaking program (equal to **DEBUG_COLLECTABLE** | **DEBUG_UNCOLLECTABLE** | **DEBUG_INSTANCES** | **DEBUG_OBJECTS** | **DEBUG_SAVEALL**).

**Footnotes**

[1] Prior to Python 2.2, the list contained all instance objects in unreachable cycles, not only those with `__del__()` methods.
26.13. inspect — Inspect live objects

New in version 2.1.

The inspect module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.
26.13.1. Types and members

The `getmembers()` function retrieves the members of an object such as a class or module. The sixteen functions whose names begin with “is” are mainly provided as convenient choices for the second argument to `getmembers()`. They also help you determine when you can expect to find the following special attributes:

<table>
<thead>
<tr>
<th>Type</th>
<th>Attribute</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>module</td>
<td><code>__doc__</code></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>__file__</code></td>
<td>filename (missing for built-in modules)</td>
<td></td>
</tr>
<tr>

<td></td>
</tr>
</tbody>
</table>

**Note:**

1. _Changed in version 2.2:_ `im_class` used to refer to the class that defined the method.

```
inspect.getmembers(object[, predicate])
```

Return all the members of an object in a list of (name, value) pairs sorted by name. If the optional `predicate` argument is supplied, only members for which the predicate returns a true value are included.

**Note:** `getmembers()` does not return metaclass attributes when the argument is a class (this behavior is inherited from the `dir()` function).

```
inspect.getmoduleinfo(path)
```

Return a tuple of values that describe how Python will interpret the file identified by `path` if it is a module, or `None` if it would not be identified as a module. The return tuple is `(name, suffix, mode, mtype)`, where `name` is the name of the module without the name of any enclosing package, `suffix` is the trailing part of the file
name (which may not be a dot-delimited extension), mode is the `open()` mode that would be used ("r" or "rb"), and mtype is an integer giving the type of the module. mtype will have a value which can be compared to the constants defined in the `imp` module; see the documentation for that module for more information on module types.

*Changed in version 2.6:* Returns a named tuple `ModuleInfo(name, suffix, mode, module_type)`.

**inspect.getmodulename(path)**
Return the name of the module named by the file path, without including the names of enclosing packages. This uses the same algorithm as the interpreter uses when searching for modules. If the name cannot be matched according to the interpreter’s rules, `None` is returned.

**inspect.ismodule(object)**
Return true if the object is a module.

**inspect.isclass(object)**
Return true if the object is a class.

**inspect.ismethod(object)**
Return true if the object is a method.

**inspect.isfunction(object)**
Return true if the object is a Python function or unnamed (lambda) function.

**inspect.isgeneratorfunction(object)**
Return true if the object is a Python generator function.

*New in version 2.6.*
inspect. **isgenerator**(object)
Return true if the object is a generator.

*New in version 2.6.*

inspect. **istraceback**(object)
Return true if the object is a traceback.

inspect. **isframe**(object)
Return true if the object is a frame.

inspect. **iscode**(object)
Return true if the object is a code.

inspect. **isbuiltin**(object)
Return true if the object is a built-in function.

inspect. **isroutine**(object)
Return true if the object is a user-defined or built-in function or method.

inspect. **isabstract**(object)
Return true if the object is an abstract base class.

*New in version 2.6.*

inspect. **ismethoddescriptor**(object)
Return true if the object is a method descriptor, but not if ismethod() or isclass() or isfunction() are true.

This is new as of Python 2.2, and, for example, is true of int.__add__. An object passing this test has a __get__ attribute but not a __set__ attribute, but beyond that the set of attributes varies. __name__ is usually sensible, and __doc__ often is.
Methods implemented via descriptors that also pass one of the other tests return false from the ismethoddescriptor() test, simply because the other tests promise more – you can, e.g., count on having the im_func attribute (etc) when an object passes ismethod().

inspect.isdatadescriptor(object)
Return true if the object is a data descriptor.

Data descriptors have both a __get__ and a __set__ attribute. Examples are properties (defined in Python), getsets, and members. The latter two are defined in C and there are more specific tests available for those types, which is robust across Python implementations. Typically, data descriptors will also have __name__ and __doc__ attributes (properties, getsets, and members have both of these attributes), but this is not guaranteed.

New in version 2.3.

inspect.isgetsetdescriptor(object)
Return true if the object is a getset descriptor.

CPython implementation detail: getsets are attributes defined in extension modules via PyGetSetDef structures. For Python implementations without such types, this method will always return False.

New in version 2.5.

inspect.ismemberdescriptor(object)
Return true if the object is a member descriptor.
**CPython implementation detail:** Member descriptors are attributes defined in extension modules via `PyMemberDef` structures. For Python implementations without such types, this method will always return `False`.

*New in version 2.5.*
26.13.2. Retrieving source code

inspect.getdoc(object)
Get the documentation string for an object, cleaned up with cleandoc().

inspect.getcomments(object)
Return in a single string any lines of comments immediately preceding the object's source code (for a class, function, or method), or at the top of the Python source file (if the object is a module).

inspect.getfile(object)
Return the name of the (text or binary) file in which an object was defined. This will fail with a TypeError if the object is a built-in module, class, or function.

inspect.getmodule(object)
Try to guess which module an object was defined in.

inspect.getsourcefile(object)
Return the name of the Python source file in which an object was defined. This will fail with a TypeError if the object is a built-in module, class, or function.

inspect.getsourcelines(object)
Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An IOError is raised if the source code cannot be retrieved.
inspect.\texttt{getsource}(\textit{object})

Return the text of the source code for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An \texttt{IOError} is raised if the source code cannot be retrieved.

inspect.\texttt{cleandoc}(\textit{doc})

Clean up indentation from docstrings that are indented to line up with blocks of code. Any whitespace that can be uniformly removed from the second line onwards is removed. Also, all tabs are expanded to spaces.

\textit{New in version 2.6.}
26.13.3. Classes and functions

inspect.getclasstree(classes[, unique])

Arrange the given list of classes into a hierarchy of nested lists. Where a nested list appears, it contains classes derived from the class whose entry immediately precedes the list. Each entry is a 2-tuple containing a class and a tuple of its base classes. If the unique argument is true, exactly one entry appears in the returned structure for each class in the given list. Otherwise, classes using multiple inheritance and their descendants will appear multiple times.

inspect.getargspec(func)

Get the names and default values of a Python function's arguments. A tuple of four things is returned: (args, varargs, varkw, defaults). args is a list of the argument names (it may contain nested lists). varargs and varkw are the names of the * and ** arguments or None. defaults is a tuple of default argument values or None if there are no default arguments; if this tuple has n elements, they correspond to the last n elements listed in args.

*Changed in version 2.6:* Returns a named tuple ArgSpec(args, varargs, keywords, defaults).

inspect.getargvalues(frame)

Get information about arguments passed into a particular frame. A tuple of four things is returned: (args, varargs, varkw, locals). args is a list of the argument names (it may contain nested lists). varargs and varkw are the names of the * and ** arguments or None. locals is the locals dictionary of the given frame.
Changed in version 2.6: Returns a named tuple `ArgInfo(args, varargs, keywords, locals)`.

```
inspect.formatargspec(args[, varargs, varkw, defaults, formatarg, formatvarargs, formatvarkw, formatvalue, join])
```

Format a pretty argument spec from the four values returned by `getargspec()`. The format* arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

```
inspect.formatargvalues(args[, varargs, varkw, locals, formatarg, formatvarargs, formatvarkw, formatvalue, join])
```

Format a pretty argument spec from the four values returned by `getargvalues()`. The format* arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

```
inspect.getmro(cls)
```

Return a tuple of class cls’s base classes, including cls, in method resolution order. No class appears more than once in this tuple. Note that the method resolution order depends on cls’s type. Unless a very peculiar user-defined metatype is in use, cls will be the first element of the tuple.

```
inspect.getcallargs(func[, *args][, **kwds])
```

Bind the `args` and `kwds` to the argument names of the Python function or method `func`, as if it was called with them. For bound methods, bind also the first argument (typically named `self`) to the associated instance. A dict is returned, mapping the argument names (including the names of the * and ** arguments, if any) to their values from `args` and `kwds`. In case of invoking `func` incorrectly, i.e. whenever `func(*args, **kwds)` would raise an
exception because of incompatible signature, an exception of the same type and the same or similar message is raised. For example:

>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...    pass
>>> getcallargs(f, 1, 2, 3)
{'a': 1, 'named': {}, 'b': 2, 'pos': (3,)}
>>> getcallargs(f, a=2, x=4)
{'a': 2, 'named': {'x': 4}, 'b': 1, 'pos': ()}
>>> getcallargs(f)
Traceback (most recent call last):
...  TypeError: f() takes at least 1 argument (0 given)

New in version 2.7.
26.13.4. The interpreter stack

When the following functions return “frame records,” each record is a tuple of six items: the frame object, the filename, the line number of the current line, the function name, a list of lines of context from the source code, and the index of the current line within that list.

**Note:** Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python’s optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a `finally` clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```python
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
        del frame
```

The optional *context* argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.
inspect.getframeinfo(frame[, context])

Get information about a frame or traceback object. A 5-tuple is returned, the last five elements of the frame's frame record.

*Changed in version 2.6:* Returns a named tuple Traceback(filename, lineno, function, code_context, index).

inspect.getouterframes(frame[, context])

Get a list of frame records for a frame and all outer frames. These frames represent the calls that lead to the creation of frame. The first entry in the returned list represents frame; the last entry represents the outermost call on frame's stack.

inspect.getinnerframes(traceback[, context])

Get a list of frame records for a traceback's frame and all inner frames. These frames represent calls made as a consequence of frame. The first entry in the list represents traceback; the last entry represents where the exception was raised.

inspect.currentframe()

Return the frame object for the caller's stack frame.

**CPython implementation detail:** This function relies on Python stack frame support in the interpreter, which isn’t guaranteed to exist in all implementations of Python. If running in an implementation without Python stack frame support this function returns None.

inspect.stack([context])

Return a list of frame records for the caller’s stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.
inspect.trace([context])

Return a list of frame records for the stack between the current frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.
This module is automatically imported during initialization. The automatic import can be suppressed using the interpreter's `-S` option.

Importing this module will append site-specific paths to the module search path.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses `sys.prefix` and `sys.exec_prefix`; empty heads are skipped. For the tail part, it uses the empty string and then `lib/site-packages` (on Windows) or `lib/python|version|/site-packages` and then `lib/site-python` (on Unix and Macintosh). For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to `sys.path` and also inspects the newly added path for configuration files.

A path configuration file is a file whose name has the form `package.pth` and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to `sys.path`. Non-existing items are never added to `sys.path`, but no check is made that the item refers to a directory (rather than a file). No item is added to `sys.path` more than once. Blank lines and lines beginning with `#` are skipped. Lines starting with `import` (followed by space or tab) are executed.

Changed in version 2.6: A space or tab is now required after the import keyword.

For example, suppose `sys.prefix` and `sys.exec_prefix` are set to
The Python X.Y library is then installed in /usr/local/lib/pythonX.Y (where only the first three characters of sys.version are used to form the installation path name). Suppose this has a subdirectory /usr/local/lib/pythonX.Y/site-packages with three subsubdirectories, foo, bar and spam, and two path configuration files, foo.pth and bar.pth. Assume foo.pth contains the following:

```
# foo package configuration
foo
bar
bletch
```

and bar.pth contains:

```
# bar package configuration
bar
```

Then the following version-specific directories are added to sys.path, in this order:

```
/usr/local/lib/pythonX.Y/site-packages/bar
/usr/local/lib/pythonX.Y/site-packages/foo
```

Note that bletch is omitted because it doesn’t exist; the bar directory precedes the foo directory because bar.pth comes alphabetically before foo.pth; and spam is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named sitecustomize, which can perform arbitrary site-specific customizations. If this import fails with an ImportError exception, it is silently ignored.
Note that for some non-Unix systems, `sys.prefix` and `sys.exec_prefix` are empty, and the path manipulations are skipped; however the import of `sitecustomize` is still attempted.

**site.PREFIXES**
A list of prefixes for site package directories

*New in version 2.6.*

**site.ENABLE_USER_SITE**
Flag showing the status of the user site directory. True means the user site directory is enabled and added to `sys.path`. When the flag is None the user site directory is disabled for security reasons.

*New in version 2.6.*

**site.USER_SITE**
Path to the user site directory for the current Python version or None

*New in version 2.6.*

**site.USER_BASE**
Path to the base directory for user site directories

*New in version 2.6.*

**PYTHONNOUSERSITE**

*New in version 2.6.*

**PYTHONUSERBASE**

*New in version 2.6.*

**site.addsitedir(sitedir, known_paths=None)**
Adds a directory to `sys.path` and processes its pth files.
site.\texttt{getsitepackages}()

Returns a list containing all global site-packages directories (and possibly site-python).

\textit{New in version 2.7.}

site.\texttt{getuserbase}()

Returns the “user base” directory path.

The “user base” directory can be used to store data. If the global variable \texttt{USER\_BASE} is not initialized yet, this function will also set it.

\textit{New in version 2.7.}

site.\texttt{getusersitepackages}()

Returns the user-specific site-packages directory path.

If the global variable \texttt{USER\_SITE} is not initialized yet, this function will also set it.

\textit{New in version 2.7.}
26.15. user — User-specific configuration hook

*Deprecated since version 2.6:* The `user` module has been removed in Python 3.0.

As a policy, Python doesn't run user-specified code on startup of Python programs. (Only interactive sessions execute the script specified in the `PYTHONSTARTUP` environment variable if it exists).

However, some programs or sites may find it convenient to allow users to have a standard customization file, which gets run when a program requests it. This module implements such a mechanism. A program that wishes to use the mechanism must execute the statement

```python
import user
```

The `user` module looks for a file `.pythonrc.py` in the user's home directory and if it can be opened, executes it (using `execfile()`) in its own (the module `user`'s) global namespace. Errors during this phase are not caught; that's up to the program that imports the `user` module, if it wishes. The home directory is assumed to be named by the `HOME` environment variable; if this is not set, the current directory is used.

The user's `.pythonrc.py` could conceivably test for `sys.version` if it wishes to do different things depending on the Python version.

A warning to users: be very conservative in what you place in your `.pythonrc.py` file. Since you don't know which programs will use it, changing the behavior of standard modules or functions is generally
not a good idea.

A suggestion for programmers who wish to use this mechanism: a simple way to let users specify options for your package is to have them define variables in their `.pythonrc.py` file that you test in your module. For example, a module `spam` that has a verbosity level can look for a variable `user.spam_verbose`, as follows:

```python
import user

verbose = bool(getattr(user, "spam_verbose", 0))
```

(The three-argument form of `getattr()` is used in case the user has not defined `spam_verbose` in their `.pythonrc.py` file.)

Programs with extensive customization needs are better off reading a program-specific customization file.

Programs with security or privacy concerns should not import this module; a user can easily break into a program by placing arbitrary code in the `.pythonrc.py` file.

Modules for general use should not import this module; it may interfere with the operation of the importing program.

**See also:**

**Module** site

Site-wide customization mechanism.
26.16. distutils — Building and installing Python modules

The `distutils` package provides support for building and installing additional modules into a Python installation. The new modules may be either 100%-pure Python, or may be extension modules written in C, or may be collections of Python packages which include modules coded in both Python and C.

This package is discussed in two separate chapters:

See also:

**Distributing Python Modules**

The manual for developers and packagers of Python modules. This describes how to prepare `distutils`-based packages so that they may be easily installed into an existing Python installation.

**Installing Python Modules**

An “administrators” manual which includes information on installing modules into an existing Python installation. You do not need to be a Python programmer to read this manual.
27. Custom Python Interpreters

The modules described in this chapter allow writing interfaces similar to Python's interactive interpreter. If you want a Python interpreter that supports some special feature in addition to the Python language, you should look at the `code` module. (The `codeop` module is lower-level, used to support compiling a possibly-incomplete chunk of Python code.)

The full list of modules described in this chapter is:

- 27.1. `code` — Interpreter base classes
  - 27.1.1. Interactive Interpreter Objects
  - 27.1.2. Interactive Console Objects
- 27.2. `codeop` — Compile Python code
27.1. code — Interpreter base classes

The `code` module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

```python
class code.InteractiveInterpreter([locals])
```

This class deals with parsing and interpreter state (the user's namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional `locals` argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key '__name__' set to '__console__' and key '__doc__' set to `None`.

```python
class code.InteractiveConsole([locals[, filename]])
```

Closely emulate the behavior of the interactive Python interpreter. This class builds on `InteractiveInterpreter` and adds prompting using the familiar `sys.ps1` and `sys.ps2`, and input buffering.

```python
code.interact([banner[, readfunc[, local]]])
```

Convenience function to run a read-eval-print loop. This creates a new instance of `InteractiveConsole` and sets `readfunc` to be used as the `raw_input()` method, if provided. If `local` is provided, it is passed to the `InteractiveConsole` constructor for use as the default namespace for the interpreter loop. The `interact()` method of the instance is then run with `banner` passed as the banner to use, if provided. The console object is discarded after use.
code.compile_command(source[, filename[, symbol]])

This function is useful for programs that want to emulate Python's interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function *almost* always makes the same decision as the real interpreter main loop.

`source` is the source string; `filename` is the optional filename from which source was read, defaulting to '<input>'; and `symbol` is the optional grammar start symbol, which should be either 'single' (the default) or 'eval'.

Returns a code object (the same as `compile(source, filename, symbol)`) if the command is complete and valid; `None` if the command is incomplete; raises `SyntaxError` if the command is complete and contains a syntax error, or raises `OverflowError` or `ValueError` if the command contains an invalid literal.
27.1.1. Interactive Interpreter Objects

InteractiveInterpreter.runsource(source[, filename[, symbol]])

Compile and run some source in the interpreter. Arguments are the same as for compile_command(); the default for filename is '<input>', and for symbol is 'single'. One several things can happen:

- The input is incorrect; compile_command() raised an exception (SyntaxError or OverflowError). A syntax traceback will be printed by calling the showsyntaxerror() method. runsourc() returns False.
- The input is incomplete, and more input is required; compile_command() returned None. runsourc() returns True.
- The input is complete; compile_command() returned a code object. The code is executed by calling the runcode() (which also handles run-time exceptions, except for SystemExit). runsourc() returns False.

The return value can be used to decide whether to use sys.ps1 or sys.ps2 to prompt the next line.

InteractiveInterpreter.runcode(code)

Execute a code object. When an exception occurs, showtraceback() is called to display a traceback. All exceptions are caught except SystemExit, which is allowed to propagate.

A note about KeyboardioInterrupt: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.

InteractiveInterpreter.showsyntaxerror([filename])
Display the syntax error that just occurred. This does not display a stack trace because there isn’t one for syntax errors. If filename is given, it is stuffed into the exception instead of the default filename provided by Python’s parser, because it always uses '<string>' when reading from a string. The output is written by the write() method.

`InteractiveInterpreter.showtraceback()`
Display the exception that just occurred. We remove the first stack item because it is within the interpreter object implementation. The output is written by the write() method.

`InteractiveInterpreter.write(data)`
Write a string to the standard error stream (sys.stderr). Derived classes should override this to provide the appropriate output handling as needed.
27.1.2. Interactive Console Objects

The `InteractiveConsole` class is a subclass of `InteractiveInterpreter`, and so offers all the methods of the interpreter objects as well as the following additions.

`InteractiveConsole.interact([banner])`
Closely emulate the interactive Python console. The optional banner argument specify the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter – since it's so close!).

`InteractiveConsole.push(line)`
Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter's `runsource()` method is called with the concatenated contents of the buffer as source. If this indicates that the command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was appended. The return value is `True` if more input is required, `False` if the line was dealt with in some way (this is the same as `runsource()`).

`InteractiveConsole.resetbuffer()`
Remove any unhandled source text from the input buffer.

`InteractiveConsole.raw_input([prompt])`
Write a prompt and read a line. The returned line does not include the trailing newline. When the user enters the EOF key sequence, `EOFError` is raised. The base implementation uses the
built-in function `raw_input()`; a subclass may replace this with a different implementation.
27.2. codeop — Compile Python code

The `codeop` module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the `code` module. As a result, you probably don’t want to use the module directly; if you want to include such a loop in your program you probably want to use the `code` module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print ‘>>>’ or ‘...’ next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The `codeop` module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

```
codeop.compile_command(source[, filename[, symbol]])
```

Tries to compile `source`, which should be a string of Python code and return a code object if `source` is valid Python code. In that case, the filename attribute of the code object will be `filename`, which defaults to `<input>`. Returns `None` if `source` is not valid Python code, but is a prefix of valid Python code.

If there is a problem with `source`, an exception will be raised. `SyntaxError` is raised if there is invalid Python syntax, and `OverflowError` or `ValueError` if there is an invalid literal.

The `symbol` argument determines whether `source` is compiled as
a statement ('single', the default) or as an expression ('eval'). Any other value will cause ValueError to be raised.

**Note:** It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

```python
class codeop.Compile
    Instances of this class have __call__() methods identical in signature to the built-in function compile(), but with the difference that if the instance compiles program text containing a __future__ statement, the instance 'remembers' and compiles all subsequent program texts with the statement in force.

class codeop.CommandCompiler
    Instances of this class have __call__() methods identical in signature to compile_command(); the difference is that if the instance compiles program text containing a __future__ statement, the instance 'remembers' and compiles all subsequent program texts with the statement in force.

A note on version compatibility: the Compile and CommandCompiler are new in Python 2.2. If you want to enable the future-tracking features of 2.2 but also retain compatibility with 2.1 and earlier versions of Python you can either write
```
try:
    from codeop import CommandCompiler
    compile_command = CommandCompiler()
    del CommandCompiler
except ImportError:
    from codeop import compile_command
```
which is a low-impact change, but introduces possibly unwanted global state into your program, or you can write:

```python
try:
    from codeop import CommandCompiler
except ImportError:
    def CommandCompiler():
        from codeop import compile_command
        return compile_command
```

and then call `CommandCompiler` every time you need a fresh compiler object.
28. Restricted Execution

**Warning:** In Python 2.3 these modules have been disabled due to various known and not readily fixable security holes. The modules are still documented here to help in reading old code that uses the `reexec` and `Bastion` modules.

Restricted execution is the basic framework in Python that allows for the segregation of trusted and untrusted code. The framework is based on the notion that trusted Python code (a supervisor) can create a “padded cell” (or environment) with limited permissions, and run the untrusted code within this cell. The untrusted code cannot break out of its cell, and can only interact with sensitive system resources through interfaces defined and managed by the trusted code. The term “restricted execution” is favored over “safe-Python” since true safety is hard to define, and is determined by the way the restricted environment is created. Note that the restricted environments can be nested, with inner cells creating subcells of lesser, but never greater, privilege.

An interesting aspect of Python’s restricted execution model is that the interfaces presented to untrusted code usually have the same names as those presented to trusted code. Therefore no special interfaces need to be learned to write code designed to run in a restricted environment. And because the exact nature of the padded cell is determined by the supervisor, different restrictions can be imposed, depending on the application. For example, it might be deemed “safe” for untrusted code to read any file within a specified directory, but never to write a file. In this case, the supervisor may redefine the built-in `open()` function so that it raises an exception whenever the `mode` parameter is `'w'`. It might also perform a `chroot()`-like operation on the `filename` parameter, such that root is always relative to some safe “sandbox” area of the filesystem. In this
case, the untrusted code would still see an built-in `open()` function in its environment, with the same calling interface. The semantics would be identical too, with `IOError`s being raised when the supervisor determined that an unallowable parameter is being used.

The Python run-time determines whether a particular code block is executing in restricted execution mode based on the identity of the `__builtins__` object in its global variables: if this is (the dictionary of) the standard `__builtin__` module, the code is deemed to be unrestricted, else it is deemed to be restricted.

Python code executing in restricted mode faces a number of limitations that are designed to prevent it from escaping from the padded cell. For instance, the function object attribute `func_globals` and the class and instance object attribute `__dict__` are unavailable.

Two modules provide the framework for setting up restricted execution environments:

- **28.1. rexec — Restricted execution framework**
  - **28.1.1. RExec Objects**
  - **28.1.2. Defining restricted environments**
  - **28.1.3. An example**
- **28.2. Bastion — Restricting access to objects**

**See also:**

**Grail Home Page**

Grail, an Internet browser written in Python, uses these modules to support Python applets. More information on the use of Python's restricted execution mode in Grail is available on the Web site.
28.1. `reexec` — Restricted execution framework

*Deprecated since version 2.6:* The `reexec` module has been removed in Python 3.0.

*Changed in version 2.3:* Disabled module.

**Warning:** The documentation has been left in place to help in reading old code that uses the module.

This module contains the `REexec` class, which supports `r_eval()`, `r_execfile()`, `r_exec()`, and `r_import()` methods, which are restricted versions of the standard Python functions `eval()`, `execfile()` and the `exec` and `import` statements. Code executed in this restricted environment will only have access to modules and functions that are deemed safe; you can subclass `REexec` to add or remove capabilities as desired.

**Warning:** While the `reexec` module is designed to perform as described below, it does have a few known vulnerabilities which could be exploited by carefully written code. Thus it should not be relied upon in situations requiring “production ready” security. In such situations, execution via sub-processes or very careful “cleansing” of both code and data to be processed may be necessary. Alternatively, help in patching known `reexec` vulnerabilities would be welcomed.

**Note:** The `REexec` class can prevent code from performing unsafe operations like reading or writing disk files, or using TCP/IP sockets. However, it does not protect against code using extremely
large amounts of memory or processor time.

```python
class rexec.RExec([hooks, verbose])
```
Returns an instance of the `RExec` class.

`hooks` is an instance of the `RHooks` class or a subclass of it. If it is omitted or `None`, the default `RHooks` class is instantiated. Whenever the `rexec` module searches for a module (even a built-in one) or reads a module's code, it doesn't actually go out to the file system itself. Rather, it calls methods of an `RHooks` instance that was passed to or created by its constructor. (Actually, the `RExec` object doesn't make these calls — they are made by a module loader object that's part of the `RExec` object. This allows another level of flexibility, which can be useful when changing the mechanics of `import` within the restricted environment.)

By providing an alternate `RHooks` object, we can control the file system accesses made to import a module, without changing the actual algorithm that controls the order in which those accesses are made. For instance, we could substitute an `RHooks` object that passes all filesystem requests to a file server elsewhere, via some RPC mechanism such as ILU. Grail's applet loader uses this to support importing applets from a URL for a directory.

If `verbose` is true, additional debugging output may be sent to standard output.

It is important to be aware that code running in a restricted environment can still call the `sys.exit()` function. To disallow restricted code from exiting the interpreter, always protect calls that cause restricted code to run with a `try/except` statement that catches the `SystemExit` exception. Removing the `sys.exit()` function from the restricted environment is not sufficient — the
restricted code could still use `raise SystemExit`. Removing `SystemExit` is not a reasonable option; some library code makes use of this and would break were it not available.

**See also:**

**Grail Home Page**

Grail is a Web browser written entirely in Python. It uses the `reexec` module as a foundation for supporting Python applets, and can be used as an example usage of this module.
28.1.1. RExec Objects

RExec instances support the following methods:

RExec. **r_eval**(code)

*code* must either be a string containing a Python expression, or a compiled code object, which will be evaluated in the restricted environment’s *__main__* module. The value of the expression or code object will be returned.

RExec. **r_exec**(code)

*code* must either be a string containing one or more lines of Python code, or a compiled code object, which will be executed in the restricted environment’s *__main__* module.

RExec. **r_execfile**(filename)

Execute the Python code contained in the file *filename* in the restricted environment's *__main__* module.

Methods whose names begin with `s_` are similar to the functions beginning with `r_`, but the code will be granted access to restricted versions of the standard I/O streams `sys.stdin`, `sys.stderr`, and `sys.stdout`.

RExec. **s_eval**(code)

*code* must be a string containing a Python expression, which will be evaluated in the restricted environment.

RExec. **s_exec**(code)

*code* must be a string containing one or more lines of Python code, which will be executed in the restricted environment.

RExec. **s_execfile**(code)
Execute the Python code contained in the file *filename* in the restricted environment.

**RExec** objects must also support various methods which will be implicitly called by code executing in the restricted environment. Overriding these methods in a subclass is used to change the policies enforced by a restricted environment.

**RExec. r_import**(modulename[, globals[, locals[, fromlist]]])

Import the module `modulename`, raising an `ImportError` exception if the module is considered unsafe.

**RExec. r_open**(filename[, mode[, bufsize]])

Method called when `open()` is called in the restricted environment. The arguments are identical to those of `open()`, and a file object (or a class instance compatible with file objects) should be returned. **RExec**'s default behaviour is allow opening any file for reading, but forbidding any attempt to write a file. See the example below for an implementation of a less restrictive `r_open()`.

**RExec. r_reload**(module)

Reload the module object `module`, re-parsing and re-initializing it.

**RExec. r_unload**(module)

Unload the module object `module` (remove it from the restricted environment's `sys.modules` dictionary).

And their equivalents with access to restricted standard I/O streams:

**RExec. s_import**(modulename[, globals[, locals[, fromlist]]])

Import the module `modulename`, raising an `ImportError` exception if the module is considered unsafe.
RExec. `s_reload(module)`
Reload the module object `module`, re-parsing and re-initializing it.

RExec. `s_unload(module)`
Unload the module object `module`. 
28.1.2. Defining restricted environments

The **RExec** class has the following class attributes, which are used by the **__init__()** method. Changing them on an existing instance won't have any effect; instead, create a subclass of **RExec** and assign them new values in the class definition. Instances of the new class will then use those new values. All these attributes are tuples of strings.

**RExec.nok_builtin_names**

Contains the names of built-in functions which will *not* be available to programs running in the restricted environment. The value for **RExec** is ('open', 'reload', '__import__'). (This gives the exceptions, because by far the majority of built-in functions are harmless. A subclass that wants to override this variable should probably start with the value from the base class and concatenate additional forbidden functions — when new dangerous built-in functions are added to Python, they will also be added to this module.)

**RExec.ok_builtin_modules**

Contains the names of built-in modules which can be safely imported. The value for **RExec** is ('audioop', 'array', 'binascii', 'cmath', 'errno', 'imageop', 'marshal', 'math', 'md5', 'operator', 'parser', 'regex', 'select', 'sha', '_sre', 'strop', 'struct', 'time'). A similar remark about overriding this variable applies — use the value from the base class as a starting point.

**RExec.ok_path**

Contains the directories which will be searched when an **import** is performed in the restricted environment. The value for **RExec** is the same as **sys.path** (at the time the module is loaded) for
unrestricted code.

**RExec. ok_posix_names**

Contains the names of the functions in the `os` module which will be available to programs running in the restricted environment. The value for **RExec** is ('error', 'fstat', 'listdir', 'lstat', 'readlink', 'stat', 'times', 'uname', 'getpid', 'getppid', 'getcwd', 'getuid', 'getgid', 'geteuid', 'getegid').

**RExec. ok_sys_names**

Contains the names of the functions and variables in the `sys` module which will be available to programs running in the restricted environment. The value for **RExec** is ('ps1', 'ps2', 'copyright', 'version', 'platform', 'exit', 'maxint').

**RExec. ok_file_types**

Contains the file types from which modules are allowed to be loaded. Each file type is an integer constant defined in the `imp` module. The meaningful values are `PY_SOURCE`, `PY_COMPILED`, and `C_EXTENSION`. The value for **RExec** is (C_EXTENSION, PY_SOURCE). Adding `PY_COMPILED` in subclasses is not recommended; an attacker could exit the restricted execution mode by putting a forged byte-compiled file (.pyc) anywhere in your file system, for example by writing it to /tmp or uploading it to the /incoming directory of your public FTP server.
28.1.3. An example

Let us say that we want a slightly more relaxed policy than the standard `RExec` class. For example, if we're willing to allow files in `/tmp` to be written, we can subclass the `RExec` class:

```python
class TmpWriterRExec(rexec.RExec):
    def r_open(self, file, mode='r', buf=-1):
        if mode in ('r', 'rb'):
            pass
        elif mode in ('w', 'wb', 'a', 'ab'):
            # check filename: must begin with /tmp/
            if file[:5]!='/tmp/':
                raise IOError("can't write outside /tmp")
            elif (string.find(file, '/../') >= 0 or
                  file[:3] == '/..' or file[-3:] == '/../'):
                raise IOError("'..' in filename forbidden")
        else:
            raise IOError("Illegal open() mode")
        return open(file, mode, buf)
```

Notice that the above code will occasionally forbid a perfectly valid filename; for example, code in the restricted environment won't be able to open a file called `/tmp/foo/../bar`. To fix this, the `r_open()` method would have to simplify the filename to `/tmp/bar`, which would require splitting apart the filename and performing various operations on it. In cases where security is at stake, it may be preferable to write simple code which is sometimes overly restrictive, instead of more general code that is also more complex and may harbor a subtle security hole.
28.2. Bastion — Restricting access to objects

*Deprecated since version 2.6:* The Bastion module has been removed in Python 3.0.

*Changed in version 2.3:* Disabled module.

**Note:** The documentation has been left in place to help in reading old code that uses the module.

According to the dictionary, a bastion is “a fortified area or position”, or “something that is considered a stronghold.” It’s a suitable name for this module, which provides a way to forbid access to certain attributes of an object. It must always be used with the rexec module, in order to allow restricted-mode programs access to certain safe attributes of an object, while denying access to other, unsafe attributes.

```python
Bastion.Bastion(object[, filter[, name[, class]]]])
```

Protect the object `object`, returning a bastion for the object. Any attempt to access one of the object’s attributes will have to be approved by the `filter` function; if the access is denied an `AttributeError` exception will be raised.

If present, `filter` must be a function that accepts a string containing an attribute name, and returns true if access to that attribute will be permitted; if `filter` returns false, the access is denied. The default filter denies access to any function beginning with an underscore (`_`). The bastion’s string representation will be `<Bastion for name>` if a value for `name` is provided; otherwise,
`repr(object)` will be used.

`class`, if present, should be a subclass of `BastionClass`; see the code in `bastion.py` for the details. Overriding the default `BastionClass` will rarely be required.

```python
class Bastion: BastionClass(getfunc, name)
```

Class which actually implements bastion objects. This is the default class used by `Bastion()`. The `getfunc` parameter is a function which returns the value of an attribute which should be exposed to the restricted execution environment when called with the name of the attribute as the only parameter. `name` is used to construct the `repr()` of the `BastionClass` instance.
29. Importing Modules

The modules described in this chapter provide new ways to import other Python modules and hooks for customizing the import process.

The full list of modules described in this chapter is:

- **29.1. imp** — Access the import internals
  - 29.1.1. Examples
- **29.2. importlib** — Convenience wrappers for `__import__()`
- **29.3. imputil** — Import utilities
  - 29.3.1. Examples
- **29.4. zipimport** — Import modules from Zip archives
  - 29.4.1. zipimporter Objects
  - 29.4.2. Examples
- **29.5. pkgutil** — Package extension utility
- **29.6. modulefinder** — Find modules used by a script
  - 29.6.1. Example usage of `ModuleFinder`
- **29.7. runpy** — Locating and executing Python modules
29.1. `imp` — Access the `import` internals

This module provides an interface to the mechanisms used to implement the `import` statement. It defines the following constants and functions:

`imp.get_magic()`
Return the magic string value used to recognize byte-compiled code files (.pyc files). (This value may be different for each Python version.)

`imp.get_suffixes()`
Return a list of 3-element tuples, each describing a particular type of module. Each triple has the form `(suffix, mode, type)`, where `suffix` is a string to be appended to the module name to form the filename to search for, `mode` is the mode string to pass to the built-in `open()` function to open the file (this can be `'r'` for text files or `'rb'` for binary files), and `type` is the file type, which has one of the values `PY_SOURCE`, `PY_COMPILED`, or `C_EXTENSION`, described below.

`imp.find_module(name[, path])`
Try to find the module `name`. If `path` is omitted or `None`, the list of directory names given by `sys.path` is searched, but first a few special places are searched: the function tries to find a built-in module with the given name (`C_BUILTIN`), then a frozen module (`PY_FROZEN`), and on some systems some other places are looked in as well (on Windows, it looks in the registry which may point to a specific file).
Otherwise, *path* must be a list of directory names; each directory is searched for files with any of the suffixes returned by `get_suffixes()` above. Invalid names in the list are silently ignored (but all list items must be strings).

If search is successful, the return value is a 3-element tuple :`
(file, pathname, description):

*file* is an open file object positioned at the beginning, *pathname* is the pathname of the file found, and *description* is a 3-element tuple as contained in the list returned by `get_suffixes()` describing the kind of module found.

If the module does not live in a file, the returned *file* is *None*, *pathname* is the empty string, and the *description* tuple contains empty strings for its suffix and mode; the module type is indicated as given in parentheses above. If the search is unsuccessful, *ImportError* is raised. Other exceptions indicate problems with the arguments or environment.

If the module is a package, *file* is *None*, *pathname* is the package path and the last item in the *description* tuple is *PKG_DIRECTORY*.

This function does not handle hierarchical module names (names containing dots). In order to find *P.*M*, that is, submodule *M* of package *P*, use `find_module()` and `load_module()` to find and load package *P*, and then use `find_module()` with the *path* argument set to *P.*__path__. When *P* itself has a dotted name, apply this recipe recursively.

```
imp.load_module(name, file, pathname, description)
```

Load a module that was previously found by `find_module()` (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was
already imported, it is equivalent to a `reload()`! The `name` argument indicates the full module name (including the package name, if this is a submodule of a package). The `file` argument is an open file, and `pathname` is the corresponding file name; these can be `None` and `'`, respectively, when the module is a package or not being loaded from a file. The `description` argument is a tuple, as would be returned by `get_suffixes()`, describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually `ImportError`) is raised.

**Important:** the caller is responsible for closing the `file` argument, if it was not `None`, even when an exception is raised. This is best done using a `try ... finally` statement.

`imp.new_module(name)`

Return a new empty module object called `name`. This object is not inserted in `sys.modules`.

`imp.lock_held()`

Return `True` if the import lock is currently held, else `False`. On platforms without threads, always return `False`.

On platforms with threads, a thread executing an import holds an internal lock until the import is complete. This lock blocks other threads from doing an import until the original import completes, which in turn prevents other threads from seeing incomplete module objects constructed by the original thread while in the process of completing its import (and the imports, if any, triggered by that).

`imp.acquire_lock()`

Acquire the interpreter’s import lock for the current thread. This
lock should be used by import hooks to ensure thread-safety when importing modules. On platforms without threads, this function does nothing.

Once a thread has acquired the import lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

On platforms without threads, this function does nothing.

New in version 2.3.

**imp. release_lock()**
Release the interpreter's import lock. On platforms without threads, this function does nothing.

New in version 2.3.

The following constants with integer values, defined in this module, are used to indicate the search result of `find_module()`.

**imp. PY_SOURCE**
The module was found as a source file.

**imp. PY_COMPILED**
The module was found as a compiled code object file.

**imp. C_EXTENSION**
The module was found as dynamically loadable shared library.

**imp. PKG_DIRECTORY**
The module was found as a package directory.

**imp. C_BUILTIN**
The module was found as a built-in module.

**imp. PY_FROZEN**
The module was found as a frozen module (see `init_frozen()`).

The following constant and functions are obsolete; their functionality is available through `find_module()` or `load_module()`. They are kept around for backward compatibility:

```python
imp. SEARCH_ERROR
Unused.
```

```python
imp. init_builtin(name)
Initialize the built-in module called `name` and return its module object along with storing it in `sys.modules`. If the module was already initialized, it will be initialized again. Re-initialization involves the copying of the built-in module’s `__dict__` from the cached module over the module’s entry in `sys.modules`. If there is no built-in module called `name`, `None` is returned.
```

```python
imp. init_frozen(name)
Initialize the frozen module called `name` and return its module object. If the module was already initialized, it will be initialized again. If there is no frozen module called `name`, `None` is returned. (Frozen modules are modules written in Python whose compiled byte-code object is incorporated into a custom-built Python interpreter by Python’s `freeze` utility. See `Tools/freeze/` for now.)
```

```python
imp. is_builtin(name)
Return 1 if there is a built-in module called `name` which can be initialized again. Return -1 if there is a built-in module called `name` which cannot be initialized again (see `init_builtin()`). Return 0 if there is no built-in module called `name`.
```

```python
imp. is_frozen(name)
Return `True` if there is a frozen module (see `init_frozen()`)
```
called *name*, or *False* if there is no such module.

**imp. load_compiled**(name, pathname[, file])

Load and initialize a module implemented as a byte-compiled code file and return its module object. If the module was already initialized, it will be initialized again. The *name* argument is used to create or access a module object. The *pathname* argument points to the byte-compiled code file. The *file* argument is the byte-compiled code file, open for reading in binary mode, from the beginning. It must currently be a real file object, not a user-defined class emulating a file.

**imp. load_dynamic**(name, pathname[, file])

Load and initialize a module implemented as a dynamically loadable shared library and return its module object. If the module was already initialized, it will be initialized again. Re-initialization involves copying the *dict* attribute of the cached instance of the module over the value used in the module cached in *sys.modules*. The *pathname* argument must point to the shared library. The *name* argument is used to construct the name of the initialization function: an external C function called *initname()* in the shared library is called. The optional *file* argument is ignored. (Note: using shared libraries is highly system dependent, and not all systems support it.)

**imp. load_source**(name, pathname[, file])

Load and initialize a module implemented as a Python source file and return its module object. If the module was already initialized, it will be initialized again. The *name* argument is used to create or access a module object. The *pathname* argument points to the source file. The *file* argument is the source file, open for reading as text, from the beginning. It must currently be a real file object, not a user-defined class emulating a file. Note that if a properly
matching byte-compiled file (with suffix .pyc or .pyo) exists, it will be used instead of parsing the given source file.

class imp. NullImporter(path_string)

The NullImporter type is a PEP 302 import hook that handles non-directory path strings by failing to find any modules. Calling this type with an existing directory or empty string raises ImportError. Otherwise, a NullImporter instance is returned.

Python adds instances of this type to sys.path_importer_cache for any path entries that are not directories and are not handled by any other path hooks on sys.path_hooks. Instances have only one method:

find_module(fullname[, path])

This method always returns None, indicating that the requested module could not be found.

New in version 2.5.
29.1.1. Examples

The following function emulates what was the standard import statement up to Python 1.4 (no hierarchical module names). (This implementation wouldn’t work in that version, since `find_module()` has been extended and `load_module()` has been added in 1.4.)

```python
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=None):
    # Fast path: see if the module has already been imported.
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller handle it.
    fp, pathname, description = imp.find_module(name)

    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close fp explicitly
        if fp:
            fp.close()
```

A more complete example that implements hierarchical module names and includes a `reload()` function can be found in the module `knee`. The `knee` module can be found in `Demo/imputil/` in the Python source distribution.
29.2. `importlib` — Convenience wrappers for `__import__()`

New in version 2.7.

This module is a minor subset of what is available in the more full-featured package of the same name from Python 3.1 that provides a complete implementation of `import`. What is here has been provided to help ease in transitioning from 2.7 to 3.1.

`importlib.import_module(name, package=None)`

Import a module. The `name` argument specifies what module to import in absolute or relative terms (e.g. either `pkg.mod` or `..mod`). If the name is specified in relative terms, then the `package` argument must be specified to the package which is to act as the anchor for resolving the package name (e.g. `import_module('..mod', 'pkg.subpkg')` will import `pkg.mod`). The specified module will be inserted into `sys.modules` and returned.
This module provides a very handy and useful mechanism for custom `import` hooks. Compared to the older `ihooks` module, `imputil` takes a dramatically simpler and more straight-forward approach to custom `import` functions.

```python
class imputil.ImportManager([fs_imp])
    Manage the import process.

    install([namespace])
        Install this ImportManager into the specified namespace.

    uninstall()
        Restore the previous import mechanism.

    add_suffix(suffix, importFunc)
        Undocumented.
```

```python
class imputil.Importer
    Base class for replacing standard import functions.

    import_top(name)
        Import a top-level module.

    get_code(parent, modname, fqname)
        Find and retrieve the code for the given module.

        `parent` specifies a parent module to define a context for importing. It may be `None`, indicating no particular context for
the search.

*modname* specifies a single module (not dotted) within the parent.

*fqname* specifies the fully-qualified module name. This is a (potentially) dotted name from the “root” of the module namespace down to the modname.

If there is no parent, then modname==fqname.

This method should return *None*, or a 3-tuple.

- If the module was not found, then *None* should be returned.
- The first item of the 2- or 3-tuple should be the integer 0 or 1, specifying whether the module that was found is a package or not.
- The second item is the code object for the module (it will be executed within the new module’s namespace). This item can also be a fully-loaded module object (e.g. loaded from a shared lib).
- The third item is a dictionary of name/value pairs that will be inserted into new module before the code object is executed. This is provided in case the module’s code expects certain values (such as where the module was found). When the second item is a module object, then these names/values will be inserted *after* the module has been loaded/initialized.

*class* `imputil.BuiltinImporter`

Emulate the import mechanism for built-in and frozen modules. This is a sub-class of the `Importer` class.
get_code (parent, modname, fqname)
    Undocumented.

imputil.py_suffix_importer (filename, finfo, fqname)
    Undocumented.

class imputil.DynLoadSuffixImporter([desc])
    Undocumented.

import_file (filename, finfo, fqname)
    Undocumented.
29.3.1. Examples

This is a re-implementation of hierarchical module import.

This code is intended to be read, not executed. However, it does work – all you need to do to enable it is “import knee”.

(The name is a pun on the clunkier predecessor of this module, “ni”.)

```python
import sys, imp, __builtin__

# Replacement for __import__()

def import_hook(name, globals=None, locals=None, fromlist=None):
    parent = determine_parent(globals)
    q, tail = find_head_package(parent, name)
    m = load_tail(q, tail)
    if not fromlist:
        return q
    if hasattr(m, '__path__'):
        ensure_fromlist(m, fromlist)
    return m

def determine_parent(globals):
    if not globals or not globals.has_key('__name__'):
        return None
    pname = globals['__name__']
    if globals.has_key('__path__'):
        parent = sys.modules[pname]
        assert globals is parent.__dict__
        return parent
    if '.' in pname:
        i = pname.rfind('.')
        pname = pname[:i]
        parent = sys.modules[pname]
        assert parent.__name__ == pname
        return parent
    return None

def find_head_package(parent, name):
    if '.' in name:
        i = name.find('.')
        head = name[:i]
```
tail = name[i+1:]
else:
    head = name
    tail = ""
if parent:
    qname = "%s.%s" % (parent.__name__, head)
else:
    qname = head
q = import_module(head, qname, parent)
if q: return q, tail
if parent:
    qname = head
    parent = None
    q = import_module(head, qname, parent)
    if q: return q, tail
    raise ImportError("No module named " + qname)

def load_tail(q, tail):
    m = q
    while tail:
        i = tail.find('.
        if i < 0: i = len(tail)
        head, tail = tail[:i], tail[i+1:]
        mname = "%s.%s" % (m.__name__, head)
        m = import_module(head, mname, m)
        if not m:
            raise ImportError("No module named " + mname)
    return m

def ensure_fromlist(m, fromlist, recursive=0):
    for sub in fromlist:
        if sub == "*":
            if not recursive:
                try:
                    all = m.__all__
                except AttributeError:
                    pass
                else:
                    ensure_fromlist(m, all, 1)
                continue
        if sub != "*" and not hasattr(m, sub):
            subname = "%s.%s" % (m.__name__, sub)
            submod = import_module(sub, subname, m)
            if not submod:
                raise ImportError("No module named " + subname)

def import_module(partname, fqname, parent):
try:
    return sys.modules[fqname]
except KeyError:
    pass
try:
    fp, pathname, stuff = imp.find_module(partname, parent and parent
except ImportError:
    return None
try:
    m = imp.load_module(fqname, fp, pathname, stuff)
finally:
    if fp: fp.close()
if parent:
    setattr(parent, partname, m)
return m

# Replacement for reload()
def reload_hook(module):
    name = module.__name__
    if '.' not in name:
        return import_module(name, name, None)
    i = name.rfind('.
    pname = name[:i]
    parent = sys.modules[pname]
    return import_module(name[i+1:], name, parent)

# Save the original hooks
original_import = __builtins__.__import__
original_reload = __builtins__.reload

# Now install our hooks
__builtins__.__import__ = import_hook
__builtins__.reload = reload_hook

Also see the importers module (which can be found in Demo/imputil/ in the Python source distribution) for additional examples.
Standard Library » 29. Importing Modules »
29.4. zipimport — Import modules from Zip archives

New in version 2.3.

This module adds the ability to import Python modules (*.py, *.py[co]) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the built-in `import` mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `/tmpexample.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but only files `.py` and `.py[co]` are available for import. ZIP import of dynamic modules (`.pyd`, `.so`) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` or `.pyo` file, meaning that if a ZIP archive doesn’t contain `.pyc` files, importing may be rather slow.

Using the built-in `reload()` function will fail if called on a module loaded from a ZIP archive; it is unlikely that `reload()` would be needed, since this would imply that the ZIP has been altered during runtime.

ZIP archives with an archive comment are currently not supported.

**PKZIP Application Note**
Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.

**PEP 273 - Import Modules from Zip Archives**
Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in PEP 273, but uses an implementation written by Just van Rossum that uses the import hooks described in PEP 302.

**PEP 302 - New Import Hooks**
The PEP to add the import hooks that help this module work.

This module defines an exception:

```python
exception zipimport.ZipImportError
    Exception raised by zipimporter objects. It's a subclass of ImportError, so it can be caught as ImportError, too.
```

29.4.1. zipimporter Objects

`zipimporter` is the class for importing ZIP files.

class zipimport.zipimporter(archivepath)
    Create a new zipimporter instance. `archivepath` must be a path to a ZIP file, or to a specific path within a ZIP file. For example, an `archivepath` of `foo/bar.zip/lib` will look for modules in the `lib` directory inside the ZIP file `foo/bar.zip` (provided that it exists).

`ZipImportError` is raised if `archivepath` doesn’t point to a valid ZIP archive.

find_module(fullname[, path])
    Search for a module specified by `fullname`. `fullname` must be the fully qualified (dotted) module name. It returns the zipimporter instance itself if the module was found, or `None` if it wasn’t. The optional `path` argument is ignored—it's there for compatibility with the importer protocol.

get_code(fullname)
    Return the code object for the specified module. Raise `ZipImportError` if the module couldn’t be found.

get_data(pathname)
    Return the data associated with `pathname`. Raise `IOError` if the file wasn’t found.

get_filename(fullname)
    Return the value `__file__` would be set to if the specified module was imported. Raise `ZipImportError` if the module couldn’t be found.
New in version 2.7.

`get_source(fullname)`

Return the source code for the specified module. Raise `ZipImportError` if the module couldn't be found, return `None` if the archive does contain the module, but has no source for it.

`is_package(fullname)`

Return True if the module specified by `fullname` is a package. Raise `ZipImportError` if the module couldn't be found.

`load_module(fullname)`

Load the module specified by `fullname`. `fullname` must be the fully qualified (dotted) module name. It returns the imported module, or raises `ZipImportError` if it wasn't found.

`archive`

The file name of the importer’s associated ZIP file, without a possible subpath.

`prefix`

The subpath within the ZIP file where modules are searched. This is the empty string for zipimporter objects which point to the root of the ZIP file.

The `archive` and `prefix` attributes, when combined with a slash, equal the original `archivepath` argument given to the `zipimporter` constructor.
29.4.2. Examples

Here is an example that imports a module from a ZIP archive - note that the `zipimport` module is not explicitly used.

```bash
$ unzip -l /tmp/example.zip
Archive: /tmp/example.zip
    Length    Date    Time    Name
         ----    ----    ----    ----
        8467   11-26-02 22:30    jwzthreading.py
         ----
        8467
$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, '/tmp/example.zip')  # Add .zip file to
>>> import jwzthreading
>>> jwzthreading.__file__
'/tmp/example.zip/jwzthreading.py'
```
29. Importing Modules

The Python Standard Library » 29. Importing Modules »
New in version 2.3.

This module provides functions to manipulate packages:

```
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

This will add to the package's `__path__` all subdirectories of directories on `sys.path` named after the package. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for `*.pkg` files beginning where `*` matches the `name` argument. This feature is similar to `*.pth` files (see the `site` module for more information), except that it doesn’t special-case lines starting with `import`. A `*.pkg` file is trusted at face value: apart from checking for duplicates, all entries found in a `*.pkg` file are added to the path, regardless of whether they exist on the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not modified; an extended copy is returned. Items are only appended to the copy at the end.
It is assumed that `sys.path` is a sequence. Items of `sys.path` that are not (Unicode or 8-bit) strings referring to existing directories are ignored. Unicode items on `sys.path` that cause errors when used as filenames may cause this function to raise an exception (in line with `os.path.isdir()` behavior).

```python
pkgutil.get_data(package, resource)
```

Get a resource from a package.

This is a wrapper for the **PEP 302** loader `get_data()` API. The package argument should be the name of a package, in standard module format (foo.bar). The resource argument should be in the form of a relative filename, using `/` as the path separator. The parent directory name `..` is not allowed, and nor is a rooted name (starting with a `/`).

The function returns a binary string that is the contents of the specified resource.

For packages located in the filesystem, which have already been imported, this is the rough equivalent of:

```python
d = os.path.dirname(sys.modules[package].__file__)
data = open(os.path.join(d, resource), 'rb').read()
```

If the package cannot be located or loaded, or it uses a **PEP 302** loader which does not support `get_data()`, then `None` is returned.
29.6. modulefinder — Find modules used by a script

*New in version 2.3.*

This module provides a `ModuleFinder` class that can be used to determine the set of modules imported by a script. `modulefinder.py` can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

```python
modulefinder.AddPackagePath(pkg_name, path)
```

Record that the package named `pkg_name` can be found in the specified `path`.

```python
modulefinder.ReplacePackage(oldname, newname)
```

Allows specifying that the module named `oldname` is in fact the package named `newname`. The most common usage would be to handle how the `_xmlplus` package replaces the `xml` package.

```python
class modulefinder.ModuleFinder([path=None, debug=0, excludes=[], replace_paths=[]])
```

This class provides `run_script()` and `report()` methods to determine the set of modules imported by a script. `path` can be a list of directories to search for modules; if not specified, `sys.path` is used. `debug` sets the debugging level; higher values make the class print debugging messages about what it's doing. `excludes` is a list of module names to exclude from the analysis. `replace_paths` is a list of `(oldpath, newpath)` tuples that will be replaced in module paths.

```python
report()
```
Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.

run_script(pathname)

Analyze the contents of the pathname file, which must contain Python code.

modules

A dictionary mapping module names to modules. See Example usage of ModuleFinder
29.6.1. Example usage of `ModuleFinder`

The script that is going to get analyzed later on (bacon.py):

```python
import re, itertools
try:
    import baconhameggs
except ImportError:
    pass
try:
    import guido.python.ham
except ImportError:
    pass
```

The script that will output the report of bacon.py:

```python
from modulefinder import ModuleFinder
finder = ModuleFinder()
finder.run_script('bacon.py')
print 'Loaded modules:'
for name, mod in finder.modules.iteritems():
    print '%s: %s' % (name, ', '.join(mod.globalnames.keys()[:3]))
print '-'*50
print 'Modules not imported:'
print '\n'.join(finder.badmodules.iterkeys())
```

Sample output (may vary depending on the architecture):

```
Loaded modules:
  _types:
    copy_reg:  _inverted_registry,_slotnames,__all__
    sre_compile:  isstring,_sre,_optimize_unicode
    _sre:
    sre_constants:  REPEAT_ONE,makedict,AT_END_LINE
sys:
```
re: __module__,finditer,_expand
itertools:
__main__: re,itertools,baconhameggs
sre_parse: __getslice__,_PATTERNENDERS,SRE_FLAG_UNICODE
array:
types: __module__,IntType,TypeType
-------------------------------
Modules not imported:
guido.python.ham
baconhameggs
29.7. runpy — Locating and executing Python modules

New in version 2.5.

The runpy module is used to locate and run Python modules without importing them first. Its main use is to implement the -m command line switch that allows scripts to be located using the Python module namespace rather than the filesystem.

The runpy module provides two functions:

```python
runpy.run_module(mod_name, init_globals=None, run_name=None, alter_sys=False)
```

Execute the code of the specified module and return the resulting module globals dictionary. The module’s code is first located using the standard import mechanism (refer to PEP 302 for details) and then executed in a fresh module namespace.

If the supplied module name refers to a package rather than a normal module, then that package is imported and the __main__ submodule within that package is then executed and the resulting module globals dictionary returned.

The optional dictionary argument init_globals may be used to pre-populate the module’s globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by run_module().

The special global variables __name__, __file__, __loader__ and __package__ are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables -
other variables may be set implicitly as an interpreter implementation detail).

__name__ is set to run_name if this optional argument is not None, to mod_name + '.__main__' if the named module is a package and to the mod_name argument otherwise.

__file__ is set to the name provided by the module loader. If the loader does not make filename information available, this variable is set to None.

__loader__ is set to the PEP 302 module loader used to retrieve the code for the module (This loader may be a wrapper around the standard import mechanism).

__package__ is set to mod_name if the named module is a package and to mod_name.rpartition('.')[0] otherwise.

If the argument alter_sys is supplied and evaluates to True, then sys.argv[0] is updated with the value of __file__ and sys.modules[__name__] is updated with a temporary module object for the module being executed. Both sys.argv[0] and sys.modules[__name__] are restored to their original values before the function returns.

Note that this manipulation of sys is not thread-safe. Other threads may see the partially initialised module, as well as the altered list of arguments. It is recommended that the sys module be left alone when invoking this function from threaded code.

**Changed in version 2.7:** Added ability to execute packages by looking for a __main__ submodule

runpy.run_path(file_path, init_globals=None, run_name=None)
Execute the code at the named filesystem location and return the resulting module globals dictionary. As with a script name supplied to the CPython command line, the supplied path may refer to a Python source file, a compiled bytecode file or a valid sys.path entry containing a __main__ module (e.g. a zipfile containing a top-level __main__.py file).

For a simple script, the specified code is simply executed in a fresh module namespace. For a valid sys.path entry (typically a zipfile or directory), the entry is first added to the beginning of sys.path. The function then looks for and executes a __main__ module using the updated path. Note that there is no special protection against invoking an existing __main__ entry located elsewhere on sys.path if there is no such module at the specified location.

The optional dictionary argument init_globals may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by run_path().

The special global variables __name__, __file__, __loader__ and __package__ are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

__name__ is set to run_name if this optional argument is not None and to '<run_path>' otherwise.

__file__ is set to the name provided by the module loader. If the loader does not make filename information available, this variable is set to None. For a simple script, this will be set to file_path.
__loader__ is set to the **PEP 302** module loader used to retrieve the code for the module (This loader may be a wrapper around the standard import mechanism). For a simple script, this will be set to **None**.

__package__ is set to __name__.rpartition('.')[0].

A number of alterations are also made to the `sys` module. Firstly, `sys.path` may be altered as described above. `sys.argv[0]` is updated with the value of `file_path` and `sys.modules[__name__]` is updated with a temporary module object for the module being executed. All modifications to items in `sys` are reverted before the function returns.

Note that, unlike `run_module()`, the alterations made to `sys` are not optional in this function as these adjustments are essential to allowing the execution of `sys.path` entries. As the thread safety limitations still apply, use of this function in threaded code should be either serialised with the import lock or delegated to a separate process.

*New in version 2.7.*

30. Python Language Services

Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

- **30.1. parser** — Access Python parse trees
  - 30.1.1. Creating ST Objects
  - 30.1.2. Converting ST Objects
  - 30.1.3. Queries on ST Objects
  - 30.1.4. Exceptions and Error Handling
  - 30.1.5. ST Objects
  - 30.1.6. Examples
    - 30.1.6.1. Emulation of `compile()`
    - 30.1.6.2. Information Discovery
- **30.2. Abstract Syntax Trees**
  - 30.2.1. Node classes
  - 30.2.2. Abstract Grammar
  - 30.2.3. `ast` Helpers
- **30.3. symtable** — Access to the compiler’s symbol tables
  - 30.3.1. Generating Symbol Tables
  - 30.3.2. Examining Symbol Tables
- **30.4. symbol** — Constants used with Python parse trees
- **30.5. token** — Constants used with Python parse trees
- **30.6. keyword** — Testing for Python keywords
- **30.7. tokenize** — Tokenizer for Python source
- **30.8. tabnanny** — Detection of ambiguous indentation
- **30.9. pyc1br** — Python class browser support
  - 30.9.1. Class Objects
  - 30.9.2. Function Objects
• 30.10. py_compile — Compile Python source files
• 30.11. compileall — Byte-compile Python libraries
• 30.12. dis — Disassembler for Python bytecode
  • 30.12.1. Python Bytecode Instructions
• 30.13. pickletools — Tools for pickle developers
30.1. parser — Access Python parse trees

The **parser** module provides an interface to Python’s internal parser and byte-code compiler. The primary purpose for this interface is to allow Python code to edit the parse tree of a Python expression and create executable code from this. This is better than trying to parse and modify an arbitrary Python code fragment as a string because parsing is performed in a manner identical to the code forming the application. It is also faster.

**Note:** From Python 2.5 onward, it's much more convenient to cut in at the Abstract Syntax Tree (AST) generation and compilation stage, using the **ast** module.

The **parser** module exports the names documented here also with “st” replaced by “ast”; this is a legacy from the time when there was no other AST and has nothing to do with the AST found in Python 2.5. This is also the reason for the functions’ keyword arguments being called ast, not st. The “ast” functions will be removed in Python 3.0.

There are a few things to note about this module which are important to making use of the data structures created. This is not a tutorial on editing the parse trees for Python code, but some examples of using the **parser** module are presented.

Most importantly, a good understanding of the Python grammar processed by the internal parser is required. For full information on the language syntax, refer to *The Python Language Reference*. The parser itself is created from a grammar specification defined in the
file `Grammar/Grammar` in the standard Python distribution. The parse trees stored in the ST objects created by this module are the actual output from the internal parser when created by the `expr()` or `suite()` functions, described below. The ST objects created by `sequence2st()` faithfully simulate those structures. Be aware that the values of the sequences which are considered “correct” will vary from one version of Python to another as the formal grammar for the language is revised. However, transporting code from one Python version to another as source text will always allow correct parse trees to be created in the target version, with the only restriction being that migrating to an older version of the interpreter will not support more recent language constructs. The parse trees are not typically compatible from one version to another, whereas source code has always been forward-compatible.

Each element of the sequences returned by `st2list()` or `st2tuple()` has a simple form. Sequences representing non-terminal elements in the grammar always have a length greater than one. The first element is an integer which identifies a production in the grammar. These integers are given symbolic names in the C header file `Include/graminit.h` and the Python module `symbol`. Each additional element of the sequence represents a component of the production as recognized in the input string: these are always sequences which have the same form as the parent. An important aspect of this structure which should be noted is that keywords used to identify the parent node type, such as the keyword `if` in an `if_stmt`, are included in the node tree without any special treatment. For example, the `if` keyword is represented by the tuple `(1, 'if')`, where 1 is the numeric value associated with all `NAME` tokens, including variable and function names defined by the user. In an alternate form returned when line number information is requested, the same token might be represented as `(1, 'if', 12)`, where the 12 represents the line number at which the terminal symbol was
Terminal elements are represented in much the same way, but without any child elements and the addition of the source text which was identified. The example of the `if` keyword above is representative. The various types of terminal symbols are defined in the C header file `Include/token.h` and the Python module `token`.

The ST objects are not required to support the functionality of this module, but are provided for three purposes: to allow an application to amortize the cost of processing complex parse trees, to provide a parse tree representation which conserves memory space when compared to the Python list or tuple representation, and to ease the creation of additional modules in C which manipulate parse trees. A simple “wrapper” class may be created in Python to hide the use of ST objects.

The `parser` module defines functions for a few distinct purposes. The most important purposes are to create ST objects and to convert ST objects to other representations such as parse trees and compiled code objects, but there are also functions which serve to query the type of parse tree represented by an ST object.

**See also:**

- **Module `symbol`**
  - Useful constants representing internal nodes of the parse tree.
- **Module `token`**
  - Useful constants representing leaf nodes of the parse tree and functions for testing node values.
30.1.1. Creating ST Objects

ST objects may be created from source code or from a parse tree. When creating an ST object from source, different functions are used to create the 'eval' and 'exec' forms.

```python
parser.expr(source)
```

The `expr()` function parses the parameter `source` as if it were an input to `compile(source, 'file.py', 'eval')`. If the parse succeeds, an ST object is created to hold the internal parse tree representation, otherwise an appropriate exception is thrown.

```python
parser.suite(source)
```

The `suite()` function parses the parameter `source` as if it were an input to `compile(source, 'file.py', 'exec')`. If the parse succeeds, an ST object is created to hold the internal parse tree representation, otherwise an appropriate exception is thrown.

```python
parser.sequence2st(sequence)
```

This function accepts a parse tree represented as a sequence and builds an internal representation if possible. If it can validate that the tree conforms to the Python grammar and all nodes are valid node types in the host version of Python, an ST object is created from the internal representation and returned to the called. If there is a problem creating the internal representation, or if the tree cannot be validated, a `ParserError` exception is thrown. An ST object created this way should not be assumed to compile correctly; normal exceptions thrown by compilation may still be initiated when the ST object is passed to `compilest()`. This may indicate problems not related to syntax (such as a `MemoryError` exception), but may also be due to constructs such as the result of parsing `del f(θ)`, which escapes the Python
parser but is checked by the bytecode compiler.

Sequences representing terminal tokens may be represented as either two-element lists of the form \((1, 'name')\) or as three-element lists of the form \((1, 'name', 56)\). If the third element is present, it is assumed to be a valid line number. The line number may be specified for any subset of the terminal symbols in the input tree.

`parser.tuple2st(sequence)`

This is the same function as `sequence2st()`. This entry point is maintained for backward compatibility.
30.1.2. Converting ST Objects

ST objects, regardless of the input used to create them, may be converted to parse trees represented as list- or tuple- trees, or may be compiled into executable code objects. Parse trees may be extracted with or without line numbering information.

`parser.st2list(ast[, line_info])`

This function accepts an ST object from the caller in `ast` and returns a Python list representing the equivalent parse tree. The resulting list representation can be used for inspection or the creation of a new parse tree in list form. This function does not fail so long as memory is available to build the list representation. If the parse tree will only be used for inspection, `st2tuple()` should be used instead to reduce memory consumption and fragmentation. When the list representation is required, this function is significantly faster than retrieving a tuple representation and converting that to nested lists.

If `line_info` is true, line number information will be included for all terminal tokens as a third element of the list representing the token. Note that the line number provided specifies the line on which the token ends. This information is omitted if the flag is false or omitted.

`parser.st2tuple(ast[, line_info])`

This function accepts an ST object from the caller in `ast` and returns a Python tuple representing the equivalent parse tree. Other than returning a tuple instead of a list, this function is identical to `st2list()`.

If `line_info` is true, line number information will be included for all terminal tokens as a third element of the list representing the
token. This information is omitted if the flag is false or omitted.

```
parser.compile(ast[, filename='<syntax-tree>'])
```

The Python byte compiler can be invoked on an ST object to produce code objects which can be used as part of an `exec` statement or a call to the built-in `eval()` function. This function provides the interface to the compiler, passing the internal parse tree from `ast` to the parser, using the source file name specified by the `filename` parameter. The default value supplied for `filename` indicates that the source was an ST object.

Compiling an ST object may result in exceptions related to compilation; an example would be a `SyntaxError` caused by the parse tree for `del f(θ)`: this statement is considered legal within the formal grammar for Python but is not a legal language construct. The `SyntaxError` raised for this condition is actually generated by the Python byte-compiler normally, which is why it can be raised at this point by the `parser` module. Most causes of compilation failure can be diagnosed programmatically by inspection of the parse tree.
30.1.3. Queries on ST Objects

Two functions are provided which allow an application to determine if an ST was created as an expression or a suite. Neither of these functions can be used to determine if an ST was created from source code via `expr()` or `suite()` or from a parse tree via `sequence2st()`.

**parser.** `isexpr(ast)`

When `ast` represents an 'eval' form, this function returns true, otherwise it returns false. This is useful, since code objects normally cannot be queried for this information using existing built-in functions. Note that the code objects created by `compilest()` cannot be queried like this either, and are identical to those created by the built-in `compile()` function.

**parser.** `issuite(ast)`

This function mirrors `isexpr()` in that it reports whether an ST object represents an 'exec' form, commonly known as a “suite.” It is not safe to assume that this function is equivalent to `not isexpr(ast)`, as additional syntactic fragments may be supported in the future.
30.1.4. Exceptions and Error Handling

The parser module defines a single exception, but may also pass other built-in exceptions from other portions of the Python runtime environment. See each function for information about the exceptions it can raise.

exception `parser.ParserError`

Exception raised when a failure occurs within the parser module. This is generally produced for validation failures rather than the built in `SyntaxError` thrown during normal parsing. The exception argument is either a string describing the reason of the failure or a tuple containing a sequence causing the failure from a parse tree passed to `sequence2st()` and an explanatory string. Calls to `sequence2st()` need to be able to handle either type of exception, while calls to other functions in the module will only need to be aware of the simple string values.

Note that the functions `compilest()`, `expr()`, and `suite()` may throw exceptions which are normally thrown by the parsing and compilation process. These include the built in exceptions `MemoryError`, `OverflowError`, `SyntaxError`, and `SystemError`. In these cases, these exceptions carry all the meaning normally associated with them. Refer to the descriptions of each function for detailed information.
30.1.5. ST Objects

Ordered and equality comparisons are supported between ST objects. Pickling of ST objects (using the pickle module) is also supported.

**parser.STType**

The type of the objects returned by expr(), suite() and sequence2st().

ST objects have the following methods:

**ST.compile([filename])**

Same as compilest(st, filename).

**ST.isexpr()**

Same as isexpr(st).

**ST.issuite()**

Same as issuite(st).

**ST.tolist([line_info])**

Same as st2list(st, line_info).

**ST.totuple([line_info])**

Same as st2tuple(st, line_info).
30.1.6. Examples

The parser modules allows operations to be performed on the parse tree of Python source code before the bytecode is generated, and provides for inspection of the parse tree for information gathering purposes. Two examples are presented. The simple example demonstrates emulation of the `compile()` built-in function and the complex example shows the use of a parse tree for information discovery.

30.1.6.1. Emulation of `compile()`

While many useful operations may take place between parsing and bytecode generation, the simplest operation is to do nothing. For this purpose, using the `parser` module to produce an intermediate data structure is equivalent to the code

```python
>>> code = compile('a + 5', 'file.py', 'eval')
>>> a = 5
>>> eval(code)
10
```

The equivalent operation using the `parser` module is somewhat longer, and allows the intermediate internal parse tree to be retained as an ST object:

```python
>>> import parser
>>> st = parser.expr('a + 5')
>>> code = st.compile('file.py')
>>> a = 5
>>> eval(code)
10
```

An application which needs both ST and code objects can package this code into readily available functions:
import parser

def load_suite(source_string):
    st = parser.suite(source_string)
    return st, st.compile()

def load_expression(source_string):
    st = parser.expr(source_string)
    return st, st.compile()

30.1.6.2. Information Discovery

Some applications benefit from direct access to the parse tree. The remainder of this section demonstrates how the parse tree provides access to module documentation defined in docstrings without requiring that the code being examined be loaded into a running interpreter via `import`. This can be very useful for performing analyses of untrusted code.

Generally, the example will demonstrate how the parse tree may be traversed to distill interesting information. Two functions and a set of classes are developed which provide programmatic access to high level function and class definitions provided by a module. The classes extract information from the parse tree and provide access to the information at a useful semantic level, one function provides a simple low-level pattern matching capability, and the other function defines a high-level interface to the classes by handling file operations on behalf of the caller. All source files mentioned here which are not part of the Python installation are located in the `Demo/parser/` directory of the distribution.

The dynamic nature of Python allows the programmer a great deal of flexibility, but most modules need only a limited measure of this when defining classes, functions, and methods. In this example, the only definitions that will be considered are those which are defined in the top level of their context, e.g., a function defined by a `def`
statement at column zero of a module, but not a function defined within a branch of an if ... else construct, though there are some good reasons for doing so in some situations. Nesting of definitions will be handled by the code developed in the example.

To construct the upper-level extraction methods, we need to know what the parse tree structure looks like and how much of it we actually need to be concerned about. Python uses a moderately deep parse tree so there are a large number of intermediate nodes. It is important to read and understand the formal grammar used by Python. This is specified in the file Grammar/Grammar in the distribution. Consider the simplest case of interest when searching for docstrings: a module consisting of a docstring and nothing else. (See file docstring.py.)

"""Some documentation.
"""

Using the interpreter to take a look at the parse tree, we find a bewildering mass of numbers and parentheses, with the documentation buried deep in nested tuples.

```python
>>> import parser
>>> import pprint
>>> st = parser.suite(open('docstring.py').read())
>>> tup = st.totuple()
>>> pprint.pprint(tup)
(257,
 (264,
  (265,
   (266,
    (267,
     (307,
      (287,
       (288,
        (289,
         (290,
          (292,
           (293,
```

The numbers at the first element of each node in the tree are the node types; they map directly to terminal and non-terminal symbols in the grammar. Unfortunately, they are represented as integers in the internal representation, and the Python structures generated do not change that. However, the `symbol` and `token` modules provide symbolic names for the node types and dictionaries which map from the integers to the symbolic names for the node types.

In the output presented above, the outermost tuple contains four elements: the integer 257 and three additional tuples. Node type 257 has the symbolic name `file_input`. Each of these inner tuples contains an integer as the first element; these integers, 264, 4, and 0, represent the node types `stmt`, `NEWLINE`, and `ENDMARKER`, respectively. Note that these values may change depending on the version of Python you are using; consult `symbol.py` and `token.py` for details of the mapping. It should be fairly clear that the outermost node is related primarily to the input source rather than the contents of the file, and may be disregarded for the moment. The `stmt` node is much more interesting. In particular, all docstrings are found in subtrees which are formed exactly as this node is formed, with the only difference being the string itself. The association between the docstring in a similar tree and the defined entity (class, function, or module) which it describes is given by the position of the docstring subtree within the tree defining the described structure.
By replacing the actual docstring with something to signify a variable component of the tree, we allow a simple pattern matching approach to check any given subtree for equivalence to the general pattern for docstrings. Since the example demonstrates information extraction, we can safely require that the tree be in tuple form rather than list form, allowing a simple variable representation to be `['variable_name']`. A simple recursive function can implement the pattern matching, returning a Boolean and a dictionary of variable name to value mappings. (See file example.py.)

```python
from types import ListType, TupleType

def match(pattern, data, vars=None):
    if vars is None:
        vars = {}
    if type(pattern) is ListType:
        vars[pattern[0]] = data
        return 1, vars
    if type(pattern) is not TupleType:
        return (pattern == data), vars
    if len(data) != len(pattern):
        return 0, vars
    for pattern, data in map(None, pattern, data):
        same, vars = match(pattern, data, vars)
        if not same:
            break
    return same, vars
```

Using this simple representation for syntactic variables and the symbolic node types, the pattern for the candidate docstring subtrees becomes fairly readable. (See file example.py.)

```python
import symbol
import token

DOCSTRING_STMT_PATTERN = (
    symbol.stmt,
    (symbol.simple_stmt,
      (symbol.small_stmt,
        (symbol.expr_stmt,
          (symbol.testlist,
```
(symbol.test,
(symbol.and_test,
(symbol.not_test,
(symbol.comparison,
(symbol.expr,
(symbol.xor_expr,
(symbol.and_expr,
(symbol.shift_expr,
(symbol.arith_expr,
(symbol.term,
(symbol.factor,
(symbol.power,
(symbol.atom,
(token.STRING, ['docstring'])
)))))))))))))))),
(token.NEWLINE, '')
))

Using the match() function with this pattern, extracting the module
docstring from the parse tree created previously is easy:
>>> found, vars = match(DOCSTRING_STMT_PATTERN, tup[1])
>>> found
1
>>> vars
{'docstring': '"""Some documentation.\n"""'}

Once specific data can be extracted from a location where it is
expected, the question of where information can be expected needs
to be answered. When dealing with docstrings, the answer is fairly
simple: the docstring is the first stmt node in a code block
( file_input or suite node types). A module consists of a single
file_input node, and class and function definitions each contain
exactly one suite node. Classes and functions are readily identified
as subtrees of code block nodes which start with (stmt,
(compound_stmt,
(classdef,
... or (stmt,
(compound_stmt,
(funcdef, ... . Note that these subtrees cannot be matched by
match() since it does not support multiple sibling nodes to match
without regard to number. A more elaborate matching function could


be used to overcome this limitation, but this is sufficient for the example.

Given the ability to determine whether a statement might be a docstring and extract the actual string from the statement, some work needs to be performed to walk the parse tree for an entire module and extract information about the names defined in each context of the module and associate any docstrings with the names. The code to perform this work is not complicated, but bears some explanation.

The public interface to the classes is straightforward and should probably be somewhat more flexible. Each “major” block of the module is described by an object providing several methods for inquiry and a constructor which accepts at least the subtree of the complete parse tree which it represents. The ModuleInfo constructor accepts an optional name parameter since it cannot otherwise determine the name of the module.

The public classes include ClassInfo, FunctionInfo, and ModuleInfo. All objects provide the methods get_name(), get_docstring(), get_class_names(), and get_class_info(). The ClassInfo objects support get_method_names() and get_method_info() while the other classes provide get_function_names() and get_function_info().

Within each of the forms of code block that the public classes represent, most of the required information is in the same form and is accessed in the same way, with classes having the distinction that functions defined at the top level are referred to as “methods.” Since the difference in nomenclature reflects a real semantic distinction from functions defined outside of a class, the implementation needs to maintain the distinction. Hence, most of the functionality of the public classes can be implemented in a common base class, SuiteInfoBase, with the accessors for function and method
information provided elsewhere. Note that there is only one class
which represents function and method information; this parallels the
use of the `def` statement to define both types of elements.

Most of the accessor functions are declared in `SuiteInfoBase` and do
not need to be overridden by subclasses. More importantly, the
extraction of most information from a parse tree is handled through a
method called by the `SuiteInfoBase` constructor. The example code
for most of the classes is clear when read alongside the formal
grammar, but the method which recursively creates new information
objects requires further examination. Here is the relevant part of the
`SuiteInfoBase` definition from `example.py`:

```python
class SuiteInfoBase:
    _docstring = ''
    _name = ''

    def __init__(self, tree = None):
        self._class_info = {}
        self._function_info = {}  
        if tree:
            self._extract_info(tree)

    def _extract_info(self, tree):
        # extract docstring
        if len(tree) == 2:
            found, vars = match(DOCSTRING_STMT_PATTERN[1], tree)
        else:
            found, vars = match(DOCSTRING_STMT_PATTERN, tree[3])
        if found:
            self._docstring = eval(vars['docstring'])
        # discover inner definitions
        for node in tree[1:]:
            found, vars = match(COMPOUND_STMT_PATTERN, node)
            if found:
                cstmt = vars['compound']
                if cstmt[0] == symbol.funcdef:
                    name = cstmt[2][1]
                    self._function_info[name] = FunctionInfo(cstmt)
                elif cstmt[0] == symbol.classdef:
                    name = cstmt[2][1]
                    self._class_info[name] = ClassInfo(cstmt)
```
After initializing some internal state, the constructor calls the `_extract_info()` method. This method performs the bulk of the information extraction which takes place in the entire example. The extraction has two distinct phases: the location of the docstring for the parse tree passed in, and the discovery of additional definitions within the code block represented by the parse tree.

The initial `if` test determines whether the nested suite is of the “short form” or the “long form.” The short form is used when the code block is on the same line as the definition of the code block, as in

```python
def square(x): "Square an argument."; return x ** 2
```

while the long form uses an indented block and allows nested definitions:

```python
def make_power(exp):
    "Make a function that raises an argument to the exponent \`e
    def raiser(x, y=exp):
        return x ** y
    return raiser
```

When the short form is used, the code block may contain a docstring as the first, and possibly only, `small_stmt` element. The extraction of such a docstring is slightly different and requires only a portion of the complete pattern used in the more common case. As implemented, the docstring will only be found if there is only one `small_stmt` node in the `simple_stmt` node. Since most functions and methods which use the short form do not provide a docstring, this may be considered sufficient. The extraction of the docstring proceeds using the `match()` function as described above, and the value of the docstring is stored as an attribute of the `SuiteInfoBase` object.
After docstring extraction, a simple definition discovery algorithm operates on the \texttt{stmt} nodes of the \texttt{suite} node. The special case of the short form is not tested; since there are no \texttt{stmt} nodes in the short form, the algorithm will silently skip the single \texttt{simple_stmt} node and correctly not discover any nested definitions.

Each statement in the code block is categorized as a class definition, function or method definition, or something else. For the definition statements, the name of the element defined is extracted and a representation object appropriate to the definition is created with the defining subtree passed as an argument to the constructor. The representation objects are stored in instance variables and may be retrieved by name using the appropriate accessor methods.

The public classes provide any accessors required which are more specific than those provided by the \texttt{SuiteInfoBase} class, but the real extraction algorithm remains common to all forms of code blocks. A high-level function can be used to extract the complete set of information from a source file. (See file \texttt{example.py}.)

```python
def get_docs(fileName):
    import os
    import parser

    source = open(fileName).read()
    basename = os.path.basename(os.path.splitext(fileName)[0])
    st = parser.suite(source)
    return ModuleInfo(st.totuple(), basename)
```

This provides an easy-to-use interface to the documentation of a module. If information is required which is not extracted by the code of this example, the code may be extended at clearly defined points to provide additional capabilities.
30.2. Abstract Syntax Trees

*New in version 2.5:* The low-level `ast` module containing only the node classes.

*New in version 2.6:* The high-level `ast` module containing all helpers.

The `ast` module helps Python applications to process trees of the Python abstract syntax grammar. The abstract syntax itself might change with each Python release; this module helps to find out programmatically what the current grammar looks like.

An abstract syntax tree can be generated by passing `ast.PyCF_ONLY_AST` as a flag to the `compile()` built-in function, or using the `parse()` helper provided in this module. The result will be a tree of objects whose classes all inherit from `ast.AST`. An abstract syntax tree can be compiled into a Python code object using the built-in `compile()` function.
30.2.1. Node classes

class ast.AST

This is the base of all AST node classes. The actual node classes are derived from the Parser/Python.asdl file, which is reproduced below. They are defined in the _ast C module and re-exported in ast.

There is one class defined for each left-hand side symbol in the abstract grammar (for example, ast.stmt or ast.expr). In addition, there is one class defined for each constructor on the right-hand side; these classes inherit from the classes for the left-hand side trees. For example, ast.BinOp inherits from ast.expr. For production rules with alternatives (aka “sums”), the left-hand side class is abstract: only instances of specific constructor nodes are ever created.

_fields

Each concrete class has an attribute _fields which gives the names of all child nodes.

Each instance of a concrete class has one attribute for each child node, of the type as defined in the grammar. For example, ast.BinOp instances have an attribute left of type ast.expr.

If these attributes are marked as optional in the grammar (using a question mark), the value might be None. If the attributes can have zero-or-more values (marked with an asterisk), the values are represented as Python lists. All possible attributes must be present and have valid values when compiling an AST with compile().
Instances of `ast.expr` and `ast.stmt` subclasses have `lineno` and `col_offset` attributes. The `lineno` is the line number of source text (1-indexed so the first line is line 1) and the `col_offset` is the UTF-8 byte offset of the first token that generated the node. The UTF-8 offset is recorded because the parser uses UTF-8 internally.

The constructor of a class `ast.T` parses its arguments as follows:

- If there are positional arguments, there must be as many as there are items in `T._fields`; they will be assigned as attributes of these names.
- If there are keyword arguments, they will set the attributes of the same names to the given values.

For example, to create and populate an `ast.UnaryOp` node, you could use

```python
node = ast.UnaryOp()
node.op = ast.USub()
node.operand = ast.Num()
node.operand.n = 5
node.operand.lineno = 0
node.operand.col_offset = 0
node.lineno = 0
node.col_offset = 0
```

or the more compact

```python
node = ast.UnaryOp(ast.USub(), ast.Num(5, lineno=0, col_offset=0),
                   lineno=0, col_offset=0)
```

*New in version 2.6:* The constructor as explained above was added. In Python 2.5 nodes had to be created by calling the class constructor without arguments and setting the attributes
afterwards.
30.2.2. Abstract Grammar

The module defines a string constant `__version__` which is the decimal Subversion revision number of the file shown below.

The abstract grammar is currently defined as follows:
30.2.3. ast Helpers

New in version 2.6.

Apart from the node classes, ast module defines these utility functions and classes for traversing abstract syntax trees:

**`ast.parse(expr, filename='<unknown>', mode='exec')`**

Parse an expression into an AST node. Equivalent to `compile(expr, filename, mode, ast.PyCF_ONLY_AST)`.

**`ast.literal_eval(node_or_string)`**

Safely evaluate an expression node or a string containing a Python expression. The string or node provided may only consist of the following Python literal structures: strings, numbers, tuples, lists, dicts, booleans, and `None`.

This can be used for safely evaluating strings containing Python expressions from untrusted sources without the need to parse the values oneself.

**`ast.get_docstring(node, clean=True)`**

Return the docstring of the given node (which must be a `FunctionDef`, `ClassDef` or `Module` node), or `None` if it has no docstring. If `clean` is true, clean up the docstring’s indentation with `inspect.cleandoc()`.

**`ast.fix_missing_locations(node)`**

When you compile a node tree with `compile()`, the compiler expects `lineno` and `col_offset` attributes for every node that supports them. This is rather tedious to fill in for generated nodes, so this helper adds these attributes recursively where not already set, by setting them to the values of the parent node. It
works recursively starting at \textit{node}.

\texttt{ast.increment.lineno(node, n=1)}

Increment the line number of each node in the tree starting at \textit{node} by \textit{n}. This is useful to “move code” to a different location in a file.

\texttt{ast.copy.location(new_node, old_node)}

Copy source location (\texttt{lineno} and \texttt{col_offset}) from \textit{old_node} to \textit{new_node} if possible, and return \textit{new_node}.

\texttt{ast.iter.fields(node)}

Yield a tuple of (\texttt{fieldname, value}) for each field in \texttt{node._fields} that is present on \textit{node}.

\texttt{ast.iter.child.nodes(node)}

Yield all direct child nodes of \textit{node}, that is, all fields that are nodes and all items of fields that are lists of nodes.

\texttt{ast.walk(node)}

Recursively yield all child nodes of \textit{node}, in no specified order. This is useful if you only want to modify nodes in place and don’t care about the context.

\texttt{class ast.NodeVisitor}

A node visitor base class that walks the abstract syntax tree and calls a visitor function for every node found. This function may return a value which is forwarded by the \texttt{visit()} method.

This class is meant to be subclassed, with the subclass adding visitor methods.

\texttt{visit(node)}

Visit a node. The default implementation calls the method called \texttt{self.visit\_classname} where \texttt{classname} is the name of
the node class, or `generic_visit()` if that method doesn’t exist.

```python
generic_visit(node)
```

This visitor calls `visit()` on all children of the node.

Note that child nodes of nodes that have a custom visitor method won’t be visited unless the visitor calls `generic_visit()` or visits them itself.

Don’t use the `NodeVisitor` if you want to apply changes to nodes during traversal. For this a special visitor exists (`NodeTransformer`) that allows modifications.

```python
class ast.NodeTransformer
    A NodeVisitor subclass that walks the abstract syntax tree and allows modification of nodes.
```

The `NodeTransformer` will walk the AST and use the return value of the visitor methods to replace or remove the old node. If the return value of the visitor method is `None`, the node will be removed from its location, otherwise it is replaced with the return value. The return value may be the original node in which case no replacement takes place.

Here is an example transformer that rewrites all occurrences of name lookups (foo) to `data['foo']`:

```python
class RewriteName(NodeTransformer):
    def visit_Name(self, node):
        return copy_location(Subscript(
            value=Name(id='data', ctx=Load()),
            slice=Index(value=Str(s=node.id)),
            ctx=node.ctx
        ), node)
```
Keep in mind that if the node you’re operating on has child nodes you must either transform the child nodes yourself or call the `generic_visit()` method for the node first.

For nodes that were part of a collection of statements (that applies to all statement nodes), the visitor may also return a list of nodes rather than just a single node.

Usually you use the transformer like this:

```python
node = YourTransformer().visit(node)
```

```python
ast.dump(node, annotate_fields=True, include_attributes=False)
```

Return a formatted dump of the tree in `node`. This is mainly useful for debugging purposes. The returned string will show the names and the values for fields. This makes the code impossible to evaluate, so if evaluation is wanted `annotate_fields` must be set to False. Attributes such as line numbers and column offsets are not dumped by default. If this is wanted, `include_attributes` can be set to `True`. 
Symbol tables are generated by the compiler from AST just before bytecode is generated. The symbol table is responsible for calculating the scope of every identifier in the code. `symtable` provides an interface to examine these tables.
30.3.1. Generating Symbol Tables

```
symtable.symtable(code, filename, compile_type)
```

Return the toplevel SymbolTable for the Python source `code`. `filename` is the name of the file containing the code. `compile_type` is like the `mode` argument to `compile()`.
30.3.2. Examining Symbol Tables

class symtable.SymbolTable
A namespace table for a block. The constructor is not public.

get_type()
Return the type of the symbol table. Possible values are 'class', 'module', and 'function'.

get_id()
Return the table's identifier.

get_name()
Return the table's name. This is the name of the class if the table is for a class, the name of the function if the table is for a function, or 'top' if the table is global (get_type() returns 'module').

get_lineno()
Return the number of the first line in the block this table represents.

is_optimized()
Return True if the locals in this table can be optimized.

is_nested()
Return True if the block is a nested class or function.

has_children()
Return True if the block has nested namespaces within it. These can be obtained with get_children().

has_exec()
Return True if the block uses exec.
has_import_star()
    Return True if the block uses a starred from-import.

get_identifiers()
    Return a list of names of symbols in this table.

lookup(name)
    Lookup name in the table and return a Symbol instance.

getSymbols()
    Return a list of Symbol instances for names in the table.

getChildren()
    Return a list of the nested symbol tables.

class symtable.Function
    A namespace for a function or method. This class inherits
    SymbolTable.

getParameters()
    Return a tuple containing names of parameters to this
    function.

getLocals()
    Return a tuple containing names of locals in this function.

getGlobals()
    Return a tuple containing names of globals in this function.

getFrees()
    Return a tuple containing names of free variables in this
    function.

class symtable.Class
    A namespace of a class. This class inherits SymbolTable.
get_methods()
Return a tuple containing the names of methods declared in the class.

class symtable.Symbol
An entry in a SymbolTable corresponding to an identifier in the source. The constructor is not public.

get_name()
Return the symbol's name.

is_referenced()
Return True if the symbol is used in its block.

is_imported()
Return True if the symbol is created from an import statement.

is_parameter()
Return True if the symbol is a parameter.

is_global()
Return True if the symbol is global.

is_declared_global()
Return True if the symbol is declared global with a global statement.

is_local()
Return True if the symbol is local to its block.

is_free()
Return True if the symbol is referenced in its block, but not assigned to.

is_assigned()
Return `True` if the symbol is assigned to in its block.

`is_namespace()`
Return `True` if name binding introduces new namespace.

If the name is used as the target of a function or class statement, this will be true.

For example:

```python
g>>> table = symtable.symtable("def some_func(): pass", "s"
g>>> table.lookup("some_func").is_namespace()
True
```

Note that a single name can be bound to multiple objects. If the result is `True`, the name may also be bound to other objects, like an int or list, that does not introduce a new namespace.

`get_namespaces()`
Return a list of namespaces bound to this name.

`get_namespace()`
Return the namespace bound to this name. If more than one namespace is bound, a `ValueError` is raised.
30.4. `symbol` — Constants used with Python parse trees

This module provides constants which represent the numeric values of internal nodes of the parse tree. Unlike most Python constants, these use lower-case names. Refer to the file `Grammar/Grammar` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one additional data object:

```
symbol.sym_name
```

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

See also:

**Module parser**

The second example for the `parser` module shows how to use the `symbol` module.
30.5. token — Constants used with Python parse trees

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file Grammar/Grammar in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one data object and some functions. The functions mirror definitions in the Python C header files.

**token.tok_name**

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

**token.ISTERMINAL(x)**

Return true for terminal token values.

**token.ISNONTERMINAL(x)**

Return true for non-terminal token values.

**token.ISEOF(x)**

Return true if x is the marker indicating the end of input.

See also:

**Module parser**

The second example for the parser module shows how to use the symbol module.
This module allows a Python program to determine if a string is a keyword.

```
keyword.iskeyword(s)
```

Return true if `s` is a Python keyword.

```
keyword.kwlist
```

Sequence containing all the keywords defined for the interpreter. If any keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.
The `tokenize` module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing “pretty-printers,” including colorizers for on-screen displays.

The primary entry point is a *generator*:

```python
tokenize.generate_tokens(readline)
```

The `generate_tokens()` generator requires one argument, `readline`, which must be a callable object which provides the same interface as the `readline()` method of built-in file objects (see section *File Objects*). Each call to the function should return one line of input as a string.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple `(srow, scol)` of ints specifying the row and column where the token begins in the source; a 2-tuple `(erow, ecol)` of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed (the last tuple item) is the logical line; continuation lines are included.

*New in version 2.2.*

An older entry point is retained for backward compatibility:

```python
tokenize.tokenize(readline[, tokeneater])
```

The `tokenize()` function accepts two parameters: one representing the input stream, and one providing an output
mechanism for \texttt{tokenize}.

The first parameter, \texttt{readline}, must be a callable object which provides the same interface as the \texttt{readline()} method of built-in file objects (see section \textit{File Objects}). Each call to the function should return one line of input as a string. Alternately, \texttt{readline} may be a callable object that signals completion by raising \texttt{StopIteration}.

\textit{Changed in version 2.5: Added \texttt{StopIteration} support.}

The second parameter, \texttt{tokeneater}, must also be a callable object. It is called once for each token, with five arguments, corresponding to the tuples generated by \texttt{generate_tokens()}.

All constants from the \texttt{token} module are also exported from \texttt{tokenize}, as are two additional token type values that might be passed to the \texttt{tokeneater} function by \texttt{tokenize()}:

\texttt{tokenize.COMMENT}

Token value used to indicate a comment.

\texttt{tokenize.NL}

Token value used to indicate a non-terminating newline. The NEWLINE token indicates the end of a logical line of Python code; NL tokens are generated when a logical line of code is continued over multiple physical lines.

Another function is provided to reverse the tokenization process. This is useful for creating tools that tokenize a script, modify the token stream, and write back the modified script.

\texttt{tokenize.untokenize(iterable)}

Converts tokens back into Python source code. The \texttt{iterable} must return sequences with at least two elements, the token type and
the token string. Any additional sequence elements are ignored.

The reconstructed script is returned as a single string. The result is guaranteed to tokenize back to match the input so that the conversion is lossless and round-trips are assured. The guarantee applies only to the token type and token string as the spacing between tokens (column positions) may change.

*New in version 2.5.*

Example of a script re-writer that transforms float literals into Decimal objects:

```python
def decistmt(s):
    """Substitute Decimals for floats in a string of statements.
    >>> from decimal import Decimal
    >>> s = 'print +21.3e-5*-1234/81.7'
    >>> decistmt(s)
    "print +Decimal ('21.3e-5')*-Decimal ('1234')/Decimal ('81"
    >>> exec(s)
    -3.21716034272e-007
    >>> exec(decistmt(s))
    -3.217160342717258261933904529E-7
    """
    result = []
    g = generate_tokens(StringIO(s).readline)  # tokenize the
    for toknum, tokval, __, __, __ in g:
        if toknum == NUMBER and '.' in tokval:  # replace NUMBE
            result.extend([
                (NAME, 'Decimal'),
                (OP, '('),
                (STRING, repr(tokval)),
                (OP, ')')
            ])
        else:
            result.append((toknum, tokval))
    return untokenize(result)
```
30.8. tabnanny — Detection of ambiguous indentation

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function `check()` described below.

**Note:** The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

`tabnanny.check(file_or_dir)`

If `file_or_dir` is a directory and not a symbolic link, then recursively descend the directory tree named by `file_or_dir`, checking all `.py` files along the way. If `file_or_dir` is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the `print` statement.

`tabnanny.verbose`

Flag indicating whether to print verbose messages. This is incremented by the `-v` option if called as a script.

`tabnanny.filename_only`

Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the `-q` option if called as a script.

`exception tabnanny.NannyNag`

Raised by `tokeneater()` if detecting an ambiguous indent. Captured and handled in `check()`.

`tabnanny.tokeneater(type, token, start, end, line)`
This function is used by `check()` as a callback parameter to the function `tokenize.tokenize()`.

See also:

**Module tokenize**

Lexical scanner for Python source code.
30.9. pyc1br — Python class browser support

The pyc1br module can be used to determine some limited information about the classes, methods and top-level functions defined in a module. The information provided is sufficient to implement a traditional three-pane class browser. The information is extracted from the source code rather than by importing the module, so this module is safe to use with untrusted code. This restriction makes it impossible to use this module with modules not implemented in Python, including all standard and optional extension modules.

pyclbr.readmodule(module[, path=None])

Read a module and return a dictionary mapping class names to class descriptor objects. The parameter module should be the name of a module as a string; it may be the name of a module within a package. The path parameter should be a sequence, and is used to augment the value of sys.path, which is used to locate module source code.

pyclbr.readmodule_ex(module[, path=None])

Like readmodule(), but the returned dictionary, in addition to mapping class names to class descriptor objects, also maps top-level function names to function descriptor objects. Moreover, if the module being read is a package, the key '__path__' in the returned dictionary has as its value a list which contains the package search path.
30.9.1. Class Objects

The class objects used as values in the dictionary returned by readmodule() and readmodule_ex() provide the following data members:

Class. module
The name of the module defining the class described by the class descriptor.

Class. name
The name of the class.

Class. super
A list of class objects which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by readmodule() are listed as a string with the class name instead of as class objects.

Class. methods
A dictionary mapping method names to line numbers.

Class. file
Name of the file containing the class statement defining the class.

Class. lineno
The line number of the class statement within the file named by file.
30.9.2. Function Objects

The Function objects used as values in the dictionary returned by `readmodule_ex()` provide the following data members:

Function. `module`

The name of the module defining the function described by the function descriptor.

Function. `name`

The name of the function.

Function. `file`

Name of the file containing the `def` statement defining the function.

Function. `lineno`

The line number of the `def` statement within the file named by `file`.
30.10. py_compile — Compile Python source files

The `py_compile` module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

**exception** `py_compile.PyCompileError`

Exception raised when an error occurs while attempting to compile the file.

`py_compile.compile(file[, cfile[, dfile[, dorate]]]])`

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file name `file`. The byte-code is written to `cfile`, which defaults to `file + 'c'` (`'o'` if optimization is enabled in the current interpreter). If `dfile` is specified, it is used as the name of the source file in error messages instead of `file`. If `dorate` is true, a `PyCompileError` is raised when an error is encountered while compiling `file`. If `dorate` is false (the default), an error string is written to `sys.stderr`, but no exception is raised.

`py_compile.main([args])`

Compile several source files. The files named in `args` (or on the command line, if `args` is not specified) are compiled and the resulting bytecode is cached in the normal manner. This function does not search a directory structure to locate source files; it only
compiles files named explicitly.

When this module is run as a script, the \texttt{main()} is used to compile all the files named on the command line. The exit status is nonzero if one of the files could not be compiled.

\textit{Changed in version 2.6:} Added the nonzero exit status when module is run as a script.

\textbf{See also:}

\textbf{Module compileall}

Utilities to compile all Python source files in a directory tree.
30.11. compileall — Byte-compile Python libraries

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree, allowing users without permission to write to the libraries to take advantage of cached byte-code files.

This module may also be used as a script (using the -m Python flag) to compile Python sources. Directories to recursively traverse (passing -l stops the recursive behavior) for sources are listed on the command line. If no arguments are given, the invocation is equivalent to -l sys.path. Printing lists of the files compiled can be disabled with the -q flag. In addition, the -x option takes a regular expression argument. All files that match the expression will be skipped.

compileall.compile_dir(dir[, maxlevels[, ddir[, force[, rx[, quiet]]]]]])

Recursively descend the directory tree named by dir, compiling all .py files along the way. The maxlevels parameter is used to limit the depth of the recursion; it defaults to 10. If ddir is given, it is used as the base path from which the filenames used in error messages will be generated. If force is true, modules are re-compiled even if the timestamps are up to date.

If rx is given, it specifies a regular expression of file names to exclude from the search; that expression is searched for in the full path.

If quiet is true, nothing is printed to the standard output in normal operation.
`compileall.compile_path([skip_curdir, maxlevels, force])`

Byte-compile all the `.py` files found along `sys.path`. If `skip_curdir` is true (the default), the current directory is not included in the search. The `maxlevels` and `force` parameters default to 0 and are passed to the `compile_dir()` function.

To force a recompile of all the `.py` files in the `Lib/` subdirectory and all its subdirectories:

```python
import compileall

compileall.compile_dir('Lib/', force=True)

# Perform same compilation, excluding files in .svn directories
import re
compileall.compile_dir('Lib/', rx=re.compile('/\.[.]svn'), force=True)
```

See also:

**Module py_compile**

Byte-compile a single source file.
30.12. dis — Disassembler for Python bytecode

The dis module supports the analysis of Python bytecode by disassembling it. Since there is no Python assembler, this module defines the Python assembly language. The Python bytecode which this module takes as an input is defined in the file Include/opcode.h and used by the compiler and the interpreter.

Example: Given the function myfunc():

```python
def myfunc(alist):
    return len(alist)
```

the following command can be used to get the disassembly of myfunc():

```plaintext
>>> dis.dis(myfunc)
    2           0  LOAD_GLOBAL               0 (len)
    3           0  LOAD_FAST                 0 (alist)
    6           1  CALL_FUNCTION
    9           0  RETURN_VALUE
```

(The “2” is a line number).

The dis module defines the following functions and constants:

```plaintext
dis.dis([bytesource])
```

Disassemble the bytesource object. bytesource can denote either a module, a class, a method, a function, or a code object. For a module, it disassembles all functions. For a class, it disassembles all methods. For a single code sequence, it prints one line per bytecode instruction. If no object is provided, it disassembles the last traceback.
dis. **distb**([*tb*])
Disassembles the top-of-stack function of a traceback, using the last traceback if none was passed. The instruction causing the exception is indicated.

**disassemble**(*code*, [,*lasti]*)
Disassembles a code object, indicating the last instruction if *lasti* was provided. The output is divided in the following columns:

1. the line number, for the first instruction of each line
2. the current instruction, indicated as -->
3. a labelled instruction, indicated with >>
4. the address of the instruction,
5. the operation code name,
6. operation parameters, and
7. interpretation of the parameters in parentheses.
The parameter interpretation recognizes local and global variable names, constant values, branch targets, and compare operators.

**disco**(*code*, [,*lasti]*)
A synonym for **disassemble**(). It is more convenient to type, and kept for compatibility with earlier Python releases.

**findlinestarts**(*code*)
This generator function uses the **co_firstlineno** and **co_lnotab** attributes of the code object *code* to find the offsets which are starts of lines in the source code. They are generated as (offset, lineno) pairs.

**findlabels**(*code*)
Detect all offsets in the code object *code* which are jump targets, and return a list of these offsets.

**opname**
Sequence of operation names, indexable using the bytecode.

dis. **opmap**
   Dictionary mapping bytecodes to operation names.

dis. **cmp_op**
   Sequence of all compare operation names.

dis. **hasconst**
   Sequence of bytecodes that have a constant parameter.

dis. **hasfree**
   Sequence of bytecodes that access a free variable.

dis. **hasname**
   Sequence of bytecodes that access an attribute by name.

dis. **hasjrel**
   Sequence of bytecodes that have a relative jump target.

dis. **hasjabs**
   Sequence of bytecodes that have an absolute jump target.

dis. **haslocal**
   Sequence of bytecodes that access a local variable.

dis. **hascompare**
   Sequence of bytecodes of Boolean operations.
30.12.1. Python Bytecode Instructions

The Python compiler currently generates the following bytecode instructions.

**STOP_CODE()**
Indicates end-of-code to the compiler, not used by the interpreter.

**NOP()**
Do nothing code. Used as a placeholder by the bytecode optimizer.

**POP_TOP()**
Removes the top-of-stack (TOS) item.

**ROT_TWO()**
Swaps the two top-most stack items.

**ROT_THREE()**
Lifts second and third stack item one position up, moves top down to position three.

**ROT_FOUR()**
Lifts second, third and forth stack item one position up, moves top down to position four.

**DUP_TOP()**
Duplicates the reference on top of the stack.

Unary Operations take the top of the stack, apply the operation, and push the result back on the stack.

**UNARY_POSITIVE()**
Implements $\text{TOS} = +\text{TOS}$. 
**UNARY_NEGATIVE()**
Implements \( \text{TOS} = -\text{TOS} \).

**UNARY_NOT()**
Implements \( \text{TOS} = \text{not} \ \text{TOS} \).

**UNARY_CONVERT()**
Implements \( \text{TOS} = \`\text{TOS}`\).

**UNARY_INVERT()**
Implements \( \text{TOS} = \sim\text{TOS} \).

**GET_ITER()**
Implements \( \text{TOS} = \text{iter} (\text{TOS}) \).

Binary operations remove the top of the stack (TOS) and the second top-most stack item (TOS1) from the stack. They perform the operation, and put the result back on the stack.

**BINARY_POWER()**
Implements \( \text{TOS} = \text{TOS1} ** \text{TOS} \).

**BINARY_MULTIPLY()**
Implements \( \text{TOS} = \text{TOS1} * \text{TOS} \).

**BINARY_DIVIDE()**
Implements \( \text{TOS} = \text{TOS1} / \text{TOS} \) when from \text{__future__} import \text{division} is not in effect.

**BINARY_FLOOR_DIVIDE()**
Implements \( \text{TOS} = \text{TOS1} // \text{TOS} \).

**BINARY_TRUE_DIVIDE()**
Implements \( \text{TOS} = \text{TOS1} / \text{TOS} \) when from \text{__future__} import \text{division} is not in effect.
division is in effect.

**BINARY_MODULO()**
Implements \( TOS = TOS1 \% TOS \).

**BINARY_ADD()**
Implements \( TOS = TOS1 + TOS \).

**BINARY_SUBTRACT()**
Implements \( TOS = TOS1 - TOS \).

**BINARY_SUBSCR()**
Implements \( TOS = TOS1[TOS] \).

**BINARY_LSHIFT()**
Implements \( TOS = TOS1 << TOS \).

**BINARY_RSHIFT()**
Implements \( TOS = TOS1 >> TOS \).

**BINARY_AND()**
Implements \( TOS = TOS1 \& TOS \).

**BINARY_XOR()**
Implements \( TOS = TOS1 ^ TOS \).

**BINARY_OR()**
Implements \( TOS = TOS1 | TOS \).

In-place operations are like binary operations, in that they remove TOS and TOS1, and push the result back on the stack, but the operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.
INPLACE_POWER()
   Implements in-place TOS = TOS1 ** TOS.

INPLACE_MULTIPLY()
   Implements in-place TOS = TOS1 * TOS.

INPLACE_DIVIDE()
   Implements in-place TOS = TOS1 / TOS when from __future__
   import division is not in effect.

INPLACE_FLOOR_DIVIDE()
   Implements in-place TOS = TOS1 // TOS.

INPLACE_TRUE_DIVIDE()
   Implements in-place TOS = TOS1 / TOS when from __future__
   import division is in effect.

INPLACE_MODULO()
   Implements in-place TOS = TOS1 % TOS.

INPLACE_ADD()
   Implements in-place TOS = TOS1 + TOS.

INPLACE_SUBTRACT()
   Implements in-place TOS = TOS1 - TOS.

INPLACE_LSHIFT()
   Implements in-place TOS = TOS1 << TOS.

INPLACE_RSHIFT()
   Implements in-place TOS = TOS1 >> TOS.

INPLACE_AND()
Implements in-place $TOS = TOS1 \& TOS$.

**INPLACE\_XOR()**
Implements in-place $TOS = TOS1 \^ TOS$.

**INPLACE\_OR()**
Implements in-place $TOS = TOS1 \mid TOS$.

The slice opcodes take up to three parameters.

**SLICE+0()**
Implements $TOS = TOS[:]$.

**SLICE+1()**
Implements $TOS = TOS1[TOS:]$.

**SLICE+2()**
Implements $TOS = TOS1[:TOS]$.

**SLICE+3()**
Implements $TOS = TOS2[TOS1:TOS]$.

Slice assignment needs even an additional parameter. As any statement, they put nothing on the stack.

**STORE\_SLICE+0()**
Implements $TOS[:] = TOS1$.

**STORE\_SLICE+1()**
Implements $TOS1[TOS:] = TOS2$.

**STORE\_SLICE+2()**
Implements $TOS1[:TOS] = TOS2$. 
STORE_SLICE+3()
    Implements $TOS2[TOS1:TOS] = TOS3$.

DELETE_SLICE+0()
    Implements $del TOS[::]$.

DELETE_SLICE+1()
    Implements $del TOS1[TOS:]$.

DELETE_SLICE+2()
    Implements $del TOS1[:TOS]$.

DELETE_SLICE+3()
    Implements $del TOS2[TOS1:TOS]$.

STORE_SUBSCR()
    Implements $TOS1[TOS] = TOS2$.

DELETE_SUBSCR()
    Implements $del TOS1[TOS]$.

Miscellaneous opcodes.

PRINT_EXPR()
    Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with POP_STACK.

PRINT_ITEM()
    Prints TOS to the file-like object bound to sys.stdout. There is one such instruction for each item in the print statement.

PRINT_ITEM_TO()
    Like PRINT_ITEM, but prints the item second from TOS to the file-
like object at TOS. This is used by the extended print statement.

**PRINT_NEWLINE()**
Prints a new line on `sys.stdout`. This is generated as the last operation of a `print` statement, unless the statement ends with a comma.

**PRINT_NEWLINE_TO()**
Like PRINT_NEWLINE, but prints the new line on the file-like object on the TOS. This is used by the extended print statement.

**BREAK_LOOP()**
Terminates a loop due to a `break` statement.

**CONTINUE_LOOP(target)**
Continues a loop due to a `continue` statement. `target` is the address to jump to (which should be a `FOR_ITER` instruction).

**LIST_APPEND(i)**
Calls `list.append(TOS[-i], TOS)`. Used to implement list comprehensions. While the appended value is popped off, the list object remains on the stack so that it is available for further iterations of the loop.

**LOAD_LOCALS()**
Pushes a reference to the locals of the current scope on the stack. This is used in the code for a class definition: After the class body is evaluated, the locals are passed to the class definition.

**RETURN_VALUE()**
Returns with TOS to the caller of the function.

**YIELD_VALUE()**
Pops \texttt{tos} and yields it from a \textit{generator}.

\textbf{IMPORT\_STAR()}  
Loads all symbols not starting with '\_' directly from the module \texttt{TOS} to the local namespace. The module is popped after loading all names. This opcode implements \texttt{from module import *}.

\textbf{EXEC\_STMT()}  
Implements \texttt{exec TOS2,TOS1,TOS}. The compiler fills missing optional parameters with \texttt{None}.

\textbf{POP\_BLOCK()}  
Removes one block from the block stack. Per frame, there is a stack of blocks, denoting nested loops, try statements, and such.

\textbf{END\_FINALLY()}  
Terminates a \texttt{finally} clause. The interpreter recalls whether the exception has to be re-raised, or whether the function returns, and continues with the outer-next block.

\textbf{BUILD\_CLASS()}  
Creates a new class object. \texttt{TOS} is the methods dictionary, \texttt{TOS1} the tuple of the names of the base classes, and \texttt{TOS2} the class name.

\textbf{SETUP\_WITH}(\textit{delta})  
This opcode performs several operations before a with block starts. First, it loads \texttt{__exit__()} from the context manager and pushes it onto the stack for later use by \texttt{WITH\_CLEANUP}. Then, \texttt{__enter__()} is called, and a finally block pointing to \texttt{delta} is pushed. Finally, the result of calling the enter method is pushed onto the stack. The next opcode will either ignore it (\texttt{POP\_TOP}), or store it in (a) variable(s) (\texttt{STORE\_FAST}, \texttt{STORE\_NAME}, or
UNPACK_SEQUENCE.

WITH_CLEANUP()
Cleans up the stack when a `with` statement block exits. On top of the stack are 1–3 values indicating how/why the finally clause was entered:

- TOP = `None`
- (TOP, SECOND) = `(WHY_{RETURN, CONTINUE})`, retval
- TOP = `WHY_`*; no retval below it
- (TOP, SECOND, THIRD) = `exc_info()`

Under them is EXIT, the context manager’s `__exit__()` bound method.

In the last case, `EXIT(TOP, SECOND, THIRD)` is called, otherwise `EXIT(None, None, None)`.

EXIT is removed from the stack, leaving the values above it in the same order. In addition, if the stack represents an exception, and the function call returns a ‘true’ value, this information is “zapped”, to prevent `END_FINALLY` from re-raising the exception. (But non-local gotos should still be resumed.)

All of the following opcodes expect arguments. An argument is two bytes, with the more significant byte last.

STORE_NAME`(namei)`
Implements `name = TOS`. `namei` is the index of `name` in the attribute `co_names` of the code object. The compiler tries to use `STORE_FAST` or `STORE_GLOBAL` if possible.

DELETE_NAME`(namei)`
Implements `del name`, where `namei` is the index into `co_names`
attribute of the code object.

**UNPACK_SEQUENCE** *(count)*

Unpacks TOS into *count* individual values, which are put onto the stack right-to-left.

**DUP_TOPX** *(count)*

Duplicate *count* items, keeping them in the same order. Due to implementation limits, *count* should be between 1 and 5 inclusive.

**STORE_ATTR** *(namei)*

Implements TOS.name = TOS1, where *namei* is the index of name in co_names.

**DELETE_ATTR** *(namei)*

Implements del TOS.name, using *namei* as index into co_names.

**STORE_GLOBAL** *(namei)*

Works as STORE_NAME, but stores the name as a global.

**DELETE_GLOBAL** *(namei)*

Works as DELETE_NAME, but deletes a global name.

**LOAD_CONST** *(consti)*

Pushes co_consts[consti] onto the stack.

**LOAD_NAME** *(namei)*

Pushes the value associated with co_names[namei] onto the stack.

**BUILD_TUPLE** *(count)*

Creates a tuple consuming *count* items from the stack, and pushes the resulting tuple onto the stack.
**BUILD_LIST**(count)
Works as **BUILD_TUPLE**, but creates a list.

**BUILD_MAP**(count)
Pushes a new dictionary object onto the stack. The dictionary is pre-sized to hold count entries.

**LOAD_ATTR**(namei)
Replaces TOS with `getattr(TOS, co_names[namei])`.

**COMPARE_OP**(opname)
Performs a Boolean operation. The operation name can be found in `cmp_op[opname]`.

**IMPORT_NAME**(namei)
Imports the module `co_names[namei]`. TOS and TOS1 are popped and provide the `fromlist` and `level` arguments of `__import__()`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent **STORE_FAST** instruction modifies the namespace.

**IMPORT_FROM**(namei)
Loads the attribute `co_names[namei]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a **STORE_FAST** instruction.

**JUMP_FORWARD**(delta)
Increments bytecode counter by delta.

**POP_JUMP_IF_TRUE**(target)
If TOS is true, sets the bytecode counter to target. TOS is popped.

**POP_JUMP_IF_FALSE**(target)
If TOS is false, sets the bytecode counter to target. TOS is popped.

\textbf{JUMP\_IF\_TRUE\_OR\_POP}(target)

If TOS is true, sets the bytecode counter to target and leaves TOS on the stack. Otherwise (TOS is false), TOS is popped.

\textbf{JUMP\_IF\_FALSE\_OR\_POP}(target)

If TOS is false, sets the bytecode counter to target and leaves TOS on the stack. Otherwise (TOS is true), TOS is popped.

\textbf{JUMP\_ABSOLUTE}(target)

Set bytecode counter to target.

\textbf{FOR\_ITER}(delta)

TOS is an \textit{iterator}. Call its \texttt{next()} method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted TOS is popped, and the bytecode counter is incremented by \textit{delta}.

\textbf{LOAD\_GLOBAL}(namei)

Loads the global named \texttt{co_names[namei]} onto the stack.

\textbf{SETUP\_LOOP}(delta)

Pushes a block for a loop onto the block stack. The block spans from the current instruction with a size of \textit{delta} bytes.

\textbf{SETUP\_EXCEPT}(delta)

Pushes a try block from a try-except clause onto the block stack. \textit{delta} points to the first except block.

\textbf{SETUP\_FINALLY}(delta)

Pushes a try block from a try-except clause onto the block stack. \textit{delta} points to the finally block.
STORE_MAP()
Store a key and value pair in a dictionary. Pops the key and value while leaving the dictionary on the stack.

LOAD_FAST(var_num)
Pushes a reference to the local \texttt{co_varnames[var_num]} onto the stack.

STORE_FAST(var_num)
Stores TOS into the local \texttt{co_varnames[var_num]}.

DELETE_FAST(var_num)
Deletes local \texttt{co_varnames[var_num]}.

LOAD_CLOSURE(i)
Pushes a reference to the cell contained in slot \texttt{i} of the cell and free variable storage. The name of the variable is \texttt{co_cellvars[i]} if \texttt{i} is less than the length of \texttt{co_cellvars}. Otherwise it is \texttt{co_freevars[i - len(co_cellvars)]}.

LOAD_DEREF(i)
Loads the cell contained in slot \texttt{i} of the cell and free variable storage. Pushes a reference to the object the cell contains on the stack.

STORE_DEREF(i)
Stores TOS into the cell contained in slot \texttt{i} of the cell and free variable storage.

SET_LINENO(lineno)
This opcode is obsolete.

RAISE_VARARGS(argc)
Raises an exception. \texttt{argc} indicates the number of parameters to
the raise statement, ranging from 0 to 3. The handler will find the traceback as TOS2, the parameter as TOS1, and the exception as TOS.

**CALL_FUNCTION**(argc)
Calls a function. The low byte of argc indicates the number of positional parameters, the high byte the number of keyword parameters. On the stack, the opcode finds the keyword parameters first. For each keyword argument, the value is on top of the key. Below the keyword parameters, the positional parameters are on the stack, with the right-most parameter on top. Below the parameters, the function object to call is on the stack. Pops all function arguments, and the function itself off the stack, and pushes the return value.

**MAKE_FUNCTION**(argc)
Pushes a new function object on the stack. TOS is the code associated with the function. The function object is defined to have argc default parameters, which are found below TOS.

**MAKE_CLOSURE**(argc)
Creates a new function object, sets its func_closure slot, and pushes it on the stack. TOS is the code associated with the function, TOS1 the tuple containing cells for the closure’s free variables. The function also has argc default parameters, which are found below the cells.

**BUILD_SLICE**(argc)
Pushes a slice object on the stack. argc must be 2 or 3. If it is 2, slice(TOS1, TOS) is pushed; if it is 3, slice(TOS2, TOS1, TOS) is pushed. See the slice() built-in function for more information.

**EXTENDED_ARG**(ext)
Prefixes any opcode which has an argument too big to fit into the
default two bytes. ext holds two additional bytes which, taken together with the subsequent opcode’s argument, comprise a four-byte argument, ext being the two most-significant bytes.

**CALL_FUNCTION_VAR**(argc)

Calls a function. argc is interpreted as in CALL_FUNCTION. The top element on the stack contains the variable argument list, followed by keyword and positional arguments.

**CALL_FUNCTION_KW**(argc)

Calls a function. argc is interpreted as in CALL_FUNCTION. The top element on the stack contains the keyword arguments dictionary, followed by explicit keyword and positional arguments.

**CALL_FUNCTION_VAR_KW**(argc)

Calls a function. argc is interpreted as in CALL_FUNCTION. The top element on the stack contains the keyword arguments dictionary, followed by the variable-arguments tuple, followed by explicit keyword and positional arguments.

**HAVE_ARGUMENT()**

This is not really an opcode. It identifies the dividing line between opcodes which don’t take arguments < HAVE_ARGUMENT and those which do >= HAVE_ARGUMENT.
30.13. pickletools — Tools for pickle developers

New in version 2.3.

This module contains various constants relating to the intimate details of the pickle module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the pickle and cPickle implementations; ordinary users of the pickle module probably won’t find the pickletools module relevant.

```
pickletools.dis(pickle[, out=None, memo=None, indentlevel=4])
```

Outputs a symbolic disassembly of the pickle to the file-like object `out`, defaulting to `sys.stdout`. `pickle` can be a string or a file-like object. `memo` can be a Python dictionary that will be used as the pickle’s memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by `MARK` opcodes in the stream, are indented by `indentlevel` spaces.

```
pickletools.genops(pickle)
```

Provides an iterator over all of the opcodes in a pickle, returning a sequence of `(opcode, arg, pos)` triples. `opcode` is an instance of an `OpcodeInfo` class; `arg` is the decoded value, as a Python object, of the opcode’s argument; `pos` is the position at which this opcode is located. `pickle` can be a string or a file-like object.

```
pickletools.optimize(picklestring)
```

Returns a new equivalent pickle string after eliminating unused `PUT` opcodes. The optimized pickle is shorter, takes less
transmission time, requires less storage space, and unpickles more efficiently.

New in version 2.6.
31. Python compiler package

*Deprecated since version 2.6:* The `compiler` package has been removed in Python 3.0.

The Python compiler package is a tool for analyzing Python source code and generating Python bytecode. The compiler contains libraries to generate an abstract syntax tree from Python source code and to generate Python bytecode from the tree.

The `compiler` package is a Python source to bytecode translator written in Python. It uses the built-in parser and standard `parser` module to generated a concrete syntax tree. This tree is used to generate an abstract syntax tree (AST) and then Python bytecode.

The full functionality of the package duplicates the built-in compiler provided with the Python interpreter. It is intended to match its behavior almost exactly. Why implement another compiler that does the same thing? The package is useful for a variety of purposes. It can be modified more easily than the built-in compiler. The AST it generates is useful for analyzing Python source code.

This chapter explains how the various components of the `compiler` package work. It blends reference material with a tutorial.
31.1. The basic interface

The top-level of the package defines four functions. If you import `compiler`, you will get these functions and a collection of modules contained in the package.

`compiler.parse(buf)`

Returns an abstract syntax tree for the Python source code in `buf`. The function raises `SyntaxError` if there is an error in the source code. The return value is a `compiler.ast.Module` instance that contains the tree.

`compiler.parseFile(path)`

Return an abstract syntax tree for the Python source code in the file specified by `path`. It is equivalent to `parse(open(path).read())`.

`compiler.walk(ast, visitor[, verbose])`

Do a pre-order walk over the abstract syntax tree `ast`. Call the appropriate method on the `visitor` instance for each node encountered.

`compiler.compile(source, filename, mode, flags=None, dont_inherit=None)`

Compile the string `source`, a Python module, statement or expression, into a code object that can be executed by the `exec` statement or `eval()`. This function is a replacement for the built-in `compile()` function.

The `filename` will be used for run-time error messages.

The `mode` must be ‘exec’ to compile a module, ‘single’ to compile a single (interactive) statement, or ‘eval’ to compile an
expression.

The flags and dont_inherit arguments affect future-related statements, but are not supported yet.

compiler.compileFile(source)

Compiles the file source and generates a .pyc file.

The compiler package contains the following modules: ast, consts, future, misc, pyassem, pycodegen, symbols, transformer, and visitor.
There are some problems with the error checking of the compiler package. The interpreter detects syntax errors in two distinct phases. One set of errors is detected by the interpreter’s parser, the other set by the compiler. The compiler package relies on the interpreter’s parser, so it gets the first phases of error checking for free. It implements the second phase itself, and that implementation is incomplete. For example, the compiler package does not raise an error if a name appears more than once in an argument list: `def f(x, x): ...`

A future version of the compiler should fix these problems.
31.3. Python Abstract Syntax

The compiler.ast module defines an abstract syntax for Python. In the abstract syntax tree, each node represents a syntactic construct. The root of the tree is Module object.

The abstract syntax offers a higher level interface to parsed Python source code. The parser module and the compiler written in C for the Python interpreter use a concrete syntax tree. The concrete syntax is tied closely to the grammar description used for the Python parser. Instead of a single node for a construct, there are often several levels of nested nodes that are introduced by Python’s precedence rules.

The abstract syntax tree is created by the compiler.transformer module. The transformer relies on the built-in Python parser to generate a concrete syntax tree. It generates an abstract syntax tree from the concrete tree.

The transformer module was created by Greg Stein and Bill Tutt for an experimental Python-to-C compiler. The current version contains a number of modifications and improvements, but the basic form of the abstract syntax and of the transformer are due to Stein and Tutt.

31.3.1. AST Nodes

The compiler.ast module is generated from a text file that describes each node type and its elements. Each node type is represented as a class that inherits from the abstract base class compiler.ast.Node and defines a set of named attributes for child nodes.

```python
class compiler.ast.Node
    The Node instances are created automatically by the parser
```
generator. The recommended interface for specific Node instances is to use the public attributes to access child nodes. A public attribute may be bound to a single node or to a sequence of nodes, depending on the Node type. For example, the bases attribute of the class node, is bound to a list of base class nodes, and the doc attribute is bound to a single node.

Each Node instance has a lineno attribute which may be None. XXX Not sure what the rules are for which nodes will have a useful lineno.

All Node objects offer the following methods:

gETCHILDREN()

Returns a flattened list of the child nodes and objects in the order they occur. Specifically, the order of the nodes is the order in which they appear in the Python grammar. Not all of the children are Node instances. The names of functions and classes, for example, are plain strings.

gETCHILDNODES()

Returns a flattened list of the child nodes in the order they occur. This method is like getChildren(), except that it only returns those children that are Node instances.

Two examples illustrate the general structure of Node classes. The while statement is defined by the following grammar production:

```
while_stmt:    "while" expression ":" suite
["else" ":" suite]
```

The While node has three attributes: test, body, and else_. (If the natural name for an attribute is also a Python reserved word, it can’t be used as an attribute name. An underscore is appended to the
word to make it a legal identifier, hence `else_` instead of `else`.)

The `if` statement is more complicated because it can include several tests.

```plaintext
if_stmt: 'if' test ':' suite ('elif' test ':' suite)* ['else' ':' suite]
```

The `If` node only defines two attributes: `tests` and `else_`. The `tests` attribute is a sequence of test expression, consequent body pairs. There is one pair for each `if/elif` clause. The first element of the pair is the test expression. The second elements is a `Stmt` node that contains the code to execute if the test is true.

The `getChildren()` method of `If` returns a flat list of child nodes. If there are three `if/elif` clauses and no `else` clause, then `getChildren()` will return a list of six elements: the first test expression, the first `Stmt`, the second test expression, etc.

The following table lists each of the `Node` subclasses defined in `compiler.ast` and each of the public attributes available on their instances. The values of most of the attributes are themselves `Node` instances or sequences of instances. When the value is something other than an instance, the type is noted in the comment. The attributes are listed in the order in which they are returned by `getChildren()` and `getChildNodes()`.

### 31.3.2. Assignment nodes

There is a collection of nodes used to represent assignments. Each assignment statement in the source code becomes a single `Assign` node in the AST. The `nodes` attribute is a list that contains a node for each assignment target. This is necessary because assignment can be chained, e.g. `a = b = 2`. Each `Node` in the list will be one of the following classes: `AssAttr`, `AssList`, `AssName`, or `AssTuple`.

Each target assignment node will describe the kind of object being assigned to: `AssName` for a simple name, e.g. `a = 1`. `AssAttr` for an attribute assigned, e.g. `a.x = 1`. `AssList` and `AssTuple` for list and tuple expansion respectively, e.g. `a, b, c = a_tuple`.

The target assignment nodes also have a `flags` attribute that indicates whether the node is being used for assignment or in a
delete statement. The AssName is also used to represent a delete statement, e.g. del x.

When an expression contains several attribute references, an assignment or delete statement will contain only one AssAttr node – for the final attribute reference. The other attribute references will be represented as Getattr nodes in the expr attribute of the AssAttr instance.

31.3.3. Examples

This section shows several simple examples of ASTs for Python source code. The examples demonstrate how to use the parse() function, what the repr of an AST looks like, and how to access attributes of an AST node.

The first module defines a single function. Assume it is stored in /tmp/doublelib.py.

"""This is an example module.

This is the docstring.
"""

def double(x):
    "Return twice the argument"
    return x * 2

In the interactive interpreter session below, I have reformatted the long AST reprs for readability. The AST reprs use unqualified class names. If you want to create an instance from a repr, you must import the class names from the compiler.ast module.

```python
>>> import compiler
>>> mod = compiler.parseFile("/tmp/doublelib.py")
>>> mod
Module('This is an example module.

This is the docstring.
',
    file=None,
    linecache=None)
```
Stmt([Function(None, 'double', ['x'], [], 0,
    'Return twice the argument',
    Stmt([Return(Mul((Name('x'), Const(2))))]))])
>>> from compiler.ast import *
>>> Module('This is an example module.

This is the docstring.

Stmt([Function(None, 'double', ['x'], [], 0,
    'Return twice the argument',
    Stmt([Return(Mul((Name('x'), Const(2))))]))])
Module('This is an example module.

This is the docstring.

Stmt([Function(None, 'double', ['x'], [], 0,
    'Return twice the argument',
    Stmt([Return(Mul((Name('x'), Const(2))))]))])
>>> mod.doc
'This is an example module.

This is the docstring.

>>> for node in mod.node.nodes:
    ...      print node
    ...
Function(None, 'double', ['x'], [], 0, 'Return twice the argument
Stmt([Return(Mul((Name('x'), Const(2))))]))
>>> func = mod.node.nodes[0]
>>> func.code
Stmt([Return(Mul((Name('x'), Const(2))))])
31.4. Using Visitors to Walk ASTs

The visitor pattern is ... The compiler package uses a variant on the visitor pattern that takes advantage of Python’s introspection features to eliminate the need for much of the visitor’s infrastructure.

The classes being visited do not need to be programmed to accept visitors. The visitor need only define visit methods for classes it is specifically interested in; a default visit method can handle the rest.

XXX The magic visit() method for visitors.

```python
compiler.visitor.walk(tree, visitor[, verbose])
```

```text
class compiler.visitor.ASTVisitor
    The ASTVisitor is responsible for walking over the tree in the correct order. A walk begins with a call to preorder(). For each node, it checks the visitor argument to preorder() for a method named ‘visitNodeType,’ where NodeType is the name of the node's class, e.g. for a While node a visitWhile() would be called. If the method exists, it is called with the node as its first argument.

    The visitor method for a particular node type can control how child nodes are visited during the walk. The ASTVisitor modifies the visitor argument by adding a visit method to the visitor; this method can be used to visit a particular child node. If no visitor is found for a particular node type, the default() method is called.

    ASTVisitor objects have the following methods:

    XXX describe extra arguments
```
\texttt{default}(node[, ...])

\texttt{dispatch}(node[, ...])

\texttt{preorder}(tree, visitor)
The code generator is a visitor that emits bytecodes. Each visit method can call the `emit()` method to emit a new bytecode. The basic code generator is specialized for modules, classes, and functions. An assembler converts that emitted instructions to the low-level bytecode format. It handles things like generation of constant lists of code objects and calculation of jump offsets.
32. Miscellaneous Services

The modules described in this chapter provide miscellaneous services that are available in all Python versions. Here's an overview:

- **32.1. formatter — Generic output formatting**
  - 32.1.1. The Formatter Interface
  - 32.1.2. Formatter Implementations
  - 32.1.3. The Writer Interface
  - 32.1.4. Writer Implementations
32.1. formatter — Generic output formatting

This module supports two interface definitions, each with multiple implementations. The formatter interface is used by the HTMLParser class of the htmllib module, and the writer interface is required by the formatter interface.

Formatter objects transform an abstract flow of formatting events into specific output events on writer objects. Formatters manage several stack structures to allow various properties of a writer object to be changed and restored; writers need not be able to handle relative changes nor any sort of “change back” operation. Specific writer properties which may be controlled via formatter objects are horizontal alignment, font, and left margin indentations. A mechanism is provided which supports providing arbitrary, non-exclusive style settings to a writer as well. Additional interfaces facilitate formatting events which are not reversible, such as paragraph separation.

Writer objects encapsulate device interfaces. Abstract devices, such as file formats, are supported as well as physical devices. The provided implementations all work with abstract devices. The interface makes available mechanisms for setting the properties which formatter objects manage and inserting data into the output.
32.1.1. The Formatter Interface

Interfaces to create formatters are dependent on the specific formatter class being instantiated. The interfaces described below are the required interfaces which all formatters must support once initialized.

One data element is defined at the module level:

`formatter.AS_IS`

Value which can be used in the font specification passed to the `push_font()` method described below, or as the new value to any other `push_property()` method. Pushing the `AS_IS` value allows the corresponding `pop_property()` method to be called without having to track whether the property was changed.

The following attributes are defined for formatter instance objects:

`formatter.writer`

The writer instance with which the formatter interacts.

`formatter.end_paragraph(blanklines)`

Close any open paragraphs and insert at least `blanklines` before the next paragraph.

`formatter.add_line_break()`

Add a hard line break if one does not already exist. This does not break the logical paragraph.

`formatter.add_hor_rule(*args, **kw)`

Insert a horizontal rule in the output. A hard break is inserted if there is data in the current paragraph, but the logical paragraph is not broken. The arguments and keywords are passed on to the writer’s `send_line_break()` method.
formatter.add_flow_data(data)
Provide data which should be formatted with collapsed whitespace. Whitespace from preceding and successive calls to add_flow_data() is considered as well when the whitespace collapse is performed. The data which is passed to this method is expected to be wordwrapped by the output device. Note that any word-wrapping still must be performed by the writer object due to the need to rely on device and font information.

formatter.add_literal_data(data)
Provide data which should be passed to the writer unchanged. Whitespace, including newline and tab characters, are considered legal in the value of data.

formatter.add_label_data(format, counter)
Insert a label which should be placed to the left of the current left margin. This should be used for constructing bulleted or numbered lists. If the format value is a string, it is interpreted as a format specification for counter, which should be an integer. The result of this formatting becomes the value of the label; if format is not a string it is used as the label value directly. The label value is passed as the only argument to the writer's send_label_data() method. Interpretation of non-string label values is dependent on the associated writer.

Format specifications are strings which, in combination with a counter value, are used to compute label values. Each character in the format string is copied to the label value, with some characters recognized to indicate a transform on the counter value. Specifically, the character '1' represents the counter value formatter as an Arabic number, the characters 'A' and 'a' represent alphabetic representations of the counter value in upper and lower case, respectively, and 'I' and 'i' represent the counter value in Roman numerals, in upper and lower case.
Note that the alphabetic and roman transforms require that the counter value be greater than zero.

formatter.\texttt{flush\_softspace}()  
Send any pending whitespace buffered from a previous call to \texttt{add\_flowing\_data()} to the associated writer object. This should be called before any direct manipulation of the writer object.

formatter.\texttt{push\_alignment}(align)  
Push a new alignment setting onto the alignment stack. This may be \texttt{AS\_IS} if no change is desired. If the alignment value is changed from the previous setting, the writer's \texttt{new\_alignment()} method is called with the \texttt{align} value.

formatter.\texttt{pop\_alignment}()  
Restore the previous alignment.

formatter.\texttt{push\_font}((size, italic, bold, teletype))  
Change some or all font properties of the writer object. Properties which are not set to \texttt{AS\_IS} are set to the values passed in while others are maintained at their current settings. The writer's \texttt{new\_font()} method is called with the fully resolved font specification.

formatter.\texttt{pop\_font}()  
Restore the previous font.

formatter.\texttt{push\_margin}(margin)  
Increase the number of left margin indentations by one, associating the logical tag \texttt{margin} with the new indentation. The initial margin level is 0. Changed values of the logical tag must be true values; false values other than \texttt{AS\_IS} are not sufficient to change the margin.
formatter. `pop_margin()`
  Restore the previous margin.

formatter. `push_style(*styles)`
  Push any number of arbitrary style specifications. All styles are pushed onto the styles stack in order. A tuple representing the entire stack, including `AS_IS` values, is passed to the writer’s `new_styles()` method.

formatter. `pop_style([n=1])`
  Pop the last `n` style specifications passed to `push_style()`. A tuple representing the revised stack, including `AS_IS` values, is passed to the writer’s `new_styles()` method.

formatter. `set_spacing(spacing)`
  Set the spacing style for the writer.

formatter. `assert_line_data([flag=1])`
  Inform the formatter that data has been added to the current paragraph out-of-band. This should be used when the writer has been manipulated directly. The optional `flag` argument can be set to false if the writer manipulations produced a hard line break at the end of the output.
32.1.2. Formatter Implementations

Two implementations of formatter objects are provided by this module. Most applications may use one of these classes without modification or subclassing.

```python
class formatter_NullFormatter([writer])
    A formatter which does nothing. If writer is omitted, a NullWriter instance is created. No methods of the writer are called by NullFormatter instances. Implementations should inherit from this class if implementing a writer interface but don’t need to inherit any implementation.

class formatter_AbstractFormatter(writer)
    The standard formatter. This implementation has demonstrated wide applicability to many writers, and may be used directly in most circumstances. It has been used to implement a full-featured World Wide Web browser.
```
32.1.3. The Writer Interface

Interfaces to create writers are dependent on the specific writer class being instantiated. The interfaces described below are the required interfaces which all writers must support once initialized. Note that while most applications can use the `AbstractFormatter` class as a formatter, the writer must typically be provided by the application.

```python
writer.flush()
    Flush any buffered output or device control events.
```

```python
writer.new_alignment(align)
    Set the alignment style. The `align` value can be any object, but by convention is a string or `None`, where `None` indicates that the writer’s “preferred” alignment should be used. Conventional `align` values are 'left', 'center', 'right', and 'justify'.
```

```python
writer.new_font(font)
    Set the font style. The value of `font` will be `None`, indicating that the device’s default font should be used, or a tuple of the form `(size, italic, bold, teletype)`. Size will be a string indicating the size of font that should be used; specific strings and their interpretation must be defined by the application. The `italic`, `bold`, and `teletype` values are Boolean values specifying which of those font attributes should be used.
```

```python
writer.new_margin(margin, level)
    Set the margin level to the integer `level` and the logical tag to `margin`. Interpretation of the logical tag is at the writer’s discretion; the only restriction on the value of the logical tag is that it not be a false value for non-zero values of `level`.
```

```python
writer.new_spacing(spacing)
```
Set the spacing style to *spacing*.

```python
writer.new_styles(styles)
```

Set additional styles. The `styles` value is a tuple of arbitrary values; the value `AS_IS` should be ignored. The `styles` tuple may be interpreted either as a set or as a stack depending on the requirements of the application and writer implementation.

```python
writer.send_line_break()
```

Break the current line.

```python
writer.send_paragraph(blankline)
```

Produce a paragraph separation of at least `blankline` blank lines, or the equivalent. The `blankline` value will be an integer. Note that the implementation will receive a call to `send_line_break()` before this call if a line break is needed; this method should not include ending the last line of the paragraph. It is only responsible for vertical spacing between paragraphs.

```python
writer.send_hor_rule(*args, **kw)
```

Display a horizontal rule on the output device. The arguments to this method are entirely application- and writer-specific, and should be interpreted with care. The method implementation may assume that a line break has already been issued via `send_line_break()`.

```python
writer.send_flowing_data(data)
```

Output character data which may be word-wrapped and re-flowed as needed. Within any sequence of calls to this method, the writer may assume that spans of multiple whitespace characters have been collapsed to single space characters.

```python
writer.send_literal_data(data)
```

Output character data which has already been formatted for
display. Generally, this should be interpreted to mean that line breaks indicated by newline characters should be preserved and no new line breaks should be introduced. The data may contain embedded newline and tab characters, unlike data provided to the send_formatted_data() interface.

**writer.send_label_data(data)**

Set *data* to the left of the current left margin, if possible. The value of *data* is not restricted; treatment of non-string values is entirely application- and writer-dependent. This method will only be called at the beginning of a line.
32.1.4. Writer Implementations

Three implementations of the writer object interface are provided as examples by this module. Most applications will need to derive new writer classes from the `NullWriter` class.

```python
class formatter.NullWriter
    A writer which only provides the interface definition; no actions are taken on any methods. This should be the base class for all writers which do not need to inherit any implementation methods.
```

```python
class formatter.AbstractWriter
    A writer which can be used in debugging formatters, but not much else. Each method simply announces itself by printing its name and arguments on standard output.
```

```python
class formatter.DumbWriter([file[, maxcol=72]])
    Simple writer class which writes output on the file object passed in as `file` or, if `file` is omitted, on standard output. The output is simply word-wrapped to the number of columns specified by `maxcol`. This class is suitable for reflowing a sequence of paragraphs.
```
33. MS Windows Specific Services

This chapter describes modules that are only available on MS Windows platforms.

- 33.1. _winreg – Windows registry access
  - 33.1.1. Constants
    - 33.1.1.1. HKEY_* Constants
    - 33.1.1.2. Access Rights
      - 33.1.1.2.1. 64-bit Specific
    - 33.1.1.3. Value Types
  - 33.1.2. Registry Handle Objects
33.1. _winreg – Windows registry access

*Platforms:* Windows

**Note:** The _winreg module has been renamed to winreg in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

*New in version 2.0.*

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a *handle object* is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

This module offers the following functions:

- **_winreg.CloseKey(hkey)**
  Closes a previously opened registry key. The *hkey* argument specifies a previously opened key.

  **Note:** If *hkey* is not closed using this method (or via *hkey.Close()*), it is closed when the *hkey* object is destroyed by Python.

- **_winreg.ConnectRegistry(computer_name, key)**
  Establishes a connection to a predefined registry handle on another computer, and returns a *handle object*.

  *computer_name* is the name of the remote computer, of the form *r"\computername"*. If *None*, the local computer is used.
key is the predefined handle to connect to.

The return value is the handle of the opened key. If the function fails, a WindowsError exception is raised.

_winreg.CreateKey(key, sub_key)
Creates or opens the specified key, returning a handle object.

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the key this method opens or creates.

If key is one of the predefined keys, sub_key may be None. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, a WindowsError exception is raised.

_winreg.CreateKeyEx(key, sub_key[, res[, sam]])
Creates or opens the specified key, returning a handle object.

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the key this method opens or creates.

res is a reserved integer, and must be zero. The default is zero.

sam is an integer that specifies an access mask that describes the desired security access for the key. Default is
**KEY_ALL_ACCESS.** See *Access Rights* for other allowed values.

If `key` is one of the predefined keys, `sub_key` may be `None`. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, a `WindowsError` exception is raised.

*New in version 2.7.*

```
_winreg.DeleteKey(key, sub_key)
```

Deletes the specified key.

- `key` is an already open key, or any one of the predefined `HKEY_* constants`.

- `sub_key` is a string that must be a subkey of the key identified by the `key` parameter. This value must not be `None`, and the key may not have subkeys.

*This method can not delete keys with subkeys.*

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, a `WindowsError` exception is raised.

```
_winreg.DeleteKeyEx(key, sub_key[, sam[, res]])
```

Deletes the specified key.

**Note:** The `DeleteKeyEx()` function is implemented with the `RegDeleteKeyEx` Windows API function, which is specific to 64-bit versions of Windows. See the `RegDeleteKeyEx`
key is an already open key, or any one of the predefined HKEY_ * constants.

sub_key is a string that must be a subkey of the key identified by the key parameter. This value must not be None, and the key may not have subkeys.

res is a reserved integer, and must be zero. The default is zero.

sam is an integer that specifies an access mask that describes the desired security access for the key. Default is KEY_WOW64_64KEY. See Access Rights for other allowed values.

This method can not delete keys with subkeys.

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, a WindowsError exception is raised.

On unsupported Windows versions, NotImplementedError is raised.

New in version 2.7.

_winreg. DeleteValue(key, value)
Removes a named value from a registry key.

key is an already open key, or one of the predefined HKEY_ * constants.

value is a string that identifies the value to remove.

_winreg. EnumKey(key, index)
Enumerates subkeys of an open registry key, returning a string.
key is an already open key, or any one of the predefined HKEY_* constants.

index is an integer that identifies the index of the key to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until a WindowsError exception is raised, indicating, no more values are available.

_winreg.EnumValue(key, index)
Enumerates values of an open registry key, returning a tuple.

key is an already open key, or any one of the predefined HKEY_* constants.

index is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until a WindowsError exception is raised, indicating no more values.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>A string that identifies the value name</td>
</tr>
<tr>
<td>1</td>
<td>An object that holds the value data, and whose type depends on the underlying registry type</td>
</tr>
<tr>
<td>2</td>
<td>An integer that identifies the type of the value data (see table in docs for SetValueEx())</td>
</tr>
</tbody>
</table>

_winreg.ExpandEnvironmentStrings(unicode)
Expands environment variable placeholders %NAME% in unicode strings like REG_EXPAND_SZ:

```python
>>> ExpandEnvironmentStrings(u"%windir%")
```
New in version 2.6.

_Winreg. **FlushKey**(key)

Writes all the attributes of a key to the registry.

*key* is an already open key, or one of the predefined _HKEY_* constants._

It is not necessary to call _FlushKey()_ to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike _CloseKey()_, the _FlushKey()_ method returns only when all the data has been written to the registry. An application should only call _FlushKey()_ if it requires absolute certainty that registry changes are on disk.

**Note:** If you don’t know whether a _FlushKey()_ call is required, it probably isn’t.

_Winreg. **LoadKey**(key, sub_key, file_name)

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

*key* is a handle returned by _ConnectRegistry()_ or one of the constants _HKEY_USERS_ or _HKEY_LOCAL_MACHINE._

*sub_key* is a string that identifies the subkey to load.

*file_name* is the name of the file to load registry data from. This file must have been created with the _SaveKey()_ function. Under the file allocation table (FAT) file system, the filename may not have an extension.
A call to `LoadKey()` fails if the calling process does not have the `SE_RESTORE_PRIVILEGE` privilege. Note that privileges are different from permissions – see the `RegLoadKey` documentation for more details.

If `key` is a handle returned by `ConnectRegistry()`, then the path specified in `file_name` is relative to the remote computer.

```python
_winreg.OpenKey(key, sub_key[, res[, sam]])
```

Opens the specified key, returning a `handle object`.

- `key` is an already open key, or any one of the predefined `HKEY_` constants.
- `sub_key` is a string that identifies the sub_key to open.
- `res` is a reserved integer, and must be zero. The default is zero.
- `sam` is an integer that specifies an access mask that describes the desired security access for the key. Default is `KEY_READ`. See `Access Rights` for other allowed values.

The result is a new handle to the specified key.

If the function fails, `WindowsError` is raised.

```python
_winreg.OpenKeyEx()
```

The functionality of `OpenKeyEx()` is provided via `OpenKey()`, by the use of default arguments.

```python
_winreg.QueryInfoKey(key)
```

Returns information about a key, as a tuple.

- `key` is an already open key, or one of the predefined `HKEY_` constants.
The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>An integer giving the number of sub keys this key has.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the number of values this key has.</td>
</tr>
<tr>
<td>2</td>
<td>A long integer giving when the key was last modified (if available) as 100's of nanoseconds since Jan 1, 1600.</td>
</tr>
</tbody>
</table>

_winreg.QueryValue(key, sub_key)

Retrieves the unnamed value for a key, as a string.

*key* is an already open key, or one of the predefined *HKEY_* *constants*.

*sub_key* is a string that holds the name of the subkey with which the value is associated. If this parameter is *None* or empty, the function retrieves the value set by the *SetValue()* method for the key identified by *key*.

Values in the registry have name, type, and data components. This method retrieves the data for a key's first value that has a NULL name. But the underlying API call doesn't return the type, so always use *QueryValueEx()* if possible.

_winreg.QueryValueEx(key, value_name)

Retrieves the type and data for a specified value name associated with an open registry key.

*key* is an already open key, or one of the predefined *HKEY_* *constants*.

*value_name* is a string indicating the value to query.

The result is a tuple of 2 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>The value of the registry item.</td>
</tr>
<tr>
<td>---</td>
<td>--------------------------------</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the registry type for this value (see table in docs for <em>SetValueEx</em>())</td>
</tr>
</tbody>
</table>

_winreg_. **SaveKey**(key, file_name)

Saves the specified key, and all its subkeys to the specified file.

*key* is an already open key, or one of the predefined _HKEY_* constants.

*file_name* is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the _LoadKey()_ method.

If *key* represents a key on a remote computer, the path described by *file_name* is relative to the remote computer. The caller of this method must possess the _SeBackupPrivilege_ security privilege. Note that privileges are different than permissions – see the Conflicts Between User Rights and Permissions documentation for more details.

This function passes NULL for *security_attributes* to the API.

_winreg_. **SetValue**(key, sub_key, type, value)

Associates a value with a specified key.

*key* is an already open key, or one of the predefined _HKEY_* constants.

*sub_key* is a string that names the subkey with which the value is associated.

*type* is an integer that specifies the type of the data. Currently this must be _REG_SZ_, meaning only strings are supported. Use the
**SetValueEx()** function for support for other data types.

*value* is a string that specifies the new value.

If the key specified by the *sub_key* parameter does not exist, the SetValue function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the *key* parameter must have been opened with **KEY_SET_VALUE** access.

```python
_winterg.SetValueEx(key, value_name, reserved, type, value)
```
Stores data in the value field of an open registry key.

*key* is an already open key, or one of the predefined **HKEY_* constants**.

*value_name* is a string that names the subkey with which the value is associated.

*type* is an integer that specifies the type of the data. See **Value Types** for the available types.

*reserved* can be anything – zero is always passed to the API.

*value* is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the key parameter must have been opened with **KEY_SET_VALUE** access.

To open the key, use the **CreateKey()** or **OpenKey()** methods.
Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

_winreg.**DisableReflectionKey**(key)
Disables registry reflection for 32-bit processes running on a 64-bit operating system.

*key* is an already open key, or one of the predefined **HKEY_** constants.

Will generally raise **NotImplemented** if executed on a 32-bit operating system.

If the key is not on the reflection list, the function succeeds but has no effect. Disabling reflection for a key does not affect reflection of any subkeys.

_winreg.**EnableReflectionKey**(key)
Restores registry reflection for the specified disabled key.

*key* is an already open key, or one of the predefined **HKEY_** constants.

Will generally raise **NotImplemented** if executed on a 32-bit operating system.

Restoring reflection for a key does not affect reflection of any subkeys.

_winreg.**QueryReflectionKey**(key)
Determines the reflection state for the specified key.

*key* is an already open key, or one of the predefined **HKEY_** constants.
Returns `True` if reflection is disabled.

Will generally raise `NotImplemented` if executed on a 32-bit operating system.
33.1.1. Constants

The following constants are defined for use in many _winreg functions.

33.1.1.1. HKEY_* Constants

_winreg. HKEY_CLASSES_ROOT
Registry entries subordinate to this key define types (or classes) of documents and the properties associated with those types. Shell and COM applications use the information stored under this key.

_winreg. HKEY_CURRENT_USER
Registry entries subordinate to this key define the preferences of the current user. These preferences include the settings of environment variables, data about program groups, colors, printers, network connections, and application preferences.

_winreg. HKEY_LOCAL_MACHINE
Registry entries subordinate to this key define the physical state of the computer, including data about the bus type, system memory, and installed hardware and software.

_winreg. HKEY_USERS
Registry entries subordinate to this key define the default user configuration for new users on the local computer and the user configuration for the current user.

_winreg. HKEY_PERFORMANCE_DATA
Registry entries subordinate to this key allow you to access performance data. The data is not actually stored in the registry; the registry functions cause the system to collect the data from its source.
_winreg. HKEY_CURRENT_CONFIG
Contains information about the current hardware profile of the local computer system.

_ winreg. HKEY_DYN_DATA
This key is not used in versions of Windows after 98.

33.1.1.2. Access Rights

For more information, see Registry Key Security and Access.

_ winreg. KEY_ALL_ACCESS
Combines the STANDARD_RIGHTS_REQUIRED, KEY_QUERY_VALUE, KEY_SET_VALUE, KEY_CREATE_SUB_KEY, KEY_ENUMERATE_SUB_KEYS, KEY_NOTIFY, and KEY_CREATE_LINK access rights.

_ winreg. KEY_WRITE
Combines the STANDARD_RIGHTS_WRITE, KEY_SET_VALUE, and KEY_CREATE_SUB_KEY access rights.

_ winreg. KEY_READ
Combines the STANDARD_RIGHTS_READ, KEY_QUERY_VALUE, KEY_ENUMERATE_SUB_KEYS, and KEY_NOTIFY values.

_ winreg. KEY_EXECUTE
Equivalent to KEY_READ.

_ winreg. KEY_QUERY_VALUE
Required to query the values of a registry key.

_ winreg. KEY_SET_VALUE
Required to create, delete, or set a registry value.

_ winreg. KEY_CREATE_SUB_KEY
Required to create a subkey of a registry key.
_winreg.KEY_ENUMERATE_SUB_KEYS
Required to enumerate the subkeys of a registry key.

_winreg.KEY_NOTIFY
Required to request change notifications for a registry key or for subkeys of a registry key.

_winreg.KEY_CREATE_LINK
Reserved for system use.

33.1.1.2.1. 64-bit Specific

For more information, see Accessing an Alternate Registry View.

_winreg.KEY_WOW64_64KEY
Indicates that an application on 64-bit Windows should operate on the 64-bit registry view.

_winreg.KEY_WOW64_32KEY
Indicates that an application on 64-bit Windows should operate on the 32-bit registry view.

33.1.1.3. Value Types

For more information, see Registry Value Types.

_winreg.REG_BINARY
Binary data in any form.

_winreg.REG_DWORD
32-bit number.

_winreg.REG_DWORD_LITTLE_ENDIAN
A 32-bit number in little-endian format.

_winreg.REG_DWORD_BIG_ENDIAN
A 32-bit number in big-endian format.
_winreg.REG_EXPAND_SZ
Null-terminated string containing references to environment variables (\%PATH\%).

_winreg.REG_LINK
A Unicode symbolic link.

_winreg.REG_MULTI_SZ
A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)

_winreg.REG_NONE
No defined value type.

_winreg.REG_RESOURCE_LIST
A device-driver resource list.

_winreg.REG_FULL_RESOURCE_DESCRIPTOR
A hardware setting.

_winreg.REG_RESOURCE_REQUIREMENTS_LIST
A hardware resource list.

_winreg.REG_SZ
A null-terminated string.
33.1.2. Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the close() method on the object, or the CloseKey() function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for __nonzero__() – thus:

```python
if handle:
    print "Yes"
```

will print Yes if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the built-in int() function), in which case the underlying Windows handle value is returned. You can also use the Detach() method to return the integer handle, and also disconnect the Windows handle from the handle object.

PyHKEY.Close()

Closes the underlying Windows handle.

If the handle is already closed, no error is raised.
**PyHKEY.** **Detach()**

Detaches the Windows handle from the handle object.

The result is an integer (or long on 64 bit Windows) that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.

**PyHKEY.** **__enter__()**

**PyHKEY.** **__exit__(**\*exc_info\*)**

The HKEY object implements **__enter__()** and **__exit__()** and thus supports the context protocol for the **with** statement:

```python
with OpenKey(HKEY_LOCAL_MACHINE, "foo") as key:
    ...  # work with key
```

will automatically close **key** when control leaves the **with** block.

*New in version 2.6.*
34. Undocumented Modules

Here’s a quick listing of modules that are currently undocumented, but that should be documented. Feel free to contribute documentation for them! (Send via email to docs@python.org.)

The idea and original contents for this chapter were taken from a posting by Fredrik Lundh; the specific contents of this chapter have been substantially revised.
34.1. Miscellaneous useful utilities

Some of these are very old and/or not very robust; marked with “hmm.”

ihooks
   — Import hook support (for rexec; may become obsolete). Removed in Python 3.x.
34.2. Platform specific modules

These modules are used to implement the `os.path` module, and are not documented beyond this mention. There's little need to document these.

**ntpath**
- Implementation of `os.path` on Win32, Win64, WinCE, and OS/2 platforms.

**posixpath**
- Implementation of `os.path` on POSIX.

**bsddb185**
- Backwards compatibility module for systems which still use the Berkeley DB 1.85 module. It is normally only available on certain BSD Unix-based systems. It should never be used directly.
34.3. Multimedia

audiodev
— Platform-independent API for playing audio data. Removed in Python 3.x.

toaiff
— Convert “arbitrary” sound files to AIFF files; should probably become a tool or demo. Requires the external program **sox**. Removed in Python 3.x.
34.4. Obsolete

These modules are not normally available for import; additional work must be done to make them available.

These extension modules written in C are not built by default. Under Unix, these must be enabled by uncommenting the appropriate lines in Modules/Setup in the build tree and either rebuilding Python if the modules are statically linked, or building and installing the shared object if using dynamically-loaded extensions.

timing
    — Measure time intervals to high resolution (use time.clock() instead). Removed in Python 3.x.
34.5. SGI-specific Extension modules

The following are SGI specific, and may be out of touch with the current version of reality.

**cl**
— Interface to the SGI compression library.

**sv**
— Interface to the “simple video” board on SGI Indigo (obsolete hardware). Removed in Python 3.x.
1. Getting Started
1.1. Introduction

The simplest way to get started with embedding IronPython in your application is to use the Python class defined in IronPython.Hosting. This class includes functions for creating IronPython script engines and accessing commonly used Python-specific functionality. Much of the functionality is exposed as .NET extension methods so that it seamlessly extends the normal DLR hosting API surface.

Most of the functions in the Python class have overloads that operate on either a ScriptRuntime or a ScriptEngine. These functions provide identical functionality but both forms are provided for convenience for when you may be working with either an engine or an entire runtime.
1.2. Samples

1.2.1. Hello World

The simplest program to start off with is always Hello World. Here is a simple Hello World app that creates a Python engine from C#:

```csharp
using System;
using IronPython.Hosting;

public class HelloWorld {
    public static void Main(string[] args) {
        var engine = Python.CreateEngine();
        engine.CreateScriptSourceFromString("print 'hello world'");
    }
}
```

Compile using:
```
```

Here's the equivalent program in VB.NET:

```vbnet
Imports System
Imports IronPython.Hosting

Public Class HelloWorld
    Public Shared Sub Main(ByVal args As String())
        Python.CreateEngine.CreateScriptSourceFromString("print 'hello world'").Execute
    End Sub
End Class
```

Compile using:
```
```

And again in IronPython:
1.2.2. Calling Python from C#

This sample demonstrates how to get functions and classes defined in Python and access them from your .NET application.

In order to get back the results of executed Python code we need to first create a ScriptScope in which we can execute the code. We then execute the code we're interested inside of that scope and fetch the values back out. To get the values back out we use the GetVariable method defined on ScriptScope. There is both a generic version of this method as well as a non-generic version - here we use the generic version which allows us to perform conversions on the result of the variable. One of the most convenient conversions for functions and classes is to convert these objects to delegates. This allows us to repeatedly call the same function or class with different arguments.

C# Example:

```csharp
using System;
using IronPython.Hosting;

public class CallingPython {
    public static void Main(string[] args) {
        var engine = Python.CreateEngine();
        var scope = engine.CreateScope();
        var source = engine.CreateScriptSourceFromString("def adder(arg1, arg2):
" +
"    return arg1 + arg2
" +
"class MyClass(object):
" +
"    def __init__(self, value):
" +
source.Execute(scope);

var adder = scope.GetVariable<Func<object, object, object>>("adder");
Console.WriteLine(adder(2, 2));
Console.WriteLine(adder(2.0, 2.5));

var myClass = scope.GetVariable<Func<object, object>>("MyClass");
var myInstance = myClass("hello");

Console.WriteLine(engine.Operations.GetMember(myInstance, "value");

Compile using:

VB.NET Example:

Imports System
Imports IronPython.Hosting

Public Class CallingPython
    Public Shared Sub Main(ByVal args As String())
        Dim engine = Python.CreateEngine
        Dim scope = engine.CreateScope
        engine.CreateScriptSourceFromString(""
            "def adder(arg1, arg2):
            "    return arg1 + arg2"
            "class MyClass(object):
            "    def __init__(self, value):
            "        self.value = value"
        ").Execute(scope)

        Dim variable As Func(Of Object, Object, Object) = scope.GetVariable(Of Func(Of Object, Object, Object))("adder")
        Console.WriteLine(variable.Invoke(2, 2))
        Console.WriteLine(variable.Invoke(2, 2.5))

        Dim obj2 As Object = scope.GetVariable(Of Func(Of Object, Object))("MyClass").Invoke("hello")
        Console.WriteLine(engine.Operations.GetMember(obj2, "value");
    End Sub
End Class
Compile using:

```
vbc   CallingPython.vb  /r:IronPython.dll  /r:Microsoft.Scripting.dll
/r:Microsoft.Scripting.Core.dll
```

IronPython Example:

```python
import clr
clr.AddReference('IronPython')
from IronPython.Hosting import Python
from System import Console

engine = Python.CreateEngine()

scope = engine.CreateScope()
source = engine.CreateScriptSourceFromString(
    "def adder(arg1, arg2):
        return arg1 + arg2"
    "class MyClass(object):
        def __init__(self, value):
            self.value = value"
)
source.Execute(scope)

adder = scope.adder
Console.WriteLine(adder(2, 2))
Console.WriteLine(adder(2.0, 2.5))

myClass = scope.MyClass
myInstance = myClass("hello")

Console.WriteLine(engine.Operations.GetMember(myInstance, "value"))
```

1.2.3. Exposing Application Object Model

Another common theme in hosting your IronPython in your application is exposing your own object model to users scripting your application. To do this is the exact opposite of calling Python from C#. Instead of getting values from a ScriptScope you will simply inject the object model into the ScriptScope.
C# Example:

```csharp
using System;
using IronPython.Hosting;

public class CallingDotNet {
    private static void Main(string[] args) {
        var engine = Python.CreateEngine();
        var scope = engine.CreateScope();

        scope.SetVariable("my_object_model", new CallingDotNet());
        engine.CreateScriptSourceFromString("my_object_model.Foo(42)").Execute(scope);
    }

    public void Foo(int arg) {
        Console.WriteLine("You gave me a {0}", arg);
    }
}
```

Compile using:
```
```

VB.NET Example:

```vbnet
Imports System
Imports IronPython.Hosting

Public Class CallingDotNet
    Private Shared Sub Main(ByVal args As String())
        Dim engine As ScriptEngine = Python.CreateEngine
        Dim scope As ScriptScope = engine.CreateScope
        scope.SetVariable("my_object_model", New CallingDotNet)
        engine.CreateScriptSourceFromString("my_object_model.Foo(42)").Execute(scope)
    End Sub

    Public Sub Foo(ByVal arg As Integer)
        Console.WriteLine("You gave me a {0}", arg)
    End Sub
End Class
```
Compile using:
    vbc  CallingDotNet.vb  /r:IronPython.dll  /r:Microsoft.Scripting.dll
    /r:Microsoft.Scripting.Core.dll

IronPython Example:

class CallingPython(object):
    def Foo(self, value):
        print 'You gave me', value

import clr
clr.AddReference('IronPython')
from IronPython.Hosting import Python
from System import Console

engine = Python.CreateEngine()
scope = engine.CreateScope()

scope.SetVariable("my_object_model", CallingPython())
engine.CreateScriptSourceFromString("my_object_model.Foo(42)").
1.3. Reference

The Python class defines the following functions:

**ScriptRuntime CreateRuntime()**

Creates a new ScriptRuntime with the IronPython scripting engine pre-configured.

**ScriptRuntime CreateRuntime(IDictionary<string, object> options)**

Creates a new ScriptRuntime with the IronPython scripting engine pre-configured and additional options.

**ScriptRuntime CreateRuntime(AppDomain domain)**

Creates a new ScriptRuntime with the IronPython scripting engine pre-configured in the specified AppDomain. The remote ScriptRuntime may be manipulated from the local domain but all code will run in the remote domain.

**ScriptRuntime CreateRuntime(AppDomain domain, IDictionary<string, object> options)**

Creates a new ScriptRuntime with the IronPython scripting engine pre-configured in the specified AppDomain with additional options. The remote ScriptRuntime may be manipulated from the local domain but all code will run in the remote domain.

**ScriptEngine CreateEngine()**

Creates a new ScriptRuntime and returns the ScriptEngine for IronPython. If the ScriptRuntime is required it can be acquired from the Runtime property on the engine.

**ScriptEngine CreateEngine(IDictionary<string, object> options)**

Creates a new ScriptRuntime with the specified options and returns the ScriptEngine for IronPython. If the ScriptRuntime is
requierd it can be acquired from the Runtime property on the engine.

**ScriptEngine** `CreateEngine(AppDomain domain)`

Creates a new ScriptRuntime and returns the ScriptEngine for IronPython. If the ScriptRuntime is requierd it can be acquired from the Runtime property on the engine.

The remote ScriptRuntime may be manipulated from the local domain but all code will run in the remote domain.

**ScriptEngine** `CreateEngine(AppDomain domain, IDictionary<string, object> options)`

Creates a new ScriptRuntime with the specified options and returns the ScriptEngine for IronPython. If the ScriptRuntime is requierd it can be acquired from the Runtime property on the engine.

The remote ScriptRuntime may be manipulated from the local domain but all code will run in the remote domain.

**ScriptEngine** `GetEngine(ScriptRuntime runtime)`

Given a ScriptRuntime gets the ScriptEngine for IronPython.

**ScriptScope** `GetSysModule(this ScriptRuntime runtime)`

**ScriptScope** `GetSysModule(this ScriptEngine engine)`

Gets a ScriptScope which is the Python sys module for the provided ScriptRuntime or ScriptEngine.

**ScriptScope** `GetBuiltInModule(this ScriptRuntime runtime)`

**ScriptScope** `GetBuiltInModule(this ScriptEngine engine)`

Gets a ScriptScope which is the Python __builtin__ module for the provided ScriptRuntime or ScriptEngine.
**ScriptScope** `ScriptScope GetClrModule(this ScriptRuntime runtime)`

**ScriptScope** `ScriptScope GetClrModule(this ScriptEngine engine)`

Gets a ScriptScope which is the Python clr module for the provided ScriptRuntime or ScriptEngine.

**ScriptScope** `ScriptScope ImportModule(this ScriptRuntime runtime, string moduleName)`

**ScriptScope** `ScriptScope ImportModule(this ScriptEngine engine, string moduleName)`

Imports the Python module by the given name and returns its ScriptScope. If the module does not exist an exception is raised.

**void** `void SetHostVariables(this ScriptRuntime runtime, string prefix, string executable, string version)`

**void** `void SetHostVariables(this ScriptEngine engine, string prefix, string executable, string version)`

Sets `sys.exec_prefix`, `sys.executable` and `sys.version` and adds the prefix to `sys.path`

**void** `void SetTrace(this ScriptEngine engine, TracebackDelegate traceFunc)`

**void** `void SetTrace(this ScriptRuntime runtime, TracebackDelegate traceFunc)`

Enables call tracing for the current thread in this ScriptEngine.

TracebackDelegate will be called back for each function entry, exit, exception, and line change.

**void** `void CallTracing(this ScriptRuntime runtime, object traceFunc, params object[] args)`
void CallTracing(this ScriptEngine engine, object traceFunc, 
params object[] args)

    Provides nested level debugging support when SetTrace or 
    SetProfile are used.

    This saves the current tracing information and then calls the 
    provided object.

ScriptRuntimeSetup CreateRuntimeSetup(IDictionary<string, 
object> options)

    Creates a ScriptRuntimeSetup object which includes the Python 
    script engine with the specified options.

    The ScriptRuntimeSetup object can then be additional configured 
    and used to create a ScriptRuntime.

LanguageSetup CreateLanguageSetup(IDictionary<string, object> 
options)

    Creates a LanguageSetup object which includes the Python 
    script engine with the specified options.

    The LanguageSetup object can be used with other 
    LanguageSetup objects from other languages to configure a 
    ScriptRuntimeSetup object.

2. DLR Hosting APIs »
One of the top DLR features is common hosting support for all languages implemented on the DLR. The primary goal is supporting .NET applications hosting the DLR’s ScriptRuntime and engines for the following high-level scenarios:

- SilverLight hosting in browsers
- MerlinWeb on the server
- Interaction consoles where the ScriptRuntime is possibly isolated in another app domain.
- Editing tool with colorization, completion, and parameter tips (may only work on live objects in v1)
- PowerShell, C#, and VB.NET code using dynamic objects and operating on them dynamically in the same app domain

A quick survey of functionality includes:

- Create ScriptRuntimes locally or in remote app domains.
- Execute snippets of code.
- Execute files of code in their own execution context (ScriptScope).
- Explicitly choose language engines to use or just execute files to let the DLR find the right engine.
- Create scopes privately or publicly for executing code in.
- Create scopes, set variables in the scope to provide host object models, and publish the scopes for dynamic languages to import, require, etc.
- Create scopes, set variables to provide object models, and execute code within the scopes.
- Fetch dynamic objects and functions from scopes bound to names or execute expressions that return objects.
- Call dynamic functions as host command implementations or event handlers.
- Get reflection information for object members, parameter information, and documentation.
- Control how files are resolved when dynamic languages import other files of code.

Hosts always start by calling statically on the ScriptRuntime to create a ScriptRuntime. In the simplest case, the host can set globals and execute files that access the globals. In more advanced scenarios, hosts can fully control language engines, get services from them, work with compiled code, explicitly execute code in specific scopes, interact in rich ways with dynamic objects from the ScriptRuntime, and so on.
1.1. High-level Hosting Model Concepts

The hosting APIs can be grouped by levels of engagement. Level One uses a couple of types for executing code in scopes and working with variable bindings in those scopes. Level Two involves a few more types and supports more control over how code executes, using compiled code in various scopes, and using various sources of code. Level Three opens up to several advanced concepts such as overriding how filenames are resolved, providing custom source content readers, reflecting over objects for design-time tool support, providing late bound variable values from the host, and using remote ScriptRuntimes.

There are three basic mechanisms for partially isolating state for code executions within a process. .NET offers Appdomains, which allows for code to run at different trust levels and to be completely torn down and unloaded. The DLR offers multiple ScriptRuntimes within an AppDomain, each having its own global object of name bindings, distinct references to .NET namespaces from specified assemblies, distinct options, etc. The DLR also provides ScriptScopes which provide variable binding isolation, and you can execute code in different scopes to work with distinct bindings of free variable references.
It is important for the DLR to support distinct ScriptRuntimes within .NET's AppDomains for a couple of reasons. First, key customers betting on us require the lighter-weight isolation than what AppDomains provide. Second, consider two independent .NET components loading as extensions to an application. Each component wants to provide scripting support to end users. The components should be able to do so without having to worry about how they might clash with other script-enabled components. Multiple ScriptRuntimes also makes the main application's job easier since it does not have to provide a model for independent components getting access to and coordinating code executions around a central ScriptRuntime. There's a rich set of ways to execute code. Our goal is to strike a balance between convenient execution methods on various objects and keeping redundancy across the types to a minimum. The diagram below shows how to navigate to the key objects for running code. The Sections on Levels One and Level Two below talk about types in this diagram (green being Level One types):
1.2. Level One – Script Runtimes, Scopes, and Executing Files and Snippets

For simple application programmability, you want to provide a host object model that dynamic languages code can use. You then want to execute files of code that consume that object model. You may also want to get the values of variables from the dynamic language code to use dynamic functions as command implementations or event handlers.

There are two types you will use at this level. The ScriptRuntime class is the starting point for hosting. You create a runtime with this class. The ScriptRuntime represents global script state, such as referenced assemblies and a global object (a ScriptScope). The ScriptScope class essentially represents a namespace. Hosts can bind variable names in ScriptScopes, fetch variable values, etc. Hosts can execute code within different scopes to isolate free variable resolutions.

There are a lot of members on these types because they are also used for Level Two and Level Three. For Level One you only need a few members and can ignore the rest. You need to create a ScriptRuntime, from which you might use ExecuteFile or Globals. The Globals object lets you set variables to provide access to a host object model. From ScriptScope, you will likely only use GetVariable and SetVariable.

These types are shown in the diagram:
The ScriptRuntime.GetEngine and ScriptScope.Engine are bridges to more advanced hosting functionality. In Level Two and Level Three scenarios, the other members of ScriptRuntime and ScriptScope will be useful along with ScriptEngine.

1.2.1. Code Sample – Application Programmability

Sample:

```csharp
public class Level_1 {
    ScriptRuntime env = ScriptRuntime.CreateFromConfiguration();
    MyHostObjectModel hostOM = new MyHostObjectModel();

    /// <summary>
    /// Shows setting Host OM on globals so that dynamic languages
    /// can import, require, etc., to access the host's OM.
    ```
/// </summary>
/// my_user_script.py:
/// import HostModule
/// def foo () ...  
/// HostModule.UserCommands["foo"] = foo
///
public void RunFile_Isolated_Scope_ImportsFromHost() {
    env.Globals.SetVariable("HostModule", hostOM);
    // Imagine this runs my_user_script.py above.
    env.ExecuteFile(GetFileFromUserOrSettings());
}

delegate void Command();

/// </summary>
/// Shows getting command implementations from dynamic lang
/// Assumes menu item text is command name in table.
/// Builds on previous function.
/// </summary>
public void Run_User_Command_from_MenuItem (string menuItemName)
{
    // UserCommands is Dictionary<string, Command>.
    hostOM.UserCommands[menuItemName]();
}

/// </summary>
/// Shows discovering command implementations from globals
/// Above user code explicitly added commands, but this code finds
/// commands matching a delegate type, Command.
/// </summary>
public void Collect_User_Commands_From_File (string menuItemName)
{
    env.Globals.SetVariable("HostModule", hostOM);
    ScriptScope scope = env.ExecuteFile(GetFileFromUserOrSettings());
    // UserCommands is dictionary from string to Command.
    Command fun;
    foreach (string id in scope.GetVariableNames()) {
        bool got_fun = scope.TryGetVariable<Command>(id, out fun);
        if (got_fun) {
            my_OM.UserCommands[id] = fun;
        }
    }
}
1.3. Level Two – Engines, Compiled Code, Sources, and Object Operations

The next level of engagement involves operating directly with engines and abstractions of source code and compiled code. You can compile code and run it in any scope or its default scope. You also have more control over how you provide sources to the DLR.

Besides the new types you’ll use for Level Two scenarios, you will likely use more of the ScriptRuntime and ScriptScope classes. You’ll certainly use their members to get to engines. You’ll likely use more flavors of getting and setting variables on scopes as you have richer interactions with dynamic code. You might use the ability of scopes to support executing multiple languages within one scope, using execute methods on engines.

The main new types you’ll use in Level Two scenarios are ScriptEngines, ScriptSources, and ObjectOperations. ScriptEngines are the work horse. They offer various ways to execute code and create ScriptScopes and ScriptSources. There are several members on ScriptEngine for working with ScriptScope variables. These give you the engine's specific language view of variable operations in any scope, regardless of any language possibly associated with the scope. ScriptSources offer methods for executing code in various ways from different kinds of sources.

You may use ScriptRuntime.LoadAssembly to add namespaces to ScriptRuntime.Globals from a .NET assembly. The top-level namespaces in the assembly become members of Globals. You can access sub namespaces as members of the top-level namespaces. Languages can then make the .NET assembly contents available via their mechanisms, such as import, require, notion of globals, etc.
ObjectOperations provide a large catalogue of object operations such as member access, conversions, indexing, and operations like addition. There are several introspection and tool support services that we'll discuss in Level Three scenarios. You get ObjectOperation instances from engines, and they are bound to their engines for the semantics of the operations. There is a default instance of ObjectOperations you can share across all uses of the engine. However, very advanced hosts can create new instances of ObjectOperations, which is explained in the references section.

These are the main types of level two:
public class Level_2 {
    ScriptRuntime env = ScriptRuntime.CreateFromConfiguration();

    public void REPL_fragments {
        ScriptSource input;
        object result;
        // Assume user has chosen a context with the REPL's
        // default scope and the Python language.
        ScriptScope defaultScope = env.CreateScope();
        ScriptEngine curEngine = env.GetEngine("py");

        // Use interactive source units for special REPL variab
        // or syntax, such as IPy's underscore or VB's '?',
        // provided by standard interpreters for the languages.
        ScriptSource input = curEngine
            .CreateScriptSourceFromString
            // E.g., input is "x = 'foo'".
            (GetInputAsString(),
                SourceCodeKind.InteractiveCode);
        result = input.Execute(defaultScope);
        REPLOutput.WriteLine(curEngine
            .Operations
            .GetObjectCodeRepresentation(result));

        // Assume user has chosen somehow to switch to Ruby.
        curEngine = env.GetEngine("rb");
        // E.g., input is "puts x"
        input = curEngine
            .CreateScriptSourceFromString
            (GetInputAsString(),
                SourceCodeKind.InteractiveCode);
        result = input.Execute(defaultScope);
        System.Console.WriteLine(curEngine
            .Operations
            .GetObjectCodeRepresentation(result));

        // Assume user has chosen to execute a file from anothe
        // language, and you want to set the REPL's context to
        // file's scope. Use scope now for interactions like a
// and save it for use with this file later.
ScriptScope scope = env.ExecuteFile(GetFileFromUserOrEditor());
curEngine = scope.Engine;
}

public delegate string OnLoadDelegate();

// MerlinWeb:
public void ReUse_CompiledCode_Different_Scopes()
{
    ScriptEngine engine = env.GetEngine("rb");
    CompiledCode compiledCode
        = engine.CreateScriptSourceFromFile("foo.rb").Compile();

    // on each request, create new scope with custome dicti
    // for latebound look up of elements on page.
    IAttributesCollection attrColl = GetNewMyAttrColl();
    attrColl["Page"] = thisRequestPage;
    ScriptScope scope = env.CreateScope(attrColl);
    compiledCode.Execute(scope);
    // Expect on_Load function name to be defined, or throw
    // Could have used scope.GetVariable but it's case-sens
    engine.GetVariable<OnLoadDelegate>(scope, "on_Load")();
}
1.4. Level Three – Full Control, Remoting, Tool Support, and More

Level three engagement as a host gives you full control over the ScriptRuntime. There are many things hosts can do at this level from controlling runtime configuration, to handling runtime exceptions, to using remote ScriptRuntimes, to providing full programming tool support with completion, parameter info pop-ups, and colorization.

With level three support, you can create a ScriptRuntimeSetup object to control which languages are available or set options for a ScriptRuntime’s behavior. For example, you can limit the ScriptRuntime certain versions of particular languages. You can also use .NET application configuration to allow users to customize what languages are available.

Another simple mechanism in level three is deriving from ScriptHost. This lets you provide a custom PlatformAdaptationLayer object to override file name resolution. For example, you might only load files from a particular directory or go to a web server for files. A host communicates its sub type of ScriptHost to the DLR when it creates a ScriptRuntime. Many hosts can just use the DLR’s default ScriptHost. ScriptHost looks like:
The ObjectOperations class provides language-specific operations on objects, including some tool building support. ObjectOperations includes introspection of objects via members such as GetMemberNames, IsCallable, GetCallSignatures, GetDocumentation, and GetCodeRepresentation. These give you a language-specific view in that you see members of objects and signatures from the flavor of a specific language. For example, you would see the Python meta-programming members of objects that Python manifests on objects. ObjectOperations enables you to build tool support for dynamic languages on the DLR, but you need another set of objects for parsing code.

Hosts can get parsing support for providing colorization in editors and interpreters. The following are the types used for that functionality:

Hosts that implement tools for programmers will likely also create ScriptSources and implement TextContentProviders so that tokenizers can read input directly from the host’s data structures. For example, an editor with a file in memory (in an editor buffer) could implement a TextContentProviders that reads input directly from the buffer’s data structure. The types relating to sources are:
2. DLR Hosting APIs »
2. ScriptRuntime

This class is the starting point for hosting. For Level One scenarios, you just create ScriptScopes, use Globals, and use ExecuteFile. For Level Two scenarios, you can get to ScriptEngines and so on.

ScriptRuntime represents global script state. This includes referenced assemblies, a “global object” (ScriptRuntime.Globals), “published” scopes (scopes bound to a name on Globals), available language engines, etc.

ScriptRuntime has a single constructor and two convenience factory methods. You can create multiple instances of a ScriptRuntime in a single AppDomain. For information on configuring a ScriptRuntime for what languages it allows, global settings, language settings, etc., see ScriptRuntimeSetup.

ScriptRuntime Overview:

public class ScriptRuntime : MarshalByRefObject {
    public ScriptRuntime(ScriptRuntimeSetup setup) {
    }
    public static ScriptRuntime CreateFromConfiguration() {
    }
    public static ScriptRuntime CreateRemote(AppDomain domain, ...

    public ScriptScope ExecuteFile(string path);  
    public ScriptScope Globals { get; set; } 
    public ScriptScope CreateScope(); 
    public ScriptScope CreateScope(IAttributesCollection storage) 

    public ScriptEngine GetEngine(string languageId); 
    public ScriptEngine GetEngineByFileExtension(string extension) 
    public string[] GetRegisteredFileExtensions(); 
    public string[] GetRegisteredLanguageIdentifiers();

    public void LoadAssembly(Assembly assm); 

    public ObjectOperations Operations { get; } 
    public ObjectOperations CreateOperations() { } 

    public ScriptRuntimeSetup Setup { get {} } 
}
public ScriptHost Host { get; }
public ScriptIO IO { get; }
public void Shutdown()
2.1. ScriptRuntime Members

**ScriptRuntime**(ScriptRuntimeSetup *setup*)

The constructor requires a ScriptRuntimeSetup, which gives the host full control of the languages allowed in the ScriptRuntime, their options, and the global runtime options.

This method ensures the list of languages in the setup object has no duplicate elements based on the LanguageSetup.TypeName property (just comparing them as strings at this point). Later, when engines fault in, the DLR also ensures that none of the assembly-qualified types actually identify the same type.

This method ensures the list of languages in the setup have no conflicting LanguageSetup.Names elements or Language.FileExtensions elements. After calling this method, modifying the ScriptRuntimeSetup object throws an exception.

**ScriptRuntime** `CreateFromConfiguration()`

**ScriptRuntime** `CreateRemote`(AppDomain *domain*, ScriptRuntimeSetup *setup*)

These factory methods construct and return ScriptRuntimes. They primarily are for convenience and discoverability via editors that complete members on types.

CreateFromConfiguration is just a convenience for:

```csharp
ew ScriptRuntime(ScriptRuntimeSetup.ReadConfiguration())
```

CreateRemote creates the ScriptRuntime in the specified domain, instantiates the ScriptRuntimeSetup.HostType in that domain, and returns the ScriptRuntime. Any arguments specified in ScriptRuntimeSetup.HostArguments must derive from MBRO or serialize across app domain boundaries. The same holds for

**ScriptScope ExecuteFile(string path);**

This method executes the source identified in the path argument and returns the new ScriptScope in which the source executed. This method calls on the ScriptRuntime.Host to get the PlatformAdaptationLayer and then calls on it to resolve and open the path. ExecuteFile determines the language engine to use from the path's extension and the ScriptRuntime’s configuration, comparing extensions case-insensitively.

This convenience method exists for Level 1 hosting scenarios where the path is likely an absolute pathname or a filename that naturally resolves with standard .NET BCL file open calls.

Each time this method is called it create a fresh ScriptScope in which to run the source. Calling Engine.GetScope returns the last ScriptScope created for repeated invocations of ExecuteFile on the same path.

This method adds variable name bindings within the ScriptRuntime.Globals object as appropriate for the language. Dynamic language code can then access and drill into objects bound to those names. For example, the IronPython loader adds the base file name to the ScriptRuntime.Globals as a Python module, and when IronPython is importing names, it looks in ScriptRuntime.Globals to find names to import. IronRuby's loader adds constants and modules to the ScriptRuntime.Globals object. DLR JScript adds all globals there.

In Globals, each language decides its own semantics for name conflicts, but the expected model is last-writer-wins. Languages do have the ability to add names to Globals so that only code executing in that language can see the global names. In this
case, other languages would not have the ability to clobber the name bindings. For example, Python might do this for its special built-in modules. However, most names should be added so that all languages can see the bindings and interoperate with the objects bound to the names.

**ScriptScope Globals { get; set; }**

This property returns the “global object” or name bindings of the ScriptRuntime as a ScriptScope. You can set the globals scope, which you might do if you created a ScriptScope with an IAttributesCollection so that your host could late bind names.

**ScriptScope CreateScope();**

**ScriptScope CreateScope(IAttributesCollection storage);**

This method returns a new ScriptScope.

The storage parameter lets you supply the dictionary of the scope so that you can provide late bound values for some name lookups. If storage is null, this method throws an ArgumentNullException.

**ScriptEngine GetEngine(string languageId);**

This method returns the one engine associated with this ScriptRuntime that matches the languageId argument, compared case-insensitively. This loads the engine and initializes it if needed.

If languageId is null, or it does not map to an engine in the ScriptRuntime’s configuration, then this method throws an exception.

**ScriptEngine GetEngineByFileExtension(string extension);**

This method takes a file extension and returns the one engine associated with this ScriptRuntime that matches the extension argument. This strips one leading period if extension starts with a
This loads the engine and initializes it if needed. The file extension associations are determined by the ScriptRuntime configuration (see configuration section above). This method compares extensions case-insensitively.

If extension is null, or it does not map to an engine in the ScriptRuntime's configuration, then this method throws an exception.

`string[] GetRegisteredFileExtensions();`

This method returns an array of strings (without periods) where each element is a registered file extension for this ScriptRuntime. Each file extension maps to a language engine based on the ScriptRuntime configuration (see configuration section above). If there are none, this returns an empty array.

`string[] GetRegisteredLanguageIdentifiers();`

This method returns an array of strings where each element is a registered language identifier for this ScriptRuntime. Each language identifier maps to a language engine based on the ScriptRuntime configuration (see configuration section above). Typically all registered file extensions are also language identifiers. If there are no language identifiers, this returns an empty array.

`void LoadAssembly(Assembly assm);`

This method walks the assembly's namespaces and adds name bindings in ScriptRuntime.Globals to represent namespaces available in the assembly. Each top-level namespace name becomes a name in Globals, bound to a dynamic object representing the namespace. Within each top-level namespace object, the DLR binds names to dynamic objects representing each sub namespace or type.
By default, the DLR seeds the ScriptRuntime with Mscorlib and System assemblies. You can avoid this by setting the ScriptRuntimeSetup option “NoDefaultReferences” to true.

When this method encounters the same fully namespace-qualified type name, it merges names together objects representing the namespaces. If you called LoadAssembly on two different assemblies, each contributing to System.Foo.Bar namespace, then all names within System.Foo.Bar from both assemblies will be present in the resulting object representing Bar.

**Operations()**

This property returns a default, language-neutral ObjectOperations. ObjectOperations lets you perform various operations on objects. When the objects do not provide their own behaviors for performing the operations, this ObjectOperations uses general .NET semantics. Because there are many situations when general .NET semantics are insufficient due to dynamic objects often not using straight .NET BCL types, this ObjectOperations will throw exceptions when one produced by a ScriptEngine would succeed.

Because an ObjectOperations object caches rules for the types of objects and operations it processes, using the default ObjectOperations for many objects could degrade the caching benefits. Eventually the cache for some operations could degrade to a point where ObjectOperations stops caching and does a full search for an implementation of the requested operation for the given objects. For simple hosting situations, this is sufficient behavior.

**ObjectOperations CreateOperations()**

These methods return a new ObjectOperations object. See the Operations property for why you might want to call this and for
limitations of ObjectOperations provided by a ScriptRuntime instead of one obtained from a ScriptEngine.

There currently is little guidance on how to choose when to create new ObjectOperations objects. However, there is a simple heuristic. If you were to perform some operations over and over on the same few types of objects, it would be advantageous to create an ObjectOperations just for use with those few cases. If you perform different operations with many types of objects just once or twice, you can use the default instance provided by the ObjectOperations property.

```csharp
ScriptRuntimeSetup Setup { get {} }
```

This property returns a read-only ScriptRuntimeSetup object describing the configuration information used to create the ScriptRuntime.

```csharp
ScriptHost Host { get; }
```

This property returns the ScriptHost associated with the ScriptRuntime. This is not settable because the ScriptRuntime must create the host from a supplied type to support remote ScriptRuntime creation. Setting it would also be bizarre because it would be similar to changing the owner of the ScriptRuntime.

```csharp
ScriptIO IO { get; }
```

This property returns the ScriptIO associated with the ScriptRuntime. The ScriptIO lets you control the standard input and output streams for code executing in the ScriptRuntime.

```csharp
void Shutdown()
```

This method announces to the language engines that are loaded that the host is done using the ScriptRuntime. Languages that have a shutdown hook or mechanism for code to release system resources on shutdown will invoke their shutdown protocols.

There are no other guarantees from this method. For example, It
is undefined when code executing (possibly on other threads) will stop running. Also, any calls on the ScriptRuntime, hosting API objects associated with the runtime, or dynamic objects extracted from the runtime have undefined behavior.
2. DLR Hosting APIs »
3. ScriptScope

This class represents a namespace essentially. Hosts can bind variable names in ScriptScopes, fetch variable values, etc. Hosts can execute code within scopes for distinct name bindings.

ScriptScopes also have some convenience members and an optional language affinity. Scopes use the language to look up names and convert values. If the ScriptScope has no default language, then these convenience methods throw an exception, and the Engine property returns null.

Hosts can store ScriptScopes as the values of names on ScriptRuntime.Globals or in other scopes. When dynamic language code encounters a ScriptScope as an object, the DLR manifests the scope as a dynamic object. This means that normal object member access sees the variables stored in the ScriptScope first. Languages executing code that is doing the object member access get a chance to find members if the members are not variables in the ScriptScope. The language might bind to the .NET static type members documented here. They might detect the .NET type is ScriptScope and throw a missing member exception, use meta-programming hooks to give dynamic language code a chance to produce the member, or return sentinel objects according to the language's semantics.

Hosts can use ScriptScopes (regardless of whether they have a language affinity) to execute any kind of code within their namespace context. ScriptEngine methods that execute code take a ScriptScope argument. There are parallel methods on engines for getting and setting variables so that hosts can request a name lookup with any specific language's semantics in any ScriptScope.

You create instances of ScriptScopes using the CreateScope and
ExecuteFile methods on ScriptRuntimes or CreateScope on ScriptEngine.

Note, members that take or return ObjectHandles are not present on Silverlight.

ScriptScope Overview:

```csharp
public class ScriptScope : MarshalByRefObject {
    public ScriptScope(ScriptEngine engine, Scope scope);

    public object GetVariable(string name);
    public ObjectHandle GetVariableHandle(string name);
    public bool RemoveVariable(string name);
    public void SetVariable(string name, object value);
    public void SetVariable(string name, ObjectHandle handle);
    public bool TryGetVariable(string name, out object value);
    public bool TryGetVariableHandle(string name, out ObjectHandle handle);
    public T GetVariable<T>(string name);
    public bool TryGetVariable<T>(string name, out T value);
    public bool ContainsVariable(string name);

    public IEnumerable<string> GetVariableNames();
    public IEnumerable<KeyValuePair<string, object>> GetItems();

    public ScriptEngine Engine { get; }
}
```
3.1. ScriptScope Members

**ScriptScope**(ScriptEngine *engine*, Scope *scope*)

Creates a new ScriptScope associated with the provided engine and who's local storage is scope.

object GetVariable(string name);

ObjectHandle GetVariableHandle(string name);

T GetVariable<T>(string name);

These methods fetch the value of a variable stored in the scope.

If there is no engine associated with the scope (see ScriptRuntime.CreateScope), then the name lookup is a case-sensitive, literal lookup of the name in the scope's dictionary. If there is a default engine, then the name lookup uses that language's semantics.

GetVariableHandle is useful when the ScriptScope is remote so that you get back an ObjectHandle referring to the value.

GetVariable<T> uses implicit conversion. It throws a NotSupportedException if the engine cannot perform the requested type conversion. If there is no associated engine, this method uses standard .NET conversion, which could throw an ArgumentException.

If you need an explicit conversion to T, you can use scope.Engine.Operations.ExplicitConvertTo<T>.

void SetVariable(string name, object value);

void SetVariable(string name, ObjectHandle handle);

These methods assign a value to a variable in the scope,
overwriting any previous value.

If there is no engine associated with the scope (see ScriptRuntime.CreateScope), then the name mapping is a case-sensitive, literal mapping of the name in the scope's dictionary. If there is a default engine, then the name lookup uses that language's semantics.

bool TryGetVariable(string name, out object value);

bool TryGetVariableHandle(string name, out ObjectHandle handle);

bool TryGetVariable<T>(string name, out T value);

These methods fetch the value of a variable stored in the scope and return a Boolean indicating success of the lookup. When the method's result is false, then it assigns null to value.

If there is no engine associated with the scope (see ScriptRuntime.CreateScope), then the name lookup is a case-sensitive, literal lookup of the name in the scope's dictionary. If there is a default engine, then the name lookup uses that language's semantics.

TryGetVariableHandle is useful when the ScriptScope is remote so that you get back an ObjectHandle referring to the value.

TryGetVariable<T> uses implicit conversion. It throws a NotSupportedException if the engine cannot perform the requested type conversion. If there is no associated engine, this method uses standard .NET conversion, which could throw an ArgumentException.

If you need an explicit conversion to T, you can use scope.Engine.Operations.TryExplicitConvertTo<T>.

bool ContainsVariable(string name);
This method returns whether the variable is exists in this scope and has a value.

If there is no engine associated with the scope (see ScriptRuntime.CreateScope), then the name lookup is a literal lookup of the name in the scope’s dictionary. Therefore, it is case-sensitive for example. If there is a default engine, then the name lookup uses that language’s semantics.

**IEnumerable<string> GetVariableNames();**

This method returns an enumeration of strings, one string for each variable name in this scope. If there are no names, then it returns an empty array. Modifying the array has no impact on the ScriptScope. This method returns a new instance for the result of each call.

**IEnumerable<KeyValuePair<string, object>> GetItems();**

This method returns an IEnumerable of variable name/value pairs, one for each variable name in this scope. If there are no names, then the enumeration is empty. Modifying the array has no impact on the ScriptScope. This method returns a new instance for the result of each call, and modifying the scope while using the enumeration has undefined behavior.

**bool RemoveVariable(string name);**

This method removes the variable name and returns whether the variable existed and had a value in the scope when you called this method.

If there is no engine associated with the scope (see ScriptRuntime.CreateScope), then the name lookup is a literal lookup of the name in the scope’s dictionary. Therefore, it is case-sensitive for example. If there is a default engine, then the name lookup uses that language’s semantics.

Some languages may refuse to remove some variables. If the
scope has an associated language that has variables that cannot be removed, and name identifies such a variable, it is undefined what happens. Languages vary on whether this is a no-op or exceptional.

**ScriptEngine Engine { get;}**

This property returns the engine associated with this scope. If the scope was created without a language affinity, then this property returns null.
2. DLR Hosting APIs »
4. ScriptEngine

ScriptEngines represent a language implementation in the DLR, and they are the work horse for intermediate and advanced hosting scenarios. ScriptEngines offer various ways to execute code and create ScriptScopes and ScriptSources. ScriptSources offer methods for executing code in various ways from different kinds of sources. ScriptEngines offer the more common or convenience methods for executing code.

There are several members on ScriptEngine for working with ScriptScope variables. These give you the engine’s specific language view of variable operations in any scope, regardless of the scope’s associated language, if any.

There is only one instance of a ScriptEngine for a given language in a given ScriptRuntime. You get to engines with ScriptRuntime’s methods or the Engine property of ScriptScope.

Note, members that take or return ObjectHandles are not present on Silverlight.

ScriptEngine Overview:

```csharp
public class ScriptEngine : MarshalByRefObject {
    public ScriptRuntime Runtime { get; }
    public string LanguageDisplayName { get; }
    public string[] GetRegisteredIdentifiers();
    public string[] GetRegisteredExtensions();

    public object Execute(string expression);
    public object Execute<T>(string expression, ScriptScope scope)
    public T Execute<T>(string code);
    public T Execute<T>(string expression, ScriptScope scope)
    public ObjectHandle ExecuteAndWrap(string expression)
    public ObjectHandle ExecuteAndWrap(string expression, ScriptScope scope)
    public ScriptScope ExecuteFile(string path)
    public ScriptScope ExecuteFile(string path, ScriptScope scope)
```
public ScriptScope GetScope(string path);

public ObjectOperations Operations { get; }
public ObjectOperations CreateOperations();
public ObjectOperations CreateOperations(ScriptScope Scope);

public ScriptSource CreateScriptSourceFromString(string expression);
public ScriptSource CreateScriptSourceFromString(string expression, string path);
public ScriptSource CreateScriptSourceFromString(string code, SourceCodeKind kind);
public ScriptSource CreateScriptSourceFromString(string code, string path, SourceCodeKind kind);

public ScriptSource CreateScriptSourceFromFile(string path);
public ScriptSource CreateScriptSourceFromFile(string path, System.Text.Encoding encoding);
public ScriptSource CreateScriptSourceFromFile(string path, System.Text.Encoding encoding, SourceCodeKind kind);

public ScriptSource CreateScriptSource(StreamContentProvider contentProvider, string path);
public ScriptSource CreateScriptSource(StreamContentProvider contentProvider, string path, System.Text.Encoding encoding);
public ScriptSource CreateScriptSource(StreamContentProvider contentProvider, string path, System.Text.Encoding encoding, SourceCodeKind kind);
public ScriptSource CreateScriptSource(TextContentProvider contentProvider, string path, SourceCodeKind kind);
public ScriptSource CreateScriptSource(CodeObject content);
public ScriptSource CreateScriptSource(CodeObject content, string path);
public ScriptSource CreateScriptSource(System.CodeDom.CodeObject code, string path, SourceCodeKind kind);

public ScriptScope CreateScope();
public ScriptScope CreateScope(IAttributesCollection globals);
public ScriptScope CreateScope(Object globals);

public object GetVariable(ScriptScope scope, string name);
public ObjectHandle GetVariableHandle(ScriptScope scope, string name, string path);
public void SetVariable(ScriptScope scope, string name, object value);
public void SetVariable(ScriptScope scope, string name, ObjectHandle value);
public bool TryGetVariable(ScriptScope scope, string name, out object value);
public bool TryGetVariableHandle(ScriptScope scope, string name, out ObjectHandle value);
public bool ContainsVariable(ScriptScope scope, string name);
public T GetVariable<T>(ScriptScope scope, string name);
public bool TryGetVariable<T>(ScriptScope scope, string name, out T value);

public ServiceType GetService<ServiceType>(params object[] args) where ServiceType : class;

public LanguageSetup Setup { get; }
public CompilerOptions GetCompilerOptions() {}
public CompilerOptions GetCompilerOptions(ScriptScope scope)
public ICollection<string> GetSourceSearchPaths() {}
public void SetSearchPaths (ICollection<string> paths) {} public System.Version LanguageVersion { get; }
4.1. ScriptEngine Members

**ScriptEngine**

ScriptEngine has no public constructors. To get a ScriptEngine instance call GetEngine on a ScriptRuntime instance.

**ScriptRuntime Runtime { get; }

This property returns the ScriptRuntime for the context in which this engine executes.

**string LanguageDisplayName { get; }

This property returns a display name for the engine or language that is suitable for UI.

**string[] GetRegisteredIdentifiers();

**string[] GetRegisteredExtensions();

These methods return unique identifiers for this engine and file extensions that map to this engine and its language. This information comes from configuration data passed to ScriptRuntime.Create.

Modifying the results of these methods has no effect on configuration of this engine.

**object Execute(string expression);**

**object Execute(string expression, ScriptScope scope);**

**T Execute<T>(string expression);**

**T Execute<T>(string expression, ScriptScope scope)**

**ObjectHandle ExecuteAndWrap(string expression)**

**ObjectHandle ExecuteAndWrap(string expression, ScriptScope scope)**
These methods execute the strings as expressions and return a result in various ways. There are complementary overloads that take a ScriptScope. The overloads that do not take scopes create a new scope for each execution. These methods throw the scope away and use it for side effects only, returning the result in the same way the complementary overload does.

Execute<T> returns the result as the specified type, using the engine's Operations.ConvertTo<T> method. If this method cannot convert to the specified type, then it throws a NotSupportedException.

ExecuteAndWrap returns an ObjectHandle for use when the engine and/or scope are remote.

**ScriptScope ExecuteFile(string path)**

**ScriptScope ExecuteFile(string path, ScriptScope scope)**

These methods execute the strings the contents of files and return the scope in which the string executed. The overload that does not take a ScriptScope creates a new one each time it is called.

**ScriptScope GetScope(string path);**

This method returns the ScriptScope in which the specified path/source executed. This method works in conjunction with LoadFile and language implementer APIs for loading dynamic language libraries (see LoadFile’s side note). The path argument needs to match a ScriptSource's Path property because it is the key to finding the ScriptScope. Hosts need to make sure they create ScriptSources (see ScriptHost as well as methods on ScriptEngine) with their Path properties set appropriately (for example, resolving relative paths to canonical full pathnames, FileInfo.FullPath for standard .NET resolved paths).
GetScope is primarily useful for tools that need to map files to their execution scopes when the tool did not create the scope. For example, an editor and interpreter tool might execute a file, Foo, that imports or requires a file, Bar. The editor end user might later open the Bar and want to execute expressions in its context. The tool would need to find Bar’s ScriptScope for setting the appropriate context in its interpreter window. This method helps with this scenario.

Languages may return null. For example, Ruby's require expression executes a file's contents in the calling scope. Since Ruby does not have a distinct scope in which the file executed in this case, they return null for such files.

**ObjectOperations Operations { get; }**

This property returns a default ObjectOperations for the engine. ObjectOperations lets you perform various operations on objects. Because an ObjectOperations object caches rules for the types of objects and operations it processes, using the default ObjectOperations for many objects could degrade the caching benefits. Eventually the cache for some operations could degrade to a point where ObjectOperations stops caching and does a full search for an implementation of the requested operation for the given objects. For simple hosting situations, this is sufficient behavior.

See CreateOperations for alternatives.

**ObjectOperations CreateOperations();**

**ObjectOperations CreateOperations(ScriptScope Scope);**

These methods return a new ObjectOperations object. See the Operations property for why you might want to call this.

There currently is little guidance on how to choose when to create new ObjectOperations objects. However, there is a simple
heuristic. If you were to perform some operations over and over on the same few types of objects, it would be advantageous to create an ObjectOperations just for use with those few cases. If you perform different operations with many types of objects just once or twice, you can use the default instance provided by the ObjectOperations property.

The overload that takes a ScriptScope supports pretty advanced or subtle scenarios. It allows you to get an ObjectOperations that uses the execution context built up in a ScriptScope. For example, the engine affiliated with the scope could be IronPython, and you could execute code that did an “import clr” or “from __future__ import true_division”. These change execution behaviors within that ScriptScope. If you obtained objects from that scope or executing expressions in that scope, you may want to operate on those objects with the same execution behaviors; however, you generally do not need to worry about these subtleties for typical object interactions.

```csharp
ScriptSource CreateScriptSourceFromString(string expression);

ScriptSource CreateScriptSourceFromString(string expression, string path);

ScriptSource CreateScriptSourceFromString(string code, SourceCodeKind kind);

ScriptSource CreateScriptSourceFromString(string code, string path, SourceCodeKind kind);
```

These methods return ScriptSource objects from string contents. These are factory methods for creating ScriptSources with this language binding.

The default SourceCodeKind is AutoDetect.

The ScriptSource’s Path property defaults to null. When path is
non-null, if executing the resulting ScriptSource would create a ScriptScope, then path should map to the ScriptScope via GetScope.

```csharp
ScriptSource CreateScriptSourceFromFile(string path);

ScriptSource CreateScriptSourceFromFile(string path, System.Text.Encoding encoding);

ScriptSource CreateScriptSourceFromFile(string path, System.Text.Encoding encoding, SourceCodeKind kind);
```

These methods return ScriptSource objects from file contents. These are factory methods for creating ScriptSources with this language binding. The path’s extension does NOT have to be registered or valid for the engine. This method does NOT go through the PlatformAdaptationLayer to open the file; it goes directly to the file system via .NET.

The default SourceCodeKind is File.

The ScriptSource’s Path property will be the path argument, which needs to be in some canonical form according to the host if the host is using GetScope to find the source’s execution context later.

Creating the ScriptSource does not open the file. Any exceptions that will be thrown on opening or reading the file happen when you use the ScriptSource to execute or compile the source.

The encoding defaults to the platform encoding.

```csharp
ScriptSource CreateScriptSource(StreamContentProvider contentProvider, string path)

ScriptSource CreateScriptSource(StreamContentProvider contentProvider, string path, System.Text.Encoding encoding)
```
ScriptSource **CreateScriptSource** (StreamContentProvider *contentProvider*, string *path*, System.Text.Encoding *encoding*, SourceCodeKind *kind*)

This is a factory method for creating a ScriptSources with this language binding.

This version lets you supply binary (sequence of bytes) stream input. This is useful when opening files that may contain language-specific encodings that are marked in the first few bytes of the file's contents. There is a default StreamContentProvider used internally if you call CreateScriptSourceFromFile. The encoding defaults to the platform encoding if the language doesn't recognize some other encoding (for example, one marked in the file's first few bytes).

ScriptSource **CreateScriptSource** (TextContentProvider *contentProvider*, string *path*, SourceCodeKind *kind*)

This is a factory method for creating a ScriptSources with this language binding.

This version lets you supply input from Unicode strings or stream readers. This could be useful for implementing a TextReader over internal host data structures, such as an editor's text representation.

ScriptSource **CreateScriptSource** (System.CodeDom.CodeObject *code*, string *path*, SourceCodeKind *kind*)

ScriptSource **CreateScriptSource** (CodeObject *content*)

ScriptSource **CreateScriptSource** (CodeObject *content*, string *path*)

ScriptSource **CreateScriptSource** (CodeObject *content*, SourceCodeKind *kind*)

This is a factory method for creating a ScriptSources with this language binding.

This version is for supporting language independent code generation. The expected CodeDom support is extremely minimal for syntax-independent expression of semantics. Languages may do more, but hosts should only expect CodeMemberMethod support, and only sub nodes consisting of the following:

- CodeSnippetStatement
- CodeSnippetExpression
- CodePrimitiveExpression
- CodeMethodInvokeExpression
- CodeExpressionStatement (for holding MethodInvoke)

This support exists primarily for ASP.NET pages that contain snippets of DLR languages, and these requirements were very limited. When the CodeObject argument does not match this specification, you will get a type cast error, but if the language supports more options, you could get different errors per engine.

The path argument in all cases is a unique ID that the host may use to retrieve the scope in which the source executes via Engine.GetScope.

ScriptScope `CreateScope());
ScriptScope `CreateScope(IAttributesCollection globals);
ScriptScope `CreateScope(Object globals);

This method returns a new ScriptScope with this engine as the default language for the scope.

The globals parameter lets you supply the dictionary of the scope
so that you can provide late bound values for some name lookups. If globals is null, this method throws an ArgumentException. If globals is not an IAttributesCollection, then it must implement IDynamicMetaObjectProvider; otherwise, this method throws an exception because language engines will not be able to reliably execute code in the scope.

```csharp
object GetVariable(ScriptScope scope, string name);

ObjectHandle GetVariableHandle(ScriptScope scope, string name);

T GetVariable<T>(ScriptScope scope, string name);
```

These methods return the value of variables in the scope argument. These methods are duals to the members on ScriptScope, and they look up variables with this engine's semantics, regardless of any language association in the ScriptScope. For example, if this engine's language is case-insensitive or provides name mappings so that variables appear with naming conventions in this engine's language, these methods help you look up names with the behaviors of this engine's language.

GetVariable<T> uses the IDynamicObject protocol to convert the resulting object to T if the object is an IDynamicObject. It uses implicit conversions. If you need an explicit conversion to T, you can use Engine.Operations.ExplicitConvertTo<T>.

GetVariable<T> throws a NotSupportedException if the engine cannot perform the requested type conversion.

If any argument is null, these throw an ArgumentException.

```csharp
bool RemoveVariable(ScriptScope scope, string name);
```

This method removes a variable from the scope, performing a language-specific lookup, and returns whether the variable
existed and had a value in the scope when you called this method. See “GetVariable* Methods” for why we offer this dual to ScriptScope's member.

Some languages may refuse to remove some variables. If the ObjectOperations' associated language has variables that cannot be removed, and name identifies such a variable, it is undefined what happens. Languages vary on whether this is a no-op or exceptional.

If either argument is null, this throws an ArgumentNullException.

```csharp
void SetVariable(ScriptScope scope, string name, object value);

void SetVariable(ScriptScope scope, string name, ObjectHandle value);
    This method sets a variable's value in the scope, performing a language-specific mapping to store a value for name. See “GetVariable* Methods” for why we offer this dual to ScriptScope's member.

    If the scope or name argument is null, these throw an ArgumentNullException.

bool TryGetVariable(ScriptScope scope, string name, out object value);

bool TryGetVariableHandle(ScriptScope scope, string name, out ObjectHandle value);

bool TryGetVariable<T>(ScriptScope scope, string name, out T value);
    These methods try to get a variable's value from the scope, performing a language-specific lookup, and return a Boolean indicating success of the lookup. When the method's result is false, then it assigns null to value. See “GetVariable* Methods” for why we offer this dual to ScriptScope’s member.
GetVariable<T> uses the IDynamicObject protocol to convert the resulting object to T if the object is an IDynamicObject. It uses implicit conversions. If you need an explicit conversion to T, you can use Engine.Operations.TryExplicitConvertTo<T>.

TryGetVariable<T> throws a NotSupportedException if the engine cannot perform the requested type conversion.

TryGetVariableHandle is useful when the ScriptScope is remote so that you get back an ObjectHandle referring to the value.

If the scope or name argument is null, these throw an ArgumentNullException.

bool ContainsVariable(ScriptScope scope, string name);
This method returns whether the scope contains a binding for the variable name, performing a language-specific lookup. See “GetVariable* Methods” for why we offer this dual to ScriptScope’s member.

ServiceType GetService<ServiceType>(params object[] args) where ServiceType : class;
This method returns a language-specific service. It provides a point of extensibility for a language implementation to offer more functionality than the standard engine members discussed here. If the specified service is not available, this returns null.

The following are services expected to be supported:

ExceptionOperations This duplicates some members of Exception and can return a string in the style of this engine’s language to describe the exception argument.

TokenCategorizer This is for building tools that want to scan languages and get token info, such as colorization categories.

This type will change and be spec’ed external to this document
eventually, see the section below for this type.

OptionsParser This can parse a command shell (cmd.exe) style command line string. Hosts that are trying to be an interactive console or incorporate standard command line switches of a language’s console can get the engine’s command line parser.

This is a place holder for DLR v2. Its design will definitely change. We have a big open issue to redesign language and DLR support for building interactive UI, interpreters, tools, etc., with some common support around command lines and consoles.

CommandLine is a helper object for parsing and processing interactive console input, maintaining a history of input, etc.

This is a place holder for DLR v2. Its design will definitely change. We have a big open issue to redesign language and DLR support for building interactive UI, interpreters, tools, etc., with some common support around command lines and consoles.

ScriptConsole This is a helper object for the UI of an interpreter, how output is displayed and how we get input. If the language does not implement a ScriptConsole, there is a default Console object they can return. This is a place holder for DLR v2. Its design will definitely change. We have a big open issue to redesign language and DLR support for building interactive UI, interpreters, tools, etc., with some common support around command lines and consoles. Need to distinguish this and CommandLine.

LanguageSetup Setup { get; }
This property returns a read-only LanguageSetup describing the configuration used to instantiate this engine.
CompilerOptions GetCompilerOptions() {}

CompilerOptions GetCompilerOptions(ScriptScope scope) {}
This method returns the compiler options object for the engine’s language. The overload that takes a ScriptScope returns options that represent any accrued imperative options state from the scope (for example, “from futures import truedivision” in python). To operate on the options before passing them to ScriptSource.Compile, for example, you may need to cast the result to the documented subtype of CompilerOptions for the language you’re manipulating.

If scope is null, this throws an ArgumentNullException.

CompilerOptions type will likely change by the time the DLR Hosting APIs move into the .NET libraries, possibly becoming Dictionary<str,obj>.

ICollection<string> GetSearchPaths () {}
This method returns the search paths used by the engine for loading files when a script wants to import or require another file of code. These are also the paths used by ScriptRuntime.UseFile.

These paths do not affect ScriptRuntime.ExecuteFile. The ScriptHost’s PlatformAdaptationLayer (or the default’s direct use of .NET file APIs) controls partial file name resolution for ExecuteFile.

void SetSearchPaths (ICollection<string> paths){}
This method sets the search paths used by the engine for loading files when a script wants to import or require another file of code. Setting these paths affects ScriptRuntime.UseFile.

These paths do not affect ScriptRuntime.ExecuteFile. The ScriptHost's PlatformAdaptationLayer (or the default's direct use
of .NET file APIs) controls partial file name resolution for ExecuteFile.

```csharp
System.Version LanguageVersion { get; }
```

This property returns the language’s version.
5. ScriptSource

ScriptSource represents source code and offer a variety of ways to execute or compile the source. You can get ScriptSources from factory methods on ScriptEngine, and ScriptSources are tied to the engine that created them. The associated engine provides the execution and compilation semantics for the source.

ScriptSources have properties that direct the parsing of and report aspects of the source. For example, the source could be marked as being an expression or a statement, for language that need to distinguish expressions and statements semantically for how to parse them. The code could be marked as being interactive, which means the language's parser should handle standard interpreter affordances the language might support (for example, Python's "_" variable or VB's "?" syntax).

ScriptSources also have a Path property. This is mostly useful for those marked as being a file. The Path is the key for engines recognizing ScriptSources they have seen before so that they do not repeatedly load files when load-once semantics should apply (see ScriptEngine.LoadFile). The Path also helps the engine find the ScriptScope the file executed in (see ScriptEngine.GetScope), which is useful for some tool host scenarios. The host defines what a canonical representation of a path is. The host needs to set the path to the same string when it intends for ScriptSources to match for the purposes of the above functions on ScriptEngine.

You can create ScriptSource objects with factory methods on ScriptEngine.

Note, members that take or return ObjectHandles are not present on Silverlight.
ScriptSource Overview:

```csharp
public sealed class ScriptSource : MarshalByRefObject {
    internal ScriptSource();
    public string Path { get; }
    public SourceCodeKind Kind { get; }

    public ScriptCodeParseResult GetCodeProperties();
    public ScriptCodeParseResult GetCodeProperties(CompilerOptions options);

    public ScriptEngine Engine { get; }

    public CompiledCode Compile();
    public CompiledCode Compile(ErrorListener sink);
    public CompiledCode Compile(CompilerOptions options);
    public CompiledCode Compile(CompilerOptions options, ErrorListener sink);

    public object Execute();
    public object Execute(ScriptScope scope);
    public ObjectHandle ExecuteAndWrap();
    public ObjectHandle ExecuteAndWrap(ScriptScope scope);
    public T Execute<T>();
    public T Execute<T>(ScriptScope scope);
    public int ExecuteProgram();

    public ScriptCodeReader GetReader();
    public Encoding DetectEncoding();

    // line/file mapping:
    public string GetCode();
    public string GetCodeLine(int line);
    public string[] GetCodeLines(int start, int count);
    public SourceSpan MapLine(SourceSpan span);
    public SourceLocation MapLine(SourceLocation loc);
    public int MapLine(int line);
    public string MapLineToFile(int line);
}
```
5.1. ScriptSource Members

ScriptSource

ScriptSource has no public constructor. A ScriptSource must be constructed by calling CreateScriptSource on a ScriptEngine.

string Path { get; }

This property returns the identifier for this script source. In many cases the Path doesn't matter. It is mostly useful for file ScriptSources. The Path is the key for engines to recognize ScriptSources they have seen before so that they do not repeatedly load files when load-once semantics should apply. The Path also helps the engine find the ScriptScope the file executed in, which is useful for some tool host scenarios (see ScriptEngine.GetScope).

The Path is null if not set explicitly on construction. The path has the value the ScriptSource was created with. In the case of relative file paths, for example, the DLR does not convert them to absolute or canonical representations.

SourceCodeKind Kind { get; }

This property returns the kind of source this ScriptSource represents. This property is a hint to the ScriptEngine how to parse the code ScriptSource (as an expression, statement, whole file, etc.).

If you're unsure, File can be used to direct the language to generally parse the code. For languages that are expression-based, they should interpret Statement as Expression.

ScriptCodeParseResult getCodeProperties();

ScriptCodeParseResult getCodeProperties(CompilerOptions options);
This method returns the properties of the code to support tools. The values indicate the state of parsing the source relative to completeness, or whether the source is complete enough to execute.

CompilerOptions type will likely change by the time the DLR Hosting APIs move into the .NET libraries, possibly becoming Dictionary<str, obj>.

ScriptEngine Engine { get; }

This property returns the language engine associated with this ScriptSource. There is always a language tied to the source for convenience. Also, we do not think it is useful to support having a piece of code that could perhaps be parsed by multiple languages.

CompiledCode Compile();

CompiledCode Compile(ErrorListener sink);

CompiledCode Compile(CompilerOptions options);

CompiledCode Compile(CompilerOptions options, ErrorListener sink);

These methods compile the source and return a CompileCode object that can be executed repeatedly in its default scope or in other scopes without having to recompile the code.

Each call to Compile returns a new CompiledCode object. Each call to Compile always calls on its content provider to get sources, and the default file content provider always re-opens the file and reads its contents.

If any arguments are null, these throw ArgumentNullExceptions.

If you supply an error listener, and there were errors, these methods return null. Otherwise, it leaves any raised exceptions
These methods do not take a ScriptScope to compile against. That would prevent compilation from choosing optimized scope implementations. You can always execute compiled code against any scope (see Execute* methods).

CompilerOptions type will likely change by the time the DLR Hosting APIs move into the .NET libraries, possibly becoming Dictionary<str,obj>.

object Execute();

object Execute(ScriptScope scope);

ObjectHandle ExecuteAndWrap();

ObjectHandle ExecuteAndWrap(ScriptScope scope);

T Execute<T>();

T Execute<T>(ScriptScope scope);

int ExecuteProgram();

These methods execute the source code and return a result in various ways. There are complementary overloads that take a ScriptScope and those that do not. The overloads with no arguments create a new scope for each execution. These methods throw the scope away and use it for side effects only, returning the result in the same way the complementary overload does.

These methods always execute the ScriptSource. Even when the source is a file, and the associated engine’s language has an execute-at-most-once mechanism, these methods always execute the source contents.

Each call to Execute always calls on its content provider to get
sources, and the default file content provider always re-opens the file and reads its contents.

Execute returns an object that is the resulting value of running the code. When the ScriptSource is a file or statement, the language decides what is an appropriate value to return. Some languages return the value produced by the last expression or statement, but languages that are not expression based may return null.

ExecuteAndWrap returns an ObjectHandle for use when the engine and/or scope are remote.

Execute<T> returns the result as the specified type, using the associated engine’s Operations.ConvertTo<T> method. If this method cannot convert to the specified type, then it throws an exception.

ExecuteProgram runs the source as though it were launched from an OS command shell and returns a process exit code indicating the success or error condition of executing the code. Each time this method is called it creates a fresh ScriptScope in which to run the source, and if you were to use ScriptEngine.GetScope, you’d get whatever last ScriptScope the engine created for the source.

ScriptCodeReader GetReader();

This method returns a derived type of TextReader that is bound to this ScriptSource. Every time you call this method you get a new ScriptCodeReader reset to beginning parsing state, and no two instances interfere with each other.

Encoding DetectEncoding() {} 

This method returns the encoding for the source. The language associated with the source has the chance to read the beginning of the file if it has any special handling for encodings based on
the first few bytes of the file. This method could return an encoding different than what the source was created with.

**string GetCode();**

This method returns all the source code contents as a string. The result may share storage with the string passed to create the ScriptSource.

Each call to GetCode always calls on its content provider to get sources, and the default file content provider always re-opens the file and reads its contents.

**string GetCodeLine(int line);**

**string[] GetCodeLines(int start, int count);**

These methods return a string (or strings) for the line (or lines) indexed. Count is one-based. The count argument can be greater than the number of lines. The start argument cannot be zero or negative.

The line and count arguments can cause indexing to go beyond the end of the source. GetCodeLine returns null in that case. GetCodeLines returns strings only for existing lines and does not throw an exception or include nulls in the array. If start is beyond the end, the result is an empty array.

**SourceSpan MapLine(SourceSpan span);**

**SourceLocation MapLine(SourceLocation loc);**

**public int MapLine(int line);**

These methods map physical line numbers to virtual line numbers for reporting errors or other information to users. These are useful for languages that support line number directives for their parsers and error reporting.

**string MapLineToFile(int line);**
This method maps a physical line number to a .NET CLR pdb or file with symbol information in it. The result is an absolute path or relative path that resolves in a standard .NET way to the appropriate file.
2. DLR Hosting APIs »
6. ObjectOperations

This utility class provides operations on objects. The operations work on objects emanating from a ScriptRuntime or straight up .NET static objects. The behaviors of this class are language-specific, depending on which language owns the instance you’re using.

You get ObjectOperations objects from ScriptEngines. The operations have a language-specific behavior determined by the engine from which you got the ObjectOperations object. For example, calling GetMember on most objects to get the “__dict__” member using an ObjectOperations obtained from an IronPython ScriptEngine will return the object’s dictionary of members. However, using an ObjectOperations obtained from an IronRuby engine, would raise a member missing exception.

The reason ObjectOperations is a utility class that is not static is that the instances provide a context of caching for performing the operations. If you were to perform several operations over and over on the same few objects, it would be advantageous to create a special ObjectOperations just for use with those few objects. If you perform different operations with many objects just once or twice, you can use the default instance provided by the ScriptEngine.

Half of the methods do the same thing as their complement, one works with objects of type object while the other works with ObjectHandles. We need the overloads for clear method selection and to allow for an ObjectHandle to be treated as object should that be interesting.

You obtain objectOperation objects from ScriptEngines’ Operations property and CreateOperations method.

Note, members that take or return ObjectHandles are not present on
Silverlight.

ObjectOperations Overview:

```csharp
public sealed class ObjectOperations : MarshalByRefObject {
    public ScriptEngine Engine { get; }
    public ObjectHandle Add(ObjectHandle self, ObjectHandle other);
    public object Add(object self, object other);
    public object BitwiseAnd(object self, object other);
    public ObjectHandle BitwiseAnd(ObjectHandle self, ObjectHan
    public ObjectHandle BitwiseOr(ObjectHandle self, ObjectHan
    public object BitwiseOr(object self, object other);
    public bool ContainsMember(ObjectHandle obj, String name);
    public bool ContainsMember(object obj, String name, bool ig
    public bool ContainsMember(object obj, String name);
    public T ConvertTo<T>(object obj);

public void RemoveMember(ObjectHandle obj, String name);
public void RemoveMember(object obj, String name, bool ignoreCase);
public ObjectHandle RightShift(ObjectHandle self, ObjectHandle other);
public object RightShift(object self, object other);
public void SetMember(object obj, String name, object value);
public void SetMember(object obj, String name, object value);
public bool TryExplicitConvertTo<T>(object obj, out T result);
public bool TryExplicitConvertTo<T>(ObjectHandle obj, out T result);
public bool TryExplicitConvertTo<T>(ObjectHandle obj, Type type, out T result);
public bool TryGetMember(object obj, String name, bool ignoreCase, out object value);
public bool TryGetMember(ObjectHandle obj, String name, out ObjectHandle value);
public bool TryGetMember(object obj, String name, out object value);
public T Unwrap<T>(ObjectHandle obj);
6.1. ObjectOperations Members

ObjectOperations

ObjectOperations has no public constructors. To get an ObjectOperations access the Operations property or call CreateOperations on a ScriptEngine.

ScriptEngine Engine { get; }

This property returns the engine bound to this ObjectOperations. The engine binding provides the language context or semantics applied to each requested operation.

bool IsCallable(object obj)

bool IsCallable(ObjectHandle obj)

These methods returns whether the object is callable. Languages should return delegates when fetching the value of variables or executing expressions that result in callable objects. However, sometimes you'll get objects that are callable, but they are not wrapped in a delegate. Note, even if this method returns true, a call may fail due to incorrect number of arguments or incorrect types of arguments.

object Invoke(object obj, params object[] parameters)

ObjectHandle Invoke(ObjectHandle obj, params ObjectHandle[] parameters)

ObjectHandle Invoke(ObjectHandle obj, params object[] parameters)

These methods invoke objects that are callable. In general you should not need to call these methods. Languages should return delegates when fetching the value of variables or executing expressions that result in callable objects. However, sometimes
you'll get objects that are callable, but they are not wrapped in a delegate. If you're calling an object multiple times, you can use ConvertTo to get a strongly typed delegate that you can call more efficiently. You'll also need to use Invoke for objects that are remote.

If any obj arguments are null, then these throw an ArgumentNullException.

```csharp
object InvokeMember(object obj, string memberName, params object[] parameters)
```
This method invokes the specified member name on the specified object.

```csharp
ObjectHandle CreateInstance(ObjectHandle obj, params ObjectHandle[] parameters)
ObjectHandle CreateInstance(ObjectHandle obj, params object[] parameters)
object CreateInstance(object obj, params object[] parameters)
```
These methods create objects when the input object can be instantiated.

If any obj arguments are null, then these throw an ArgumentNullException.

```csharp
T GetMember<T>(ObjectHandle obj, String name)
T GetMember<T>(object obj, String name, bool ignoreCase)
object GetMember(object obj, String name)
object GetMember(object obj, String name, bool ignoreCase)
ObjectHandle GetMember(ObjectHandle obj, String name)
```
T GetMember<T>(object obj, String name)
These methods return a named member of an object.

The generic overloads do not modify obj to convert to the requested type. If they cannot perform the requested conversion to the concrete type, then they throw a NotSupportedException. You can use Unwrap<T> after ConvertTo<T> on ObjectHandle to get a local T for the result.

If the specified member does not exist, or if it is write-only, then these throw exceptions.

bool TryGetMember(object obj, String name, bool ignoreCase, out object value)

bool TryGetMember(ObjectHandle obj, String name, out ObjectHandle value)

bool TryGetMember(object obj, String name, out object value)
These methods try to get a named member of an object. They return whether name was a member of obj and set the out value to name’s value. If the name was not a member of obj, then this method sets value to null.

If obj or name is null, then these throw an ArgumentNullException.

bool ContainsMember(ObjectHandle obj, String name)

bool ContainsMember(object obj, String name, bool ignoreCase)

bool ContainsMember(object obj, String name)
These methods return whether the name is a member of obj.

bool RemoveMember(object obj, String name)
bool RemoveMember(ObjectHandle obj, String name)

bool RemoveMember(object obj, String name, bool ignoreCase)

These methods remove name from obj so that it is no longer a member of obj. If the object or the language binding of this ObjectOperations allows read-only or non-removable members, and name identifies such a member, then it is undefined what happens. Languages vary on whether this is a no-op or exceptional.

If any arguments are null, then these throw an ArgumentNullException.

void SetMember(object obj, String name, object value, bool ignoreCase)

void SetMember(ObjectHandle obj, String name, ObjectHandle value)

void SetMember<T>(object obj, String name, T value, bool ignoreCase)

void SetMember<T>(object obj, String name, T value)

void SetMember<T>(ObjectHandle obj, String name, T value)

void SetMember(object obj, String name, object value)

These members set the value of a named member of an object. There are generic overloads that can be used to avoid boxing values and casting of strongly typed members.

If the object or the language binding of this ObjectOperations supports read-only members, and name identifies such a member, then these methods throw a NotSupportedException.

If any arguments are null, then these throw an
ArgumentNullException.

T ConvertTo<T>(object obj)

ObjectHandle ConvertTo<T>(ObjectHandle obj)

object ConvertTo(object obj, Type type)

ObjectHandle ConvertTo(ObjectHandle obj, Type type)

These methods convert an object to the requested type using implicit conversions, and they do not modify obj. Obj may be returned if it is already the requested type. You can use Unwrap<T> after ConvertTo<T> on ObjectHandle to get a local T for the result.

If any of the arguments is null, then these throw an ArgumentNullException.

If these methods cannot perform the requested conversion, then they throw a NotSupportedException.

public T ExplicitConvertTo<T>(object obj)

object ExplicitConvertTo(object obj, Type type)

ObjectHandle ExplicitConvertTo(ObjectHandle obj, Type type)

ObjectHandle ExplicitConvertTo<T>(ObjectHandle obj)

These methods convert an object to the requested type using explicit conversions, which may be lossy. Otherwise these methods are the same as the ConvertTo* methods.

bool TryConvertTo<T>(ObjectHandle obj, out ObjectHandle result)

bool TryConvertTo(object obj, Type type, out object result)
bool TryConvertTo<T>(object obj, out T result)

bool TryConvertTo(ObjectHandle obj, Type type, out ObjectHandle result)

These methods try to convert an object to the requested type using implicit conversions, and they do not modify obj. They return whether they could perform the conversion and set the out result parameter. If the methods could not perform the conversion, then they set result to null.

You can use Unwrap<T> after calling overloads on ObjectHandle to get a local T for the result.

If they cannot perform the conversion to the requested type, then they throw a NotSupportedException.

If obj is null, then these throw an ArgumentNullException.

bool TryExplicitConvertTo<T>(object obj, out T result)

bool TryExplicitConvertTo<T>(ObjectHandle obj, out ObjectHandle result)

bool TryExplicitConvertTo(ObjectHandle obj, Type type, out ObjectHandle result)

bool TryExplicitConvertTo(object obj, Type type, out object result)

These methods try to convert an object to the requested type using explicit conversions, which may be lossy. Otherwise these methods are the same as TryConvertTo* methods.

T Unwrap<T>(ObjectHandle obj)

This method unwraps the remote object reference, converting it to the specified type before returning it. If this method cannot
perform the requested conversion to the concrete type, then it throws a NotSupportedException. If the requested T does not serialize back to the calling app domain, the CLR throws an exception.

```
string Format(object obj)
string Format(ObjectHandle obj)
```

These methods return a string representation of obj that is parseable by the language. ConvertTo operations that request a string return a display string for the object that is not necessarily parseable as input for evaluation.

```
IList<string> GetMemberNames(object obj)
IList<string> GetMemberNames(ObjectHandle obj)
```

These methods return an array of all the member names that obj has explicitly, determined by the language associated with this ObjectOperations. Computed or late bound member names may not be in the result.

```
string GetDocumentation(object obj)
string GetDocumentation(ObjectHandle obj)
```

These methods return the documentation for obj. When obj is a static .NET object, this returns xml documentation comment information associated with the DLL containing obj’s type. If there is no available documentation for the object, these return the empty string. Some languages do not have documentation hooks for objects, in which case they return the empty string.

```
IList<string> GetCallSignatures(object obj)
IList<string> GetCallSignatures(ObjectHandle obj)
```

These methods return arrays of stings, each one describing a call
signature that obj supports. If the object is not callable, these throw a NotSupportedException.

object **DoOperation**(ExpressionType *operation*, object *target*)

**public** T**Result** **DoOperation**<T**Target**, T**Result**> *(ExpressionType *operation*, T**Target** *target*)

**public** object **DoOperation**(ExpressionType *operation*, object *target*, object *other*)

**public** T**Result** **DoOperation**<T**Target**, T**Other**, T**Result**> *(ExpressionType *operation*, T**Target** *target*, T**Other** *other*)

**public** object **DoOperation**(ExpressionType *op*, ObjectHandle *target*)

**public** ObjectHandle **DoOperation**(ExpressionType *op*, ObjectHandle *target*, ObjectHandle *other*)

These methods perform the specified unary and binary operations on the supplied target and other objects, returning the results. If the specified operator cannot be performed on the object or objects supplied, then these throw an exception. See the Expression Tree spec for information on the expected semantics of the operators.

The Hosting APIs share the ExpressionType enum with Expression Trees and the dynamic object interop protocol to specify what operation to perform. Most values overlap making a distinct enum just another concept to learn, but this enum contains values for operations used in Expression Trees that do not make sense when passed to this method (for example, Block, Try, and Throw). These methods pass the operation to the language that created the ObjectOperations object, and the language handles the ExpressionType as it sees fit. For example, IronPython only supports the following ExpressionType values:
object Add(object self, object other)

ObjectHandle Add(ObjectHandle self, ObjectHandle other)
    These methods are convenience members that are equivalent to:
    DoOperation(ExpressionType.Add, self, other)

object Subtract(object self, object other)

ObjectHandle Subtract(ObjectHandle self, ObjectHandle other)
    These methods are convenience members that are equivalent to:
    DoOperation(ExpressionType.Subtract, self, other)

object Power(object self, object other)

ObjectHandle Power(ObjectHandle self, ObjectHandle other)
    These methods are convenience members that are equivalent to:
    DoOperation(ExpressionType.Power, self, other)

object Multiply(object self, object other)

ObjectHandle Multiply(ObjectHandle self, ObjectHandle other)
    These methods are convenience members that are equivalent to:
    DoOperation(ExpressionType.Multiply, self, other)

object Divide(object self, object other)

ObjectHandle Divide(ObjectHandle self, ObjectHandle other)
    These methods are convenience members that are equivalent to:
    DoOperation(ExpressionType.Divide, self, other)

ObjectHandle Modulo(ObjectHandle self, ObjectHandle other)

object Modulo(object self, object other)
    These methods are convenience members that are equivalent to:
    DoOperation(ExpressionType.Modulo, self, other)
object **LeftShift**(object *self*, object *other*)

ObjectHandle **LeftShift**(ObjectHandle *self*, ObjectHandle *other*)
These methods are convenience members that are equivalent to:
  DoOperation(ExpressionType.LeftShift, *self*, *other*)

object **RightShift**(object *self*, object *other*)

ObjectHandle **RightShift**(ObjectHandle *self*, ObjectHandle *other*)
These methods are convenience members that are equivalent to:
  DoOperation(ExpressionType.RightShift, *self*, *other*)

object **BitwiseAnd**(object *self*, object *other*)

ObjectHandle **BitwiseAnd**(ObjectHandle *self*, ObjectHandle *other*)
These methods are convenience members that are equivalent to:
  DoOperation(ExpressionType.BitwiseAnd, *self*, *other*)

object **BitwiseOr**(object *self*, object *other*)

ObjectHandle **BitwiseOr**(ObjectHandle *self*, ObjectHandle *other*)
These methods are convenience members that are equivalent to:
  DoOperation(ExpressionType.BitwiseOr, *self*, *other*)

object **ExclusiveOr**(object *self*, object *other*)

ObjectHandle **ExclusiveOr**(ObjectHandle *self*, ObjectHandle *other*)
These methods are convenience members that are equivalent to:
  DoOperation(ExpressionType.ExclusiveOr, *self*, *other*)

bool **Equal**(object *self*, object *other*)

bool **Equal**(ObjectHandle *self*, ObjectHandle *other*)
These methods are convenience members that are equivalent to:
  DoOperation(ExpressionType.Equal, *self*, *other*)
bool **NotEqual**(object *self*, object *other*)

bool **NotEqual**(ObjectHandle *self*, ObjectHandle *other*)

These methods are convenience members that are equivalent to:
DoOperation(ExpressionType.Equal, *self*, *other*)

bool **LessThan**(object *self*, object *other*)

bool **LessThan**(ObjectHandle *self*, ObjectHandle *other*)

These methods are convenience members that are equivalent to:
DoOperation(ExpressionType.LessThan, *self*, *other*)

bool **LessThanOrEqual**(ObjectHandle *self*, ObjectHandle *other*)

bool **LessThanOrEqual**(object *self*, object *other*)

These methods are convenience members that are equivalent to:
DoOperation(ExpressionType.LessThanOrEqual, *self*, *other*)

bool **GreaterThan**(object *self*, object *other*)

bool **GreaterThan**(ObjectHandle *self*, ObjectHandle *other*)

These methods are convenience members that are equivalent to:
DoOperation(ExpressionType.GreaterThan, *self*, *other*)

bool **GreaterThanOrEqual**(object *self*, object *other*)

bool **GreaterThanOrEqual**(ObjectHandle *self*, ObjectHandle *other*)

These methods are convenience members that are equivalent to:
DoOperation(ExpressionType.GreaterThanOrEqual, *self*, *other*)
2. DLR Hosting APIs »
7. SourceCodeKind

This enum identifies parsing hints to languages for ScriptSource objects. For example, some languages need to know if they are parsing a Statement or an Expression, or they may allow special syntax or variables for InteractiveCode.
7.1. Members

The Summary section shows the type as it is defined (to indicate values of members), and this section documents the intent of the members.

<table>
<thead>
<tr>
<th>Enum Value</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unspecified</td>
<td>Should not be used.</td>
</tr>
<tr>
<td>Expression</td>
<td>Start parsing an expression.</td>
</tr>
<tr>
<td>Statements</td>
<td>Start parsing one or more statements if there's special syntax for multiple statements.</td>
</tr>
<tr>
<td>SingleStatement</td>
<td>Start parsing a single statement, guaranteeing there's only one if that is significant to the language.</td>
</tr>
<tr>
<td>File</td>
<td>Start parsing at the beginning of a file.</td>
</tr>
<tr>
<td>InteractiveCode</td>
<td>Start parsing at a legal input to a REPL.</td>
</tr>
<tr>
<td>AutoDetect</td>
<td>The language best determines how to parse the input. It may choose Interactive (supporting special syntax or variables), Expression, or Statement.</td>
</tr>
</tbody>
</table>
2. DLR Hosting APIs »
8. ScriptCodeParseResult

This enum identifies final parsing state for a ScriptSource objects. It helps with interactive tool support.
## 8.1. Members

<table>
<thead>
<tr>
<th>Enum Value</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Complete</td>
<td>There is no reportable state after parsing.</td>
</tr>
<tr>
<td>Invalid</td>
<td>The source is syntactically invalid and cannot be parsed.</td>
</tr>
<tr>

9. CompiledCode

CompiledCode represents code that has been compiled to execute repeatedly without having to compile it each time, and it represents the default ScriptScope the code runs in. The default scope may have optimized variable storage and lookup for the code. You can always execute the code in any ScriptScope if you need it to execute in a clean scope each time, or you want to accumulate side effects from the code in another scope.

You can get CompiledCode from Compile methods on ScriptSource. CompiledCode objects have an internal reference to the engine that produced them. Because they have a default scope in which to execute, and the use for CompiledCode objects is to execute them, they have several execute methods.

Note, members that take or return ObjectHandles are not present on Silverlight.

CompiledCode Summary:

```csharp
public class CompiledCode : MarshallByRefObject {
    public ScriptScope DefaultScope { get; }
    public ScriptEngine Engine { get; }
    public object Execute() {
    public object Execute(ScriptScope scope) {
    public ObjectHandle ExecuteAndWrap() {
    public ObjectHandle ExecuteAndWrap(ScriptScope scope) {
    public T Execute<T>() {
    public T Execute<T>(ScriptScope scope) {
    }
```
9.1. CompiledCode Members

CompiledCode

CompiledCode has no public constructors. To create a CompiledCode call Compile on a ScriptSource object.

ScriptScope DefaultScope { get; }

This property returns the default ScriptScope in which the code executes. This allows you to extract variable values after executing the code or insert variable bindings before executing the code.

ScriptEngine Engine { get; }

This property returns the engine that produced the compiled code.

object Execute() {}

object Execute(ScriptScope scope) {}

ObjectHandle ExecuteAndWrap() {}

ObjectHandle ExecuteAndWrap(ScriptScope scope) {}

T Execute<T>() {}

T Execute<T>(ScriptScope scope) {}

These methods execute the compiled code in a variety of ways. Half of the overloads do the same thing as their complement, one executes in the default scope while the other takes a ScriptScope in which to execute the code. If invoked on null, this throws an ArgumentNullException.

ExecuteAndWrap returns an ObjectHandle for use when the engine and/or scope are remote.
Execute<T> returns the result as the specified type, using the engine's Operations.ConvertTo<T> method. If this method cannot convert to the specified type, then it throws an exception.
10. **ScriptRuntimeSetup**

This class gives hosts full control over how a ScriptRuntime gets configured. You can instantiate this class, fill in the setup information, and then instantiate a ScriptRuntime with the setup instance. Once you pass the setup object to create a ScriptRuntime, attempts to modify its contents throws an exception.

There is also a static method as a helper to hosts for reading .NET application configuration. Hosts that want to be able to use multiple DLR-hostable languages, allow users to change what languages are available, and not have to rebuild can use the DLR’s default application configuration model. See ReadConfiguration for the XML details.

You can also get these objects from ScriptRuntime.Setup. These instances provide access to the configuration information used to create the ScriptRuntime. These instances will be read-only and throws exceptions if you attempt to modify them. Hosts may not have created a ScriptRuntimeSetup object and may not have configuration information without the Setup property.

**ScriptRuntimeSetup Summary:**

```csharp
public sealed class ScriptRuntimeSetup {
    public ScriptRuntimeSetup();
    public IList<LanguageSetup> LanguageSetups { get; }
    public bool DebugMode { get; set; }
    public bool PrivateBinding { get; set; }
    public Type HostType { get; set; }
    public Dictionary<string, object> Options { get; }
    public object[,] HostArguments {get; set; }
    public static ScriptRuntimeSetup ReadConfiguration();
    public static ScriptRuntimeSetup ReadConfiguration(Stream c
```
### 10.1. ScriptRuntimeSetup Members

**ScriptRuntimeSetup();**

The constructor returns an empty ScriptRuntimeSetup object, with no languages preconfigured.

**static ScriptRuntimeSetup ReadConfiguration();**

**static ScriptRuntimeSetup ReadConfiguration(Stream configFileStream);**

These methods read application configuration and return a ScriptRuntimeSetup initialized from the application configuration data. Hosts can modify the result before using the ScriptRuntimeSetup object to instantiate a ScriptRuntime.

**IList<LanguageSetup> LanguageSetups { get; }**

This property returns a list of LanguageSetup objects, each describing one language the ScriptRuntime will allow. When you instantiate the ScriptRuntime, it will ensure there is only one element in the list with a given LanguageSetup.TypeName value.

**Type HostType { get; set; }**

This property gets and sets the ScriptHost type that the DLR should instantiate when it creates the ScriptRuntime. The DLR instantiates the host type in the app domain where it creates the ScriptRuntime object. See ScriptHost for more information.

**object[] HostArguments {get; set; }**

This property gets and sets an array of argument values that should be passed to the HostType's constructor. The objects must be MBRO or serializable when creating a remote ScriptRuntime.

Here's an example:
Dictionary<string, object> Options { get; }

This property returns a dictionary of global options for the ScriptRuntime. There are two options explicit on the ScriptRuntimeSetup type, DebugMode and PrivateBinding. The Options property is an flexibility point for adding options later. Names are case-sensitive.

There is one specially named global option, “SearchPaths”. If this value is present, languages should add these paths to their default search paths. If your intent is to replace an engine’s default paths, then you can use Engine.SetSearchPaths (perhaps on the ScriptHost.EngineCreated callback).

bool DebugMode { get; set; }

This property controls whether the ScriptRuntime instance and engines compiles code for debuggability.

bool PrivateBinding { get; set; }

This property controls whether the ScriptRuntime instance and engines will use reflection to access private members of types when binding object members in dynamic operations. Setting this to true only works in app domains running in full trust.
10.2. Configuration Structure

These lines must be included in the .config file as the first element under the <configuration> element for the DLR’s default reader to work:

```xml
<configSections>
    <section name="microsoft.scripting"
        type="Microsoft.Scripting.Hosting.Configuration.Section, Microsoft.Scripting, Version=1.0.0.5000, Culture=neutral, PublicKeyToken=31bf3856ad364e35"/>
</configSections>

The structure of the configuration section is the following (with some notes below):

```xml
<microsoft.scripting
    [debugMode="{bool}"?]
    [privateBinding="{bool}"?]

    <languages>
        <!- BasicMap with type attribute as key. Inherits language nodes, overwrites previous nodes based on key -->
        <language names="{semicolon-separated}" extensions="{semicolon-separated, optional-dot}" type="{assembly-qualified type name}" [displayName="{string}"?] />
    </languages>

    <options>
        <!- AddRemoveClearMap with option as key. If language Attribute is present, the key is option cross language -->
        <set option="{string}" value="{string}" [language="{language-name}"?] />
        <clear />
        <remove option="{string}" [language="{language-name}"?] />
    </options>

</microsoft.scripting>
```

Attributes enclosed in [...]? are optional. {bool} is whatever Convert.ToBoolean(string) works for ("true", "False", "TRUE", "1", "0").

The <languages> tag inherits content from parent .config files. You cannot remove a language in a child .config file once it is defined in a
parent .config file. You can redefine a language if the value of the “type” attribute is the same as a defined in a parent .config file (last writer wins). If the displayName attribute is missing, ReadConfiguration sets it to the first name in the names attribute. If names is the empty string, then ReadConfiguration sets the display name to the type attribute. The names and extensions attributes support semi-colon and comma as separators.

<options> tag inherits options from parent .config files. You can set, remove, and clear options (removes them all). The key in the options dictionary is a pair of option and language attributes. Language attribute is optional. If specified, the option applies to the language whose simple name is stated; otherwise, it applies to all languages. <remove option="foo"/> removes the option from common options dictionary, not from all language dictionaries. <remove option="foo" language="rb"/> removes the option from Ruby language options.
10.3. Default DLR Configuration

The default application configuration section for using the DLR languages we ship for the desktop is (of course, you need correct type names from your current version):

```xml
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <configSections>
    <section name="microsoft.scripting"
      type="Microsoft.Scripting.Hosting.Configuration.Section, Microsoft.Scripting, Version=1.0.0.5000, Culture=neutral, PublicKeyToken=31bf3856ad364e35"/>
  </configSections>

  <microsoft.scripting>
    <languages>
      <language names="IronPython;Python;py" extensions=".py"
        displayName="IronPython v2.0"
        type="IronPython.Runtime.PythonContext, IronPython, Version=2.0.0.5000, Culture=neutral, PublicKeyToken=31bf3856ad364e35"/>
      <language names="IronRuby;Ruby;rb" extensions=".rb"
        displayName="IronRuby v1.0"
        type="IronRuby.Runtime.RubyContext, IronRuby, Version=1.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35"/>
    </languages>
  </microsoft.scripting>
</configuration>
```
2. DLR Hosting APIs »
11. LanguageSetup

This class represents a language configuration for use in a ScriptRuntimeSetup when instantiating a ScriptRuntime. Once you pass the setup object to create a ScriptRuntime, attempts to modify its contents throws an exception.

You can also get these objects from ScriptRuntime.Setup and ScriptEngine.Setup. These instances provide access to the configuration information used to create the ScriptRuntime. These instances will be read-only and throws exceptions if you attempt to modify them. Hosts may not have created a ScriptRuntimeSetup object and may not have language setup information without the Setup properties.

LanguageSetup Summary:

```csharp
public sealed class LanguageSetup {
    public LanguageSetup(string typeName, string displayName)
    public LanguageSetup(string typeName, string displayName, IEnumerable<string> names, IEnumerable<string> fileExtensions);
    public string TypeName { get; set; }
    public string DisplayName { get; set; }
    public IList<string> Names { get; }
    public IList<string> FileExtensions { get; }
    public Dictionary<string, object> Options { get; }
    public bool InterpretedMode { get; set; }
    public bool ExceptionDetail { get; set; }
    public bool PerfStats { get; set; }
    public T GetOption<T>(string name, T defaultValue)
}
```
11.1. LanguageSetup Members

LanguageSetup(string typeName, string displayName)

LanguageSetup(string typeName, string displayName, IEnumerable<string> names, IEnumerable<string> fileExtensions);

The minimal construction requires an assembly-qualified type name for the language and a display name. You can set other properties after instantiating the setup object.

These ensure typeName and displayName are not null or empty. The collections can be empty but not null so that you can fill them in after instantiating this type.

string TypeName { get; set; }

This property gets or sets the assembly-qualified type name of the language. This is the type the DLR loads when, for example, it needs to execute files with the specified file extensions.

string DisplayName { get; set; }

This property gets or sets a suitably descriptive name for displaying in UI or for debugging. It often includes the version number in case different versions of the same language are configured.

IList<string> Names { get; }

This property returns a list of names for the language. These can be nicknames or simple names used programmatically (for example, language=python on a web page or in a user’s options UI).

IList<string> FileExtensions { get; }

This property gets the list of file extensions that map to this language in the ScriptRuntime.
bool InterpretedMode { get; set; }

This property gets or sets whether the language engine interprets sources or compiles and executes them. Not all languages respond to this option.

This method pulls the value from Options in case it is set there via application .config instead of via the property setter. It defaults to false. If the host or reading .config set this option, then it will be in Options with the key “InterpretedMode”.

bool ExceptionDetail { get; set; }

This property gets or sets whether the language engine should print exception details (for example, a call stack) when it catches exceptions. Not all languages respond to this option.

This method pulls the value from Options in case it is set there via application .config instead of via the property setter. It defaults to false. If the host or reading .config set this option, then it will be in Options with the key “ExceptionDetail”.

bool PerfStats { get; set; }

This property gets or sets whether the language engine gathers performance statistics. Not all languages respond to this option. Typically the languages dump the information when the application shuts down.

This method pulls the value from Options in case it is set there via application .config instead of via the property setter. It defaults to false. If the host or reading .config set this option, then it will be in Options with the key “ExceptionDetail”.

Dictionary<string, object> Options { get; }

This property returns the list dictionary of options for the language. Option names are case-sensitive. The list of valid options for a given language must be found in its documentation.
The method looks up name in the Options dictionary and returns the value associated with name, converting it to type T. If the name is not present, this method returns defaultValue.
2. DLR Hosting APIs »
12. ExceptionOperations

This class provides language-specific utilities for working with exceptions coming from executing code. You access instances of this type from Engine.GetService.

ExceptionOperations Summary:

```csharp
public sealed class ExceptionOperations : MarshalByRefObject {
    public string FormatException(Exception exception);
    public void GetExceptionMessage(Exception exception, out string message, out string errorTypeName);
}
```
12.1. ExceptionOperations Members

**ExceptionOperations**

ExceptionOperations objects cannot be directly created. To get an ExceptionOperations instance call `ScriptEngine.GetService<ExceptionOperations>();`
13. ScriptIO

This class lets you control input and output by default for dynamic code running via DLR hosting. You can access the instance of this class from the IO property on ScriptRuntime.

ScriptIO Summary:

```csharp
public sealed class ScriptIO : MarshalByRefObject
    /// Used for binary IO.
    public Stream InputStream { get; }
    public Stream OutputStream { get; }
    public Stream ErrorStream { get; }

    /// Used for pure unicode IO.
    public TextReader InputReader { get; }
    public TextWriter OutputWriter { get; }
    public TextWriter ErrorWriter { get; }

    /// What encoding are the unicode reader/writers using.
    public Encoding InputEncoding { get; }
    public Encoding OutputEncoding { get; }
    public Encoding ErrorEncoding { get; }

    public void SetOutput(Stream stream, Encoding encoding);
    public void SetOutput(Stream stream, TextWriter writer);

    public void SetErrorOutput(Stream stream, Encoding encoding);
    public void SetErrorOutput(Stream stream, TextWriter writer);

    public void SetInput(Stream stream, Encoding encoding);
    public void SetInput(Stream stream, TextReader reader, Encoding encoding);

    public void RedirectToConsole();
```
### 13.1. ScriptIO Members

**ScriptIO**

ScriptIO instances cannot be created. To get a ScriptIO access the IO property on a ScriptRuntime object.

**Stream OutputStream { get; }**

This property returns the standard output stream for the ScriptRuntime. This is a binary stream. All code and engines should output binary data here for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct output to a file or stream, then that language's output would go there as directed by the code.

**Stream InputStream { get; }**

This property returns the standard input stream for the ScriptRuntime. This is a binary stream. All code and engines should read binary data from here for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct input from a file or stream, then that language's input would come from there as directed by the code.

**Stream ErrorStream { get; }**

This property returns the standard error output stream for the ScriptRuntime. This is a binary stream. All code and engines should send error binary output here for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct error output to a file or stream, then that language's error output would go there as directed by the code.

**TextReader InputReader { get; }**

This property returns the standard input reader for the ScriptRuntime. This is a unicode reader. All code and engines should read text from here for this ScriptRuntime. Of course, if a
language has a mechanism to programmatically direct input from a file or stream, then that language’s input would come from there as directed by the code.

TextWriter OutputWriter { get; }
This property returns the standard output writer for the ScriptRuntime. All code and engines should send text output here for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct output to a file or stream, then that language’s output would go there as directed by the code.

TextWriter ErrorWriter { get; }
This property returns the standard error output writer for the ScriptRuntime. All code and engines should send text error output here for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct error output to a file or stream, then that language's output would go there as directed by the code.

Encoding InputEncoding { get; }
This property returns the encoding used by the TextReader returned from InputReader.

Encoding OutputEncoding { get; }
This property returns the encoding used by the TextWriters returned from the OutputWriter property.

Encoding ErrorEncoding { get; }
This property returns the encoding used by the TextWriters returned from the ErrorWriter property.

void SetOutput(Stream stream, Encoding encoding);
void SetOutput(Stream stream, TextWriter writer);
This method sets the standard output stream for the ScriptRuntime. All code and engines should send output to the
specified stream for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct output to a file or stream, then that language's output would go there as directed by the code.

The first method is useful if the host just captures binary stream output. The second method is useful if the host captures unicode text and binary output. Note, if you pass just a stream and an encoding, the this method creates a default StreamWriter, which writes a BOM on first usage. To avoid this, you'll need to pass your own TextWriter.

If any argument to these methods is null, they throw an ArgumentException.

```csharp
void SetErrorOutput(Stream stream, Encoding encoding);
void SetErrorOutput(Stream stream, TextWriter writer);
```

This method sets the standard error output stream for the ScriptRuntime. All code and engines should send error output to the specified stream for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct error output to a file or stream, then that language’s output would go there as directed by the code.

The first method is useful if the host just captures binary stream output. The second method is useful if the host captures unicode text and binary output.

If any argument to these methods is null, they throw an ArgumentException.

```csharp
void SetInput(Stream stream, Encoding encoding);
void SetInput(Stream stream, TextReader reader, Encoding encoding);
```

This method sets the standard input stream for the
ScriptRuntime. All code and engines should read input here for this ScriptRuntime. Of course, if a language has a mechanism to programmatically direct input from a file or stream, then that language’s input would come from there as directed by the code.

```csharp
void RedirectToConsole();
```

This method makes all the standard IO for the ScriptRuntime go to System.Console. Of course, if a language has a mechanism to programmatically direct output to a file or stream, then that language’s output would go there as directed by the code.
2. DLR Hosting APIs »
14. ScriptHost

ScriptHost represents the host to the ScriptRuntime. Hosts can derive from this type and overload behaviors by returning a custom PlatformAdaptationLayer. Hosts can also handle callbacks for some events such as when engines get created.

The ScriptHost object lives in the same app domain as the ScriptRuntime in remote scenarios.

Derived types from ScriptHost can have arguments passed to them via ScriptRuntimeSetup’s HostArguments property. For example:

```csharp
class MyHost : ScriptHost {
    public MyHost(string foo, int bar) {}
}
setup = new ScriptRuntimeSetup()
setup.HostType = typeof(MyHost)
setup.HostArguments = new object[] { ?some foo?, 123 }
ScriptRuntime.CreateRemote(otherAppDomain, setup)
```

The DLR instantiates the ScriptHost when the DLR initializes a ScriptRuntime. The host can get at the instance with ScriptRuntime.Host.

ScriptHost Overview:
14.1. ScriptHost Members

**ScriptHost**

Creates a new ScriptHost.

**ScriptRuntime Runtime { get; }**

This property returns the ScriptRuntime to which this ScriptHost is attached.
2. DLR Hosting APIs »
15. PlatformAdaptionLayer

This class abstracts system operations used by the DLR that could possibly be platform specific. Hosts can derive from this class and implement operations, such as opening a file. For example, the Silverlight PAL could go to the server to fetch a file.

To use a custom PAL, you derive from this type and implement the members important to you. You also need to derive a custom ScriptHost that returns the custom PAL instance. Then when you create your ScriptRuntime, you explicitly create a ScriptRuntimeSetup and set the HostType property to your custom ScriptHost.

PlatformAdaptionLayer Summary:

```csharp
public class PlatformAdaptionLayer {
    public static readonly PlatformAdaptionLayer Default;

    public virtual Assembly LoadAssembly(string name);
    public virtual Assembly LoadAssemblyFromPath(string path);

    public virtual void TerminateScriptExecution(int exitCode);

    public StringComparer PathComparer { get; }
    public virtual bool FileExists(string path);
    public virtual bool DirectoryExists(string path);

    public virtual Stream OpenInputFileStream(string path, FileMode mode, FileAccess access, FileShare share);
    public virtual Stream OpenInputFileStream(string path, FileMode mode, FileAccess access, FileShare share, int bufferSize);
    public virtual Stream OpenOutputFileStream(string path);

    public virtual string[] GetFiles(string path, string search);
    public virtual string GetFullPath(string path);
}
```
15.1. PlatformAdaptionLayer Members

PlatformAdaptionLayer

Usually you do not create instances of the base PlatformAdaptionLayer class. Instead you subclass it and provide your derived type via the ScriptHost for a ScriptRuntime.
3. .NET Interop
1. An Introduction to Distutils

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the *Installing Python Modules* chapter.
1.1. Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (*setup.py* by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.
1.2. A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called `foo`, contained in a file `foo.py`, then your setup script can be as simple as this:

```python
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section Writing the Setup Script for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run:

```bash
python setup.py sdist
```
which will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your `foo` module, all she has to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```bash
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils commands they use: the `sdist` command is almost exclusively for module developers, while `install` is more often for installers (although most developers will want to install their own code occasionally).

If you want to make things really easy for your users, you can create one or more built distributions for them. For instance, if you are running on a Windows machine, and want to make things easy for other Windows users, you can create an executable installer (the most appropriate type of built distribution for this platform) with the `bdist_wininst` command. For example:

```bash
python setup.py bdist_wininst
```

will create an executable installer, `foo-1.0.win32.exe`, in the current directory.
Other useful built distribution formats are RPM, implemented by the `bdist_rpm` command, Solaris `pkgtool` (`bdist_pkgtool`), and HP-UX `swinstall` (`bdist_sdux`). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The `bdist_rpm` command uses the `rpm` executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time by running

```
python setup.py bdist --help-formats
```
1.3. General Python terminology

If you’re reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module
the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module
a module written in Python and contained in a single .py file (and possibly associated .pyc and/or .pyo files). Sometimes referred to as a “pure module.”

extension module
a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (.so) file for Python extensions on Unix, a DLL (given the .pyd extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package
a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file __init__.py.

root package
the root of the hierarchy of packages. (This isn’t really a package, since it doesn’t have an __init__.py file. But we have to call it
something.) The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don’t belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in sys.path contributes modules to the root package.
1.4. Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution
a collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are Numeric Python, PyXML, PIL (the Python Imaging Library), or mxBase. (This would be called a *package*, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution
a module distribution that contains only pure Python modules and packages. Sometimes referred to as a “pure distribution.”

non-pure module distribution
a module distribution that contains at least one extension module. Sometimes referred to as a “non-pure distribution.”

distribution root
the top-level directory of your source tree (or source distribution); the directory where `setup.py` exists. Generally `setup.py` will be run from this directory.
2. Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section *A Simple Example* above, the setup script consists mainly of a call to `setup()`, and most information supplied to the Distutils by the module developer is supplied as keyword arguments to `setup()`.

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```python
#!/usr/bin/env python
from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='http://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
)
```

There are only two differences between this and the trivial one-file distribution presented in section *A Simple Example*: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a
couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section *Additional meta-data*.

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```python
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```
2.1. Listing whole packages

The *packages* option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the *packages* list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package `distutils` is found in the directory `distutils` relative to the distribution root. Thus, when you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyways.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the *package_dir* option to tell the Distutils about your convention. For example, say you keep all Python source under `lib`, so that modules in the “root package” (i.e., not in any package at all) are in `lib`, modules in the `foo` package are in `lib/foo`, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file `lib/foo/__init__.py` exists.

Another possible convention is to put the `foo` package right in `lib`,
the `foo.bar` package in `lib/bar`, etc. This would be written in the setup script as

```python
package_dir = {'foo': 'lib'}
```

A `package: dir` entry in the `package_dir` dictionary implicitly applies to all packages below `package`, so the `foo.bar` case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although `package_dir` applies recursively, you must explicitly list all packages in `packages`: the Distutils will not recursively scan your source tree looking for any directory with an `__init__.py` file.)
2.2. Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the “root package” (i.e., no package at all). This simplest case was shown in section A Simple Example; here is a slightly more involved example:

```python
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the “root” package, the other in the `pkg` package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.
2.3. Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it's not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to setup(), the ext_modules option. ext_modules is just a list of Extension instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called foo and implemented by foo.c. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```
Extension('foo', ['foo.c'])
```

The Extension class can be imported from distutils.core along with setup(). Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
)
```

The Extension class (actually, the underlying extension-building machinery implemented by the build_ext command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.
2.3.1. Extension names and packages

The first argument to the `Extension` constructor is always the name of the extension, including any package names. For example,

```python
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```python
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the `pkg` package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python’s namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to `setup()`. For example,

```python
setup(...,
    ext_package='pkg',
    ext_modules=[Extension('foo', ['foo.c']),
                 Extension('subpkg.bar', ['bar.c'])],
)
```

will compile `foo.c` to the extension `pkg.foo`, and `bar.c` to `pkg.subpkg.bar`.

2.3.2. Extension source files

The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish
C++ source files: .cc and .cpp seem to be recognized by both Unix and Windows compilers.

However, you can also include SWIG interface (.i) files in the list; the build_ext command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

** SWIG support is rough around the edges and largely untested! **

This warning notwithstanding, options to SWIG can be currently passed like this:

```python
setup(...,
    ext_modules=[Extension('_foo', ['foo.i'],
      swig_opts=['-modern', '-I../include'],
      py_modules=['foo'],
    )
)
```

Or on the commandline like this:

```
> python setup.py build_ext --swig-opts="-modern -I../include"
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (.mc) files and resource definition (.rc) files for Visual C++. These will be compiled to binary resource (.res) files and linked into the executable.

** 2.3.3. Preprocessor options **

Three optional arguments to Extension will help if you need to specify include directories to search or preprocessor macros to define/undefine: include_dirs, define_macros, and undef_macros.
For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

```python
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```python
Extension('foo', ['foo.c'], include_dirs=['/usr/include/X11'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```c
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_header` command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory—`/usr/local/include/python1.5` in this case—is always included in the search path when building Python extensions, the best approach is to write C code like

```c
#include <Numerical/arrayobject.h>
```

If you must put the `Numerical` include directory right into your header search path, though, you can find that directory using the Distutils `distutils.sysconfig` module:

```python
from distutils.sysconfig import get_python_inc
incdir = os.path.join(get_python_inc(plat_specific=1), 'Numeric')
```
Even though this is quite portable—it will work on any Python installation, regardless of platform—it's probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef Macros` options. `define_macros` takes a list of `(name, value)` tuples, where `name` is the name of the macro to define (a string) and `value` is its value: either a string or `None`. (Defining a macro `FOO` to `None` is the equivalent of a bare `#define FOO` in your C source: with most compilers, this sets `FOO` to the string `1`.) `undef_macros` is just a list of macros to undefine.

For example:

```
Extension(...,
    define_macros=[('NDEBUG', '1'),
                  ('HAVE_STRFTIME', None)],
    undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

### 2.3.4. Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and
**runtime_library_dirs** is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```python
Extension(...,
    libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in **library_dirs**:

```python
Extension(...,
    library_dirs=['/usr/X11R6/lib'],
    libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

** Should mention clib libraries here or somewhere else! **

**2.3.5. Other options**

There are still some other options which can be used to handle special cases.

The **optional** option is a boolean; if it is true, a build failure in the extension will not abort the build process, but instead simply not install the failing extension.

The **extra_objects** option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

**extra_compile_args** and **extra_link_args** can be used to specify additional command line options for the respective compiler and
linker command lines.

*export_symbols* is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add `initmodule` to the list of exported symbols.

The *depends* option is a list of files that the extension depends on (for example header files). The build command will call the compiler on the sources to rebuild extension if any on this files has been modified since the previous build.
2.4. Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.
2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the `requires` keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include `'mymodule'` and `'xml.parsers.expat'`.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
<  >  ==
<=  >=  !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.

Let's look at a bunch of examples:
Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the *provides* keyword argument to `setup()`.

The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

<table>
<thead>
<tr>
<th>Provides Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>mypkg</td>
<td>Provide <em>mypkg</em>, using the distribution version</td>
</tr>
<tr>
<td>mypkg (1.1)</td>
<td>Provide <em>mypkg</em> version 1.1, regardless of the distribution version</td>
</tr>
</tbody>
</table>

A package can declare that it obsoletes other packages using the *obsoletes* keyword argument. The value for this is similar to that of the *requires* keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all versions of the named module or package are understood to be obsoleted.
2.5. Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don’t require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word “python”, the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `--executable` (or `-e`) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```python
setup(…,
     scripts=['scripts/xmlproc_parse', 'scripts/xmlproc_val'])
```

*Changed in version 2.7:* All the scripts will also be added to the `MANIFEST` file if no template is provided. See *Specifying the files to distribute.*
2.6. Installing Package Data

Often, additional files need to be installed into a package. These files are often data that’s closely related to the package’s implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called **package data**.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```plaintext
setup.py
src/
    mypkg/
        __init__.py
        module.py
        data/
            tables.dat
            spoons.dat
            forks.dat
```

The corresponding call to `setup()` might be:

```python
setup(...,
```
New in version 2.4.

Changed in version 2.7: All the files that match `package_data` will be added to the MANIFEST file if no template is provided. See `Specifying the files to distribute`. 
2.7. Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn’t fit in the previous categories.

`data_files` specifies a sequence of `(directory, files)` pairs in the following way:

```python
setup(...,
    data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                ('config', ['cfg/data.cfg']),
                ('/etc/init.d', ['init-script'])]
)
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each `(directory, files)` pair in the sequence specifies the installation directory and the files to install there. If `directory` is a relative path, it is interpreted relative to the installation prefix (Python’s `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in `files` is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from `files` is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the `install` command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.

*Changed in version 2.7:* All the files that match `data_files` will be added to the `MANIFEST` file if no template is provided. See *Specifying*
the files to distribute.
## 2.8. Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

<table>
<thead>
<tr>
<th>Meta-Data</th>
<th>Description</th>
<th>Value</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>name of the package</td>
<td>short string</td>
<td>(1)</td>
</tr>
<tr>
<td>version</td>
<td>version of this release</td>
<td>short string</td>
<td>(1)(2)</td>
</tr>
<tr>
<td>author</td>
<td>package author’s name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>author_email</td>
<td>email address of the package author</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer</td>
<td>package maintainer’s name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer_email</td>
<td>email address of the package maintainer</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>url</td>
<td>home page for the package</td>
<td>URL</td>
<td>(1)</td>
</tr>
<tr>
<td>description</td>
<td>short, summary description of the package</td>
<td>short string</td>
<td></td>
</tr>
<tr>
<td>long_description</td>
<td>longer description of the package</td>
<td>long string</td>
<td>(5)</td>
</tr>
<tr>
<td>download_url</td>
<td>location where the package may be downloaded</td>
<td>URL</td>
<td>(4)</td>
</tr>
<tr>
<td>classifiers</td>
<td>a list of classifiers</td>
<td>list of strings</td>
<td>(4)</td>
</tr>
<tr>
<td>platforms</td>
<td>a list of platforms</td>
<td>list of strings</td>
<td></td>
</tr>
<tr>
<td>license</td>
<td>license for the package</td>
<td>short string</td>
<td>(6)</td>
</tr>
</tbody>
</table>

Notes:

1. These fields are required.
2. It is recommended that versions take the form
3. Either the author or the maintainer must be identified.
4. These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the PyPI website.
5. The `long_description` field is used by PyPI when you are registering a package, to build its home page.
6. The `license` field is a text indicating the license covering the package where the license is not a selection from the “License” Trove classifiers. See the `Classifier` field. Notice that there's a `licence` distribution option which is deprecated but still acts as an alias for `license`.

'Short string'
A single line of text, not more than 200 characters.

'Long string'
Multiple lines of plain text in reStructuredText format (see http://docutils.sf.net/).

'List of strings'
See below.

None of the string values may be Unicode.

Encoding the version information is an art in itself. Python packages generally adhere to the version format `major.minor[.patch][sub]`. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are “a1,a2,...,aN” (for alpha releases, where functionality and API may change), “b1,b2,...,bN” (for beta releases, which only fix bugs) and
“pr1,pr2,...,prN” (for final pre-release release testing). Some examples:

0.1.0
the first, experimental release of a package

1.0.1a2
the second alpha release of the first patch version of 1.0

classifiers are specified in a Python list:

```python
setup(...,
   classifiers=[
      'Development Status :: 4 - Beta',
      'Environment :: Console',
      'Environment :: Web Environment',
      'Intended Audience :: End Users/Desktop',
      'Intended Audience :: Developers',
      'Intended Audience :: System Administrators',
      'License :: OSI Approved :: Python Software Foundation',
      'Operating System :: MacOS :: MacOS X',
      'Operating System :: Microsoft :: Windows',
      'Operating System :: POSIX',
      'Programming Language :: Python',
      'Topic :: Communications :: Email',
      'Topic :: Office/Business',
      'Topic :: Software Development :: Bug Tracking',
   ],
)
```

If you wish to include classifiers in your setup.py file and also wish to remain backwards-compatible with Python releases prior to 2.2.3, then you can include the following code fragment in your setup.py before the setup() call.

```python
# patch distutils if it can't cope with the "classifiers" or "download_url" keywords
from sys import version
if version < '2.2.3':
   from distutils.dist import DistributionMetadata
   DistributionMetadata.classifiers = None
```
2.9. Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the DISTUTILS_DEBUG environment variable can be set to anything except an empty string, and distutils will now print detailed information what it is doing, and prints the full traceback in case an exception occurs.
3. Writing the Setup Configuration File

Often, it’s not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user’s system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, setup.cfg, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers [1]—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, setup.cfg (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in setup.py by editing setup.cfg
- you can provide non-standard defaults for options that are not easily set in setup.py
- installers can override anything in setup.cfg using the command-line options to setup.py

The basic syntax of the configuration file is simple:

```
[command]
option=value
...
```
where \textit{command} is one of the Distutils commands (e.g. \texttt{build\_py}, \texttt{install}), and \textit{option} is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a '\'#\' character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal \texttt{--help} option, e.g.

\begin{verbatim}
> python setup.py --help build_ext
[...]
Options for 'build_ext' command:
--build-lib (-b) directory for compiled extension modules
--build-temp (-t) directory for temporary files (build by-
--inplace (-i) ignore build-lib and put compiled extens
--include-dirs (-I) list of directories to search for header
--define (-D) C preprocessor macros to define
--undef (-U) C preprocessor macros to undefine
--swig-opts list of SWIG command line options
[...]
\end{verbatim}

Note that an option spelled \texttt{--foo-bar} on the command-line is spelled \texttt{foo\_bar} in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension \texttt{pkg\_ext}, and you want the compiled extension file (\texttt{ext.so} on Unix, say) to be put in the same source directory as your pure Python modules \texttt{pkg\_mod1} and \texttt{pkg\_mod2}. You can always use the \texttt{--inplace} option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the \texttt{build\_ext} command
explicitly, and remember to provide \texttt{--inplace}. An easier way is to “set and forget” this option, by encoding it in \texttt{setup.cfg}, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify \texttt{build_ext}. If you include \texttt{setup.cfg} in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don’t change from run to run; for example, \texttt{bdist_rpm} needs to know everything required to generate a “spec” file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to \texttt{bdist_rpm}, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils’ own \texttt{setup.cfg}:

```
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
           README.txt
           USAGE.txt
doc/
    examples/
```

Note that the \texttt{doc_files} option is simply a whitespace-separated
string split across multiple lines for readability.

**See also:**

*Syntax of config files* in “Installing Python Modules”

More information on the configuration files is available in the manual for system administrators.

**Footnotes**

[1] This ideal probably won’t be achieved until auto-configuration is fully supported by the Distutils.
4. Creating a Source Distribution

As shown in section *A Simple Example*, you use the **sdist** command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven’t specified any **sdist** options in the setup script or config file), **sdist** creates the archive of the default format for the current platform. The default format is a gzip’ed tar file (**.tar.gz**) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the **--formats** option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>zip</td>
<td>zip file (<strong>.zip</strong>)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>gztar</td>
<td>gzip’ed tar file (<strong>.tar.gz</strong>)</td>
<td>(2)</td>
</tr>
<tr>
<td>bztar</td>
<td>bzip2’ed tar file (<strong>.tar.bz2</strong>)</td>
<td></td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (<strong>.tar.Z</strong>)</td>
<td>(4)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (<strong>.tar</strong>)</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. default on Windows
2. default on Unix
3. requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)
4. requires the **compress** program. Notice that this format is now pending for deprecation and will be removed in the future
versions of Python.

When using any `tar` format (`gztar`, `bztar`, `ztar` or `tar`) under Unix, you can specify the `owner` and `group` names that will be set for each member of the archive.

For example, if you want all files of the archive to be owned by root:

```
python setup.py sdist --owner=root --group=root
```
4.1. Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the `sdist` command puts a minimal default set into the source distribution:

- all Python source files implied by the `py_modules` and `packages` options
- all C source files mentioned in the `ext_modules` or `libraries` options (getting C library sources currently broken—no `get_source_files()` method in `build_clib.py`!)
- scripts identified by the `scripts` option See *Installing Scripts*.
- anything that looks like a test script: `test/test*.py` (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- `README.txt` (or `README`), `setup.py` (or whatever you called your setup script), and `setup.cfg`
- all files that matches the `package_data` metadata. See *Installing Package Data*.
- all files that matches the `data_files` metadata. See *Installing Additional Files*.

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a `manifest template`, called `MANIFEST.in` by default. The manifest
template is just a list of instructions for how to generate your manifest file, MANIFEST, which is the exact list of files to include in your source distribution. The sdist command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do supply your own MANIFEST, you must specify everything: the default set of files described above does not apply in this case.

See The MANIFEST.in template section for a syntax reference.
4.2. Manifest-related options

The normal course of operations for the `sdist` command is as follows:

- if the manifest file, `MANIFEST` doesn’t exist, read `MANIFEST.in` and create the manifest
- if neither `MANIFEST` nor `MANIFEST.in` exist, create a manifest with just the default file set
- if either `MANIFEST.in` or the setup script (`setup.py`) are more recent than `MANIFEST`, recreate `MANIFEST` by reading `MANIFEST.in`
- use the list of files now in `MANIFEST` (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use the `--no-defaults` and `--no-prune` to disable the standard “include” and “exclude” sets.

Second, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

`-o` is a shortcut for `--manifest-only`. 
4.3. The MANIFEST.in template

A MANIFEST.in file can be added in a project to define the list of files to include in the distribution built by the sdist command.

When sdist is run, it will look for the MANIFEST.in file and interpret it to generate the MANIFEST file that contains the list of files that will be included in the package.

This mechanism can be used when the default list of files is not enough. (See Specifying the files to distribute).

4.3.1. Principle

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, let’s look at the Distutils’ own manifest template:

```
include *.txt
recursive-includes examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching *.txt, all files anywhere under the examples directory matching *.txt or *.py, and exclude all directories matching examples/sample?/build. All of this is done after the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the --no-defaults option to disable the standard set entirely.)

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we
have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils “build” tree (default build/)
- all files in directories named RCS, CVS, .svn, .hg, .git, .bzr or .darcs

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the --no-defaults option, and you can disable the standard exclude set with --no-prune.

Following the Distutils’ own manifest template, let’s trace how the sdist command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the distutils and distutils/command subdirectories (because packages corresponding to those two directories were mentioned in the packages option in the setup script—see section Writing the Setup Script)
2. include README.txt, setup.py, and setup.cfg (standard files)
3. include test/test*.py (standard files)
4. include *.txt in the distribution root (this will find README.txt a second time, but such redundancies are weeded out later)
5. include anything matching *.txt or *.py in the sub-tree under examples,
6. exclude all files in the sub-trees starting at directories matching examples/sample?/build—this may exclude files included by the previous two steps, so it’s important that the prune command in the manifest template comes after the recursive-include
7. exclude the entire build tree, and any RCS, CVS, .svn, .hg, .git, .bzr and _darcs directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.

### 4.3.2. Commands

The manifest template commands are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>include pat1 pat2 ...</td>
<td>include all files matching any of the listed patterns</td>
</tr>
<tr>
<td>exclude pat1 pat2 ...</td>
<td>exclude all files matching any of the listed patterns</td>
</tr>
<tr>
<td>recursive-incluedir pat1</td>
<td>include all files under dir matching any of the listed patterns</td>
</tr>
<tr>
<td>recursive-exclude dir pat2</td>
<td>exclude all files under dir matching any of the listed patterns</td>
</tr>
<tr>
<td>global-incluedat1 pat2</td>
<td>include all files anywhere in the source tree matching — &amp; any of the listed patterns</td>
</tr>
<tr>
<td>global-exclude pat1 pat2</td>
<td>exclude all files anywhere in the source tree matching — &amp; any of the listed patterns</td>
</tr>
<tr>
<td>prune dir</td>
<td>exclude all files under dir</td>
</tr>
<tr>
<td>graft dir</td>
<td>include all files under dir</td>
</tr>
</tbody>
</table>

The patterns here are Unix-style “glob” patterns: * matches any sequence of regular filename characters, ? matches any single
regular filename character, and \[range\] matches any of the characters in range (e.g., a-z, a-zA-Z, a-f0-9_). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.
A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called packagers springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the bdist command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:
then the Distutils builds my module distribution (the Distutils itself in this case), does a “fake” installation (also in the build directory), and creates the default type of built distribution for my platform. The default format for built distributions is a “dumb” tar file on Unix, and a simple executable installer on Windows. (That tar file is considered “dumb” because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates Distutils-1.0.plat.tar.gz; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run python setup.py install. (The “right place” is either the root of the filesystem or Python’s prefix directory, depending on the options given to the bdist_dumb command; the default is to make dumb distributions relative to prefix.)

Obviously, for pure Python distributions, this isn’t any simpler than just running python setup.py install—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating “smart” built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn’t include any extensions.

The bdist command has a --formats option, similar to the sdist command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a Unix system, create Distutils-1.0.plat.zip—again, this archive would be unpacked from the root directory to
install the Distutils.

The available formats for built distributions are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>gztar</td>
<td>gzipped tar file (.tar.gz)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(3)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td>(3)</td>
</tr>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(2),(4)</td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>pkgtool</td>
<td>Solaris pkgtool</td>
<td></td>
</tr>
<tr>
<td>sdux</td>
<td>HP-UX swinstall</td>
<td></td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>wininst</td>
<td>self-extracting ZIP file for Windows</td>
<td>(4)</td>
</tr>
<tr>
<td>msi</td>
<td>Microsoft Installer.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. default on Unix
2. default on Windows
3. requires external utilities: tar and possibly one of gzip, bzip2, or compress
4. requires either external zip utility or zipfile module (part of the standard Python library since Python 1.6)
5. requires external rpm utility, version 3.0.4 or better (use rpm --version to find out which version you have)

You don't have to use the bdist command with the --formats option; you can also use the command that directly implements the format you're interested in. Some of these bdist "sub-commands" actually generate several similar formats; for instance, the bdist_dumb command generates all the "dumb" archive formats (tar, ztar, gztar, and zip), and bdist_rpm generates both binary and source RPMs. The bdist sub-commands, and the formats generated by
each, are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Formats</th>
</tr>
</thead>
<tbody>
<tr>
<td>bdist_dumb</td>
<td>tar, ztar, gztar, zip</td>
</tr>
<tr>
<td>bdist_rpm</td>
<td>rpm, srpm</td>
</tr>
<tr>
<td>bdist_wininst</td>
<td>wininst</td>
</tr>
<tr>
<td>bdist_msi</td>
<td>msi</td>
</tr>
</tbody>
</table>

The following sections give details on the individual `bdist_*` commands.
5.1. Creating dumb built distributions

** Need to document absolute vs. prefix-relative packages here, but first I have to implement it! **
5.2. Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the `bdist_rpm` command:

```
python setup.py bdist_rpm
```

or the `bdist` command with the `--format` option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple `bdist_*` commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.org>
bdist_wininst --target_version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the `bdist_rpm` command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:
<table>
<thead>
<tr>
<th>RPM <code>.spec</code> file option or section</th>
<th>Distutils setup script option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
<td><code>name</code></td>
</tr>
<tr>
<td>Summary (in preamble)</td>
<td><code>description</code></td>
</tr>
<tr>
<td>Version</td>
<td><code>version</code></td>
</tr>
<tr>
<td>Vendor</td>
<td><code>author</code> and <code>author_email</code>, or — &amp; <code>maintainer</code> and <code>maintainer_email</code></td>
</tr>
<tr>
<td>Copyright</td>
<td><code>license</code></td>
</tr>
<tr>
<td>Url</td>
<td><code>url</code></td>
</tr>
<tr>
<td><code>%description</code> (section)</td>
<td><code>long_description</code></td>
</tr>
</tbody>
</table>

Additionally, there are many options in `.spec` files that don’t have corresponding options in the setup script. Most of these are handled through options to the `bdist_rpm` command as follows:

<table>
<thead>
<tr>
<th>RPM <code>.spec</code> file option or section</th>
<th><code>bdist_rpm</code> option</th>
<th>default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Release</td>
<td><code>release</code></td>
<td>“1”</td>
</tr>
<tr>
<td>Group</td>
<td><code>group</code></td>
<td>“Development/Libraries”</td>
</tr>
<tr>
<td>Vendor</td>
<td><code>vendor</code></td>
<td>(see above)</td>
</tr>
<tr>
<td>Packager</td>
<td><code>packager</code></td>
<td>(none)</td>
</tr>
<tr>
<td>Provides</td>
<td><code>provides</code></td>
<td>(none)</td>
</tr>
<tr>
<td>Requires</td>
<td><code>requires</code></td>
<td>(none)</td>
</tr>
<tr>
<td>Conflicts</td>
<td><code>conflicts</code></td>
<td>(none)</td>
</tr>
<tr>
<td>Obsoletes</td>
<td><code>obsoletes</code></td>
<td>(none)</td>
</tr>
<tr>
<td>Distribution</td>
<td><code>distribution_name</code></td>
<td>(none)</td>
</tr>
<tr>
<td>BuildRequires</td>
<td><code>build_requires</code></td>
<td>(none)</td>
</tr>
<tr>
<td>Icon</td>
<td><code>icon</code></td>
<td>(none)</td>
</tr>
</tbody>
</table>

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it’s usually best to put them in the setup configuration file, `setup.cfg`—see section *Writing the Setup Configuration File*. If you distribute or package many Python
module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (~/.pydistutils.cfg). If you want to temporarily disable this file, you can pass the --no-user-cfg option to setup.py.

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a .spec file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the .spec file)
2. create the source RPM
3. create the “binary” RPM (which may or may not contain binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the --spec-only option to make bdist_rpm just create the .spec file and exit; in this case, the .spec file will be written to the “distribution directory”—normally dist/, but customizable with the --dist-dir option. (Normally, the .spec file winds up deep in the “build tree,” in a temporary directory created by bdist_rpm.)
5.3. Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

```
python setup.py bdist_wininst
```

or the **bdist** command with the **--formats** option:

```
python setup.py bdist --formats=wininst
```

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like `foo-1.0.win32.exe`. These installers can even be created on Unix platforms or Mac OS X.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form `foo-1.0.win32-py2.0.exe`. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into bytecode after installation on the target system in normal and optimizing mode. If you don’t want this to happen for some reason, you can run the **bdist_wininst** command with the **--no-target-compile** and/or the **--no-target-optimize** option.
By default the installer will display the cool “Python Powered” logo when it is run, but you can also supply your own 152x261 bitmap which must be a Windows .bmp file with the --bitmap option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the --title option.

The installer file will be written to the “distribution directory” — normally dist/, but customizable with the --dist-dir option.
5.4. Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the \texttt{--plat-name} option to the build command. Valid values are currently ‘win32’, ‘win-amd64’ and ‘win-ia64’. For example, on a 32bit version of Windows, you could execute:

\begin{verbatim}
python setup.py build --plat-name=win-amd64
\end{verbatim}

to build a 64bit version of your extension. The Windows Installers also support this option, so the command:

\begin{verbatim}
python setup.py build --plat-name=win-amd64 bdist_wininst
\end{verbatim}

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targeting - it is not possible from a binary installation of Python (as the .lib etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the PCBuild/PCbuild.sln solution in the Python source tree and build the “x64” configuration of the ‘pythoncore’ project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel->
5.4.1. The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified with the `--install-script` option. The basename of the script must be specified, and the script filename must also be listed in the scripts argument to the setup function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to `-install`, and again at uninstallation time before the files are removed with `argv[1]` set to `-remove`.

The installation script runs embedded in the windows installer, every output (`sys.stdout`, `sys.stderr`) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

`directory_created(path)`
`file_created(path)`

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register `path` with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

`get_special_folder_path(csidl_string)`

This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. `csidl_string` must be one of the following strings:
If the folder cannot be retrieved, OSError is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft’s documentation of the SHGetSpecialFolderPath() function.

```python
def create_shortcut(target, description, filename, arguments, workdir, iconpath, iconindex):
    # This function creates a shortcut. target is the path to the program to be started by the shortcut. description is the description of the shortcut. filename is the title of the shortcut that the user will see. arguments specifies the command line arguments, if any. workdir is the working directory for the program. iconpath is the file containing the icon for the shortcut, and iconindex is the index of the icon in the file iconpath. Again, for details consult the Microsoft documentation for the IShellLink interface.
```
5.5. Vista User Access Control (UAC)

Starting with Python 2.6, bdist_wininst supports a \texttt{--user-access-control} option. The default is 'none' (meaning no UAC handling is done), and other valid values are 'auto' (meaning prompt for UAC elevation if Python was installed for all users) and 'force' (meaning always prompt for elevation).
6. Registering with the Package Index

The Python Package Index (PyPI) holds meta-data describing distributions packaged with distutils. The distutils command `register` is used to submit your distribution’s meta-data to the index. It is invoked as follows:

```
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either:
  1. use your existing login,
  2. register as a new user,
  3. have the server generate a new password for you (and email it to you),
  4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.

Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and `register` will then submit your meta-data to the index.

You may submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you may submit it again and the index will be updated.
PyPI holds a record for each (name, version) combination submitted. The first user to submit information for a given name is designated the Owner of that name. They may submit changes through the register command or through the web interface. They may also designate other users as Owners or Maintainers. Maintainers may edit the package information, but not designate other Owners or Maintainers.

By default PyPI will list all versions of a given package. To hide certain versions, the Hidden property should be set to yes. This must be edited through the web interface.
6.1. The .pypirc file

The format of the .pypirc file is as follows:

```
[distutils]
index-servers =
    pypi

[pypi]
repository: <repository-url>
username: <username>
password: <password>
```

The distutils section defines a index-servers variable that lists the name of all sections describing a repository.

Each section describing a repository defines three variables:

- **repository**, that defines the url of the PyPI server. Defaults to http://www.python.org/pypi.
- **username**, which is the registered username on the PyPI server.
- **password**, that will be used to authenticate. If omitted the user will be prompt to type it when needed.

If you want to define another server a new section can be created and listed in the index-servers variable:

```
[distutils]
index-servers =
    pypi
    other

[pypi]
repository: <repository-url>
username: <username>
password: <password>
```
[other]
repository: http://example.com/pypi
username: <username>
password: <password>

**register** can then be called with the -r option to point the repository to work with:

```bash
python setup.py register -r http://example.com/pypi
```

For convenience, the name of the section that describes the repository may also be used:

```bash
python setup.py register -r other
```
7. Uploading Packages to the Package Index

*New in version 2.5.*

The Python Package Index (PyPI) not only stores the package info, but also the package data if the author of the package wishes to. The `distutils` command **upload** pushes the distribution files to PyPI.

The command is invoked immediately after building one or more distribution files. For example, the command

```python
python setup.py sdist bdist_wininst upload
```
