1 PEP 218: Built-In Set Objects

Python 2.3 introduced the sets module. C implementations of set data types have now been added to the Python core as two new built-in types, `set(iterable)` and `frozenset(iterable)`. They provide high speed operations for membership testing, for eliminating duplicates from sequences, and for mathematical operations like unions, intersections, differences, and symmetric differences.

```python
>>> a = set('abracadabra')  # form a set from a string
>>> 'z' in a                # fast membership testing
False
>>> a                      # unique letters in a
set(['a', 'r', 'b', 'c', 'd'])
>>> ''.join(a)             # convert back into a string
'arbcd'

>>> b = set('alacazam')     # form a second set
>>> a - b                   # letters in a but not in b
set(['r', 'd', 'b'])

>>> a | b                   # letters in either a or b
set(['a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'])

>>> a & b                   # letters in both a and b
set(['a', 'c'])

>>> a ^= b                  # letters in a or b but not both
set(['r', 'd', 'b', 'm', 'z', 'l'])

>>> a.add('z')              # add a new element
>>> a.update('wxy')         # add multiple new elements
>>> a                      # add multiple new elements
set(['a', 'c', 'b', 'd', 'r', 'w', 'y', 'x', 'z'])

>>> a.remove('x')           # take one element out
>>> a                      # take one element out
set(['a', 'c', 'b', 'd', 'r', 'w', 'y', 'z'])
```

The `frozenset` type is an immutable version of `set`. Since it is immutable and hashable, it may be used as a dictionary key or as a member of another set.

The `sets` module remains in the standard library, and may be useful if you wish to subclass the `Set` or `ImmutableSet` classes. There are currently no plans to deprecate the module.

**PEP 218, Adding a Built-In Set Object Type**

Originally proposed by Greg Wilson and ultimately implemented by Raymond Hettinger.
2 PEP 237: Unifying Long Integers and Integers

The lengthy transition process for this PEP, begun in Python 2.2, takes another step forward in Python 2.4. In 2.3, certain integer operations that would behave differently after int/long unification triggered FutureWarning warnings and returned values limited to 32 or 64 bits (depending on your platform). In 2.4, these expressions no longer produce a warning and instead produce a different result that's usually a long integer.

The problematic expressions are primarily left shifts and lengthy hexadecimal and octal constants. For example, \(2 \ll 32\) results in a warning in 2.3, evaluating to 0 on 32-bit platforms. In Python 2.4, this expression now returns the correct answer, 8589934592.

See Also:

PEP 237, Unifying Long Integers and Integers
Original PEP written by Moshe Zadka and GvR. The changes for 2.4 were implemented by Kalle Svensson.
3 PEP 289: Generator Expressions

The iterator feature introduced in Python 2.2 and the `itertools` module make it easier to write programs that loop through large data sets without having the entire data set in memory at one time. List comprehensions don't fit into this picture very well because they produce a Python list object containing all of the items. This unavoidably pulls all of the objects into memory, which can be a problem if your data set is very large. When trying to write a functionally-styled program, it would be natural to write something like:

```python
links = [link for link in get_all_links() if not link.followed]
for link in links:
    ...
```

instead of

```python
for link in get_all_links():
    if link.followed:
        continue
    ...
```

The first form is more concise and perhaps more readable, but if you're dealing with a large number of link objects you'd have to write the second form to avoid having all link objects in memory at the same time.

Generator expressions work similarly to list comprehensions but don't materialize the entire list; instead they create a generator that will return elements one by one. The above example could be written as:

```python
links = (link for link in get_all_links() if not link.followed)
for link in links:
    ...
```

Generator expressions always have to be written inside parentheses, as in the above example. The parentheses signalling a function call also count, so if you want to create a iterator that will be immediately passed to a function you could write:

```python
print sum(obj.count for obj in list_all_objects())
```

Generator expressions differ from list comprehensions in various small ways.
Most notably, the loop variable (\texttt{obj} in the above example) is not accessible outside of the generator expression. List comprehensions leave the variable assigned to its last value; future versions of Python will change this, making list comprehensions match generator expressions in this respect.

\section*{See Also:}

PEP 289, \textit{Generator Expressions}

Proposed by Raymond Hettinger and implemented by Jiwon Seo with early efforts steered by Hye-Shik Chang.
4 PEP 292: Simpler String Substitutions

Some new classes in the standard library provide an alternative mechanism for substituting variables into strings; this style of substitution may be better for applications where untrained users need to edit templates.

The usual way of substituting variables by name is the % operator:

```python
>>> '%(page)i: %(title)s' % {'page':2, 'title': 'The Best of Times'}
'2: The Best of Times'
```

When writing the template string, it can be easy to forget the "i" or "s" after the closing parenthesis. This isn't a big problem if the template is in a Python module, because you run the code, get an "Unsupported format character" ValueError, and fix the problem. However, consider an application such as Mailman where template strings or translations are being edited by users who aren't aware of the Python language. The format string's syntax is complicated to explain to such users, and if they make a mistake, it's difficult to provide helpful feedback to them.

PEP 292 adds a Template class to the string module that uses "$" to indicate a substitution. Template is a subclass of the built-in Unicode type, so the result is always a Unicode string:

```python
>>> import string
>>> t = string.Template('$page: $title')
>>> t.substitute({'page':2, 'title': 'The Best of Times'})
u'2: The Best of Times'
```

If a key is missing from the dictionary, the substitute method will raise a KeyError. There's also a safe_substitute method that ignores missing keys:

```python
>>> t = string.SafeTemplate('$page: $title')
>>> t.safe_substitute({'page':3})
u'3: $title'
```
See Also:

PEP 292, Simpler String Substitutions
Written and implemented by Barry Warsaw.
PEP 318:

Decorators for Functions and Methods

Python 2.2 extended Python's object model by adding static methods and class methods, but it didn't extend Python's syntax to provide any new way of defining static or class methods. Instead, you had to write a `def` statement in the usual way, and pass the resulting method to a `staticmethod()` or `classmethod()` function that would wrap up the function as a method of the new type. Your code would look like this:

```python
class C:
    def meth(cls):
        ...

    meth = classmethod(meth)  # Rebind name to wrapped-up class meth
```

If the method was very long, it would be easy to miss or forget the `classmethod()` invocation after the function body.

The intention was always to add some syntax to make such definitions more readable, but at the time of 2.2's release a good syntax was not obvious. Today a good syntax still isn't obvious but users are asking for easier access to the feature; a new syntactic feature has been added to meet this need.

The new feature is called "function decorators". The name comes from the idea that `classmethod`, `staticmethod`, and friends are storing additional information on a function object; they're decorating functions with more details.

The notation borrows from Java and uses the "@" character as an indicator. Using the new syntax, the example above would be written:

```python
class C:
    @classmethod
def meth(cls):
        ...
```

The `@classmethod` is shorthand for the `meth=classmethod(meth)` assignment. More generally, if you have the following:
It's equivalent to the following pre-decorator code:

```python
def f(): ...
f = A(B(C(f)))
```

Decorators must come on the line before a function definition, and can't be on the same line, meaning that `@A def f(): ...` is illegal. You can only decorate function definitions, either at the module level or inside a class; you can't decorate class definitions.

A decorator is just a function that takes the function to be decorated as an argument and returns either the same function or some new callable thing. It's easy to write your own decorators. The following simple example just sets an attribute on the function object:

```python
>>> def deco(func):
...     func.attr = 'decorated'
...     return func
...
>>> @deco
... def f(): pass
...
>>> f
<function f at 0x402ef0d4>
>>> f.attr
'decorated'
>>> 
```

As a slightly more realistic example, the following decorator checks that the supplied argument is an integer:

```python
def require_int(func):
    def wrapper(arg):
        assert isinstance(arg, int)
        return func(arg)
    return wrapper

@require_int
def p1(arg):
    print arg

@require_int
```
def p2(arg):
    print arg*2

An example in PEP 318 contains a fancier version of this idea that lets you both specify the required type and check the returned type.

Decorator functions can take arguments. If arguments are supplied, your decorator function is called with only those arguments and must return a new decorator function; this function must take a single function and return a function, as previously described. In other words, @A @B @C(args) becomes:

def f(): ...
    _deco = C(args)
    f = A(B(_deco(f)))

Getting this right can be slightly brain-bending, but it's not too difficult.

A small related change makes the `func_name` attribute of functions writable. This attribute is used to display function names in tracebacks, so decorators should change the name of any new function that's constructed and returned.

See Also:

PEP 318, *Decorators for Functions, Methods and Classes*

Written by Kevin D. Smith, Jim Jewett, and Skip Montanaro. Several people wrote patches implementing function decorators, but the one that was actually checked in was patch #979728, written by Mark Russell.
6 PEP 322: Reverse Iteration

A new built-in function, `reversed(seq)`, takes a sequence and returns an iterator that loops over the elements of the sequence in reverse order.

```python
>>> for i in reversed(xrange(1,4)):
...     print i
...
3
2
1
```

Compared to extended slicing, such as `range(1,4)[::-1]`, `reversed()` is easier to read, runs faster, and uses substantially less memory.

Note that `reversed()` only accepts sequences, not arbitrary iterators. If you want to reverse an iterator, first convert it to a list with `list()`.

```python
>>> input = open('/etc/passwd', 'r')
>>> for line in reversed(list(input)):
...     print line
...
root:*:0:0:System Administrator:/var/root:/bin/tcsh
...
```

See Also:

PEP 322, Reverse Iteration
Written and implemented by Raymond Hettinger.
7 PEP 324: New subprocess Module

The standard library provides a number of ways to execute a subprocess, offering different features and different levels of complexity.

`os.system(command)` is easy to use, but slow (it runs a shell process which executes the command) and dangerous (you have to be careful about escaping the shell's metacharacters). The `popen2` module offers classes that can capture standard output and standard error from the subprocess, but the naming is confusing. The `subprocess` module cleans this up, providing a unified interface that offers all the features you might need.

Instead of `popen2`'s collection of classes, `subprocess` contains a single class called `Popen` whose constructor supports a number of different keyword arguments.

```python
class Popen(args, bufsize=0, executable=None, stdin=None, stdout=None, stderr=None, preexec_fn=None, close_fds=False, shell=False, cwd=None, env=None, universal_newlines=False, startupinfo=None, creationflags=0):
```

`args` is commonly a sequence of strings that will be the arguments to the program executed as the subprocess. (If the `shell` argument is true, `args` can be a string which will then be passed on to the shell for interpretation, just as `os.system()` does.)

`stdin`, `stdout`, and `stderr` specify what the subprocess's input, output, and error streams will be. You can provide a file object or a file descriptor, or you can use the constant `subprocess.PIPE` to create a pipe between the subprocess and the parent.

The constructor has a number of handy options:

- `close_fds` requests that all file descriptors be closed before running the subprocess.

- `cwd` specifies the working directory in which the subprocess will be executed (defaulting to whatever the parent's working directory is).
env is a dictionary specifying environment variables.

preexec_fn is a function that gets called before the child is started.

universal_newlines opens the child's input and output using Python's universal newline feature.

Once you've created the Popen instance, you can call its wait() method to pause until the subprocess has exited, poll() to check if it's exited without pausing, or communicate(data) to send the string data to the subprocess's standard input. communicate(data) then reads any data that the subprocess has sent to its standard output or standard error, returning a tuple (stdout_data, stderr_data).

call() is a shortcut that passes its arguments along to the Popen constructor, waits for the command to complete, and returns the status code of the subprocess. It can serve as a safer analog to os.system():

```python
sts = subprocess.call(['dpkg', '-i', '/tmp/new-package.deb'])
if sts == 0:
    # Success
    ...
else:
    # dpkg returned an error
    ...
```

The command is invoked without use of the shell. If you really do want to use the shell, you can add shell=True as a keyword argument and provide a string instead of a sequence:

```python
sts = subprocess.call('dpkg -i /tmp/new-package.deb', shell=True)
```

The PEP takes various examples of shell and Python code and shows how they'd be translated into Python code that uses subprocess. Reading this section of the PEP is highly recommended.

- 8.1 Why is Decimal needed?
- 8.2 The Decimal type
- 8.3 The Context type
8 PEP 327: Decimal Data Type

Python has always supported floating-point (FP) numbers, based on the underlying C double type, as a data type. However, while most programming languages provide a floating-point type, many people (even programmers) are unaware that floating-point numbers don't represent certain decimal fractions accurately. The new Decimal type can represent these fractions accurately, up to a user-specified precision limit.
8.1 Why is Decimal needed?

The limitations arise from the representation used for floating-point numbers. FP numbers are made up of three components:

- The sign, which is positive or negative.
- The mantissa, which is a single-digit binary number followed by a fractional part. For example, 1.01 in base-2 notation is $1 + 0/2 + 1/4$, or 1.25 in decimal notation.
- The exponent, which tells where the decimal point is located in the number represented.

For example, the number 1.25 has positive sign, a mantissa value of 1.01 (in binary), and an exponent of 0 (the decimal point doesn't need to be shifted). The number 5 has the same sign and mantissa, but the exponent is 2 because the mantissa is multiplied by 4 (2 to the power of the exponent 2); 1.25 * 4 equals 5.

Modern systems usually provide floating-point support that conforms to a standard called IEEE 754. C's `double` type is usually implemented as a 64-bit IEEE 754 number, which uses 52 bits of space for the mantissa. This means that numbers can only be specified to 52 bits of precision. If you're trying to represent numbers whose expansion repeats endlessly, the expansion is cut off after 52 bits. Unfortunately, most software needs to produce output in base 10, and common fractions in base 10 are often repeating decimals in binary. For example, 1.1 decimal is binary 1.0001100110011...; $0.1 = 1/16 + 1/32 + 1/256$ plus an infinite number of additional terms. IEEE 754 has to chop off that infinitely repeated decimal after 52 digits, so the representation is slightly inaccurate.

Sometimes you can see this inaccuracy when the number is printed:

```
>>> 1.1
1.1000000000000001
```

The inaccuracy isn't always visible when you print the number because the FP-to-decimal-string conversion is provided by the C library, and most C libraries try to produce sensible output. Even if it's not displayed, however, the inaccuracy is still there and subsequent operations can magnify the error.
For many applications this doesn't matter. If I'm plotting points and displaying them on my monitor, the difference between 1.1 and 1.1000000000000001 is too small to be visible. Reports often limit output to a certain number of decimal places, and if you round the number to two or three or even eight decimal places, the error is never apparent. However, for applications where it does matter, it's a lot of work to implement your own custom arithmetic routines.

Hence, the **Decimal** type was created.
8.2 The Decimal type

A new module, `decimal`, was added to Python's standard library. It contains two classes, `Decimal` and `Context`. `Decimal` instances represent numbers, and `Context` instances are used to wrap up various settings such as the precision and default rounding mode.

`Decimal` instances are immutable, like regular Python integers and FP numbers; once it's been created, you can't change the value an instance represents. `Decimal` instances can be created from integers or strings:

```python
>>> import decimal
>>> decimal.Decimal(1972)
Decimal("1972")
>>> decimal.Decimal("1.1")
Decimal("1.1")
```

You can also provide tuples containing the sign, the mantissa represented as a tuple of decimal digits, and the exponent:

```python
>>> decimal.Decimal((1, (1, 4, 7, 5), -2))
Decimal("-14.75")
```

Cautionary note: the sign bit is a Boolean value, so 0 is positive and 1 is negative.

Converting from floating-point numbers poses a bit of a problem: should the FP number representing 1.1 turn into the decimal number for exactly 1.1, or for 1.1 plus whatever inaccuracies are introduced? The decision was to dodge the issue and leave such a conversion out of the API. Instead, you should convert the floating-point number into a string using the desired precision and pass the string to the `Decimal` constructor:

```python
>>> f = 1.1
>>> decimal.Decimal(str(f))
Decimal("1.1")
>>> decimal.Decimal("%.12f" % f)
Decimal("1.100000000000")
```

Once you have `Decimal` instances, you can perform the usual mathematical operations on them. One limitation: exponentiation requires an integer exponent:
```python
>>> a = decimal.Decimal('35.72')
>>> b = decimal.Decimal('1.73')
>>> a+b
Decimal("37.45")
>>> a-b
Decimal("33.99")
>>> a*b
Decimal("61.7956")
>>> a/b
Decimal("20.64739884393063583815028902")
>>> a ** 2
Decimal("1275.9184")
>>> a**b
Traceback (most recent call last):
...  
decimal.InvalidOperation: x ** (non-integer)
```

You can combine `Decimal` instances with integers, but not with floating-point numbers:

```python
>>> a + 4
Decimal("39.72")
>>> a + 4.5
Traceback (most recent call last):
...
TypeError: You can interact Decimal only with int, long or Decimal d
```  

`Decimal` numbers can be used with the `math` and `cmath` modules, but note that they'll be immediately converted to floating-point numbers before the operation is performed, resulting in a possible loss of precision and accuracy. You'll also get back a regular floating-point number and not a `Decimal`.

```python
>>> import math, cmath
>>> d = decimal.Decimal('123456789012.345')
>>> math.sqrt(d)
351364.18288201344
>>> cmath.sqrt(-d)
351364.18288201344j
```

`Decimal` instances have a `sqrt()` method that returns a `Decimal`, but if you need other things such as trigonometric functions you'll have to implement them.

```python
>>> d.sqrt()
Decimal("351364.1828820134592177245001")
```
8.3 The Context type

Instances of the Context class encapsulate several settings for decimal operations:

- **prec** is the precision, the number of decimal places.
- **rounding** specifies the rounding mode. The decimal module has constants for the various possibilities: ROUND_DOWN, ROUND_CEILING, ROUND_HALF_EVEN, and various others.
- **traps** is a dictionary specifying what happens on encountering certain error conditions: either an exception is raised or a value is returned. Some examples of error conditions are division by zero, loss of precision, and overflow.

There's a thread-local default context available by calling `getcontext()`; you can change the properties of this context to alter the default precision, rounding, or trap handling. The following example shows the effect of changing the precision of the default context:

```python
>>> decimal.getcontext().prec
28
>>> decimal.Decimal(1) / decimal.Decimal(7)
Decimal("0.1428571428571428571428571429")
>>> decimal.getcontext().prec = 9
>>> decimal.Decimal(1) / decimal.Decimal(7)
Decimal("0.142857143")
```

The default action for error conditions is selectable; the module can either return a special value such as infinity or not-a-number, or exceptions can be raised:

```python
>>> decimal.Decimal(1) / decimal.Decimal(0)
Traceback (most recent call last):
...
decimal.DivisionByZero: x / 0
>>> decimal.getcontext().traps[decimal.DivisionByZero] = False
>>> decimal.Decimal(1) / decimal.Decimal(0)
Decimal("Infinity")
```

The Context instance also has various methods for formatting numbers such as `to_eng_string()` and `to_sci_string()`.
For more information, see the documentation for the `decimal` module, which includes a quick-start tutorial and a reference.

9 PEP 328: Multi-line Imports

One language change is a small syntactic tweak aimed at making it easier to import many names from a module. In a `from module import names` statement, `names` is a sequence of names separated by commas. If the sequence is very long, you can either write multiple imports from the same module, or you can use backslashes to escape the line endings like this:

```python
from SimpleXMLRPCServer import SimpleXMLRPCServer,
    SimpleXMLRPCRequestHandler,
    CGIXMLRPCRequestHandler,
    resolve_dotted_attribute
```

The syntactic change in Python 2.4 simply allows putting the names within parentheses. Python ignores newlines within a parenthesized expression, so the backslashes are no longer needed:

```python
from SimpleXMLRPCServer import (SimpleXMLRPCServer,
    SimpleXMLRPCRequestHandler,
    CGIXMLRPCRequestHandler,
    resolve_dotted_attribute)
```

The PEP also proposes that all `import` statements be absolute imports, with a leading "." character to indicate a relative import. This part of the PEP was not implemented for Python 2.4, but was completed for Python 2.5.

PEP 328, Imports: Multi-Line and Absolute/Relative
Written by Aahz. Multi-line imports were implemented by Dima Dorfman.
Release 1.01.
See About this document... for information on suggesting changes.
10 PEP 331: Locale-Independent Float/String Conversions

The `locale` modules lets Python software select various conversions and display conventions that are localized to a particular country or language. However, the module was careful to not change the numeric locale because various functions in Python's implementation required that the numeric locale remain set to the 'C' locale. Often this was because the code was using the C library's `atof()` function.

Not setting the numeric locale caused trouble for extensions that used third-party C libraries, however, because they wouldn't have the correct locale set. The motivating example was GTK+, whose user interface widgets weren't displaying numbers in the current locale.

The solution described in the PEP is to add three new functions to the Python API that perform ASCII-only conversions, ignoring the locale setting:

- `PyOS_ascii_strtod(str, ptr)` and `PyOS_ascii_atof(str, ptr)` both convert a string to a C `double`.
- `PyOS_ascii_formatd(buffer, buf_len, format, d)` converts a `double` to an ASCII string.

The code for these functions came from the GLib library (http://developer.gnome.org/arch/gtk/glib.html), whose developers kindly relicensed the relevant functions and donated them to the Python Software Foundation. The `locale` module can now change the numeric locale, letting extensions such as GTK+ produce the correct results.

- 11.1 Optimizations
11 Other Language Changes

Here are all of the changes that Python 2.4 makes to the core Python language.

- Decorators for functions and methods were added (PEP 318).
- Built-in set and frozenset types were added (PEP 218). Other new built-ins include the reversed(seq) function (PEP 322).
- Generator expressions were added (PEP 289).
- Certain numeric expressions no longer return values restricted to 32 or 64 bits (PEP 237).
- You can now put parentheses around the list of names in a from module import names statement (PEP 328).
- The dict.update() method now accepts the same argument forms as the dict constructor. This includes any mapping, any iterable of key/value pairs, and keyword arguments. (Contributed by Raymond Hettinger.)
- The string methods ljust(), rjust(), and center() now take an optional argument for specifying a fill character other than a space. (Contributed by Raymond Hettinger.)
- Strings also gained an rsplit() method that works like the split() method but splits from the end of the string.

```python
>>> 'www.python.org'.split('.', 1)
['www', 'python.org']
>>> 'www.python.org'.rsplit('.', 1)
['www.python', 'org']
```

- Three keyword parameters, cmp, key, and reverse, were added to the sort() method of lists. These parameters make some common usages of sort() simpler. All of these parameters are optional.

For the cmp parameter, the value should be a comparison function that takes two parameters and returns -1, 0, or +1 depending on how the parameters
compare. This function will then be used to sort the list. Previously this was
the only parameter that could be provided to `sort()`.

`key` should be a single-parameter function that takes a list element and
returns a comparison key for the element. The list is then sorted using the
comparison keys. The following example sorts a list case-insensitively:

```python
>>> L = ['A', 'b', 'c', 'D']
>>> L.sort()          # Case-sensitive sort
>>> L
['A', 'D', 'b', 'c']
>>> # Using 'key' parameter to sort list
>>> L.sort(key=lambda x: x.lower())
>>> L
['A', 'b', 'c', 'D']
>>> # Old-fashioned way
>>> L.sort(cmp=lambda x, y: cmp(x.lower(), y.lower()))
>>> L
['A', 'b', 'c', 'D']
```

The last example, which uses the `cmp` parameter, is the old way to perform
a case-insensitive sort. It works but is slower than using a `key` parameter.
Using `key` calls `lower()` method once for each element in the list while
using `cmp` will call it twice for each comparison, so using `key` saves on
invocations of the `lower()` method.

For simple key functions and comparison functions, it is often possible to
avoid a `lambda` expression by using an unbound method instead. For
example, the above case-insensitive sort is best written as:

```python
>>> L.sort(key=str.lower)
>>> L
['A', 'b', 'c', 'D']
```

Finally, the `reverse` parameter takes a Boolean value. If the value is true, the
list will be sorted into reverse order. Instead of `L.sort()` ;
`L.reverse()`; you can now write `L.sort(reverse=True)`.

The results of sorting are now guaranteed to be stable. This means that two
entries with equal keys will be returned in the same order as they were
input. For example, you can sort a list of people by name, and then sort the
list by age, resulting in a list sorted by age where people with the same age
are in name-sorted order.
There is a new built-in function `sorted(iterable)` that works like the in-place `list.sort()` method but can be used in expressions. The differences are:

- the input may be any iterable;
- a newly formed copy is sorted, leaving the original intact; and
- the expression returns the new sorted copy.

```python
>>> L = [9, 7, 8, 3, 2, 4, 1, 6, 5]
>>> [10+i for i in sorted(L)]  # usable in a list comprehension
[11, 12, 13, 14, 15, 16, 17, 18, 19]
>>> L  # original is left unchanged
[9, 7, 8, 3, 2, 4, 1, 6, 5]
>>> sorted('Monty Python')  # any iterable may be an input
[', ', 'M', 'P', 'h', 'n', 'o', 'o', 't', 't', 'y', 'y']
```

```python
>>> # List the contents of a dict sorted by key values
>>> colormap = dict(red=1, blue=2, green=3, black=4, yellow=5)
>>> for k, v in sorted(colormap.iteritems()):
...    print k, v
...  black 4
  blue 2
  green 3
  red 1
  yellow 5
```

Integer operations will no longer trigger an `OverflowWarning`. The `OverflowWarning` warning will disappear in Python 2.5.

The interpreter gained a new switch, `-m`, that takes a name, searches for the corresponding module on `sys.path`, and runs the module as a script. For example, you can now run the Python profiler with `python -m profile`. (Contributed by Nick Coghlan.)

The `eval(expr, globals, locals)` and `execfile(filename, globals, locals)` functions and the `exec` statement now accept any mapping type for the `locals` parameter. Previously this had to be a regular Python dictionary. (Contributed by Raymond Hettinger.)

The `zip()` built-in function and `itertools.izip()` now return an
empty list if called with no arguments. Previously they raised a 
_TypeError_ exception. This makes them more suitable for use with 
variable length argument lists:

```python
>>> def transpose(array):
...     return zip(*array)
...
>>> transpose([[1,2,3), (4,5,6)])
[(1, 4), (2, 5), (3, 6)]
>>> transpose([])
[]
```

(Contributed by Raymond Hettinger.)

- Encountering a failure while importing a module no longer leaves a 
  partially-initialized module object in _sys.modules_. The incomplete 
  module object left behind would fool further imports of the same module 
  into succeeding, leading to confusing errors. (Fixed by Tim Peters.)

- **None** is now a constant; code that binds a new value to the name "None" is 
  now a syntax error. (Contributed by Raymond Hettinger.)
11.1 Optimizations

- The inner loops for list and tuple slicing were optimized and now run about one-third faster. The inner loops for dictionaries were also optimized, resulting in performance boosts for `keys()`, `values()`, `items()`, `iterkeys()`, `itervalues()`, and `iteritems()`.(Contributed by Raymond Hettinger.)

- The machinery for growing and shrinking lists was optimized for speed and for space efficiency. Appending and popping from lists now runs faster due to more efficient code paths and less frequent use of the underlying system `realloc()`. List comprehensions also benefit. `list.extend()` was also optimized and no longer converts its argument into a temporary list before extending the base list. (Contributed by Raymond Hettinger.)

- `list()`, `tuple()`, `map()`, `filter()`, and `zip()` now run several times faster with non-sequence arguments that supply a `__len__()` method. (Contributed by Raymond Hettinger.)

- The methods `list.__getitem__()`, `dict.__getitem__()`, and `dict.__contains__()` are are now implemented as `method_descriptor` objects rather than `wrapper_descriptor` objects. This form of access doubles their performance and makes them more suitable for use as arguments to functionals: "map(mydict.__getitem__, keylist)". (Contributed by Raymond Hettinger.)

- Added a new opcode, `LIST_APPEND`, that simplifies the generated bytecode for list comprehensions and speeds them up by about a third. (Contributed by Raymond Hettinger.)

- The peephole bytecode optimizer has been improved to produce shorter, faster bytecode; remarkably, the resulting bytecode is more readable. (Enhanced by Raymond Hettinger.)

- String concatenations in statements of the form `s = s + "abc"` and `s += "abc"` are now performed more efficiently in certain circumstances.
This optimization won't be present in other Python implementations such as Jython, so you shouldn't rely on it; using the \texttt{join()} method of strings is still recommended when you want to efficiently glue a large number of strings together. (Contributed by Armin Rigo.)

The net result of the 2.4 optimizations is that Python 2.4 runs the pystone benchmark around 5\% faster than Python 2.3 and 35\% faster than Python 2.2. (pystone is not a particularly good benchmark, but it's the most commonly used measurement of Python's performance. Your own applications may show greater or smaller benefits from Python 2.4.)

Subsections

- 12.1 cookielib
- 12.2 doctest
12 New, Improved, and Deprecated Modules

As usual, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the CVS logs for all the details.

- The `asyncore` module's `loop()` function now has a `count` parameter that lets you perform a limited number of passes through the polling loop. The default is still to loop forever.

- The `base64` module now has more complete RFC 3548 support for Base64, Base32, and Base16 encoding and decoding, including optional case folding and optional alternative alphabets. (Contributed by Barry Warsaw.)

- The `bisect` module now has an underlying C implementation for improved performance. (Contributed by Dmitry Vasiliev.)

- The CJKCodecs collections of East Asian codecs, maintained by Hye-Shik Chang, was integrated into 2.4. The new encodings are:
  - Chinese (PRC): gb2312, gbk, gb18030, big5hkscs, hz
  - Chinese (ROC): big5, cp950

- Some other new encodings were added: HP Roman8, ISO_8859-11, ISO_8859-16, PCTP-154, and TIS-620.

- The UTF-8 and UTF-16 codecs now cope better with receiving partial input. Previously the `StreamReader` class would try to read more data, making it impossible to resume decoding from the stream. The `read()`
method will now return as much data as it can and future calls will resume decoding where previous ones left off. (Implemented by Walter Dörwald.)

- There is a new `collections` module for various specialized collection datatypes. Currently it contains just one type, `deque`, a double-ended queue that supports efficiently adding and removing elements from either end:

```python
>>> from collections import deque
>>> d = deque('ghi')  # make a new deque with three items
>>> d.append('j')  # add a new entry to the right side
>>> d.appendleft('f')  # add a new entry to the left side
>>> d  # show the representation of the deque
deque(['f', 'g', 'h', 'i', 'j'])
>>> d.pop()  # return and remove the rightmost item
'j'
>>> d.popleft()  # return and remove the leftmost item
'f'
>>> list(d)  # list the contents of the deque
['g', 'h', 'i']
>>> 'h' in d  # search the deque
True
```

Several modules, such as the `Queue` and `threading` modules, now take advantage of `collections.deque` for improved performance. (Contributed by Raymond Hettinger.)

- The `ConfigParser` classes have been enhanced slightly. The `read()` method now returns a list of the files that were successfully parsed, and the `set()` method raises `TypeError` if passed a `value` argument that isn't a string. (Contributed by John Belmonte and David Goodger.)

- The `curses` module now supports the `ncurses` extension `use_default_colors()`. On platforms where the terminal supports transparency, this makes it possible to use a transparent background. (Contributed by Jörg Lehmann.)

- The `difflib` module now includes an `HtmlDiff` class that creates an HTML table showing a side by side comparison of two versions of a text. (Contributed by Dan Gass.)

- The `email` package was updated to version 3.0, which dropped various deprecated APIs and removes support for Python versions earlier than 2.3.
The 3.0 version of the package uses a new incremental parser for MIME messages, available in the `email.FeedParser` module. The new parser doesn't require reading the entire message into memory, and doesn't throw exceptions if a message is malformed; instead it records any problems in the `defect` attribute of the message. (Developed by Anthony Baxter, Barry Warsaw, Thomas Wouters, and others.)

- The `heapq` module has been converted to C. The resulting tenfold improvement in speed makes the module suitable for handling high volumes of data. In addition, the module has two new functions `nlargest()` and `nsmallest()` that use heaps to find the N largest or smallest values in a dataset without the expense of a full sort. (Contributed by Raymond Hettinger.)

- The `httplib` module now contains constants for HTTP status codes defined in various HTTP-related RFC documents. Constants have names such as `OK`, `CREATED`, `CONTINUE`, and `MOVED_PERMANENTLY`; use `pydoc` to get a full list. (Contributed by Andrew Eland.)

- The `imaplib` module now supports IMAP's THREAD command (contributed by Yves Dionne) and new `deleteacl()` and `myrights()` methods (contributed by Arnaud Mazin).

- The `itertools` module gained a `groupby(iterable[, func])` function. `iterable` is something that can be iterated over to return a stream of elements, and the optional `func` parameter is a function that takes an element and returns a key value; if omitted, the key is simply the element itself. `groupby()` then groups the elements into subsequences which have matching values of the key, and returns a series of 2-tuples containing the key value and an iterator over the subsequence.

Here's an example to make this clearer. The `key` function simply returns whether a number is even or odd, so the result of `groupby()` is to return consecutive runs of odd or even numbers.

```python
>>> import itertools
>>> L = [2, 4, 6, 7, 8, 9, 11, 12, 14]
>>> for key_val, it in itertools.groupby(L, lambda x: x % 2):
...    print key_val, list(it)
...```
groupby() is typically used with sorted input. The logic for

groupby() is similar to the Unix uniq filter which makes it handy for
eliminating, counting, or identifying duplicate elements:

```python
>>> word = 'abracadabra'
>>> letters = sorted(word)  # Turn string into a sorted list of
...                   letters
['a', 'a', 'a', 'a', 'b', 'b', 'c', 'd', 'r', 'r']
>>> for k, g in itertools.groupby(letters):
...     print k, list(g)
...  a ['a', 'a', 'a', 'a', 'a']
  b ['b', 'b']
  c ['c']
  d ['d']
  r ['r', 'r']
>>> # List unique letters
>>> [k for k, g in groupby(letters)]
['a', 'b', 'c', 'd', 'r']
>>> # Count letter occurrences
>>> [(k, len(list(g))) for k, g in groupby(letters)]
[('a', 5), ('b', 2), ('c', 1), ('d', 1), ('r', 2)]
```

(Contributed by Hye-Shik Chang.)

- **itertools** also gained a function named `tee(iterator, N)` that returns
  $N$ independent iterators that replicate `iterator`. If $N$ is omitted, the default is
  2.

```python
>>> L = [1, 2, 3]
>>> i1, i2 = itertools.tee(L)
>>> i1, i2
<itertools.tee object at 0x402c2080>, <itertools.tee object at
>>> list(i1)  # Run the first iterator to exhaustion
[1, 2, 3]
>>> list(i2)  # Run the second iterator to exhaustion:
[1, 2, 3]
```

Note that `tee()` has to keep copies of the values returned by the iterator;
in the worst case, it may need to keep all of them. This should therefore be
used carefully if the leading iterator can run far ahead of the trailing iterator in a long stream of inputs. If the separation is large, then you might as well use `list()` instead. When the iterators track closely with one another, `tee()` is ideal. Possible applications include bookmarking, windowing, or lookahead iterators. (Contributed by Raymond Hettinger.)

- A number of functions were added to the `locale` module, such as `bind_textdomain_codeset()` to specify a particular encoding and a family of `gettext()` functions that return messages in the chosen encoding. (Contributed by Gustavo Niemeyer.)

- Some keyword arguments were added to the `logging` package's `basicConfig` function to simplify log configuration. The default behavior is to log messages to standard error, but various keyword arguments can be specified to log to a particular file, change the logging format, or set the logging level. For example:

  ```python
  import logging
  logging.basicConfig(filename='/var/log/application.log',
                      level=0,  # Log all messages
                      format='%(levelname):%(process):%(thread):%(message)')
  ```

  Other additions to the `logging` package include a `log(level, msg)` convenience method, as well as a `TimedRotatingFileHandler` class that rotates its log files at a timed interval. The module already had `RotatingFileHandler`, which rotated logs once the file exceeded a certain size. Both classes derive from a new `BaseRotatingHandler` class that can be used to implement other rotating handlers.

  (Changes implemented by Vinay Sajip.)

- The `marshal` module now shares interned strings on unpacking a data structure. This may shrink the size of certain pickle strings, but the primary effect is to make `.pyc` files significantly smaller. (Contributed by Martin von Loewis.)

- The `nntplib` module's `NNTP` class gained `description()` and `descriptions()` methods to retrieve newsgroup descriptions for a single group or for a range of groups. (Contributed by Jürgen A. Erhard.)
Two new functions were added to the `operator` module, 
`attrgetter(attr)` and `itemgetter(index)`. Both functions return 
callables that take a single argument and return the corresponding attribute 
or item; these callables make excellent data extractors when used with 
`map()` or `sorted()`. For example:

```python
>>> L = [('c', 2), ('d', 1), ('a', 4), ('b', 3)]
>>> map(operator.itemgetter(0), L)
['c', 'd', 'a', 'b']
>>> map(operator.itemgetter(1), L)
[2, 1, 4, 3]
>>> sorted(L, key=operator.itemgetter(1))  # Sort list by second
[('d', 1), ('c', 2), ('b', 3), ('a', 4)]
```

(Contributed by Raymond Hettinger.)

The `optparse` module was updated in various ways. The module now 
passes its messages through `gettext.gettext()`, making it possible to 
internationalize Optik's help and error messages. Help messages for options 
can now include the string '%default', which will be replaced by the 
option's default value. (Contributed by Greg Ward.)

The long-term plan is to deprecate the `rfc822` module in some future 
Python release in favor of the `email` package. To this end, the 
`email.Utils.formatdate()` function has been changed to make it 
usable as a replacement for `rfc822.formatdate()`. You may want to 
write new e-mail processing code with this in mind. (Change implemented 
by Anthony Baxter.)

A new `urandom(n)` function was added to the `os` module, returning a 
string containing `n` bytes of random data. This function provides access to 
platform-specific sources of randomness such as `/dev/urandom` on Linux 
or the Windows CryptoAPI. (Contributed by Trevor Perrin.)

Another new function: `os.path.lexists(path)` returns true if the file 
specified by `path` exists, whether or not it's a symbolic link. This differs 
from the existing `os.path.exists(path)` function, which returns false 
if `path` is a symlink that points to a destination that doesn't exist. 
(Contributed by Beni Cherniavsky.)

A new `getsid()` function was added to the `posix` module that underlies
The `os` module. (Contributed by J. Raynor.)

- The `poplib` module now supports POP over SSL. (Contributed by Hector Urtubia.)

- The `profile` module can now profile C extension functions. (Contributed by Nick Bastin.)

- The `random` module has a new method called `getrandbits(N)` that returns a long integer \( N \) bits in length. The existing `randrange()` method now uses `getrandbits()` where appropriate, making generation of arbitrarily large random numbers more efficient. (Contributed by Raymond Hettinger.)

- The regular expression language accepted by the `re` module was extended with simple conditional expressions, written as `(?<group>A|B)`. `group` is either a numeric group ID or a group name defined with `(?P<group>...)` earlier in the expression. If the specified group matched, the regular expression pattern `A` will be tested against the string; if the group didn't match, the pattern `B` will be used instead. (Contributed by Gustavo Niemeyer.)

- The `re` module is also no longer recursive, thanks to a massive amount of work by Gustavo Niemeyer. In a recursive regular expression engine, certain patterns result in a large amount of C stack space being consumed, and it was possible to overflow the stack. For example, if you matched a 30000-byte string of "a" characters against the expression `(a|b)+`, one stack frame was consumed per character. Python 2.3 tried to check for stack overflow and raise a `RuntimeError` exception, but certain patterns could sidestep the checking and if you were unlucky Python could segfault. Python 2.4's regular expression engine can match this pattern without problems.

- A new `socketpair()` function, returning a pair of connected sockets, was added to the `socket` module. (Contributed by Dave Cole.)

- The `sys.exitfunc()` function has been deprecated. Code should be using the existing `atexit` module, which correctly handles calling multiple exit functions. Eventually `sys.exitfunc()` will become a
purely internal interface, accessed only by `atexit`.

- The `tarfile` module now generates GNU-format tar files by default. (Contributed by Lars Gustaebel.)

- The `threading` module now has an elegantly simple way to support thread-local data. The module contains a `local` class whose attribute values are local to different threads.

  ```python
  import threading
  data = threading.local()
data.number = 42
data.url = ('www.python.org', 80)
  ```

  Other threads can assign and retrieve their own values for the `number` and `url` attributes. You can subclass `local` to initialize attributes or to add methods. (Contributed by Jim Fulton.)

- The `timeit` module now automatically disables periodic garbage collection during the timing loop. This change makes consecutive timings more comparable. (Contributed by Raymond Hettinger.)

- The `weakref` module now supports a wider variety of objects including Python functions, class instances, sets, frozensets, deques, arrays, files, sockets, and regular expression pattern objects. (Contributed by Raymond Hettinger.)

- The `xmlrpclib` module now supports a multi-call extension for transmitting multiple XML-RPC calls in a single HTTP operation. (Contributed by Brian Quinlan.)

- The `mpz`, `rotor`, and `xreadlines` modules have been removed.
12.1 cookielib

The cookielib library supports client-side handling for HTTP cookies, mirroring the Cookie module's server-side cookie support. Cookies are stored in cookie jars; the library transparently stores cookies offered by the web server in the cookie jar, and fetches the cookie from the jar when connecting to the server. As in web browsers, policy objects control whether cookies are accepted or not.

In order to store cookies across sessions, two implementations of cookie jars are provided: one that stores cookies in the Netscape format so applications can use the Mozilla or Lynx cookie files, and one that stores cookies in the same format as the Perl libwww library.

urllib2 has been changed to interact with cookielib: HTTPCookieProcessor manages a cookie jar that is used when accessing URLs.

This module was contributed by John J. Lee.
12.2 doctest

The `doctest` module underwent considerable refactoring thanks to Edward Loper and Tim Peters. Testing can still be as simple as running `doctest.testmod()`, but the refactorings allow customizing the module's operation in various ways.

The new `DocTestFinder` class extracts the tests from a given object's docstrings:

```python
def f(x, y):
    """""">>> f(2,2)
    4
    >>> f(3,2)
    6
    """
    return x*y
finder = doctest.DocTestFinder()
# Get list of DocTest instances
tests = finder.find(f)
```

The new `DocTestRunner` class then runs individual tests and can produce a summary of the results:

```python
runner = doctest.DocTestRunner()
for t in tests:
    tried, failed = runner.run(t)
runner.summarize(verbose=1)
```

The above example produces the following output:

```
1 items passed all tests:
  2 tests in f
2 tests in 1 items.
2 passed and 0 failed.
Test passed.
```

`DocTestRunner` uses an instance of the `OutputChecker` class to compare the expected output with the actual output. This class takes a number of different flags that customize its behaviour; ambitious users can also write a completely new subclass of `OutputChecker`. 
The default output checker provides a number of handy features. For example, with the `doctest.ELLIPSIS` option flag, an ellipsis ("...") in the expected output matches any substring, making it easier to accommodate outputs that vary in minor ways:

```python
def o(n):
    """""">>>(n)
    <__main__.C instance at 0x...>
    >>>
    """
```

Another special string, "<BLANKLINE>", matches a blank line:

```python
def p(n):
    """"""">>>(n)
    <BLANKLINE>
    >>>
    """
```

Another new capability is producing a diff-style display of the output by specifying the `doctest.REPORT_UDIFF` (unified diffs), `doctest.REPORT_CDIFF` (context diffs), or `doctest.REPORT_NDIFF` (delta-style) option flags. For example:

```python
def g(n):
    """"""">>>(n)
    here
    is
    a
    lengthy
    >>>"""
    L = 'here is a rather lengthy list of words'.split()
    for word in L[:n]:
        print word
```

Running the above function's tests with `doctest.REPORT_UDIFF` specified, you get the following output:

```
**********************************************************************
File `\`t.py\'`, line 15, in g
Failed example:
    g(4)

- 13.1 Port-Specific Changes
### 13 Build and C API Changes

Some of the changes to Python's build process and to the C API are:

- Three new convenience macros were added for common return values from extension functions: `Py_RETURN_NONE`, `Py_RETURN_TRUE`, and `Py_RETURN_FALSE`. (Contributed by Brett Cannon.)

- Another new macro, `Py_CLEAR(obj)`, decreases the reference count of `obj` and sets `obj` to the null pointer. (Contributed by Jim Fulton.)

- A new function, `PyTuple_Pack(N, obj1, obj2, ..., objN)`, constructs tuples from a variable length argument list of Python objects. (Contributed by Raymond Hettinger.)

- A new function, `PyDict_Contains(d, k)`, implements fast dictionary lookups without masking exceptions raised during the look-up process. (Contributed by Raymond Hettinger.)

- The `Py_IS_NAN(X)` macro returns 1 if its float or double argument `X` is a NaN. (Contributed by Tim Peters.)

- C code can avoid unnecessary locking by using the new `PyEval_ThreadsInitialized()` function to tell if any thread operations have been performed. If this function returns false, no lock operations are needed. (Contributed by Nick Coghlan.)

- A new function, `PyArg_VaParseTupleAndKeywords()`, is the same as `PyArg_ParseTupleAndKeywords()` but takes a `va_list` instead of a number of arguments. (Contributed by Greg Chapman.)

- A new method flag, `METH_COEXIST`, allows a function defined in slots to co-exist with a `PyCFunction` having the same name. This can halve the access time for a method such as `set.__contains__()`. (Contributed by Raymond Hettinger.)

- Python can now be built with additional profiling for the interpreter itself,
intended as an aid to people developing the Python core. Providing --enable-profiling to the configure script will let you profile the interpreter with gprof, and providing the --with-tsc switch enables profiling using the Pentium's Time-Stamp-Counter register. Note that the --with-tsc switch is slightly misnamed, because the profiling feature also works on the PowerPC platform, though that processor architecture doesn't call that register ``the TSC register''. (Contributed by Jeremy Hylton.)

- The tracebackobject type has been renamed to PyTracebackObject.
13.1 Port-Specific Changes

- The Windows port now builds under MSVC++ 7.1 as well as version 6. (Contributed by Martin von Loewis.)

Release 1.01.
See About this document... for information on suggesting changes.
14 Porting to Python 2.4

This section lists previously described changes that may require changes to your code:

- Left shifts and hexadecimal/octal constants that are too large no longer trigger a `FutureWarning` and return a value limited to 32 or 64 bits; instead they return a long integer.

- Integer operations will no longer trigger an `OverflowWarning`. The `OverflowWarning` warning will disappear in Python 2.5.

- The `zip()` built-in function and `itertools.izip()` now return an empty list instead of raising a `TypeError` exception if called with no arguments.

- `dircache.listdir()` now passes exceptions to the caller instead of returning empty lists.

- `LexicalHandler.startDTD()` used to receive the public and system IDs in the wrong order. This has been corrected; applications relying on the wrong order need to be fixed.

- `fcntl.ioctl` now warns if the `mutate` argument is omitted and relevant.

- The `tarfile` module now generates GNU-format tar files by default.

- Encountering a failure while importing a module no longer leaves a partially-initialized module object in `sys.modules`.

- `None` is now a constant; code that binds a new value to the name "None" is now a syntax error.
Release 1.01.

Acknowledgements

These people have contributed in some way to the Python documentation. This list is probably not complete -- if you feel that you or anyone else should be on this list, please let us know (send email to docs@python.org), and we will be glad to correct the problem.

It is only with the input and contributions of the Python community that Python has such wonderful documentation -- Thank You!

Fred L. Drake, Jr., editor

Release 2.4.4c1
11 October 2006

- Front Matter
- Contents
- 1. Whetting Your Appetite
- 2. Using the Python Interpreter
  - 2.1 Invoking the Interpreter
    - 2.1.1 Argument Passing
    - 2.1.2 Interactive Mode
  - 2.2 The Interpreter and Its Environment
    - 2.2.1 Error Handling
    - 2.2.2 Executable Python Scripts
    - 2.2.3 Source Code Encoding
    - 2.2.4 The Interactive Startup File
- 3. An Informal Introduction to Python
  - 3.1 Using Python as a Calculator
    - 3.1.1 Numbers
    - 3.1.2 Strings
    - 3.1.3 Unicode Strings
    - 3.1.4 Lists
  - 3.2 First Steps Towards Programming
- 4. More Control Flow Tools
  - 4.1 if Statements
  - 4.2 for Statements
  - 4.3 The range() Function
4.4 break and continue Statements, and else Clauses on Loops
4.5 pass Statements
4.6 Defining Functions
4.7 More on Defining Functions
   4.7.1 Default Argument Values
   4.7.2 Keyword Arguments
   4.7.3 Arbitrary Argument Lists
   4.7.4 Unpacking Argument Lists
   4.7.5 Lambda Forms
   4.7.6 Documentation Strings

5. Data Structures
5.1 More on Lists
   5.1.1 Using Lists as Stacks
   5.1.2 Using Lists as Queues
   5.1.3 Functional Programming Tools
   5.1.4 List Comprehensions
5.2 The del statement
5.3 Tuples and Sequences
5.4 Sets
5.5 Dictionaries
5.6 Looping Techniques
5.7 More on Conditions
5.8 Comparing Sequences and Other Types

6. Modules
6.1 More on Modules
   6.1.1 The Module Search Path
   6.1.2 "Compiled" Python files
6.2 Standard Modules
6.3 The dir() Function
6.4 Packages
   6.4.1 Importing * From a Package
   6.4.2 Intra-package References
   6.4.3 Packages in Multiple Directories

7. Input and Output
7.1 Fancier Output Formatting
7.2 Reading and Writing Files
   7.2.1 Methods of File Objects
   7.2.2 The pickle Module
8. Errors and Exceptions
   - 8.1 Syntax Errors
   - 8.2 Exceptions
   - 8.3 Handling Exceptions
   - 8.4 Raising Exceptions
   - 8.5 User-defined Exceptions
   - 8.6 Defining Clean-up Actions

9. Classes
   - 9.1 A Word About Terminology
   - 9.2 Python Scopes and Name Spaces
   - 9.3 A First Look at Classes
     - 9.3.1 Class Definition Syntax
     - 9.3.2 Class Objects
     - 9.3.3 Instance Objects
     - 9.3.4 Method Objects
   - 9.4 Random Remarks
   - 9.5 Inheritance
     - 9.5.1 Multiple Inheritance
   - 9.6 Private Variables
   - 9.7 Odds and Ends
   - 9.8 Exceptions Are Classes Too
   - 9.9 Iterators
   - 9.10 Generators
   - 9.11 Generator Expressions

10. Brief Tour of the Standard Library
    - 10.1 Operating System Interface
    - 10.2 File Wildcards
    - 10.3 Command Line Arguments
    - 10.4 Error Output Redirection and Program Termination
    - 10.5 String Pattern Matching
    - 10.6 Mathematics
    - 10.7 Internet Access
    - 10.8 Dates and Times
    - 10.9 Data Compression
    - 10.10 Performance Measurement
    - 10.11 Quality Control
    - 10.12 Batteries Included

11. Brief Tour of the Standard Library - Part II
    - 11.1 Output Formatting
11.2 Templating
11.3 Working with Binary Data Record Layouts
11.4 Multi-threading
11.5 Logging
11.6 Weak References
11.7 Tools for Working with Lists
11.8 Decimal Floating Point Arithmetic

12. What Now?
A. Interactive Input Editing and History Substitution
   A.1 Line Editing
   A.2 History Substitution
   A.3 Key Bindings
   A.4 Commentary
B. Floating Point Arithmetic: Issues and Limitations
   B.1 Representation Error
C. History and License
   C.1 History of the software
   C.2 Terms and conditions for accessing or otherwise using Python
   C.3 Licenses and Acknowledgements for Incorporated Software
      C.3.1 Mersenne Twister
      C.3.2 Sockets
      C.3.3 Floating point exception control
      C.3.4 MD5 message digest algorithm
      C.3.5 Asynchronous socket services
      C.3.6 Cookie management
      C.3.7 Profiling
      C.3.8 Execution tracing
      C.3.9 UUencode and UUdecode functions
      C.3.10 XML Remote Procedure Calls
D. Glossary
Index
About this document...
1. Whetting Your Appetite

If you ever wrote a large shell script, you probably know this feeling: you'd love to add yet another feature, but it's already so slow, and so big, and so complicated; or the feature involves a system call or other function that is only accessible from C ...Usually the problem at hand isn't serious enough to warrant rewriting the script in C; perhaps the problem requires variable-length strings or other data types (like sorted lists of file names) that are easy in the shell but lots of work to implement in C, or perhaps you're not sufficiently familiar with C.

Another situation: perhaps you have to work with several C libraries, and the usual C write/compile/test/re-compile cycle is too slow. You need to develop software more quickly. Possibly you've written a program that could use an extension language, and you don't want to design a language, write and debug an interpreter for it, then tie it into your application.

In such cases, Python may be just the language for you. Python is simple to use, but it is a real programming language, offering much more structure and support for large programs than the shell has. On the other hand, it also offers much more error checking than C, and, being a very-high-level language, it has high-level data types built in, such as flexible arrays and dictionaries that would cost you days to implement efficiently in C. Because of its more general data types Python is applicable to a much larger problem domain than Awk or even Perl, yet many things are at least as easy in Python as in those languages.

Python allows you to split your program in modules that can be reused in other Python programs. It comes with a large collection of standard modules that you can use as the basis of your programs -- or as examples to start learning to program in Python. Some of these modules provide things like file I/O, system calls, sockets, and even interfaces to graphical user interface toolkits like Tk.

Python is an interpreted language, which can save you considerable time during program development because no compilation and linking is necessary. The interpreter can be used interactively, which makes it easy to experiment with features of the language, to write throw-away programs, or to test functions during bottom-up program development. It is also a handy desk calculator.
Python enables programs to be written compactly and readably. Programs written in Python are typically much shorter than equivalent C or C++ programs, for several reasons:

- the high-level data types allow you to express complex operations in a single statement;
- statement grouping is done by indentation instead of beginning and ending brackets;
- no variable or argument declarations are necessary.

Python is extensible: if you know how to program in C it is easy to add a new built-in function or module to the interpreter, either to perform critical operations at maximum speed, or to link Python programs to libraries that may only be available in binary form (such as a vendor-specific graphics library). Once you are really hooked, you can link the Python interpreter into an application written in C and use it as an extension or command language for that application.

By the way, the language is named after the BBC show "Monty Python's Flying Circus" and has nothing to do with nasty reptiles. Making references to Monty Python skits in documentation is not only allowed, it is encouraged!

Now that you are all excited about Python, you'll want to examine it in some more detail. Since the best way to learn a language is to use it, you are invited to do so with this tutorial.

In the next chapter, the mechanics of using the interpreter are explained. This is rather mundane information, but essential for trying out the examples shown later.

The rest of the tutorial introduces various features of the Python language and system through examples, beginning with simple expressions, statements and data types, through functions and modules, and finally touching upon advanced concepts like exceptions and user-defined classes.
Subsections

- **2.1 Invoking the Interpreter**
  - 2.1.1 Argument Passing
  - 2.1.2 Interactive Mode
- **2.2 The Interpreter and Its Environment**
  - 2.2.1 Error Handling
  - 2.2.2 Executable Python Scripts
  - 2.2.3 Source Code Encoding
  - 2.2.4 The Interactive Startup File
2. Using the Python Interpreter
2.1 Invoking the Interpreter

The Python interpreter is usually installed as `/usr/local/bin/python` on those machines where it is available; putting `/usr/local/bin` in your UNIX shell's search path makes it possible to start it by typing the command

```
python
```
to the shell. Since the choice of the directory where the interpreter lives is an installation option, other places are possible; check with your local Python guru or system administrator. (E.g., `/usr/local/python` is a popular alternative location.)

Typing an end-of-file character (Control-D on UNIX, Control-Z on Windows) at the primary prompt causes the interpreter to exit with a zero exit status. If that doesn't work, you can exit the interpreter by typing the following commands:

```
import sys; sys.exit()
```

The interpreter's line-editing features usually aren't very sophisticated. On UNIX, whoever installed the interpreter may have enabled support for the GNU readline library, which adds more elaborate interactive editing and history features. Perhaps the quickest check to see whether command line editing is supported is typing Control-P to the first Python prompt you get. If it beeps, you have command line editing; see Appendix A for an introduction to the keys. If nothing appears to happen, or if P is echoed, command line editing isn't available; you'll only be able to use backspace to remove characters from the current line.

The interpreter operates somewhat like the UNIX shell: when called with standard input connected to a tty device, it reads and executes commands interactively; when called with a file name argument or with a file as standard input, it reads and executes a script from that file.

A second way of starting the interpreter is "python -c command [arg] . . .", which executes the statement(s) in command, analogous to the shell's -c option. Since Python statements often contain spaces or other characters that are special to the shell, it is best to quote command in its entirety with double quotes.
Some Python modules are also useful as scripts. These can be invoked using "python -m module [arg] ...", which executes the source file for module as if you had spelled out its full name on the command line.

Note that there is a difference between "python file" and "python <file". In the latter case, input requests from the program, such as calls to input() and raw_input(), are satisfied from file. Since this file has already been read until the end by the parser before the program starts executing, the program will encounter end-of-file immediately. In the former case (which is usually what you want) they are satisfied from whatever file or device is connected to standard input of the Python interpreter.

When a script file is used, it is sometimes useful to be able to run the script and enter interactive mode afterwards. This can be done by passing -i before the script. (This does not work if the script is read from standard input, for the same reason as explained in the previous paragraph.)
2.1.1 Argument Passing

When known to the interpreter, the script name and additional arguments thereafter are passed to the script in the variable `sys.argv`, which is a list of strings. Its length is at least one; when no script and no arguments are given, `sys.argv[0]` is an empty string. When the script name is given as `-` (meaning standard input), `sys.argv[0]` is set to `-`. When `-c command` is used, `sys.argv[0]` is set to `-c`. When `-m module` is used, `sys.argv[0]` is set to the full name of the located module. Options found after `-c command` or `-m module` are not consumed by the Python interpreter's option processing but left in `sys.argv` for the command or module to handle.
2.1.2 Interactive Mode

When commands are read from a tty, the interpreter is said to be in interactive mode. In this mode it prompts for the next command with the primary prompt, usually three greater-than signs (">>> "); for continuation lines it prompts with the secondary prompt, by default three dots ("... "). The interpreter prints a welcome message stating its version number and a copyright notice before printing the first prompt:

```
python
Python 1.5.2b2 (#1, Feb 28 1999, 00:02:06) [GCC 2.8.1] on sunos5
Copyright 1991-1995 Stichting Mathematisch Centrum, Amsterdam
``` 

Continuation lines are needed when entering a multi-line construct. As an example, take a look at this if statement:

```
>>> the_world_is_flat = 1
>>> if the_world_is_flat:
...     print "Be careful not to fall off!"
...     print "Be careful not to fall off!"
```
2.2 The Interpreter and Its Environment
2.2.1 Error Handling

When an error occurs, the interpreter prints an error message and a stack trace. In interactive mode, it then returns to the primary prompt; when input came from a file, it exits with a nonzero exit status after printing the stack trace. (Exceptions handled by an except clause in a try statement are not errors in this context.) Some errors are unconditionally fatal and cause an exit with a nonzero exit; this applies to internal inconsistencies and some cases of running out of memory. All error messages are written to the standard error stream; normal output from executed commands is written to standard output.

Typing the interrupt character (usually Control-C or DEL) to the primary or secondary prompt cancels the input and returns to the primary prompt. Typing an interrupt while a command is executing raises the KeyboardInterrupt exception, which may be handled by a try statement.
2.2.2 Executable Python Scripts

On BSD'ish UNIX systems, Python scripts can be made directly executable, like shell scripts, by putting the line

```bash
#!/usr/bin/env python
```

(assuming that the interpreter is on the user's PATH) at the beginning of the script and giving the file an executable mode. The "#!" must be the first two characters of the file. On some platforms, this first line must end with a UNIX-style line ending ("\n"), not a Mac OS ("\r") or Windows ("\r\n") line ending. Note that the hash, or pound, character, "#", is used to start a comment in Python.

The script can be given a executable mode, or permission, using the `chmod` command:

```bash
$ chmod +x myscript.py
```
2.2.3 Source Code Encoding

It is possible to use encodings different than ASCII in Python source files. The best way to do it is to put one more special comment line right after the `#!` line to define the source file encoding:

```
# -*- coding: encoding -*-
```

With that declaration, all characters in the source file will be treated as having the encoding `encoding`, and it will be possible to directly write Unicode string literals in the selected encoding. The list of possible encodings can be found in the [Python Library Reference](http://docs.python.org/library), in the section on `codecs`.

For example, to write Unicode literals including the Euro currency symbol, the ISO-8859-15 encoding can be used, with the Euro symbol having the ordinal value 164. This script will print the value 8364 (the Unicode codepoint corresponding to the Euro symbol) and then exit:

```
# -*- coding: iso-8859-15 -*-

currency = u"€"
print ord(currency)
```

If your editor supports saving files as UTF-8 with a UTF-8 byte order mark (aka BOM), you can use that instead of an encoding declaration. IDLE supports this capability if Options/General/Default Source Encoding/UTF-8 is set. Notice that this signature is not understood in older Python releases (2.2 and earlier), and also not understood by the operating system for script files with `#!` lines (only used on UNIX systems).

By using UTF-8 (either through the signature or an encoding declaration), characters of most languages in the world can be used simultaneously in string literals and comments. Using non-ASCII characters in identifiers is not supported. To display all these characters properly, your editor must recognize that the file is UTF-8, and it must use a font that supports all the characters in the file.
2.2.4 The Interactive Startup File

When you use Python interactively, it is frequently handy to have some standard commands executed every time the interpreter is started. You can do this by setting an environment variable named PYTHONSTARTUP to the name of a file containing your start-up commands. This is similar to the .profile feature of the UNIX shells.

This file is only read in interactive sessions, not when Python reads commands from a script, and not when /dev/tty is given as the explicit source of commands (which otherwise behaves like an interactive session). It is executed in the same namespace where interactive commands are executed, so that objects that it defines or imports can be used without qualification in the interactive session. You can also change the prompts sys.ps1 and sys.ps2 in this file.

If you want to read an additional start-up file from the current directory, you can program this in the global start-up file using code like "if os.path.isfile('.pythonrc.py'): execfile('.pythonrc.py')". If you want to use the startup file in a script, you must do this explicitly in the script:

```python
import os
filename = os.environ.get('PYTHONSTARTUP')
if filename and os.path.isfile(filename):
    execfile(filename)
```

Footnotes

... prompt.21

A problem with the GNU Readline package may prevent this.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
Subsections

- 3.1 Using Python as a Calculator
  - 3.1.1 Numbers
  - 3.1.2 Strings
  - 3.1.3 Unicode Strings
  - 3.1.4 Lists
- 3.2 First Steps Towards Programming
3. An Informal Introduction to Python

In the following examples, input and output are distinguished by the presence or absence of prompts (">>> " and " . . . "): to repeat the example, you must type everything after the prompt, when the prompt appears; lines that do not begin with a prompt are output from the interpreter. Note that a secondary prompt on a line by itself in an example means you must type a blank line; this is used to end a multi-line command.

Many of the examples in this manual, even those entered at the interactive prompt, include comments. Comments in Python start with the hash character, "#", and extend to the end of the physical line. A comment may appear at the start of a line or following whitespace or code, but not within a string literal. A hash character within a string literal is just a hash character.

Some examples:

```
    # this is the first comment
    SPAM = 1           # and this is the second comment
                        # ... and now a third!
    STRING = "# This is not a comment."
```
3.1 Using Python as a Calculator

Let's try some simple Python commands. Start the interpreter and wait for the primary prompt, ">>> " (It shouldn't take long.)
3.1.1 Numbers

The interpreter acts as a simple calculator: you can type an expression at it and it will write the value. Expression syntax is straightforward: the operators +, -, *, and / work just like in most other languages (for example, Pascal or C); parentheses can be used for grouping. For example:

```
>>> 2+2
4
>>> # This is a comment
... 2+2
4
>>> 2+2  # and a comment on the same line as code
4
>>> (50-5*6)/4
5
>>> # Integer division returns the floor:
... 7/3
2
>>> 7/-3
-3
```

The equal sign ("=") is used to assign a value to a variable. Afterwards, no result is displayed before the next interactive prompt:

```
>>> width = 20
>>> height = 5*9
>>> width * height
900
```

A value can be assigned to several variables simultaneously:

```
>>> x = y = z = 0  # Zero x, y and z
>>> x
0
>>> y
0
>>> z
0
```

There is full support for floating point; operators with mixed type operands convert the integer operand to floating point:

```
>>> 3 * 3.75 / 1.5
7.5
```
Complex numbers are also supported; imaginary numbers are written with a suffix of "j" or "J". Complex numbers with a nonzero real component are written as "(real+imagj)", or can be created with the "complex(real, imag)" function.

```
>>> 1j * 1J
(-1+0j)
>>> 1j * complex(0,1)
(-1+0j)
>>> 3+1j*3
(3+3j)
>>> (3+1j)*3
(9+3j)
>>> (1+2j)/(1+1j)
(1.5+0.5j)
```

Complex numbers are always represented as two floating point numbers, the real and imaginary part. To extract these parts from a complex number \(z\), use \(z\).real and \(z\).imag.

```
>>> a=1.5+0.5j
>>> a.real
1.5
>>> a.imag
0.5
```

The conversion functions to floating point and integer (float(), int() and long()) don't work for complex numbers -- there is no one correct way to convert a complex number to a real number. Use abs(\(z\)) to get its magnitude (as a float) or \(z\).real to get its real part.

```
>>> a=3.0+4.0j
>>> float(a)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: can't convert complex to float; use abs(z)
>>> a.real
3.0
>>> a.imag
4.0
>>> abs(a) # sqrt(a.real**2 + a.imag**2)
5.0
```
In interactive mode, the last printed expression is assigned to the variable `__`. This means that when you are using Python as a desk calculator, it is somewhat easier to continue calculations, for example:

```python
>>> tax = 12.5 / 100
>>> price = 100.50
>>> price * tax
12.5625
>>> price + __
113.0625
>>> round(__, 2)
113.06
```  

This variable should be treated as read-only by the user. Don't explicitly assign a value to it -- you would create an independent local variable with the same name masking the built-in variable with its magic behavior.
3.1.2 Strings

Besides numbers, Python can also manipulate strings, which can be expressed in several ways. They can be enclosed in single quotes or double quotes:

```python
>>> 'spam eggs'
'spam eggs'
>>> 'doesn\'t'
"doesn't"
>>> "doesn't"
"doesn't"
>>> "Yes," he said.
"Yes," he said.
>>> "\"Yes,\" he said."
"Yes," he said.
>>> "Isn\'t," she said.
"Isn't," she said.
```

String literals can span multiple lines in several ways. Continuation lines can be used, with a backslash as the last character on the line indicating that the next line is a logical continuation of the line:

```python
hello = "This is a rather long string containing
several lines of text just as you would do in C.\n    Note that whitespace at the beginning of the line is\n    significant."

print hello
```

Note that newlines still need to be embedded in the string using `\n`; the newline following the trailing backslash is discarded. This example would print the following:

```
This is a rather long string containing
several lines of text just as you would do in C.
    Note that whitespace at the beginning of the line is significant
```

If we make the string literal a `\`raw` string, however, the `\n` sequences are not converted to newlines, but the backslash at the end of the line, and the newline character in the source, are both included in the string as data. Thus, the example:

```python
hello = r"This is a rather long string containing\nseveral lines of text much as you would do in C."
```
print hello

would print:

This is a rather long string containing\n\nseveral lines of text much as you would do in C.

Or, strings can be surrounded in a pair of matching triple-quotes: """" or ''''. End of lines do not need to be escaped when using triple-quotes, but they will be included in the string.

print """
Usage: thingy [OPTIONS]
-h
  Display this usage message
-H hostname
  Hostname to connect to
"""

produces the following output:

Usage: thingy [OPTIONS]
-h
  Display this usage message
-H hostname
  Hostname to connect to

The interpreter prints the result of string operations in the same way as they are typed for input: inside quotes, and with quotes and other funny characters escaped by backslashes, to show the precise value. The string is enclosed in double quotes if the string contains a single quote and no double quotes, else it's enclosed in single quotes. (The print statement, described later, can be used to write strings without quotes or escapes.)

Strings can be concatenated (glued together) with the + operator, and repeated with *:

```
>>> word = 'Help' + 'A'
>>> word
'HelpA'
>>> '<' + word*5 + '>
'<HelpAHelpAHelpAHelpAHelpA>'
```

Two string literals next to each other are automatically concatenated; the first line above could also have been written "word = 'Help' 'A'"; this only works with two literals, not with arbitrary string expressions:

```
>>> 'str' 'ing' # <- This is ok
```
Strings can be subscripted (indexed); like in C, the first character of a string has subscript (index) 0. There is no separate character type; a character is simply a string of size one. Like in Icon, substrings can be specified with the slice notation: two indices separated by a colon.

```
>>> word[4]
'A'
>>> word[0:2]
'He'
>>> word[2:4]
'lp'
```

Slice indices have useful defaults; an omitted first index defaults to zero, an omitted second index defaults to the size of the string being sliced.

```
>>> word[:2]  # The first two characters
'He'
>>> word[2:]  # Everything except the first two characters
'lpA'
```

Unlike a C string, Python strings cannot be changed. Assigning to an indexed position in the string results in an error:

```
>>> word[0] = 'x'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object doesn't support item assignment
>>> word[1] = 'Splat'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object doesn't support slice assignment
```

However, creating a new string with the combined content is easy and efficient:

```
>>> 'x' + word[1:]
'xelpA'
>>> 'Splat' + word[4]
'SplatA'
```
Here's a useful invariant of slice operations: \( s[:i] + s[i:] \) equals \( s \).

```python
>>> word[:2] + word[2:]
'HelpA'
>>> word[:3] + word[3:]
'HelpA'
```

Degenerate slice indices are handled gracefully: an index that is too large is replaced by the string size, an upper bound smaller than the lower bound returns an empty string.

```python
>>> word[1:100]
'elpA'
>>> word[10:]
''
>>> word[2:1]
''
```

Indices may be negative numbers, to start counting from the right. For example:

```python
>>> word[-1]  # The last character
'A'
>>> word[-2]  # The last-but-one character
'p'
>>> word[-2:]  # The last two characters
'pA'
>>> word[:2]  # Everything except the last two characters
'Hel'
```

But note that -0 is really the same as 0, so it does not count from the right!

```python
>>> word[-0]  # (since -0 equals 0)
'H'
```

Out-of-range negative slice indices are truncated, but don't try this for single-element (non-slice) indices:

```python
>>> word[-100:]
'HelpA'
>>> word[-10]  # error
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
IndexError: string index out of range
```

The best way to remember how slices work is to think of the indices as pointing between characters, with the left edge of the first character numbered 0. Then the right edge of the last character of a string of \( n \) characters has index \( n \), for
The first row of numbers gives the position of the indices 0...5 in the string; the second row gives the corresponding negative indices. The slice from \( i \) to \( j \) consists of all characters between the edges labeled \( i \) and \( j \), respectively.

For non-negative indices, the length of a slice is the difference of the indices, if both are within bounds. For example, the length of \texttt{word[1:3]} is 2.

The built-in function \texttt{len()} returns the length of a string:

```python
>>> s = 'supercalifragilisticexpialidocious'
>>> len(s)
34
```

**Sequence Types**
Strings, and the Unicode strings described in the next section, are examples of sequence types, and support the common operations supported by such types.

**String Methods**
Both strings and Unicode strings support a large number of methods for basic transformations and searching.

**String Formatting Operations**
The formatting operations invoked when strings and Unicode strings are the left operand of the \% operator are described in more detail here.
3.1.3 Unicode Strings

Starting with Python 2.0 a new data type for storing text data is available to the programmer: the Unicode object. It can be used to store and manipulate Unicode data (see [http://www.unicode.org/](http://www.unicode.org/)) and integrates well with the existing string objects, providing auto-conversions where necessary.

Unicode has the advantage of providing one ordinal for every character in every script used in modern and ancient texts. Previously, there were only 256 possible ordinals for script characters and texts were typically bound to a code page which mapped the ordinals to script characters. This lead to very much confusion especially with respect to internationalization (usually written as "i18n" -- "i" + 18 characters + "n") of software. Unicode solves these problems by defining one code page for all scripts.

Creating Unicode strings in Python is just as simple as creating normal strings:

```python
>>> u'Hello World !'
'u'Hello World !'
```

The small "u" in front of the quote indicates that an Unicode string is supposed to be created. If you want to include special characters in the string, you can do so by using the Python *Unicode-Escape* encoding. The following example shows how:

```python
>>> u'Hello\u0020World !'
'u'Hello World !'
```

The escape sequence `\u0020` indicates to insert the Unicode character with the ordinal value 0x0020 (the space character) at the given position.

Other characters are interpreted by using their respective ordinal values directly as Unicode ordinals. If you have literal strings in the standard Latin-1 encoding that is used in many Western countries, you will find it convenient that the lower 256 characters of Unicode are the same as the 256 characters of Latin-1.

For experts, there is also a raw mode just like the one for normal strings. You have to prefix the opening quote with 'ur' to have Python use the *Raw-Unicode-Escape* encoding. It will only apply the above `\uXXXX` conversion if there is an
uneven number of backslashes in front of the small 'u'.

```python
>>> ur'Hello\\u0020World !'
u'Hello World !'
>>> ur'Hello\\u0020World !'
u'Hello\\\u0020World !'
```

The raw mode is most useful when you have to enter lots of backslashes, as can be necessary in regular expressions.

Apart from these standard encodings, Python provides a whole set of other ways of creating Unicode strings on the basis of a known encoding.

The built-in function `unicode()` provides access to all registered Unicode codecs (COders and DEcoders). Some of the more well known encodings which these codecs can convert are Latin-1, ASCII, UTF-8, and UTF-16. The latter two are variable-length encodings that store each Unicode character in one or more bytes. The default-encoding is normally set to ASCII, which passes through characters in the range 0 to 127 and rejects any other characters with an error. When a Unicode string is printed, written to a file, or converted with `str()`, conversion takes place using this default encoding.

```python
>>> u"abc"
u'abc'
>>> str(u"abc")
'abc'
```  

```python
>>> u"הצ�
  u'\xe4\xf6\xfc'
>>> str(u"הצ�")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  UnicodeEncodeError: 'ascii' codec can't encode characters in position 0-2: ordinal not in range(128)
```

To convert a Unicode string into an 8-bit string using a specific encoding, Unicode objects provide an `encode()` method that takes one argument, the name of the encoding. Lowercase names for encodings are preferred.

```python
>>> u"הצ�".encode('utf-8')
'\xc3\xa4\xc3\xb6\xc3\xbc'
```

If you have data in a specific encoding and want to produce a corresponding Unicode string from it, you can use the `unicode()` function with the encoding name as the second argument.
>>> unicode('\xc3\xa4\xc3\xb6\xc3\xbcc', 'utf-8')
u'\xe4\xf6\xfc'
3.1.4 Lists

Python knows a number of *compound* data types, used to group together other values. The most versatile is the *list*, which can be written as a list of comma-separated values (items) between square brackets. List items need not all have the same type.

```python
>>> a = ['spam', 'eggs', 100, 1234]
>>> a
['spam', 'eggs', 100, 1234]
```

Like string indices, list indices start at 0, and lists can be sliced, concatenated and so on:

```python
>>> a[0]
'spam'
>>> a[3]
1234
>>> a[-2]
100
>>> a[1:-1]
['eggs', 100]
>>> a[:2] + ['bacon', 2*2]
['spam', 'eggs', 'bacon', 4]
>>> 3*a[:3] + ['Boo!']
['spam', 'eggs', 100, 'spam', 'eggs', 100, 'spam', 'eggs', 100, 'Boo'
```

Unlike strings, which are *immutable*, it is possible to change individual elements of a list:

```python
>>> a
['spam', 'eggs', 100, 1234]
>>> a
['spam', 'eggs', 123, 1234]
```

Assignment to slices is also possible, and this can even change the size of the list:

```python
>>> # Replace some items:
... a[0:2] = [1, 12]
>>> a
[1, 12, 123, 1234]
>>> # Remove some:
... a[0:2] = []
```
'>>> a
[123, 1234]
>>> # Insert some:
... a[1:1] = ['bletch', 'xyzzy']
>>> a
[123, 'bletch', 'xyzzy', 1234]
>>> a[:0] = a    # Insert (a copy of) itself at the beginning
>>> a
[123, 'bletch', 'xyzzy', 1234, 123, 'bletch', 'xyzzy', 1234]

The built-in function \texttt{len()} also applies to lists:

\begin{verbatim}
>>> len(a)
8
\end{verbatim}

It is possible to nest lists (create lists containing other lists), for example:

\begin{verbatim}
>>> q = [2, 3]
>>> p = [1, q, 4]
>>> len(p)
3
>>> p[1]
[2, 3]
>>> p[1][0]
2
>>> p[1].append('xtra')  # See section 5.1
>>> p
[1, [2, 3, 'xtra'], 4]
>>> q
[2, 3, 'xtra']
\end{verbatim}

Note that in the last example, \texttt{p[1]} and \texttt{q} really refer to the same object! We'll come back to \textit{object semantics} later.
3.2 First Steps Towards Programming

Of course, we can use Python for more complicated tasks than adding two and two together. For instance, we can write an initial sub-sequence of the *Fibonacci* series as follows:

```python
>>> # Fibonacci series:
... # the sum of two elements defines the next
... a, b = 0, 1
>>> while b < 10:
...     print b
...     a, b = b, a+b
1
1
2
3
5
8
```

This example introduces several new features.

- The first line contains a *multiple assignment*: the variables `a` and `b` simultaneously get the new values 0 and 1. On the last line this is used again, demonstrating that the expressions on the right-hand side are all evaluated first before any of the assignments take place. The right-hand side expressions are evaluated from the left to the right.

- The *while* loop executes as long as the condition (here: `b < 10`) remains true. In Python, like in C, any non-zero integer value is true; zero is false. The condition may also be a string or list value, in fact any sequence; anything with a non-zero length is true, empty sequences are false. The test used in the example is a simple comparison. The standard comparison operators are written the same as in C: `<` (less than), `>` (greater than), `==` (equal to), `<=(less than or equal to), `>=` (greater than or equal to) and `!=` (not equal to).

- The *body* of the loop is *indented*: indentation is Python's way of grouping statements. Python does not (yet!) provide an intelligent input line editing
facility, so you have to type a tab or space(s) for each indented line. In practice you will prepare more complicated input for Python with a text editor; most text editors have an auto-indent facility. When a compound statement is entered interactively, it must be followed by a blank line to indicate completion (since the parser cannot guess when you have typed the last line). Note that each line within a basic block must be indented by the same amount.

- The `print` statement writes the value of the expression(s) it is given. It differs from just writing the expression you want to write (as we did earlier in the calculator examples) in the way it handles multiple expressions and strings. Strings are printed without quotes, and a space is inserted between items, so you can format things nicely, like this:

  ```python
  >>> i = 256*256
  >>> print 'The value of i is', i
  The value of i is 65536
  ```

A trailing comma avoids the newline after the output:

  ```python
  >>> a, b = 0, 1
  >>> while b < 1000:
  ...     print b,
  ...     a, b = b, a+b
  ...
  1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
  ```

Note that the interpreter inserts a newline before it prints the next prompt if the last line was not completed.

4. More Control Flow Tools

Besides the while statement just introduced, Python knows the usual control flow statements known from other languages, with some twists.
4.1 if Statements

Perhaps the most well-known statement type is the if statement. For example:

```python
>>> x = int(input("Please enter an integer: "))
>>> if x < 0:
    x = 0
    print 'Negative changed to zero'
>>> elif x == 0:
    print 'Zero'
>>> elif x == 1:
    print 'Single'
>>> else:
    print 'More'
```

There can be zero or more elif parts, and the else part is optional. The keyword `elif` is short for `else if`, and is useful to avoid excessive indentation. An if ... elif ... elif ... sequence is a substitute for the switch or case statements found in other languages.
4.2 for Statements

The `for` statement in Python differs a bit from what you may be used to in C or Pascal. Rather than always iterating over an arithmetic progression of numbers (like in Pascal), or giving the user the ability to define both the iteration step and halting condition (as C), Python's `for` statement iterates over the items of any sequence (a list or a string), in the order that they appear in the sequence. For example (no pun intended):

```python
>>> # Measure some strings:
... a = ['cat', 'window', 'defenestrate']
>>> for x in a:
...     print x, len(x)
...  
cat 3
window 6
defenestrate 12
```

It is not safe to modify the sequence being iterated over in the loop (this can only happen for mutable sequence types, such as lists). If you need to modify the list you are iterating over (for example, to duplicate selected items) you must iterate over a copy. The slice notation makes this particularly convenient:

```python
>>> for x in a[:]: # make a slice copy of the entire list
...     if len(x) > 6: a.insert(0, x)
... 
>>> a
['defenestrate', 'cat', 'window', 'defenestrate']
```
4.3 The range() Function

If you do need to iterate over a sequence of numbers, the built-in function range() comes in handy. It generates lists containing arithmetic progressions:

```python
>>> range(10)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
```

The given end point is never part of the generated list; `range(10)` generates a list of 10 values, the legal indices for items of a sequence of length 10. It is possible to let the range start at another number, or to specify a different increment (even negative; sometimes this is called the `step:'):

```python
>>> range(5, 10)
[5, 6, 7, 8, 9]
>>> range(0, 10, 3)
[0, 3, 6, 9]
>>> range(-10, -100, -30)
[-10, -40, -70]
```

To iterate over the indices of a sequence, combine `range()` and `len()` as follows:

```python
>>> a = ['Mary', 'had', 'a', 'little', 'lamb']
>>> for i in range(len(a)):
...     print i, a[i]
...
0 Mary
1 had
2 a
3 little
4 lamb
```
4.4 break and continue Statements, and else Clauses on Loops

The break statement, like in C, breaks out of the smallest enclosing for or while loop.

The continue statement, also borrowed from C, continues with the next iteration of the loop.

Loop statements may have an else clause; it is executed when the loop terminates through exhaustion of the list (with for) or when the condition becomes false (with while), but not when the loop is terminated by a break statement. This is exemplified by the following loop, which searches for prime numbers:

```python
>>> for n in range(2, 10):
...     for x in range(2, n):
...         if n % x == 0:
...             print n, 'equals', x, '*', n/x
...             break
...     else:
...         # loop fell through without finding a factor
...         print n, 'is a prime number'
...
2 is a prime number
3 is a prime number
4 equals 2 * 2
5 is a prime number
6 equals 2 * 3
7 is a prime number
8 equals 2 * 4
9 equals 3 * 3
```
4.5 pass Statements

The pass statement does nothing. It can be used when a statement is required syntactically but the program requires no action. For example:

```python
>>> while True:
...    pass # Busy-wait for keyboard interrupt
...```

4.6 Defining Functions

We can create a function that writes the Fibonacci series to an arbitrary boundary:

```python
>>> def fib(n):  # write Fibonacci series up to n
...     """Print a Fibonacci series up to n."""
...     a, b = 0, 1
...     while b < n:
...         print b,
...         a, b = b, a+b
...     # Now call the function we just defined:
...     fib(2000)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987 1597
```

The keyword `def` introduces a function definition. It must be followed by the function name and the parenthesized list of formal parameters. The statements that form the body of the function start at the next line, and must be indented. The first statement of the function body can optionally be a string literal; this string literal is the function’s documentation string, or docstring.

There are tools which use docstrings to automatically produce online or printed documentation, or to let the user interactively browse through code; it's good practice to include docstrings in code that you write, so try to make a habit of it.

The execution of a function introduces a new symbol table used for the local variables of the function. More precisely, all variable assignments in a function store the value in the local symbol table; whereas variable references first look in the local symbol table, then in the global symbol table, and then in the table of built-in names. Thus, global variables cannot be directly assigned a value within a function (unless named in a `global` statement), although they may be referenced.

The actual parameters (arguments) to a function call are introduced in the local symbol table of the called function when it is called; thus, arguments are passed using `call by value` (where the value is always an object reference, not the value of the object). When a function calls another function, a new local symbol table is created for that call.
A function definition introduces the function name in the current symbol table. The value of the function name has a type that is recognized by the interpreter as a user-defined function. This value can be assigned to another name which can then also be used as a function. This serves as a general renaming mechanism:

```
>>> fib
<function fib at 10042ed0>
>>> f = fib
>>> f(100)
1 1 2 3 5 8 13 21 34 55 89
```

You might object that `fib` is not a function but a procedure. In Python, like in C, procedures are just functions that don't return a value. In fact, technically speaking, procedures do return a value, albeit a rather boring one. This value is called `None` (it's a built-in name). Writing the value `None` is normally suppressed by the interpreter if it would be the only value written. You can see it if you really want to:

```
>>> print fib(0)
None
```

It is simple to write a function that returns a list of the numbers of the Fibonacci series, instead of printing it:

```
>>> def fib2(n): # return Fibonacci series up to n
...     """Return a list containing the Fibonacci series up to n.""
...     result = []
...     a, b = 0, 1
...     while b < n:
...         result.append(b)   # see below
...         a, b = b, a+b
...     return result
...
>>> f100 = fib2(100) # call it
>>> f100               # write the result
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
```

This example, as usual, demonstrates some new Python features:

- The `return` statement returns with a value from a function. `return` without an expression argument returns `None`. Falling off the end of a procedure also returns `None`.

- The statement `result.append(b)` calls a `method` of the list object
result. A method is a function that `belongs' to an object and is named `obj.methodname`, where `obj` is some object (this may be an expression), and `methodname` is the name of a method that is defined by the object's type. Different types define different methods. Methods of different types may have the same name without causing ambiguity. (It is possible to define your own object types and methods, using `classes`, as discussed later in this tutorial.) The method `append()` shown in the example is defined for list objects; it adds a new element at the end of the list. In this example it is equivalent to "result = result + [b]", but more efficient.
4.7 More on Defining Functions

It is also possible to define functions with a variable number of arguments. There are three forms, which can be combined.
4.7.1 Default Argument Values

The most useful form is to specify a default value for one or more arguments. This creates a function that can be called with fewer arguments than it is defined to allow. For example:

```python
def ask_ok(prompt, retries=4, complaint='Yes or no, please!'):
    while True:
        ok = raw_input(prompt)
        if ok in ('y', 'ye', 'yes'): return True
        if ok in ('n', 'no', 'nop', 'nope'): return False
        retries = retries - 1
        if retries < 0: raise IOError, 'refusenik user'
        print complaint
```

This function can be called either like this: `ask_ok('Do you really want to quit?')` or like this: `ask_ok('OK to overwrite the file?', 2).

This example also introduces the `in` keyword. This tests whether or not a sequence contains a certain value.

The default values are evaluated at the point of function definition in the defining scope, so that

```python
i = 5
def f(arg=i):
    print arg

i = 6
f()
```

will print 5.

**Important warning:** The default value is evaluated only once. This makes a difference when the default is a mutable object such as a list, dictionary, or instances of most classes. For example, the following function accumulates the arguments passed to it on subsequent calls:

```python
def f(a, L=[]):
    L.append(a)
    return L
```
print f(1)
print f(2)
print f(3)

This will print

[1]
[1, 2]
[1, 2, 3]

If you don't want the default to be shared between subsequent calls, you can write the function like this instead:

def f(a, L=None):
    if L is None:
        L = []
    L.append(a)
    return L
4.7.2 Keyword Arguments

Functions can also be called using keyword arguments of the form "keyword = value". For instance, the following function:

```python
def parrot(voltage, state='a stiff', action='voom', type='Norwegian Blue'):
    print '-- This parrot wouldn\'t', action,
    print 'if you put', voltage, 'volts through it.'
    print '-- Lovely plumage, the', type
    print '-- It\'s', state, '!
```

could be called in any of the following ways:

```python
parrot(1000)
parrot(action = 'V00000M', voltage = 1000000)
parrot('a thousand', state = 'pushing up the daisies')
parrot('a million', 'bereft of life', 'jump')
```

but the following calls would all be invalid:

```python
parrot()               # required argument missing
parrot(voltage=5.0, 'dead') # non-keyword argument following keyword
parrot(110, voltage=220)  # duplicate value for argument
parrot(actor='John Cleese') # unknown keyword
```

In general, an argument list must have any positional arguments followed by any keyword arguments, where the keywords must be chosen from the formal parameter names. It's not important whether a formal parameter has a default value or not. No argument may receive a value more than once -- formal parameter names corresponding to positional arguments cannot be used as keywords in the same calls. Here's an example that fails due to this restriction:

```python
>>> def function(a):
...    pass
...
>>> function(0, a=0)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: function() got multiple values for keyword argument 'a'
```

When a final formal parameter of the form **name is present, it receives a dictionary containing all keyword arguments except for those corresponding to a formal parameter. This may be combined with a formal parameter of the form
*name* (described in the next subsection) which receives a tuple containing the positional arguments beyond the formal parameter list. (*name* must occur before **name.) For example, if we define a function like this:

```python
def cheeseshop(kind, *arguments, **keywords):
    print "-- Do you have any", kind, '?'
    print "-- I'm sorry, we're all out of", kind
    for arg in arguments: print arg
    print '='*40
    keys = keywords.keys()
    keys.sort()
    for kw in keys: print kw, ':', keywords[kw]
```

It could be called like this:

```python
cheeseshop('Limburger', "It's very runny, sir.",
           "It's really very, VERY runny, sir.",
           client='John Cleese',
           shopkeeper='Michael Palin',
           sketch='Cheese Shop Sketch')
```

and of course it would print:

```
-- Do you have any Limburger ?
-- I'm sorry, we're all out of Limburger
It's very runny, sir.
It's really very, VERY runny, sir.
----------------------------------------
client : John Cleese
shopkeeper : Michael Palin
sketch : Cheese Shop Sketch
```

Note that the `sort()` method of the list of keyword argument names is called before printing the contents of the `keywords` dictionary; if this is not done, the order in which the arguments are printed is undefined.
4.7.3 Arbitrary Argument Lists

Finally, the least frequently used option is to specify that a function can be called with an arbitrary number of arguments. These arguments will be wrapped up in a tuple. Before the variable number of arguments, zero or more normal arguments may occur.

    def fprintf(file, format, *args):
        file.write(format % args)
4.7.4 Unpacking Argument Lists

The reverse situation occurs when the arguments are already in a list or tuple but need to be unpacked for a function call requiring separate positional arguments. For instance, the built-in \texttt{range()} function expects separate \textit{start} and \textit{stop} arguments. If they are not available separately, write the function call with the \texttt{*}-operator to unpack the arguments out of a list or tuple:

\begin{verbatim}
>>> range(3, 6)  # normal call with separate arguments
[3, 4, 5]
>>> args = [3, 6]
>>> range(*args)  # call with arguments unpacked from a list
[3, 4, 5]
\end{verbatim}

In the same fashion, dictionaries can deliver keyword arguments with the \texttt{**}-operator:

\begin{verbatim}
>>> def parrot(voltage, state='a stiff', action='voom):
...     print "-- This parrot wouldn't", action,
...     print "if you put", voltage, "volts through it."
...     print "E's", state, "!
...
>>> d = {"voltage": "four million", "state": "bleedin' demised", "ac
>>> parrot(**d)
-- This parrot wouldn't VOOM if you put four million volts through i
\end{verbatim}
4.7.5 Lambda Forms

By popular demand, a few features commonly found in functional programming languages like Lisp have been added to Python. With the `lambda` keyword, small anonymous functions can be created. Here's a function that returns the sum of its two arguments: "\( \text{\texttt{lambda a, b: a+b}} \)". Lambda forms can be used wherever function objects are required. They are syntactically restricted to a single expression. Semantically, they are just syntactic sugar for a normal function definition. Like nested function definitions, lambda forms can reference variables from the containing scope:

```python
>>> def make_incrementor(n):
...    return lambda x: x + n
...
>>> f = make_incrementor(42)
>>> f(0)
42
>>> f(1)
43
```
4.7.6 Documentation Strings

There are emerging conventions about the content and formatting of documentation strings.

The first line should always be a short, concise summary of the object's purpose. For brevity, it should not explicitly state the object's name or type, since these are available by other means (except if the name happens to be a verb describing a function's operation). This line should begin with a capital letter and end with a period.

If there are more lines in the documentation string, the second line should be blank, visually separating the summary from the rest of the description. The following lines should be one or more paragraphs describing the object's calling conventions, its side effects, etc.

The Python parser does not strip indentation from multi-line string literals in Python, so tools that process documentation have to strip indentation if desired. This is done using the following convention. The first non-blank line after the first line of the string determines the amount of indentation for the entire documentation string. (We can't use the first line since it is generally adjacent to the string's opening quotes so its indentation is not apparent in the string literal.) Whitespace ``equivalent'' to this indentation is then stripped from the start of all lines of the string. Lines that are indented less should not occur, but if they occur all their leading whitespace should be stripped. Equivalence of whitespace should be tested after expansion of tabs (to 8 spaces, normally).

Here is an example of a multi-line docstring:

```python
def my_function():
    ...       """Do nothing, but document it.
    ...
    ...     No, really, it doesn't do anything.
    ...
    ...     """
    ...
    ...     pass
    ...     
    >>> print my_function.__doc__
    Do nothing, but document it.
    No, really, it doesn't do anything.
```
Footnotes

... object).\footnote{4.1}

Actually, \textit{call by object reference} would be a better description, since if a mutable object is passed, the caller will see any changes the callee makes to it (items inserted into a list).

5. Data Structures

This chapter describes some things you've learned about already in more detail, and adds some new things as well.
5.1 More on Lists

The list data type has some more methods. Here are all of the methods of list objects:

**append**(*x*)

Add an item to the end of the list; equivalent to `a[len(a):] = [x]`.

**extend**(*L*)

Extend the list by appending all the items in the given list; equivalent to `a[len(a):] = L`.

**insert**(*i, x*)

Insert an item at a given position. The first argument is the index of the element before which to insert, so `a.insert(0, x)` inserts at the front of the list, and `a.insert(len(a), x)` is equivalent to `a.append(x)`.

**remove**(*x*)

Remove the first item from the list whose value is *x*. It is an error if there is no such item.

**pop**([*i]*)

Remove the item at the given position in the list, and return it. If no index is specified, `a.pop()` removes and returns the last item in the list. The item is also removed from the list. (The square brackets around the *i* in the method signature denote that the parameter is optional, not that you should type square brackets at that position. You will see this notation frequently in the [Python Library Reference](https://docs.python.org/3/library/stdtypes.html#sequence-types-tuple-list-dict).

**index**(*x*)

Return the index in the list of the first item whose value is *x*. It is an error if there is no such item.

**count**(*x*)
Return the number of times x appears in the list.

**sort()**

Sort the items of the list, in place.

**reverse()**

Reverse the elements of the list, in place.

An example that uses most of the list methods:

```python
>>> a = [66.25, 333, 333, 1, 1234.5]
>>> print a.count(333), a.count(66.25), a.count('x')
2 1 0
>>> a.insert(2, -1)
>>> a.append(333)
>>> a
[66.25, 333, -1, 333, 1, 1234.5, 333]
>>> a.index(333)
1
>>> a.remove(333)
>>> a
[66.25, -1, 333, 1, 1234.5, 333]
>>> a.reverse()
>>> a
[333, 1234.5, 1, 333, -1, 66.25]
>>> a.sort()
>>> a
[-1, 1, 66.25, 333, 333, 1234.5]
```
5.1.1 Using Lists as Stacks

The list methods make it very easy to use a list as a stack, where the last element added is the first element retrieved ("last-in, first-out"). To add an item to the top of the stack, use `append()`. To retrieve an item from the top of the stack, use `pop()` without an explicit index. For example:

```python
>>> stack = [3, 4, 5]
>>> stack.append(6)
>>> stack.append(7)
>>> stack
[3, 4, 5, 6, 7]
>>> stack.pop()
7
>>> stack
[3, 4, 5, 6]
>>> stack.pop()
6
>>> stack.pop()
5
>>> stack
[3, 4]
```
5.1.2 Using Lists as Queues

You can also use a list conveniently as a queue, where the first element added is the first element retrieved (``first-in, first-out''). To add an item to the back of the queue, use `append()` . To retrieve an item from the front of the queue, use `pop( )` with 0 as the index. For example:

```python
>>> queue = ["Eric", "John", "Michael"]
>>> queue.append("Terry")            # Terry arrives
>>> queue.append("Graham")           # Graham arrives
>>> queue.pop(0)                     # Eric
'Eric'
>>> queue.pop(0)                     # John
'John'
>>> queue                           # ['Michael', 'Terry', 'Graham']
['Michael', 'Terry', 'Graham']
```
5.1.3 Functional Programming Tools

There are three built-in functions that are very useful when used with lists: \texttt{filter()}, \texttt{map()}, and \texttt{reduce()}.

"\texttt{filter(function, sequence)}" returns a sequence consisting of those items from the sequence for which \texttt{function(item)} is true. If \texttt{sequence} is a \texttt{string} or \texttt{tuple}, the result will be of the same type; otherwise, it is always a \texttt{list}. For example, to compute some primes:

```python
>>> def f(x): return x % 2 != 0 and x % 3 != 0
... >>> filter(f, range(2, 25))
[5, 7, 11, 13, 17, 19, 23]
```

"\texttt{map(function, sequence)}" calls \texttt{function(item)} for each of the sequence's items and returns a list of the return values. For example, to compute some cubes:

```python
>>> def cube(x): return x*x*x
... >>> map(cube, range(1, 11))
[1, 8, 27, 64, 125, 216, 343, 512, 729, 1000]
```

More than one sequence may be passed; the function must then have as many arguments as there are sequences and is called with the corresponding item from each sequence (or \texttt{None} if some sequence is shorter than another). For example:

```python
>>> seq = range(8)
>>> def add(x, y): return x+y
... >>> map(add, seq, seq)
[0, 2, 4, 6, 8, 10, 12, 14]
```

"\texttt{reduce(function, sequence)}" returns a single value constructed by calling the binary function \texttt{function} on the first two items of the sequence, then on the result and the next item, and so on. For example, to compute the sum of the numbers 1 through 10:

```python
>>> def add(x,y): return x+y
... >>> reduce(add, range(1, 11))
```
If there's only one item in the sequence, its value is returned; if the sequence is empty, an exception is raised.

A third argument can be passed to indicate the starting value. In this case the starting value is returned for an empty sequence, and the function is first applied to the starting value and the first sequence item, then to the result and the next item, and so on. For example,

```python
def sum(seq):
    ... def add(x, y): return x+y
    ... return reduce(add, seq, 0)
    ...
    >>> sum(range(1, 11))
    55
    >>> sum([])
    0
```

Don't use this example's definition of `sum()`: since summing numbers is such a common need, a built-in function `sum(sequence)` is already provided, and works exactly like this. New in version 2.3.
5.1.4 List Comprehensions

List comprehensions provide a concise way to create lists without resorting to use of `map()`, `filter()` and/or `lambda`. The resulting list definition tends often to be clearer than lists built using those constructs. Each list comprehension consists of an expression followed by a `for` clause, then zero or more `for` or `if` clauses. The result will be a list resulting from evaluating the expression in the context of the `for` and `if` clauses which follow it. If the expression would evaluate to a tuple, it must be parenthesized.

```python
>>> freshfruit = ['banana', 'loganberry', 'passion fruit ']
>>> [weapon.strip() for weapon in freshfruit]
['banana', 'loganberry', 'passion fruit ']
>>> vec = [2, 4, 6]
>>> [3*x for x in vec]
[6, 12, 18]
>>> [3*x for x in vec if x > 3]
[12, 18]
>>> [3*x for x in vec if x < 2]
[]
>>> [[x, x**2] for x in vec]  # error - parens required for tuples
File "<stdin>", line 1, in ?
  [x, x**2 for x in vec]
^ SyntaxError: invalid syntax
>>> [(x, x**2) for x in vec]
[(2, 4), (4, 16), (6, 36)]
>>> vec1 = [2, 4, 6]
>>> vec2 = [4, 3, -9]
>>> [x*y for x in vec1 for y in vec2]
[8, 6, -18, 16, 12, -36, 24, 18, -54]
>>> [x+y for x in vec1 for y in vec2]
[6, 5, -7, 8, 7, -5, 10, 9, -3]
>>> [vec1[i]*vec2[i] for i in range(len(vec1))]
[8, 12, -54]
```

List comprehensions are much more flexible than `map()` and can be applied to complex expressions and nested functions:

```python
>>> [str(round(355/113.0, i)) for i in range(1,6)]
['3.1', '3.14', '3.142', '3.1416', '3.14159']
```
5.2 The del statement

There is a way to remove an item from a list given its index instead of its value: the del statement. Unlike the pop() method which returns a value, the del keyword is a statement and can also be used to remove slices from a list (which we did earlier by assignment of an empty list to the slice). For example:

```python
>>> a = [-1, 1, 66.25, 333, 333, 1234.5]
>>> del a[0]
>>> a
[1, 66.25, 333, 333, 1234.5]
>>> del a[2:4]
>>> a
[1, 66.25, 1234.5]
```

del can also be used to delete entire variables:

```python
>>> del a
```

Referencing the name a hereafter is an error (at least until another value is assigned to it). We'll find other uses for del later.
5.3 Tuples and Sequences

We saw that lists and strings have many common properties, such as indexing and slicing operations. They are two examples of sequence data types. Since Python is an evolving language, other sequence data types may be added. There is also another standard sequence data type: the tuple.

A tuple consists of a number of values separated by commas, for instance:

```python
>>> t = 12345, 54321, 'hello!
>>>
>>> t[0]
12345
>>> t
(12345, 54321, 'hello!')
>>> # Tuples may be nested:
... u = t, (1, 2, 3, 4, 5)
>>> u
((12345, 54321, 'hello!'), (1, 2, 3, 4, 5))
```

As you see, output tuples are always enclosed in parentheses, so that nested tuples are interpreted correctly; they may be input with or without surrounding parentheses, although often parentheses are necessary anyway (if the tuple is part of a larger expression).

Tuples have many uses. For example: (x, y) coordinate pairs, employee records from a database, etc. Tuples, like strings, are immutable: it is not possible to assign to the individual items of a tuple (you can simulate much of the same effect with slicing and concatenation, though). It is also possible to create tuples which contain mutable objects, such as lists.

A special problem is the construction of tuples containing 0 or 1 items: the syntax has some extra quirks to accommodate these. Empty tuples are constructed by an empty pair of parentheses; a tuple with one item is constructed by following a value with a comma (it is not sufficient to enclose a single value in parentheses). Ugly, but effective. For example:

```python
>>> empty = ()
>>> singleton = 'hello',  # <-- note trailing comma
```
>>> singleton
('hello',)

The statement \( t = 12345, 54321, 'hello!' \) is an example of \textit{tuple packing}: the values 12345, 54321 and 'hello!' are packed together in a tuple. The reverse operation is also possible:

>>> x, y, z = t

This is called, appropriately enough, \textit{sequence unpacking}. Sequence unpacking requires the list of variables on the left to have the same number of elements as the length of the sequence. Note that multiple assignment is really just a combination of tuple packing and sequence unpacking!

There is a small bit of asymmetry here: packing multiple values always creates a tuple, and unpacking works for any sequence.
5.4 Sets

Python also includes a data type for sets. A set is an unordered collection with no duplicate elements. Basic uses include membership testing and eliminating duplicate entries. Set objects also support mathematical operations like union, intersection, difference, and symmetric difference.

Here is a brief demonstration:

```python
>>> basket = ['apple', 'orange', 'apple', 'pear', 'orange', 'banana']
>>> fruit = set(basket)  # create a set without duplicates
>>> fruit
set(['orange', 'pear', 'apple', 'banana'])
>>> 'orange' in fruit  # fast membership testing
True
>>> 'crabgrass' in fruit
False

>>> # Demonstrate set operations on unique letters from two words
... >>> a = set('abracadabra')
... >>> b = set('alacazam')
... >>> a                   # unique letters in a
set(['a', 'r', 'b', 'c', 'd'])
>>> a - b               # letters in a but not in b
set(['r', 'd', 'b'])
>>> a | b               # letters in either a or b
set(['a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'])
>>> a & b               # letters in both a and b
set(['a', 'c'])
>>> a ^ b               # letters in a or b but not b
set(['r', 'd', 'b', 'm', 'z', 'l'])
```
Another useful data type built into Python is the dictionary. Dictionaries are sometimes found in other languages as "associative memories" or "associative arrays". Unlike sequences, which are indexed by a range of numbers, dictionaries are indexed by keys, which can be any immutable type; strings and numbers can always be keys. Tuples can be used as keys if they contain only strings, numbers, or tuples; if a tuple contains any mutable object either directly or indirectly, it cannot be used as a key. You can't use lists as keys, since lists can be modified in place using methods like `append()` and `extend()` or modified with slice and indexed assignments.

It is best to think of a dictionary as an unordered set of key: value pairs, with the requirement that the keys are unique (within one dictionary). A pair of braces creates an empty dictionary: `{}`. Placing a comma-separated list of key:value pairs within the braces adds initial key:value pairs to the dictionary; this is also the way dictionaries are written on output.

The main operations on a dictionary are storing a value with some key and extracting the value given the key. It is also possible to delete a key:value pair with `del`. If you store using a key that is already in use, the old value associated with that key is forgotten. It is an error to extract a value using a non-existent key.

The `keys()` method of a dictionary object returns a list of all the keys used in the dictionary, in arbitrary order (if you want it sorted, just apply the `sort()` method to the list of keys). To check whether a single key is in the dictionary, either use the dictionary's `has_key()` method or the `in` keyword.

Here is a small example using a dictionary:

```python
>>> tel = {'jack': 4098, 'sape': 4139}
>>> tel['guido'] = 4127
>>> tel
{'sape': 4139, 'guido': 4127, 'jack': 4098}
>>> tel['jack']
4098
>>> del tel['sape']
>>> tel['irv'] = 4127
```
>>> tel
{'guido': 4127, 'irv': 4127, 'jack': 4098}
>>> tel.keys()
['guido', 'irv', 'jack']
>>> tel.has_key('guido')
True
>>> 'guido' in tel
True

The `dict()` constructor builds dictionaries directly from lists of key-value pairs stored as tuples. When the pairs form a pattern, list comprehensions can compactly specify the key-value list.

```python
>>> dict([('sape', 4139), ('guido', 4127), ('jack', 4098)])
{'sape': 4139, 'jack': 4098, 'guido': 4127}
>>> dict([(x, x**2) for x in (2, 4, 6)])  # use a list comprehension
{2: 4, 4: 16, 6: 36}
```

Later in the tutorial, we will learn about Generator Expressions which are even better suited for the task of supplying key-values pairs to the `dict()` constructor.

When the keys are simple strings, it is sometimes easier to specify pairs using keyword arguments:

```python
>>> dict(sape=4139, guido=4127, jack=4098)
{'sape': 4139, 'jack': 4098, 'guido': 4127}
```
5.6 Looping Techniques

When looping through dictionaries, the key and corresponding value can be retrieved at the same time using the `iteritems()` method.

```python
>>> knights = {'gallahad': 'the pure', 'robin': 'the brave'}
>>> for k, v in knights.iteritems():
...    print k, v
...
gallahad the pure
robin the brave
```

When looping through a sequence, the position index and corresponding value can be retrieved at the same time using the `enumerate()` function.

```python
>>> for i, v in enumerate(['tic', 'tac', 'toe']):
...    print i, v
...
0 tic
1 tac
2 toe
```

To loop over two or more sequences at the same time, the entries can be paired with the `zip()` function.

```python
>>> questions = ['name', 'quest', 'favorite color']
>>> answers = ['lancelot', 'the holy grail', 'blue']
>>> for q, a in zip(questions, answers):
...    print 'What is your %s?  It is %s.' % (q, a)
...
What is your name?  It is lancelot.
What is your quest?  It is the holy grail.
What is your favorite color?  It is blue.
```

To loop over a sequence in reverse, first specify the sequence in a forward direction and then call the `reversed()` function.

```python
>>> for i in reversed(xrange(1,10,2)):
...    print i
...
9
7
5
3
```
To loop over a sequence in sorted order, use the `sorted()` function which returns a new sorted list while leaving the source unaltered.

```python
>>> basket = ['apple', 'orange', 'apple', 'pear', 'orange', 'banana']
>>> for f in sorted(set(basket)):
...    print f
...  apple
  banana
  orange
  pear
```
5.7 More on Conditions

The conditions used in while and if statements can contain any operators, not just comparisons.

The comparison operators in and not in check whether a value occurs (does not occur) in a sequence. The operators is and is not compare whether two objects are really the same object; this only matters for mutable objects like lists. All comparison operators have the same priority, which is lower than that of all numerical operators.

Comparisons can be chained. For example, a < b == c tests whether a is less than b and moreover b equals c.

Comparisons may be combined using the Boolean operators and and or, and the outcome of a comparison (or of any other Boolean expression) may be negated with not. These have lower priorities than comparison operators; between them, not has the highest priority and or the lowest, so that A and not B or C is equivalent to (A and (not B)) or C. As always, parentheses can be used to express the desired composition.

The Boolean operators and and or are so-called short-circuit operators: their arguments are evaluated from left to right, and evaluation stops as soon as the outcome is determined. For example, if A and C are true but B is false, A and B and C does not evaluate the expression C. When used as a general value and not as a Boolean, the return value of a short-circuit operator is the last evaluated argument.

It is possible to assign the result of a comparison or other Boolean expression to a variable. For example,

```python
>>> string1, string2, string3 = '', 'Trondheim', 'Hammer Dance'
>>> non_null = string1 or string2 or string3
>>> non_null
'Trondheim'
```

Note that in Python, unlike C, assignment cannot occur inside expressions. C programmers may grumble about this, but it avoids a common class of problems
encountered in C programs: typing = in an expression when == was intended.
5.8 Comparing Sequences and Other Types

Sequence objects may be compared to other objects with the same sequence type. The comparison uses lexicographical ordering: first the first two items are compared, and if they differ this determines the outcome of the comparison; if they are equal, the next two items are compared, and so on, until either sequence is exhausted. If two items to be compared are themselves sequences of the same type, the lexicographical comparison is carried out recursively. If all items of two sequences compare equal, the sequences are considered equal. If one sequence is an initial sub-sequence of the other, the shorter sequence is the smaller (lesser) one. Lexicographical ordering for strings uses the ASCII ordering for individual characters. Some examples of comparisons between sequences of the same type:

(1, 2, 3) < (1, 2, 4)  
[1, 2, 3] < [1, 2, 4]  
'ABC' < 'C' < 'Pascal' < 'Python'  
(1, 2, 3, 4) < (1, 2, 4)  
(1, 2) < (1, 2, -1)  
(1, 2, 3) == (1.0, 2.0, 3.0)  
(1, 2, ('aa', 'ab')) < (1, 2, ('abc', 'a'), 4)

Note that comparing objects of different types is legal. The outcome is deterministic but arbitrary: the types are ordered by their name. Thus, a list is always smaller than a string, a string is always smaller than a tuple, etc. The rules for comparing objects of different types should not be relied upon; they may change in a future version of the language.

6. Modules

If you quit from the Python interpreter and enter it again, the definitions you have made (functions and variables) are lost. Therefore, if you want to write a somewhat longer program, you are better off using a text editor to prepare the input for the interpreter and running it with that file as input instead. This is known as creating a script. As your program gets longer, you may want to split it into several files for easier maintenance. You may also want to use a handy function that you've written in several programs without copying its definition into each program.

To support this, Python has a way to put definitions in a file and use them in a script or in an interactive instance of the interpreter. Such a file is called a module; definitions from a module can be imported into other modules or into the main module (the collection of variables that you have access to in a script executed at the top level and in calculator mode).

A module is a file containing Python definitions and statements. The file name is the module name with the suffix .py appended. Within a module, the module's name (as a string) is available as the value of the global variable __name__. For instance, use your favorite text editor to create a file called fibo.py in the current directory with the following contents:

```python
# Fibonacci numbers module

def fib(n):  # write Fibonacci series up to n
    a, b = 0, 1
    while b < n:
        print b,
        a, b = b, a+b

def fib2(n):  # return Fibonacci series up to n
    result = []
    a, b = 0, 1
    while b < n:
        result.append(b)
        a, b = b, a+b
    return result
```

Now enter the Python interpreter and import this module with the following command:
>>> import fibo

This does not enter the names of the functions defined in `fibo` directly in the current symbol table; it only enters the module name `fibo` there. Using the module name you can access the functions:

```python
>>> fibo.fib(1000)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
>>> fibo.fib2(100)
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
>>> fibo.__name__
'fibo'
```

If you intend to use a function often you can assign it to a local name:

```python
>>> fib = fibo.fib
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 987
```
6.1 More on Modules

A module can contain executable statements as well as function definitions. These statements are intended to initialize the module. They are executed only the first time the module is imported somewhere.\footnote{\texttt{modules}}

Each module has its own private symbol table, which is used as the global symbol table by all functions defined in the module. Thus, the author of a module can use global variables in the module without worrying about accidental clashes with a user's global variables. On the other hand, if you know what you are doing you can touch a module's global variables with the same notation used to refer to its functions, \texttt{modname.itemname}.

Modules can import other modules. It is customary but not required to place all \texttt{import} statements at the beginning of a module (or script, for that matter). The imported module names are placed in the importing module's global symbol table.

There is a variant of the \texttt{import} statement that imports names from a module directly into the importing module's symbol table. For example:

\begin{verbatim}
>>> from fibo import fib, fib2
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
\end{verbatim}

This does not introduce the module name from which the imports are taken in the local symbol table (so in the example, \texttt{fibo} is not defined).

There is even a variant to import all names that a module defines:

\begin{verbatim}
>>> from fibo import *
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
\end{verbatim}

This imports all names except those beginning with an underscore (\_).
6.1.1 The Module Search Path

When a module named spam is imported, the interpreter searches for a file named spam.py in the current directory, and then in the list of directories specified by the environment variable PYTHONPATH. This has the same syntax as the shell variable PATH, that is, a list of directory names. When PYTHONPATH is not set, or when the file is not found there, the search continues in an installation-dependent default path; on UNIX, this is usually .:/usr/local/lib/python.

Actually, modules are searched in the list of directories given by the variable sys.path which is initialized from the directory containing the input script (or the current directory), PYTHONPATH and the installation-dependent default. This allows Python programs that know what they're doing to modify or replace the module search path. Note that because the directory containing the script being run is on the search path, it is important that the script not have the same name as a standard module, or Python will attempt to load the script as a module when that module is imported. This will generally be an error. See section 6.2, ``Standard Modules,'' for more information.
6.1.2 ```Compiled'' Python files

As an important speed-up of the start-up time for short programs that use a lot of standard modules, if a file called spam.pyc exists in the directory where spam.py is found, this is assumed to contain an already-``byte-compiled'' version of the module spam. The modification time of the version of spam.py used to create spam.pyc is recorded in spam.pyc, and the .pyc file is ignored if these don't match.

Normally, you don't need to do anything to create the spam.pyc file. Whenever spam.py is successfully compiled, an attempt is made to write the compiled version to spam.pyc. It is not an error if this attempt fails; if for any reason the file is not written completely, the resulting spam.pyc file will be recognized as invalid and thus ignored later. The contents of the spam.pyc file are platform independent, so a Python module directory can be shared by machines of different architectures.

Some tips for experts:

- When the Python interpreter is invoked with the -O flag, optimized code is generated and stored in .pyo files. The optimizer currently doesn't help much; it only removes assert statements. When -O is used, all bytecode is optimized; .pyc files are ignored and .py files are compiled to optimized bytecode.

- Passing two -O flags to the Python interpreter (-OO) will cause the bytecode compiler to perform optimizations that could in some rare cases result in malfunctioning programs. Currently only __doc__ strings are removed from the bytecode, resulting in more compact .pyo files. Since some programs may rely on having these available, you should only use this option if you know what you're doing.

- A program doesn't run any faster when it is read from a .pyc or .pyo file than when it is read from a .py file; the only thing that's faster about .pyc or .pyo files is the speed with which they are loaded.

- When a script is run by giving its name on the command line, the bytecode for the script is never written to a .pyc or .pyo file. Thus, the startup time of
a script may be reduced by moving most of its code to a module and having a small bootstrap script that imports that module. It is also possible to name a .pyc or .pyo file directly on the command line.

- It is possible to have a file called spam.pyc (or spam.pyo when -O is used) without a file spam.py for the same module. This can be used to distribute a library of Python code in a form that is moderately hard to reverse engineer.

- The module compileall can create .pyc files (or .pyo files when -O is used) for all modules in a directory.
6.2 Standard Modules

Python comes with a library of standard modules, described in a separate document, the *Python Library Reference* ("Library Reference" hereafter). Some modules are built into the interpreter; these provide access to operations that are not part of the core of the language but are nevertheless built in, either for efficiency or to provide access to operating system primitives such as system calls. The set of such modules is a configuration option which also depends on the underlying platform. For example, the *amoeba* module is only provided on systems that somehow support Amoeba primitives. One particular module deserves some attention: *sys*, which is built into every Python interpreter. The variables *sys.ps1* and *sys.ps2* define the strings used as primary and secondary prompts:

```python
>>> import sys
>>> sys.ps1
'>>>
>>> sys.ps2
'...
>>> sys.ps1 = 'C> '
C> print 'Yuck!'
Yuck!
C>
```

These two variables are only defined if the interpreter is in interactive mode.

The variable *sys.path* is a list of strings that determines the interpreter's search path for modules. It is initialized to a default path taken from the environment variable PYTHONPATH, or from a built-in default if PYTHONPATH is not set. You can modify it using standard list operations:

```python
>>> import sys
>>> sys.path.append('/ufs/guido/lib/python')
```
6.3 The dir() Function

The built-in function `dir()` is used to find out which names a module defines. It returns a sorted list of strings:

```python
>>> import fibo, sys
>>> dir(fibo)
['__name__', 'fib', 'fib2']
>>> dir(sys)
['__displayhook__', '__doc__', '__excepthook__', '__name__', '__stde
'stdin__', '__stdout__', '_getframe', 'api_version', 'argv', 'builtin_module_names', 'byteorder', 'callstats', 'copyright',
'displayhook', 'exc_clear', 'exc_info', 'exc_type', 'exc_value',
'exec_prefix', 'modules', 'path', 'path_hooks', 'path_importer_cache' 'platform', 'prefix', 'ps1', 'ps2', 'setcheckinterval', 'setdlopenf
'setprofile', 'setrecursionlimit', 'settrace', 'stderr', 'stdin', '
'version', 'version_info', 'warnoptions']
```

Without arguments, `dir()` lists the names you have defined currently:

```python
>>> a = [1, 2, 3, 4, 5]
>>> import fibo
>>> fib = fibo.fib
>>> dir()
['__builtins__', '__doc__', '__file__', '__name__', 'a', 'fib', 'fibo']
```

Note that it lists all types of names: variables, modules, functions, etc.

dir() does not list the names of built-in functions and variables. If you want a list of those, they are defined in the standard module `__builtin__`:

```python
>>> import __builtin__
>>> dir(__builtin__
['ArithmeticError', 'AssertionError', 'AttributeError', 'Deprecation
'EOFError', 'Ellipsis', 'EnvironmentError', 'Exception', 'False',
'FloatingPointError', 'FutureWarning', 'IOError', 'ImportError',
'IndentationError', 'IndexError', 'KeyError', 'KeyboardInterrupt',
'LookupError', 'MemoryError', 'NameError', 'None', 'NotImplemented'
'NotImplementedError', 'OSError', 'OverflowError', 'OverflowWarning
'PendingDeprecationWarning', 'ReferenceError', 'RuntimeError',
'RuntimeWarning', 'StandardError', 'StopIteration', 'SyntaxError',
'SyntaxWarning', 'SystemError', 'SystemExit', 'TabError', 'True',
'TypeError', 'UnboundLocalError', 'UnicodeDecodeError',
```

Packages are a way of structuring Python's module namespace by using `dotted module names`. For example, the module name `A.B` designates a submodule named "B" in a package named "A". Just like the use of modules saves the authors of different modules from having to worry about each other's global variable names, the use of dotted module names saves the authors of multi-module packages like NumPy or the Python Imaging Library from having to worry about each other's module names.

Suppose you want to design a collection of modules (a ``package``) for the uniform handling of sound files and sound data. There are many different sound file formats (usually recognized by their extension, for example: `.wav`, `.aiff`, `.au`), so you may need to create and maintain a growing collection of modules for the conversion between the various file formats. There are also many different operations you might want to perform on sound data (such as mixing, adding echo, applying an equalizer function, creating an artificial stereo effect), so in addition you will be writing a never-ending stream of modules to perform these operations. Here's a possible structure for your package (expressed in terms of a hierarchical filesystem):

```plaintext
Sound/
    __init__.py
    Formats/
        __init__.py
        wavread.py
        wavwrite.py
        aiffread.py
        aiffwrite.py
        auread.py
        auwrite.py
        ...
    Effects/
        __init__.py
        echo.py
        surround.py
        reverse.py
        ...
    Filters/
        __init__.py
        equalizer.py
        vocoder.py
```

- **Top-level package**: Initialize the sound package
- **Subpackage for file format conversions**
- **Subpackage for sound effects**
- **Subpackage for filters**
When importing the package, Python searches through the directories on `sys.path` looking for the package subdirectory.

The `__init__.py` files are required to make Python treat the directories as containing packages; this is done to prevent directories with a common name, such as "string", from unintentionally hiding valid modules that occur later on the module search path. In the simplest case, `__init__.py` can just be an empty file, but it can also execute initialization code for the package or set the `__all__` variable, described later.

Users of the package can import individual modules from the package, for example:

```python
import Sound.Effects.echo
```

This loads the submodule `Sound.Effects.echo`. It must be referenced with its full name.

```python
Sound.Effects.echo.echofilter(input, output, delay=0.7, atten=4)
```

An alternative way of importing the submodule is:

```python
from Sound.Effects import echo
```

This also loads the submodule `echo`, and makes it available without its package prefix, so it can be used as follows:

```python
echo.echofilter(input, output, delay=0.7, atten=4)
```

Yet another variation is to import the desired function or variable directly:

```python
from Sound.Effects.echo import echofilter
```

Again, this loads the submodule `echo`, but this makes its function `echofilter()` directly available:

```python
echofilter(input, output, delay=0.7, atten=4)
```

Note that when using `from package import item`, the item can be either a
submodule (or subpackage) of the package, or some other name defined in the package, like a function, class or variable. The `import` statement first tests whether the item is defined in the package; if not, it assumes it is a module and attempts to load it. If it fails to find it, an `ImportError` exception is raised.

Contrarily, when using syntax like `import item.subitem.subsubitem`, each item except for the last must be a package; the last item can be a module or a package but can't be a class or function or variable defined in the previous item.
6.4.1 Importing * From a Package

Now what happens when the user writes from Sound.Effects import *? Ideally, one would hope that this somehow goes out to the filesystem, finds which submodules are present in the package, and imports them all. Unfortunately, this operation does not work very well on Mac and Windows platforms, where the filesystem does not always have accurate information about the case of a filename! On these platforms, there is no guaranteed way to know whether a file ECHO.PY should be imported as a module echo, Echo or ECHO. (For example, Windows 95 has the annoying practice of showing all file names with a capitalized first letter.) The DOS 8+3 filename restriction adds another interesting problem for long module names.

The only solution is for the package author to provide an explicit index of the package. The import statement uses the following convention: if a package's __init__.py code defines a list named __all__, it is taken to be the list of module names that should be imported when from package import * is encountered. It is up to the package author to keep this list up-to-date when a new version of the package is released. Package authors may also decide not to support it, if they don't see a use for importing * from their package. For example, the file Sounds/Effects/__init__.py could contain the following code:

```python
__all__ = ["echo", "surround", "reverse"]
```

This would mean that from Sound.Effects import * would import the three named submodules of the Sound package.

If __all__ is not defined, the statement from Sound.Effects import * does not import all submodules from the package Sound.Effects into the current namespace; it only ensures that the package Sound.Effects has been imported (possibly running any initialization code in __init__.py) and then imports whatever names are defined in the package. This includes any names defined (and submodules explicitly loaded) by __init__.py. It also includes any submodules of the package that were explicitly loaded by previous import statements. Consider this code:

```python
import Sound.Effects.echo
import Sound.Effects.surround
```
from Sound.Effects import *

In this example, the echo and surround modules are imported in the current namespace because they are defined in the `Sound.Effects` package when the `from...import` statement is executed. (This also works when `__all__` is defined.)

Note that in general the practice of importing * from a module or package is frowned upon, since it often causes poorly readable code. However, it is okay to use it to save typing in interactive sessions, and certain modules are designed to export only names that follow certain patterns.

Remember, there is nothing wrong with using `from Package import specific_submodule`! In fact, this is the recommended notation unless the importing module needs to use submodules with the same name from different packages.
6.4.2 Intra-package References

The submodules often need to refer to each other. For example, the `surround` module might use the `echo` module. In fact, such references are so common that the `import` statement first looks in the containing package before looking in the standard module search path. Thus, the `surround` module can simply use `import echo` or `from echo import echofilter`. If the imported module is not found in the current package (the package of which the current module is a submodule), the `import` statement looks for a top-level module with the given name.

When packages are structured into subpackages (as with the `Sound` package in the example), there's no shortcut to refer to submodules of sibling packages - the full name of the subpackage must be used. For example, if the module `Sound.Filters.vocoder` needs to use the `echo` module in the `Sound.Effects` package, it can use `from Sound.Effects import echo`. 
6.4.3 Packages in Multiple Directories

Packages support one more special attribute, \_\_path\_. This is initialized to be a list containing the name of the directory holding the package's \_\_init\_.py before the code in that file is executed. This variable can be modified; doing so affects future searches for modules and subpackages contained in the package.

While this feature is not often needed, it can be used to extend the set of modules found in a package.

---

Footnotes

... somewhere.\footnote{6.1}

In fact function definitions are also `statements' that are `executed'; the execution enters the function name in the module's global symbol table.

Python Tutorial

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
Subsections

- 7.1 Fancier Output Formatting
- 7.2 Reading and Writing Files
  - 7.2.1 Methods of File Objects
  - 7.2.2 The pickle Module
There are several ways to present the output of a program; data can be printed in a human-readable form, or written to a file for future use. This chapter will discuss some of the possibilities.
7.1 Fancier Output Formatting

So far we've encountered two ways of writing values: expression statements and the print statement. (A third way is using the write() method of file objects; the standard output file can be referenced as sys.stdout. See the Library Reference for more information on this.)

Often you'll want more control over the formatting of your output than simply printing space-separated values. There are two ways to format your output; the first way is to do all the string handling yourself; using string slicing and concatenation operations you can create any layout you can imagine. The standard module string contains some useful operations for padding strings to a given column width; these will be discussed shortly. The second way is to use the % operator with a string as the left argument. The % operator interprets the left argument much like a sprintf()-style format string to be applied to the right argument, and returns the string resulting from this formatting operation.

One question remains, of course: how do you convert values to strings? Luckily, Python has ways to convert any value to a string: pass it to the repr() or str() functions. Reverse quotes (``) are equivalent to repr(), but they are no longer used in modern Python code and will likely not be in future versions of the language.

The str() function is meant to return representations of values which are fairly human-readable, while repr() is meant to generate representations which can be read by the interpreter (or will force a SyntaxError if there is not equivalent syntax). For objects which don't have a particular representation for human consumption, str() will return the same value as repr(). Many values, such as numbers or structures like lists and dictionaries, have the same representation using either function. Strings and floating point numbers, in particular, have two distinct representations.

Some examples:

```python
>>> s = 'Hello, world.'
>>> str(s)
'Hello, world.'
>>> repr(s)
'Hello, world.'
```
"'Hello, world.'"

```python
>>> str(0.1)
'0.1'
>>> repr(0.1)
'0.10000000000000001'
>>> x = 10 * 3.25
>>> y = 200 * 200
>>> s = 'The value of x is ' + repr(x) + ', and y is ' + repr(y) + '
>>> print s
The value of x is 32.5, and y is 40000...
>>> # The repr() of a string adds string quotes and backslashes:
... hello = 'hello, world\n'
>>> hellos = repr(hello)
>>> print hellos
'hello, world\n'
>>> # The argument to repr() may be any Python object:
... repr((x, y, ('spam', 'eggs')))
'(32.5, 40000, ('spam', 'eggs'))'
>>> # reverse quotes are convenient in interactive sessions:
... `x, y, ('spam', 'eggs')`
'(32.5, 40000, ('spam', 'eggs'))'
```

Here are two ways to write a table of squares and cubes:

```python
>>> for x in range(1, 11):
...     print repr(x).rjust(2), repr(x*x).rjust(3),
...     # Note trailing comma on previous line
...     print repr(x*x*x).rjust(4)
...
   1   1   1
   2   4   8
   3   9  27
   4  16  64
   5  25 125
   6  36 216
   7  49 343
   8  64 512
   9  81 729
  10 100 1000

>>> for x in range(1, 11):
...     print '%2d %3d %4d' % (x, x*x, x*x*x)
...
   1   1   1
   2   4   8
   3   9  27
   4  16  64
   5  25 125
   6  36 216
   7  49 343
   8  64 512
   9  81 729
(Note that in the first example, one space between each column was added by the way print works: it always adds spaces between its arguments.)

This example demonstrates the `rjust()` method of string objects, which right-justifies a string in a field of a given width by padding it with spaces on the left. There are similar methods `ljust()` and `center()`. These methods do not write anything, they just return a new string. If the input string is too long, they don't truncate it, but return it unchanged; this will mess up your column lay-out but that's usually better than the alternative, which would be lying about a value. (If you really want truncation you can always add a slice operation, as in "x.ljust(n)[:n].")

There is another method, `zfill()`, which pads a numeric string on the left with zeros. It understands about plus and minus signs:

```python
>>> '12'.zfill(5)
'00012'
>>> '-3.14'.zfill(7)
'-003.14'
>>> '3.14159265359'.zfill(5)
'3.14159265359'
```

Using the % operator looks like this:

```python
>>> import math
test: 'The value of PI is approximately %5.3f.' % math.pi
The value of PI is approximately 3.142.
```

If there is more than one format in the string, you need to pass a tuple as right operand, as in this example:

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 7678}
>>> for name, phone in table.items():
...    print '%-10s ==> %10d' % (name, phone)
...Jack        ==>        4098
Dcab        ==>        7678
Sjoerd      ==>        4127
```

Most formats work exactly as in C and require that you pass the proper type; however, if you don't you get an exception, not a core dump. The %S format is more relaxed: if the corresponding argument is not a string object, it is converted
to string using the `str()` built-in function. Using * to pass the width or precision in as a separate (integer) argument is supported. The C formats `%n` and `%p` are not supported.

If you have a really long format string that you don't want to split up, it would be nice if you could reference the variables to be formatted by name instead of by position. This can be done by using form `%\(name\)format`, as shown here:

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
>>> print 'Jack: %(Jack)d; Sjoerd: %(Sjoerd)d; Dcab: %(Dcab)d' % table
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This is particularly useful in combination with the new built-in `vars()` function, which returns a dictionary containing all local variables.
7.2 Reading and Writing Files

`open()` returns a file object, and is most commonly used with two arguments: "`open(filename, mode)`".

```python
>>> f=open('/tmp/workfile', 'w')
>>> print f
<open file '/tmp/workfile', mode 'w' at 80a0960>
```

The first argument is a string containing the filename. The second argument is another string containing a few characters describing the way in which the file will be used. *mode* can be 'r' when the file will only be read, 'w' for only writing (an existing file with the same name will be erased), and 'a' opens the file for appending; any data written to the file is automatically added to the end. 'r+' opens the file for both reading and writing. The *mode* argument is optional; 'r' will be assumed if it's omitted.

On Windows and the Macintosh, 'b' appended to the mode opens the file in binary mode, so there are also modes like 'rb', 'wb', and 'r+b'. Windows makes a distinction between text and binary files; the end-of-line characters in text files are automatically altered slightly when data is read or written. This behind-the-scenes modification to file data is fine for ASCII text files, but it'll corrupt binary data like that in JPEG or EXE files. Be very careful to use binary mode when reading and writing such files.
7.2.1 Methods of File Objects

The rest of the examples in this section will assume that a file object called \texttt{f} has already been created.

To read a file's contents, call \texttt{f.read(size)}, which reads some quantity of data and returns it as a string. \texttt{size} is an optional numeric argument. When \texttt{size} is omitted or negative, the entire contents of the file will be read and returned; it's your problem if the file is twice as large as your machine's memory. Otherwise, at most \texttt{size} bytes are read and returned. If the end of the file has been reached, \texttt{f.read()} will return an empty string ("").

\begin{verbatim}
>>> f.read()
'This is the entire file.\n'
>>> f.read()
'

f.readline() reads a single line from the file; a newline character (\texttt{\textbackslash n}) is left at the end of the string, and is only omitted on the last line of the file if the file doesn't end in a newline. This makes the return value unambiguous; if \texttt{f.readline()} returns an empty string, the end of the file has been reached, while a blank line is represented by '\n', a string containing only a single newline.

\begin{verbatim}
>>> f.readline()
'This is the first line of the file.\n'
>>> f.readline()
'Second line of the file\n'
>>> f.readline()
'

f.readlines() returns a list containing all the lines of data in the file. If given an optional parameter \texttt{sizehint}, it reads that many bytes from the file and enough more to complete a line, and returns the lines from that. This is often used to allow efficient reading of a large file by lines, but without having to load the entire file in memory. Only complete lines will be returned.

\begin{verbatim}
>>> f.readlines()
['This is the first line of the file.\n', 'Second line of the file\n'

An alternate approach to reading lines is to loop over the file object. This is
memory efficient, fast, and leads to simpler code:

```python
>>> for line in f:
    print(line),

This is the first line of the file.
Second line of the file
```

The alternative approach is simpler but does not provide as fine-grained control. Since the two approaches manage line buffering differently, they should not be mixed.

```python
f.write(string) writes the contents of string to the file, returning None.

```python
>>> f.write('This is a test\n')
```

To write something other than a string, it needs to be converted to a string first:

```python
>>> value = ('the answer', 42)
>>> s = str(value)
>>> f.write(s)
```

```python
f.tell() returns an integer giving the file object's current position in the file, measured in bytes from the beginning of the file. To change the file object's position, use "f.seek(offset, from_what)". The position is computed from adding offset to a reference point; the reference point is selected by the from_what argument. A from_what value of 0 measures from the beginning of the file, 1 uses the current file position, and 2 uses the end of the file as the reference point. from_what can be omitted and defaults to 0, using the beginning of the file as the reference point.

```python
>>> f = open('/tmp/workfile', 'r+')
>>> f.write('0123456789abcdef')
>>> f.seek(5)  # Go to the 6th byte in the file
>>> f.read(1)
'5'
>>> f.seek(-3, 2)  # Go to the 3rd byte before the end
>>> f.read(1)
'd'
```

When you're done with a file, call f.close() to close it and free up any system resources taken up by the open file. After calling f.close(), attempts to use the file object will automatically fail.
File objects have some additional methods, such as `isatty()` and `truncate()` which are less frequently used; consult the Library Reference for a complete guide to file objects.
7.2.2 The pickle Module

Strings can easily be written to and read from a file. Numbers take a bit more effort, since the read() method only returns strings, which will have to be passed to a function like int(), which takes a string like '123' and returns its numeric value 123. However, when you want to save more complex data types like lists, dictionaries, or class instances, things get a lot more complicated.

Rather than have users be constantly writing and debugging code to save complicated data types, Python provides a standard module called pickle. This is an amazing module that can take almost any Python object (even some forms of Python code!), and convert it to a string representation; this process is called pickling. Reconstructing the object from the string representation is called unpickling. Between pickling and unpickling, the string representing the object may have been stored in a file or data, or sent over a network connection to some distant machine.

If you have an object x, and a file object f that's been opened for writing, the simplest way to pickle the object takes only one line of code:

    pickle.dump(x, f)

To unpickle the object again, if f is a file object which has been opened for reading:

    x = pickle.load(f)

(There are other variants of this, used when pickling many objects or when you don't want to write the pickled data to a file; consult the complete documentation for pickle in the Python Library Reference.)

pickle is the standard way to make Python objects which can be stored and reused by other programs or by a future invocation of the same program; the technical term for this is a persistent object. Because pickle is so widely used, many authors who write Python extensions take care to ensure that new data types such as matrices can be properly pickled and unpickled.
Release 2.4.4c1, documentation updated on 11 October 2006.

- 8.5 User-defined Exceptions
- 8.6 Defining Clean-up Actions
8. Errors and Exceptions

Until now error messages haven't been more than mentioned, but if you have tried out the examples you have probably seen some. There are (at least) two distinguishable kinds of errors: syntax errors and exceptions.
8.1 Syntax Errors

Syntax errors, also known as parsing errors, are perhaps the most common kind of complaint you get while you are still learning Python:

```python
>>> while True print 'Hello world'
File "<stdin>", line 1, in ?
    while True print 'Hello world'
^ SyntaxError: invalid syntax
```

The parser repeats the offending line and displays a little `arrow' pointing at the earliest point in the line where the error was detected. The error is caused by (or at least detected at) the token *preceding* the arrow: in the example, the error is detected at the keyword `print', since a colon (":") is missing before it. File name and line number are printed so you know where to look in case the input came from a script.
8.2 Exceptions

Even if a statement or expression is syntactically correct, it may cause an error when an attempt is made to execute it. Errors detected during execution are called exceptions and are not unconditionally fatal: you will soon learn how to handle them in Python programs. Most exceptions are not handled by programs, however, and result in error messages as shown here:

```python
g>>> 10 * (1/0)
  File "<stdin>", line 1, in ?
  ZeroDivisionError: integer division or modulo by zero
```

The last line of the error message indicates what happened. Exceptions come in different types, and the type is printed as part of the message: the types in the example are `ZeroDivisionError`, `NameError` and `TypeError`. The string printed as the exception type is the name of the built-in exception that occurred. This is true for all built-in exceptions, but need not be true for user-defined exceptions (although it is a useful convention). Standard exception names are built-in identifiers (not reserved keywords).

The rest of the line provides detail based on the type of exception and what caused it.

The preceding part of the error message shows the context where the exception happened, in the form of a stack traceback. In general it contains a stack traceback listing source lines; however, it will not display lines read from standard input.

The Python Library Reference lists the built-in exceptions and their meanings.
8.3 Handling Exceptions

It is possible to write programs that handle selected exceptions. Look at the following example, which asks the user for input until a valid integer has been entered, but allows the user to interrupt the program (using Control-C or whatever the operating system supports); note that a user-generated interruption is signalled by raising the `KeyboardInterrupt` exception.

```python
>>> while True:
    ...    try:
    ...        x = int(raw_input("Please enter a number: "))
    ...        break
    ...    except ValueError:
    ...        print "Oops! That was no valid number. Try again..."
    ...
```

The `try` statement works as follows.

- First, the `try clause` (the statement(s) between the `try` and `except` keywords) is executed.

- If no exception occurs, the `except clause` is skipped and execution of the `try` statement is finished.

- If an exception occurs during execution of the `try` clause, the rest of the clause is skipped. Then if its type matches the exception named after the `except` keyword, the except clause is executed, and then execution continues after the `try` statement.

- If an exception occurs which does not match the exception named in the `except` clause, it is passed on to outer `try` statements; if no handler is found, it is an `unhandled exception` and execution stops with a message as shown above.

A `try` statement may have more than one `except` clause, to specify handlers for different exceptions. At most one handler will be executed. Handlers only handle exceptions that occur in the corresponding `try` clause, not in other handlers of the same `try` statement. An `except` clause may name multiple exceptions as a parenthesized tuple, for example:
... except (RuntimeError, TypeError, NameError):
...     pass

The last except clause may omit the exception name(s), to serve as a wildcard. Use this with extreme caution, since it is easy to mask a real programming error in this way! It can also be used to print an error message and then re-raise the exception (allowing a caller to handle the exception as well):

```python
import sys

try:
    f = open('myfile.txt')
    s = f.readline()
    i = int(s.strip())
except IOError, (errno, strerror):
    print "I/O error(%s): %s" % (errno, strerror)
except ValueError:
    print "Could not convert data to an integer."
except:
    print "Unexpected error:", sys.exc_info()[0]
    raise
```

The try ... except statement has an optional else clause, which, when present, must follow all except clauses. It is useful for code that must be executed if the try clause does not raise an exception. For example:

```python
for arg in sys.argv[1:]:
    try:
        f = open(arg, 'r')
    except IOError:
        print 'cannot open', arg
    else:
        print arg, 'has', len(f.readlines()), 'lines'
    f.close()
```

The use of the else clause is better than adding additional code to the try clause because it avoids accidentally catching an exception that wasn't raised by the code being protected by the try ... except statement.

When an exception occurs, it may have an associated value, also known as the exception's argument. The presence and type of the argument depend on the exception type.

The except clause may specify a variable after the exception name (or tuple). The variable is bound to an exception instance with the arguments stored in
instance.args. For convenience, the exception instance defines __getitem__ and __str__ so the arguments can be accessed or printed directly without having to reference .args.

```python
>>> try:
...     raise Exception('spam', 'eggs')
... except Exception, inst:
...     print type(inst)  # the exception instance
...     print inst.args  # arguments stored in .args
...     print inst       # __str__ allows args to printed directly
...     x, y = inst      # __getitem__ allows args to be unpacked
...     print 'x =', x
...     print 'y =', y
...
<type 'instance'>
('spam', 'eggs')
('spam', 'eggs')
x = spam
y = eggs
```

If an exception has an argument, it is printed as the last part (`detail`) of the message for unhandled exceptions.

Exception handlers don't just handle exceptions if they occur immediately in the try clause, but also if they occur inside functions that are called (even indirectly) in the try clause. For example:

```python
>>> def this_fails():
...     x = 1/0
...>>> try:
...     this_fails()
... except ZeroDivisionError, detail:
...     print 'Handling run-time error:', detail
...
Handling run-time error: integer division or modulo by zero
```
8.4 Raising Exceptions

The `raise` statement allows the programmer to force a specified exception to occur. For example:

```python
>>> raise NameError, 'HiThere'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: HiThere
```

The first argument to `raise` names the exception to be raised. The optional second argument specifies the exception's argument. Alternatively, the above could be written as `raise NameError('HiThere')`. Either form works fine, but there seems to be a growing stylistic preference for the latter.

If you need to determine whether an exception was raised but don't intend to handle it, a simpler form of the `raise` statement allows you to re-raise the exception:

```python
>>> try:
    ...    raise NameError, 'HiThere'
    ... except NameError:
    ...    print 'An exception flew by!'
    ...    raise
    ...
An exception flew by!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
NameError: HiThere
```
8.5 User-defined Exceptions

Programs may name their own exceptions by creating a new exception class. Exceptions should typically be derived from the Exception class, either directly or indirectly. For example:

```python
>>> class MyError(Exception):
...     def __init__(self, value):
...         self.value = value
...     def __str__(self):
...         return repr(self.value)
...
>>> try:
...     raise MyError(2*2)
... except MyError, e:
...     print 'My exception occurred, value:', e.value
...
My exception occurred, value: 4
>>> raise MyError, 'oops!'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
__main__.MyError: 'oops!'```

In this example, the default __init__ of Exception has been overridden. The new behavior simply creates the value attribute. This replaces the default behavior of creating the args attribute.

Exception classes can be defined which do anything any other class can do, but are usually kept simple, often only offering a number of attributes that allow information about the error to be extracted by handlers for the exception. When creating a module that can raise several distinct errors, a common practice is to create a base class for exceptions defined by that module, and subclass that to create specific exception classes for different error conditions:

```python
class Error(Exception):
    """Base class for exceptions in this module.""
    pass

class InputError(Error):
    """Exception raised for errors in the input.

Attributes:
    expression -- input expression in which the error occurred
    message -- explanation of the error"""
```
def __init__(self, expression, message):
    self.expression = expression
    self.message = message

class TransitionError(Error):
    """Raised when an operation attempts a state transition that's not allowed."

    Attributes:
        previous -- state at beginning of transition
        next -- attempted new state
        message -- explanation of why the specific transition is not allowed"

    def __init__(self, previous, next, message):
        self.previous = previous
        self.next = next
        self.message = message

Most exceptions are defined with names that end in ``Error,'' similar to the naming of the standard exceptions.

Many standard modules define their own exceptions to report errors that may occur in functions they define. More information on classes is presented in chapter 9, ``Classes.'
8.6 Defining Clean-up Actions

The `try` statement has another optional clause which is intended to define clean-up actions that must be executed under all circumstances. For example:

```python
>>> try:
    ...
    raise KeyboardInterrupt
    ...
finally:
    ...
    print 'Goodbye, world!'
    ...
Goodbye, world!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
KeyboardInterrupt
```

A *finally clause* is executed whether or not an exception has occurred in the `try` clause. When an exception has occurred, it is re-raised after the finally clause is executed. The finally clause is also executed `on the way out" when the `try` statement is left via a `break` or `return` statement.

The code in the finally clause is useful for releasing external resources (such as files or network connections), regardless of whether the use of the resource was successful.

A `try` statement must either have one or more except clauses or one finally clause, but not both (because it would be unclear which clause should be executed first).

9. Classes

Python's class mechanism adds classes to the language with a minimum of new syntax and semantics. It is a mixture of the class mechanisms found in C++ and Modula-3. As is true for modules, classes in Python do not put an absolute barrier between definition and user, but rather rely on the politeness of the user not to ``break into the definition." The most important features of classes are retained with full power, however: the class inheritance mechanism allows multiple base classes, a derived class can override any methods of its base class or classes, and a method can call the method of a base class with the same name. Objects can contain an arbitrary amount of private data.

In C++ terminology, all class members (including the data members) are public, and all member functions are virtual. There are no special constructors or destructors. As in Modula-3, there are no shorthands for referencing the object's members from its methods: the method function is declared with an explicit first argument representing the object, which is provided implicitly by the call. As in Smalltalk, classes themselves are objects, albeit in the wider sense of the word: in Python, all data types are objects. This provides semantics for importing and renaming. Unlike C++ and Modula-3, built-in types can be used as base classes for extension by the user. Also, like in C++ but unlike in Modula-3, most built-in operators with special syntax (arithmetic operators, subscripting etc.) can be redefined for class instances.
9.1 A Word About Terminology

Lacking universally accepted terminology to talk about classes, I will make occasional use of Smalltalk and C++ terms. (I would use Modula-3 terms, since its object-oriented semantics are closer to those of Python than C++, but I expect that few readers have heard of it.)

Objects have individuality, and multiple names (in multiple scopes) can be bound to the same object. This is known as aliasing in other languages. This is usually not appreciated on a first glance at Python, and can be safely ignored when dealing with immutable basic types (numbers, strings, tuples). However, aliasing has an (intended!) effect on the semantics of Python code involving mutable objects such as lists, dictionaries, and most types representing entities outside the program (files, windows, etc.). This is usually used to the benefit of the program, since aliases behave like pointers in some respects. For example, passing an object is cheap since only a pointer is passed by the implementation; and if a function modifies an object passed as an argument, the caller will see the change -- this eliminates the need for two different argument passing mechanisms as in Pascal.
9.2 Python Scopes and Name Spaces

Before introducing classes, I first have to tell you something about Python's scope rules. Class definitions play some neat tricks with namespaces, and you need to know how scopes and namespaces work to fully understand what's going on. Incidentally, knowledge about this subject is useful for any advanced Python programmer.

Let's begin with some definitions.

A namespace is a mapping from names to objects. Most namespaces are currently implemented as Python dictionaries, but that's normally not noticeable in any way (except for performance), and it may change in the future. Examples of namespaces are: the set of built-in names (functions such as \texttt{abs()}, and built-in exception names); the global names in a module; and the local names in a function invocation. In a sense the set of attributes of an object also form a namespace. The important thing to know about namespaces is that there is absolutely no relation between names in different namespaces; for instance, two different modules may both define a function ``maximize'' without confusion -- users of the modules must prefix it with the module name.

By the way, I use the word attribute for any name following a dot -- for example, in the expression \texttt{z.real}, \texttt{real} is an attribute of the object \texttt{z}. Strictly speaking, references to names in modules are attribute references: in the expression \texttt{modname.funcname}, \texttt{modname} is a module object and \texttt{funcname} is an attribute of it. In this case there happens to be a straightforward mapping between the module's attributes and the global names defined in the module: they share the same namespace! \footnote{9.1}

Attributes may be read-only or writable. In the latter case, assignment to attributes is possible. Module attributes are writable: you can write "\texttt{modname.the\_answer} = 42". Writable attributes may also be deleted with the \texttt{del} statement. For example, "\texttt{del modname.the\_answer}" will remove the attribute \texttt{the\_answer} from the object named by \texttt{modname}. 
Name spaces are created at different moments and have different lifetimes. The namespace containing the built-in names is created when the Python interpreter starts up, and is never deleted. The global namespace for a module is created when the module definition is read in; normally, module namespaces also last until the interpreter quits. The statements executed by the top-level invocation of the interpreter, either read from a script file or interactively, are considered part of a module called __main__, so they have their own global namespace. (The built-in names actually also live in a module; this is called __builtin__.)

The local namespace for a function is created when the function is called, and deleted when the function returns or raises an exception that is not handled within the function. (Actually, forgetting would be a better way to describe what actually happens.) Of course, recursive invocations each have their own local namespace.

A scope is a textual region of a Python program where a namespace is directly accessible. "Directly accessible" here means that an unqualified reference to a name attempts to find the name in the namespace.

Although scopes are determined statically, they are used dynamically. At any time during execution, there are at least three nested scopes whose namespaces are directly accessible: the innermost scope, which is searched first, contains the local names; the namespaces of any enclosing functions, which are searched starting with the nearest enclosing scope; the middle scope, searched next, contains the current module's global names; and the outermost scope (searched last) is the namespace containing built-in names.

If a name is declared global, then all references and assignments go directly to the middle scope containing the module's global names. Otherwise, all variables found outside of the innermost scope are read-only (an attempt to write to such a variable will simply create a new local variable in the innermost scope, leaving the identically named outer variable unchanged).

Usually, the local scope references the local names of the (textually) current function. Outside functions, the local scope references the same namespace as the global scope: the module's namespace. Class definitions place yet another namespace in the local scope.

It is important to realize that scopes are determined textually: the global scope of
a function defined in a module is that module's namespace, no matter from where or by what alias the function is called. On the other hand, the actual search for names is done dynamically, at run time -- however, the language definition is evolving towards static name resolution, at ''compile'' time, so don't rely on dynamic name resolution! (In fact, local variables are already determined statically.)

A special quirk of Python is that assignments always go into the innermost scope. Assignments do not copy data -- they just bind names to objects. The same is true for deletions: the statement "del x" removes the binding of x from the namespace referenced by the local scope. In fact, all operations that introduce new names use the local scope: in particular, import statements and function definitions bind the module or function name in the local scope. (The global statement can be used to indicate that particular variables live in the global scope.)
9.3 A First Look at Classes

Classes introduce a little bit of new syntax, three new object types, and some new semantics.
9.3.1 Class Definition Syntax

The simplest form of class definition looks like this:

```python
class Classname:
    <statement-1>
    ...
    <statement-N>
```

Class definitions, like function definitions (def statements) must be executed before they have any effect. (You could conceivably place a class definition in a branch of an if statement, or inside a function.)

In practice, the statements inside a class definition will usually be function definitions, but other statements are allowed, and sometimes useful -- we'll come back to this later. The function definitions inside a class normally have a peculiar form of argument list, dictated by the calling conventions for methods -- again, this is explained later.

When a class definition is entered, a new namespace is created, and used as the local scope -- thus, all assignments to local variables go into this new namespace. In particular, function definitions bind the name of the new function here.

When a class definition is left normally (via the end), a class object is created. This is basically a wrapper around the contents of the namespace created by the class definition; we'll learn more about class objects in the next section. The original local scope (the one in effect just before the class definition was entered) is reinstated, and the class object is bound here to the class name given in the class definition header (ClassName in the example).
9.3.2 Class Objects

Class objects support two kinds of operations: attribute references and instantiation.

Attribute references use the standard syntax used for all attribute references in Python: `obj.name`. Valid attribute names are all the names that were in the class's namespace when the class object was created. So, if the class definition looked like this:

```python
class MyClass:
    "A simple example class"
    i = 12345
    def f(self):
        return 'hello world'
```

then `MyClass.i` and `MyClass.f` are valid attribute references, returning an integer and a function object, respectively. Class attributes can also be assigned to, so you can change the value of `MyClass.i` by assignment. `__doc__` is also a valid attribute, returning the docstring belonging to the class: "A simple example class".

Class instantiation uses function notation. Just pretend that the class object is a parameterless function that returns a new instance of the class. For example (assuming the above class):

```python
x = MyClass()
```

creates a new instance of the class and assigns this object to the local variable `x`.

The instantiation operation ("calling" a class object) creates an empty object. Many classes like to create objects with instances customized to a specific initial state. Therefore a class may define a special method named `__init__()` like this:

```python
def __init__(self):
    self.data = []
```

When a class defines an `__init__()` method, class instantiation automatically invokes `__init__()` for the newly-created class instance. So in this example,
a new, initialized instance can be obtained by:

    x = MyClass()

Of course, the `__init__()` method may have arguments for greater flexibility. In that case, arguments given to the class instantiation operator are passed on to `__init__()`. For example,

    >>> class Complex:
    ...     def __init__(self, realpart, imagpart):
    ...         self.r = realpart
    ...         self.i = imagpart
    ...
    >>> x = Complex(3.0, -4.5)
    >>> x.r, x.i
    (3.0, -4.5)
9.3.3 Instance Objects

Now what can we do with instance objects? The only operations understood by instance objects are attribute references. There are two kinds of valid attribute names, data attributes and methods.

*Data attributes* correspond to ``instance variables'' in Smalltalk, and to ``data members'' in C++. Data attributes need not be declared; like local variables, they spring into existence when they are first assigned to. For example, if `x` is the instance of `MyClass` created above, the following piece of code will print the value 16, without leaving a trace:

```python
x.counter = 1
while x.counter < 10:
    x.counter = x.counter * 2
print x.counter
del x.counter
```

The other kind of instance attribute reference is a *method*. A method is a function that ``belongs to'' an object. (In Python, the term method is not unique to class instances: other object types can have methods as well. For example, list objects have methods called `append`, `insert`, `remove`, `sort`, and so on. However, in the following discussion, we'll use the term method exclusively to mean methods of class instance objects, unless explicitly stated otherwise.)

Valid method names of an instance object depend on its class. By definition, all attributes of a class that are function objects define corresponding methods of its instances. So in our example, `x.f` is a valid method reference, since `MyClass.f` is a function, but `x.i` is not, since `MyClass.i` is not. But `x.f` is not the same thing as `MyClass.f` -- it is a *method object*, not a function object.
9.3.4 Method Objects

Usually, a method is called right after it is bound:

```
x.f()
```

In the `MyClass` example, this will return the string 'hello world'. However, it is not necessary to call a method right away: `x.f` is a method object, and can be stored away and called at a later time. For example:

```
xf = x.f
while True:
    print xf()
```

will continue to print "hello world" until the end of time.

What exactly happens when a method is called? You may have noticed that `x.f()` was called without an argument above, even though the function definition for `f` specified an argument. What happened to the argument? Surely Python raises an exception when a function that requires an argument is called without any -- even if the argument isn't actually used...

Actually, you may have guessed the answer: the special thing about methods is that the object is passed as the first argument of the function. In our example, the call `x.f()` is exactly equivalent to `MyClass.f(x)`. In general, calling a method with a list of `n` arguments is equivalent to calling the corresponding function with an argument list that is created by inserting the method's object before the first argument.

If you still don't understand how methods work, a look at the implementation can perhaps clarify matters. When an instance attribute is referenced that isn't a data attribute, its class is searched. If the name denotes a valid class attribute that is a function object, a method object is created by packing (pointers to) the instance object and the function object just found together in an abstract object: this is the method object. When the method object is called with an argument list, it is unpacked again, a new argument list is constructed from the instance object and the original argument list, and the function object is called with this new argument list.
9.4 Random Remarks

Data attributes override method attributes with the same name; to avoid accidental name conflicts, which may cause hard-to-find bugs in large programs, it is wise to use some kind of convention that minimizes the chance of conflicts. Possible conventions include capitalizing method names, prefixing data attribute names with a small unique string (perhaps just an underscore), or using verbs for methods and nouns for data attributes.

Data attributes may be referenced by methods as well as by ordinary users (``clients") of an object. In other words, classes are not usable to implement pure abstract data types. In fact, nothing in Python makes it possible to enforce data hiding -- it is all based upon convention. (On the other hand, the Python implementation, written in C, can completely hide implementation details and control access to an object if necessary; this can be used by extensions to Python written in C.)

Clients should use data attributes with care -- clients may mess up invariants maintained by the methods by stamping on their data attributes. Note that clients may add data attributes of their own to an instance object without affecting the validity of the methods, as long as name conflicts are avoided -- again, a naming convention can save a lot of headaches here.

There is no shorthand for referencing data attributes (or other methods!) from within methods. I find that this actually increases the readability of methods: there is no chance of confusing local variables and instance variables when glancing through a method.

Often, the first argument of a method is called self. This is nothing more than a convention: the name self has absolutely no special meaning to Python. (Note, however, that by not following the convention your code may be less readable to other Python programmers, and it is also conceivable that a class browser program might be written that relies upon such a convention.)

Any function object that is a class attribute defines a method for instances of that class. It is not necessary that the function definition is textually enclosed in the class definition: assigning a function object to a local variable in the class is also
ok. For example:

```
# Function defined outside the class
def f1(self, x, y):
    return min(x, x+y)

class C:
    f = f1
    def g(self):
        return 'hello world'
    h = g
```

Now f, g and h are all attributes of class C that refer to function objects, and consequently they are all methods of instances of C -- h being exactly equivalent to g. Note that this practice usually only serves to confuse the reader of a program.

Methods may call other methods by using method attributes of the self argument:

```
class Bag:
    def __init__(self):
        self.data = []
    def add(self, x):
        self.data.append(x)
    def addtwice(self, x):
        self.add(x)
        self.add(x)
```

Methods may reference global names in the same way as ordinary functions. The global scope associated with a method is the module containing the class definition. (The class itself is never used as a global scope!) While one rarely encounters a good reason for using global data in a method, there are many legitimate uses of the global scope: for one thing, functions and modules imported into the global scope can be used by methods, as well as functions and classes defined in it. Usually, the class containing the method is itself defined in this global scope, and in the next section we'll find some good reasons why a method would want to reference its own class!
9.5 Inheritance

Of course, a language feature would not be worthy of the name "class" without supporting inheritance. The syntax for a derived class definition looks like this:

```
class DerivedClassName(BaseClassName):
    <statement-1>
    .
    .
    .
    <statement-N>
```

The name `BaseClassName` must be defined in a scope containing the derived class definition. In place of a base class name, other arbitrary expressions are also allowed. This can be useful, for example, when the base class is defined in another module:

```
class DerivedClassName(modname.BaseClassName):
```

Execution of a derived class definition proceeds the same as for a base class. When the class object is constructed, the base class is remembered. This is used for resolving attribute references: if a requested attribute is not found in the class, the search proceeds to look in the base class. This rule is applied recursively if the base class itself is derived from some other class.

There's nothing special about instantiation of derived classes: `DerivedClassName()` creates a new instance of the class. Method references are resolved as follows: the corresponding class attribute is searched, descending down the chain of base classes if necessary, and the method reference is valid if this yields a function object.

Derived classes may override methods of their base classes. Because methods have no special privileges when calling other methods of the same object, a method of a base class that calls another method defined in the same base class may end up calling a method of a derived class that overrides it. (For C++ programmers: all methods in Python are effectively virtual.)

An overriding method in a derived class may in fact want to extend rather than simply replace the base class method of the same name. There is a simple way to
call the base class method directly: just call
"BaseClassName.methodname(self, arguments)". This is
occasionally useful to clients as well. (Note that this only works if the base class
is defined or imported directly in the global scope.)
9.5.1 Multiple Inheritance

Python supports a limited form of multiple inheritance as well. A class definition with multiple base classes looks like this:

```python
class DerivedClassName(Base1, Base2, Base3):
    <statement-1>
    ...
    ...
    <statement-N>
```

The only rule necessary to explain the semantics is the resolution rule used for class attribute references. This is depth-first, left-to-right. Thus, if an attribute is not found in `DerivedClassName`, it is searched in `Base1`, then (recursively) in the base classes of `Base1`, and only if it is not found there, it is searched in `Base2`, and so on.

(To some people breadth first -- searching `Base2` and `Base3` before the base classes of `Base1` -- looks more natural. However, this would require you to know whether a particular attribute of `Base1` is actually defined in `Base1` or in one of its base classes before you can figure out the consequences of a name conflict with an attribute of `Base2`. The depth-first rule makes no differences between direct and inherited attributes of `Base1`.)

It is clear that indiscriminate use of multiple inheritance is a maintenance nightmare, given the reliance in Python on conventions to avoid accidental name conflicts. A well-known problem with multiple inheritance is a class derived from two classes that happen to have a common base class. While it is easy enough to figure out what happens in this case (the instance will have a single copy of "instance variables" or data attributes used by the common base class), it is not clear that these semantics are in any way useful.
9.6 Private Variables

There is limited support for class-private identifiers. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with __classname__spam, where classname is the current class name with leading underscore(s) stripped. This mangling is done without regard to the syntactic position of the identifier, so it can be used to define class-private instance and class variables, methods, variables stored in globals, and even variables stored in instances. private to this class on instances of other classes. Truncation may occur when the mangled name would be longer than 255 characters. Outside classes, or when the class name consists of only underscores, no mangling occurs.

Name mangling is intended to give classes an easy way to define ``private'' instance variables and methods, without having to worry about instance variables defined by derived classes, or mucking with instance variables by code outside the class. Note that the mangling rules are designed mostly to avoid accidents; it still is possible for a determined soul to access or modify a variable that is considered private. This can even be useful in special circumstances, such as in the debugger, and that's one reason why this loophole is not closed. (Buglet: derivation of a class with the same name as the base class makes use of private variables of the base class possible.)

Notice that code passed to exec, eval() or evalfile() does not consider the classname of the invoking class to be the current class; this is similar to the effect of the global statement, the effect of which is likewise restricted to code that is byte-compiled together. The same restriction applies to getattr(), setattr() and delattr(), as well as when referencing __dict__ directly.
9.7 Odds and Ends

Sometimes it is useful to have a data type similar to the Pascal ``record'' or C ``struct'', bundling together a few named data items. An empty class definition will do nicely:

```python
class Employee:
    pass

john = Employee()  # Create an empty employee record

# Fill the fields of the record
john.name = 'John Doe'
john.dept = 'computer lab'
john.salary = 1000
```

A piece of Python code that expects a particular abstract data type can often be passed a class that emulates the methods of that data type instead. For instance, if you have a function that formats some data from a file object, you can define a class with methods `read()` and `readline()` that get the data from a string buffer instead, and pass it as an argument.

Instance method objects have attributes, too: `m.im_self` is the instance object with the method `m`, and `m.im_func` is the function object corresponding to the method.
9.8 Exceptions Are Classes Too

User-defined exceptions are identified by classes as well. Using this mechanism it is possible to create extensible hierarchies of exceptions.

There are two new valid (semantic) forms for the raise statement:

```
raise Class, instance
raise instance
```

In the first form, `instance` must be an instance of `Class` or of a class derived from it. The second form is a shorthand for:

```
raise instance.__class__, instance
```

A class in an except clause is compatible with an exception if it is the same class or a base class thereof (but not the other way around -- an except clause listing a derived class is not compatible with a base class). For example, the following code will print B, C, D in that order:

```python
class B:
    pass
class C(B):
    pass
class D(C):
    pass

for c in [B, C, D]:
    try:
        raise c()
    except D:
        print "D"
    except C:
        print "C"
    except B:
        print "B"
```

Note that if the except clauses were reversed (with "except B" first), it would have printed B, B, B -- the first matching except clause is triggered.

When an error message is printed for an unhandled exception, the exception's class name is printed, then a colon and a space, and finally the instance
converted to a string using the built-in function \texttt{str()}. 
9.9 Iterators

By now you have probably noticed that most container objects can be looped over using a for statement:

```python
for element in [1, 2, 3]:
    print element
for element in (1, 2, 3):
    print element
for key in {'one':1, 'two':2}:
    print key
for char in "123":
    print char
for line in open("myfile.txt"):
    print line
```

This style of access is clear, concise, and convenient. The use of iterators pervades and unifies Python. Behind the scenes, the for statement calls iter() on the container object. The function returns an iterator object that defines the method next() which accesses elements in the container one at a time. When there are no more elements, next() raises a StopIteration exception which tells the for loop to terminate. This example shows how it all works:

```python
>>> s = 'abc'
>>> it = iter(s)
>>> it
<iterator object at 0x00A1DB50>
>>> it.next()
'a'
>>> it.next()
'b'
>>> it.next()
'c'
>>> it.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
    it.next()
StopIteration
```

Having seen the mechanics behind the iterator protocol, it is easy to add iterator behavior to your classes. Define a __iter__() method which returns an object with a next() method. If the class defines next(), then
__iter__() can just return self:

class Reverse:
    "Iterator for looping over a sequence backwards"
    def __init__(self, data):
        self.data = data
        self.index = len(data)
    def __iter__(self):
        return self
    def next(self):
        if self.index == 0:
            raise StopIteration
        self.index = self.index - 1
        return self.data[self.index]

>>> for char in Reverse('spam'):
    ...   print char
    ...
    m
    a
    p
    s
9.10 Generators

Generators are a simple and powerful tool for creating iterators. They are written like regular functions but use the yield statement whenever they want to return data. Each time next() is called, the generator resumes where it left-off (it remembers all the data values and which statement was last executed). An example shows that generators can be trivially easy to create:

```python
def reverse(data):
    for index in range(len(data)-1, -1, -1):
        yield data[index]

>>> for char in reverse('golf'):
    ...    print char
...
 f
 l
 o
 g
```

Anything that can be done with generators can also be done with class based iterators as described in the previous section. What makes generators so compact is that the __iter__() and next() methods are created automatically.

Another key feature is that the local variables and execution state are automatically saved between calls. This made the function easier to write and much more clear than an approach using instance variables like self.index and self.data.

In addition to automatic method creation and saving program state, when generators terminate, they automatically raise StopIteration. In combination, these features make it easy to create iterators with no more effort than writing a regular function.
9.11 Generator Expressions

Some simple generators can be coded succinctly as expressions using a syntax similar to list comprehensions but with parentheses instead of brackets. These expressions are designed for situations where the generator is used right away by an enclosing function. Generator expressions are more compact but less versatile than full generator definitions and tend to be more memory friendly than equivalent list comprehensions.

Examples:

```python
>>> sum(i*i for i in range(10))  # sum of squares
285

>>> xvec = [10, 20, 30]
>>> yvec = [7, 5, 3]
>>> sum(x*y for x,y in zip(xvec, yvec))  # dot product
260

>>> from math import pi, sin
>>> sine_table = dict((x, sin(x*pi/180)) for x in range(0, 91))

>>> unique_words = set(word for line in page for word in line.split())

>>> valedictorian = max((student.gpa, student.name) for student in graduates)

>>> data = 'golf'
>>> list(data[i] for i in range(len(data)-1,-1,-1))
['f', 'l', 'o', 'g']
```

Footnotes

... namespace!^9.1

Except for one thing. Module objects have a secret read-only attribute called `__dict__` which returns the dictionary used to implement the module's namespace; the name `__dict__` is an attribute but not a global name. Obviously, using this violates the abstraction of namespace implementation, and should be restricted to things like post-mortem
debuggers.

10. Brief Tour of the Standard Library
10.1 Operating System Interface

The `os` module provides dozens of functions for interacting with the operating system:

```python
>>> import os
>>> os.system('time 0:02')
0
>>> os.getcwd()  # Return the current working directory
'C:\Python24'
>>> os.chdir('/server/accesslogs')
```

Be sure to use the "import os" style instead of "from os import *". This will keep `os.open()` from shadowing the builtin `open()` function which operates much differently.

The builtin `dir()` and `help()` functions are useful as interactive aids for working with large modules like `os`:

```python
>>> import os
>>> dir(os)
<returns a list of all module functions>
>>> help(os)
<returns an extensive manual page created from the module's docstrings>
```

For daily file and directory management tasks, the `shutil` module provides a higher level interface that is easier to use:

```python
>>> import shutil
>>> shutil.copyfile('data.db', 'archive.db')
>>> shutil.move('/build/executables', 'installdir')
```
10.2 File Wildcards

The `glob` module provides a function for making file lists from directory wildcard searches:

```python
>>> import glob
>>> glob.glob("*.py")
['primes.py', 'random.py', 'quote.py']
```
10.3 Command Line Arguments

Common utility scripts often need to process command line arguments. These arguments are stored in the `sys` module's `argv` attribute as a list. For instance the following output results from running "python demo.py one two three" at the command line:

```python
>>> import sys
>>> print sys.argv
['demo.py', 'one', 'two', 'three']
```

The `getopt` module processes `sys.argv` using the conventions of the UNIX `getopt()` function. More powerful and flexible command line processing is provided by the `optparse` module.
10.4 Error Output Redirection and Program Termination

The `sys` module also has attributes for `stdin`, `stdout`, and `stderr`. The latter is useful for emitting warnings and error messages to make them visible even when `stdout` has been redirected:

```python
>>> sys.stderr.write('Warning, log file not found starting a new one
Warning, log file not found starting a new one
```

The most direct way to terminate a script is to use "sys.exit()".
10.5 String Pattern Matching

The `re` module provides regular expression tools for advanced string processing. For complex matching and manipulation, regular expressions offer succinct, optimized solutions:

```python
>>> import re
>>> re.findall(r'\bf[a-z]*', 'which foot or hand fell fastest')
['foot', 'fell', 'fastest']
>>> re.sub(r'(\b[a-z]+) \1', r'\1', 'cat in the the hat')
'cat in the hat'
```

When only simple capabilities are needed, string methods are preferred because they are easier to read and debug:

```python
>>> 'tea for too'.replace('too', 'two')
'tea for two'
```
10.6 Mathematics

The `math` module gives access to the underlying C library functions for floating point math:

```python
>>> import math
>>> math.cos(math.pi / 4.0)
0.70710678118654757
>>> math.log(1024, 2)
10.0
```

The `random` module provides tools for making random selections:

```python
>>> import random
>>> random.choice(['apple', 'pear', 'banana'])
'apple'
>>> random.sample(xrange(100), 10)  # sampling without replacement
[30, 83, 16, 4, 8, 81, 41, 50, 18, 33]
>>> random.random()  # random float
0.17970987693706186
>>> random.randrange(6)  # random integer chosen from range(6)
4
```
10.7 Internet Access

There are a number of modules for accessing the internet and processing internet protocols. Two of the simplest are `urllib2` for retrieving data from urls and `smtplib` for sending mail:

```
>>> import urllib2
>>> for line in urllib2.urlopen('http://tycho.usno.navy.mil/cgi-bin/  
... if 'EST' in line:  # look for Eastern Standard Time
...     print line

<BR>Nov. 25, 09:43:32 PM EST

>>> import smtplib
>>> server = smtplib.SMTP('localhost')
>>> server.sendmail('soothsayer@example.org', 'jcaesar@example.org',
                   """To: jcaesar@example.org
From: soothsayer@example.org

Beware the Ides of March.
"""
>>> server.quit()
```
10.8 Dates and Times

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. The module also supports objects that are time zone aware.

```python
# dates are easily constructed and formatted
>>> from datetime import date
>>> now = date.today()
>>> now
datetime.date(2003, 12, 2)
>>> now.strftime("%m-%d-%y. %d %b %Y is a %A on the %d day of %B.")
'12-02-03. 02 Dec 2003 is a Tuesday on the 02 day of December.'

# dates support calendar arithmetic
>>> birthday = date(1964, 7, 31)
>>> age = now - birthday
>>> age.days
14368
```
10.9 Data Compression

Common data archiving and compression formats are directly supported by modules including: \texttt{zlib}, \texttt{gzip}, \texttt{bz2}, \texttt{zipfile}, and \texttt{tarfile}.

```python
>>> import zlib
>>> s = 'witch which has which witches wrist watch'
>>> len(s)
41
>>> t = zlib.compress(s)
>>> len(t)
37
>>> zlib.decompress(t)
'witch which has which witches wrist watch'
>>> zlib.crc32(s)
226805979
```
10.10 Performance Measurement

Some Python users develop a deep interest in knowing the relative performance of different approaches to the same problem. Python provides a measurement tool that answers those questions immediately.

For example, it may be tempting to use the tuple packing and unpacking feature instead of the traditional approach to swapping arguments. The `timeit` module quickly demonstrates a modest performance advantage:

```python
>>> from timeit import Timer
>>> Timer('t=a; a=b; b=t', 'a=1; b=2').timeit()
0.57535828626024577
>>> Timer('a,b = b,a', 'a=1; b=2').timeit()
0.54962537085770791
```

In contrast to `timeit`'s fine level of granularity, the `profile` and `pstats` modules provide tools for identifying time critical sections in larger blocks of code.
10.11 Quality Control

One approach for developing high quality software is to write tests for each function as it is developed and to run those tests frequently during the development process.

The `doctest` module provides a tool for scanning a module and validating tests embedded in a program's docstrings. Test construction is as simple as cutting-and-pasting a typical call along with its results into the docstring. This improves the documentation by providing the user with an example and it allows the doctest module to make sure the code remains true to the documentation:

```python
def average(values):
    """Computes the arithmetic mean of a list of numbers."
    
    >>> print average([20, 30, 70])
    40.0
    """
    return sum(values, 0.0) / len(values)

import doctest
doctest.testmod()  # automatically validate the embedded tests
```

The `unittest` module is not as effortless as the `doctest` module, but it allows a more comprehensive set of tests to be maintained in a separate file:

```python
import unittest
class TestStatisticalFunctions(unittest.TestCase):
    def test_average(self):
        self.assertAlmostEqual(average([20, 30, 70]), 40.0)
        self.assertAlmostEqual(round(average([1, 5, 7]), 1), 4.3)
        self.assertRaises(ZeroDivisionError, average, [])
        self.assertRaises(TypeError, average, 20, 30, 70)

unittest.main()  # Calling from the command line invokes all tests
```
10.12 Batteries Included

Python has a "batteries included" philosophy. This is best seen through the sophisticated and robust capabilities of its larger packages. For example:

- The `xmlrpcclient` and `SimpleXMLRPCServer` modules make implementing remote procedure calls into an almost trivial task. Despite the names, no direct knowledge or handling of XML is needed.
- The `email` package is a library for managing email messages, including MIME and other RFC 2822-based message documents. Unlike `smtplib` and `poplib` which actually send and receive messages, the email package has a complete toolset for building or decoding complex message structures (including attachments) and for implementing internet encoding and header protocols.
- The `xml.dom` and `xml.sax` packages provide robust support for parsing this popular data interchange format. Likewise, the `csv` module supports direct reads and writes in a common database format. Together, these modules and packages greatly simplify data interchange between python applications and other tools.
- Internationalization is supported by a number of modules including `gettext`, `locale`, and the `codecs` package.

11. Brief Tour of the Standard Library - Part II

This second tour covers more advanced modules that support professional programming needs. These modules rarely occur in small scripts.
11.1 Output Formatting

The `repr` module provides an version of `repr()` for abbreviated displays of large or deeply nested containers:

```python
>>> import repr
>>> repr.repr(set('supercalifragilisticexpialidocious'))
"set(['a', 'c', 'd', 'e', 'f', 'g', ...])"
```

The `pprint` module offers more sophisticated control over printing both built-in and user defined objects in a way that is readable by the interpreter. When the result is longer than one line, the ``pretty printer'' adds line breaks and indentation to more clearly reveal data structure:

```python
>>> import pprint
t = [[[['black', 'cyan'], 'white', ['green', 'red']], [['magenta', 'yellow'], 'blue']]
... >>> pprint.pprint(t, width=30)
[[[['black', 'cyan'],
   'white',
   ['green', 'red']],
  [['magenta', 'yellow'],
   'blue']]]
```

The `textwrap` module formats paragraphs of text to fit a given screen width:

```python
>>> import textwrap
doc = """The wrap() method is just like fill() except that it returns a list of strings instead of one big string with newlines to separate the wrapped lines."""
... >>> print textwrap.fill(doc, width=40)
The wrap() method is just like fill() except that it returns a list of strings instead of one big string with newlines to separate the wrapped lines.
```

The `locale` module accesses a database of culture specific data formats. The grouping attribute of locale's format function provides a direct way of formatting numbers with group separators:

```python
>>> import locale
>>> locale.setlocale(locale.LC_ALL, 'English_United States.1252')
```

>>> conv = locale.localeconv()  # get a mapping of conventions
>>> x = 1234567.8
>>> locale.format("%d", x, grouping=True)
'1,234,567'
>>> locale.format("%s.%*f", (conv['currency_symbol'], 
... conv['frac_digits'], x), grouping=True)
'$1,234,567.80'
11.2 Templating

The `string` module includes a versatile `Template` class with a simplified syntax suitable for editing by end-users. This allows users to customize their applications without having to alter the application.

The format uses placeholder names formed by "$" with valid Python identifiers (alphanumeric characters and underscores). Surrounding the placeholder with braces allows it to be followed by more alphanumeric letters with no intervening spaces. Writing "$\$" creates a single escaped "$":

```python
>>> from string import Template
>>> t = Template('${village}folk send $10 to $cause.')
>>> t.substitute(village='Nottingham', cause='the ditch fund.') 'Nottinghamfolk send $10 to the ditch fund.'
```

The `substitute` method raises a `KeyError` when a placeholder is not supplied in a dictionary or a keyword argument. For mail-merge style applications, user supplied data may be incomplete and the `safe_substitute` method may be more appropriate -- it will leave placeholders unchanged if data is missing:

```python
>>> t = Template('Return the $item to $owner.')
>>> d = dict(item='unladen swallow')
>>> t.substitute(d)
Traceback (most recent call last):
  ...
  KeyError: 'owner'
>>> t.safe_substitute(d) 'Return the unladen swallow to $owner.'
```

Template subclasses can specify a custom delimiter. For example, a batch renaming utility for a photo browser may elect to use percent signs for placeholders such as the current date, image sequence number, or file format:

```python
>>> import time, os.path
>>> photofiles = ['img_1074.jpg', 'img_1076.jpg', 'img_1077.jpg']
>>> class BatchRename(Template):
...    delimiter = '%'
>>> fmt = raw_input('Enter rename style (%d-date %n-seqnum %f-format) Enter rename style (%d-date %n-seqnum %f-format): Ashley_%n%f
```
>>> t = BatchRename(fmt)
>>> date = time.strftime('%d%b%y')
>>> for i, filename in enumerate(photofiles):
...     base, ext = os.path.splitext(filename)
...     newname = t.substitute(d=date, n=i, f=ext)
...     print '%s --> %s' % (filename, newname)

img_1074.jpg --> Ashley_0.jpg
img_1076.jpg --> Ashley_1.jpg
img_1077.jpg --> Ashley_2.jpg

Another application for templating is separating program logic from the details of multiple output formats. This makes it possible to substitute custom templates for XML files, plain text reports, and HTML web reports.
11.3 Working with Binary Data Record Layouts

The **struct** module provides `pack()` and `unpack()` functions for working with variable length binary record formats. The following example shows how to loop through header information in a ZIP file (with pack codes "H" and "L" representing two and four byte unsigned numbers respectively):

```python
import struct

data = open('myfile.zip', 'rb').read()
start = 0
for i in range(3):  # show the first 3 file
    start += 14
    fields = struct.unpack('LLLHH', data[start:start+16])
    crc32, comp_size, uncomp_size, filenamesize, extra_size = fields
    start += 16
    filename = data[start:start+filenamesize]
    start += filenamesize
    extra = data[start:start+extra_size]
    print filename, hex(crc32), comp_size, uncomp_size
    start += extra_size + comp_size  # skip to the next header
```

```
11.4 Multi-threading

Threading is a technique for decoupling tasks which are not sequentially dependent. Threads can be used to improve the responsiveness of applications that accept user input while other tasks run in the background. A related use case is running I/O in parallel with computations in another thread.

The following code shows how the high level threading module can run tasks in background while the main program continues to run:

```python
import threading, zipfile

class AsyncZip(threading.Thread):
    def __init__(self, infile, outfile):
        threading.Thread.__init__(self)
        self.infile = infile
        self.outfile = outfile
    def run(self):
        f = zipfile.ZipFile(self.outfile, 'w', zipfile.ZIP_DEFLATED)
        f.write(self.infile)
        f.close()
        print 'Finished background zip of: ', self.infile

background = AsyncZip('mydata.txt', 'myarchive.zip')
background.start()
print 'The main program continues to run in foreground.'

background.join()    # Wait for the background task to finish
print 'Main program waited until background was done.'
```

The principal challenge of multi-threaded applications is coordinating threads that share data or other resources. To that end, the threading module provides a number of synchronization primitives including locks, events, condition variables, and semaphores.

While those tools are powerful, minor design errors can result in problems that are difficult to reproduce. So, the preferred approach to task coordination is to concentrate all access to a resource in a single thread and then use the Queue module to feed that thread with requests from other threads. Applications using Queue objects for inter-thread communication and coordination are easier to design, more readable, and more reliable.
11.5 Logging

The `logging` module offers a full featured and flexible logging system. At its simplest, log messages are sent to a file or to `sys.stderr`:

```python
import logging
logging.debug('Debugging information')
logging.info('Informational message')
logging.warning('Warning: config file %s not found', 'server.conf')
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')
```

This produces the following output:

```
WARNING:root:Warning: config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root:Critical error -- shutting down
```

By default, informational and debugging messages are suppressed and the output is sent to standard error. Other output options include routing messages through email, datagrams, sockets, or to an HTTP Server. New filters can select different routing based on message priority: `DEBUG`, `INFO`, `WARNING`, `ERROR`, and `CRITICAL`.

The logging system can be configured directly from Python or can be loaded from a user editable configuration file for customized logging without altering the application.
11.6 Weak References

Python does automatic memory management (reference counting for most objects and garbage collection to eliminate cycles). The memory is freed shortly after the last reference to it has been eliminated.

This approach works fine for most applications but occasionally there is a need to track objects only as long as they are being used by something else. Unfortunately, just tracking them creates a reference that makes them permanent. The weakref module provides tools for tracking objects without creating a reference. When the object is no longer needed, it is automatically removed from a weakref table and a callback is triggered for weakref objects. Typical applications include caching objects that are expensive to create:

```python
>>> import weakref, gc
>>> class A:
...    def __init__(self, value):
...        self.value = value
...    def __repr__(self):
...        return str(self.value)
...
>>> a = A(10)  # create a reference
>>> d = weakref.WeakValueDictionary()  # does not create a reference
>>> d['primary'] = a  # fetch the object if it is still
10
>>> del a  # remove the one reference
>>> gc.collect()  # run garbage collection right away
0
>>> d['primary']  # entry was automatically removed
Traceback (most recent call last):
  File "<pyshell#108>", line 1, in -toplevel-
    d['primary']  # entry was automatically remove
File "C:/PY24/lib/weakref.py", line 46, in __getitem__
    o = self.data[key]()
KeyError: 'primary'
```
11.7 Tools for Working with Lists

Many data structure needs can be met with the built-in list type. However, sometimes there is a need for alternative implementations with different performance trade-offs.

The `array` module provides an `array()` object that is like a list that stores only homogenous data but stores it more compactly. The following example shows an array of numbers stored as two byte unsigned binary numbers (typecode "H") rather than the usual 16 bytes per entry for regular lists of python int objects:

```python
>>> from array import array
>>> a = array('H', [4000, 10, 700, 22222])
>>> sum(a)
26932
>>> a[1:3]
array('H', [10, 700])
```

The `collections` module provides a `deque()` object that is like a list with faster appends and pops from the left side but slower lookups in the middle. These objects are well suited for implementing queues and breadth first tree searches:

```python
>>> from collections import deque
>>> d = deque(['task1', 'task2', 'task3'])
>>> d.append('task4')
>>> print 'Handling', d.popleft()
Handling task1
unsearched = deque([starting_node])
def breadth_first_search(unsearched):
    node = unsearched.popleft()
    for m in gen_moves(node):
        if is_goal(m):
            return m
        unsearched.append(m)
```

In addition to alternative list implementations, the library also offers other tools such as the `bisect` module with functions for manipulating sorted lists:

```python
>>> import bisect
>>> scores = [(100, 'perl'), (200, 'tcl'), (400, 'lua'), (500, 'python')]
```
The `heapq` module provides functions for implementing heaps based on regular lists. The lowest valued entry is always kept at position zero. This is useful for applications which repeatedly access the smallest element but do not want to run a full list sort:

```python
>>> from heapq import heapify, heappop, heappush
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> heapify(data)  # rearrange the list into
>>> heappush(data, -5)  # add a new entry
>>> [heappop(data) for i in range(3)]  # fetch the three smallest
[-5, 0, 1]
```
11.8 Decimal Floating Point Arithmetic

The `decimal` module offers a `Decimal` datatype for decimal floating point arithmetic. Compared to the built-in `float` implementation of binary floating point, the new class is especially helpful for financial applications and other uses which require exact decimal representation, control over precision, control over rounding to meet legal or regulatory requirements, tracking of significant decimal places, or for applications where the user expects the results to match calculations done by hand.

For example, calculating a 5% tax on a 70 cent phone charge gives different results in decimal floating point and binary floating point. The difference becomes significant if the results are rounded to the nearest cent:

```python
>>> from decimal import *
>>> Decimal('0.70') * Decimal('1.05')
Decimal("0.7350")
>>> .70 * 1.05
0.73499999999999999
```

The `Decimal` result keeps a trailing zero, automatically inferring four place significance from multiplicands with two place significance. Decimal reproduces mathematics as done by hand and avoids issues that can arise when binary floating point cannot exactly represent decimal quantities.

Exact representation enables the `Decimal` class to perform modulo calculations and equality tests that are unsuitable for binary floating point:

```python
>>> Decimal('1.00') % Decimal('.10')
Decimal("0.00")
>>> 1.00 % 0.10
0.9999999999999995
>>> sum([Decimal('0.1')]*10) == Decimal('1.0')
True
>>> sum([0.1]*10) == 1.0
False
```

The `decimal` module provides arithmetic with as much precision as needed:
>>> getcontext().prec = 36
>>> Decimal(1) / Decimal(7)
Decimal("0.142857142857142857142857142857142857")
12. What Now?

Reading this tutorial has probably reinforced your interest in using Python -- you should be eager to apply Python to solving your real-world problems. Now what should you do?

You should read, or at least page through, the Python Library Reference, which gives complete (though terse) reference material about types, functions, and modules that can save you a lot of time when writing Python programs. The standard Python distribution includes a lot of code in both C and Python; there are modules to read Unix mailboxes, retrieve documents via HTTP, generate random numbers, parse command-line options, write CGI programs, compress data, and a lot more; skimming through the Library Reference will give you an idea of what's available.

The major Python Web site is http://www.python.org/; it contains code, documentation, and pointers to Python-related pages around the Web. This Web site is mirrored in various places around the world, such as Europe, Japan, and Australia; a mirror may be faster than the main site, depending on your geographical location. A more informal site is http://starship.python.net/, which contains a bunch of Python-related personal home pages; many people have downloadable software there. Many more user-created Python modules can be found in the Python Package Index (PyPI).

For Python-related questions and problem reports, you can post to the newsgroup comp.lang.python, or send them to the mailing list at python-list@python.org. The newsgroup and mailing list are gatewayed, so messages posted to one will automatically be forwarded to the other. There are around 120 postings a day (with peaks up to several hundred), asking (and answering) questions, suggesting new features, and announcing new modules. Before posting, be sure to check the list of Frequently Asked Questions (also called the FAQ), or look for it in the Misc/ directory of the Python source distribution. Mailing list archives are available at http://www.python.org/pipermail/. The FAQ answers many of the questions that come up again and again, and may already contain the solution for your problem.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.

- A.1 Line Editing
- A.2 History Substitution
- A.3 Key Bindings
- A.4 Commentary
A. Interactive Input Editing and History Substitution

Some versions of the Python interpreter support editing of the current input line and history substitution, similar to facilities found in the Korn shell and the GNU Bash shell. This is implemented using the GNU Readline library, which supports Emacs-style and vi-style editing. This library has its own documentation which I won't duplicate here; however, the basics are easily explained. The interactive editing and history described here are optionally available in the UNIX and Cygwin versions of the interpreter.

This chapter does not document the editing facilities of Mark Hammond's PythonWin package or the Tk-based environment, IDLE, distributed with Python. The command line history recall which operates within DOS boxes on NT and some other DOS and Windows flavors is yet another beast.
A.1 Line Editing

If supported, input line editing is active whenever the interpreter prints a primary or secondary prompt. The current line can be edited using the conventional Emacs control characters. The most important of these are: C-A (Control-A) moves the cursor to the beginning of the line, C-E to the end, C-B moves it one position to the left, C-F to the right. Backspace erases the character to the left of the cursor, C-D the character to its right. C-K kills (erases) the rest of the line to the right of the cursor, C-Y yanks back the last killed string. C-underscore undoes the last change you made; it can be repeated for cumulative effect.
A.2 History Substitution

History substitution works as follows. All non-empty input lines issued are saved in a history buffer, and when a new prompt is given you are positioned on a new line at the bottom of this buffer. C-P moves one line up (back) in the history buffer, C-N moves one down. Any line in the history buffer can be edited; an asterisk appears in front of the prompt to mark a line as modified. Pressing the Return key passes the current line to the interpreter. C-R starts an incremental reverse search; C-S starts a forward search.
A.3 Key Bindings

The key bindings and some other parameters of the Readline library can be customized by placing commands in an initialization file called ~/.inputrc. Key bindings have the form

```
key-name: function-name
```

or

```
"string": function-name
```

and options can be set with

```
set option-name value
```

For example:

```
# I prefer vi-style editing:
set editing-mode vi

# Edit using a single line:
set horizontal-scroll-mode On

# Rebind some keys:
Meta-h: backward-kill-word
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
```

Note that the default binding for Tab in Python is to insert a Tab character instead of Readline's default filename completion function. If you insist, you can override this by putting

```
Tab: complete
```

in your ~/.inputrc. (Of course, this makes it harder to type indented continuation lines if you're accustomed to using Tab for that purpose.)

Automatic completion of variable and module names is optionally available. To enable it in the interpreter's interactive mode, add the following to your startup file:

```
A.1
```
import rlcompleter, readline
readline.parse_and_bind('tab: complete')

This binds the Tab key to the completion function, so hitting the Tab key twice suggests completions; it looks at Python statement names, the current local variables, and the available module names. For dotted expressions such as string.a, it will evaluate the expression up to the final "." and then suggest completions from the attributes of the resulting object. Note that this may execute application-defined code if an object with a __getattr__() method is part of the expression.

A more capable startup file might look like this example. Note that this deletes the names it creates once they are no longer needed; this is done since the startup file is executed in the same namespace as the interactive commands, and removing the names avoids creating side effects in the interactive environment. You may find it convenient to keep some of the imported modules, such as os, which turn out to be needed in most sessions with the interpreter.

    # Add auto-completion and a stored history file of commands to your
    # interactive interpreter. Requires Python 2.0+, readline. Autocomple
    # bound to the Esc key by default (you can change it - see readline
    #
    # Store the file in ~/.pystartup, and set an environment variable to
    # to it: "export PYTHONSTARTUP=/max/home/itamar/.pystartup" in bash
    #
    # Note that PYTHONSTARTUP does *not* expand "~", so you have to put
    # full path to your home directory.

    import atexit
    import os
    import readline
    import rlcompleter

    historyPath = os.path.expanduser("~/.pyhistory")

    def save_history(historyPath=historyPath):
        import readline
        readline.write_history_file(historyPath)

    if os.path.exists(historyPath):
        readline.read_history_file(historyPath)

    atexit.register(save_history)
    del os, atexit, readline, rlcompleter, save_history, historyPath
A.4 Commentary

This facility is an enormous step forward compared to earlier versions of the interpreter; however, some wishes are left: It would be nice if the proper indentation were suggested on continuation lines (the parser knows if an indent token is required next). The completion mechanism might use the interpreter's symbol table. A command to check (or even suggest) matching parentheses, quotes, etc., would also be useful.

Footnotes

... file:A.1
Python will execute the contents of a file identified by the PYTHONSTARTUP environment variable when you start an interactive interpreter.

- **B.1 Representation Error**
B. Floating Point Arithmetic: Issues and Limitations

Floating-point numbers are represented in computer hardware as base 2 (binary) fractions. For example, the decimal fraction

0.125

has value 1/10 + 2/100 + 5/1000, and in the same way the binary fraction

0.001

has value 0/2 + 0/4 + 1/8. These two fractions have identical values, the only real difference being that the first is written in base 10 fractional notation, and the second in base 2.

Unfortunately, most decimal fractions cannot be represented exactly as binary fractions. A consequence is that, in general, the decimal floating-point numbers you enter are only approximated by the binary floating-point numbers actually stored in the machine.

The problem is easier to understand at first in base 10. Consider the fraction 1/3. You can approximate that as a base 10 fraction:

0.3

or, better,

0.33

or, better,

0.333

and so on. No matter how many digits you're willing to write down, the result will never be exactly 1/3, but will be an increasingly better approximation of 1/3.

In the same way, no matter how many base 2 digits you're willing to use, the decimal value 0.1 cannot be represented exactly as a base 2 fraction. In base 2,
1/10 is the infinitely repeating fraction

\[ 0.000110011001100110011001100110011001100110011\ldots \]

Stop at any finite number of bits, and you get an approximation. This is why you see things like:

```python
>>> 0.1
0.10000000000000001
```

On most machines today, that is what you'll see if you enter 0.1 at a Python prompt. You may not, though, because the number of bits used by the hardware to store floating-point values can vary across machines, and Python only prints a decimal approximation to the true decimal value of the binary approximation stored by the machine. On most machines, if Python were to print the true decimal value of the binary approximation stored for 0.1, it would have to display

```python
>>> 0.1
0.1000000000000000055511151231257827021181583404541015625
```

instead! The Python prompt uses the builtin `repr()` function to obtain a string version of everything it displays. For floats, `repr(float)` rounds the true decimal value to 17 significant digits, giving

```
0.10000000000000001
```

`repr(float)` produces 17 significant digits because it turns out that's enough (on most machines) so that `eval(repr(x)) == x` exactly for all finite floats `x`, but rounding to 16 digits is not enough to make that true.

Note that this is in the very nature of binary floating-point: this is not a bug in Python, and it is not a bug in your code either. You'll see the same kind of thing in all languages that support your hardware's floating-point arithmetic (although some languages may not `display` the difference by default, or in all output modes).

Python's builtin `str()` function produces only 12 significant digits, and you may wish to use that instead. It's unusual for `eval(str(x))` to reproduce `x`, but the output may be more pleasant to look at:

```python
>>> print(str(0.1))
```
It's important to realize that this is, in a real sense, an illusion: the value in the machine is not exactly 1/10, you're simply rounding the *display* of the true machine value.

Other surprises follow from this one. For example, after seeing

```
>>> 0.1
0.10000000000000001
```

you may be tempted to use the `round()` function to chop it back to the single digit you expect. But that makes no difference:

```
>>> round(0.1, 1)
0.10000000000000001
```

The problem is that the binary floating-point value stored for "0.1" was already the best possible binary approximation to 1/10, so trying to round it again can't make it better: it was already as good as it gets.

Another consequence is that since 0.1 is not exactly 1/10, summing ten values of 0.1 may not yield exactly 1.0, either:

```
>>> sum = 0.0
>>> for i in range(10):
...     sum += 0.1
...
>>> sum
0.9999999999999989
```

Binary floating-point arithmetic holds many surprises like this. The problem with "0.1" is explained in precise detail below, in the "Representation Error" section. See *The Perils of Floating Point* for a more complete account of other common surprises.

As that says near the end, "there are no easy answers." Still, don't be unduly wary of floating-point! The errors in Python float operations are inherited from the floating-point hardware, and on most machines are on the order of no more than 1 part in $2^{**53}$ per operation. That's more than adequate for most tasks, but you do need to keep in mind that it's not decimal arithmetic, and that every float operation can suffer a new rounding error.
While pathological cases do exist, for most casual use of floating-point arithmetic you'll see the result you expect in the end if you simply round the display of your final results to the number of decimal digits you expect. `str()` usually suffices, and for finer control see the discussion of Python's `%` format operator: the `%g`, `%f` and `%e` format codes supply flexible and easy ways to round float results for display.
B.1 Representation Error

This section explains the ``0.1'' example in detail, and shows how you can perform an exact analysis of cases like this yourself. Basic familiarity with binary floating-point representation is assumed.

*Representation error* refers to fact that some (most, actually) decimal fractions cannot be represented exactly as binary (base 2) fractions. This is the chief reason why Python (or Perl, C, C++, Java, Fortran, and many others) often won't display the exact decimal number you expect:

```
>>> 0.1
0.10000000000000001
```

Why is that? 1/10 is not exactly representable as a binary fraction. Almost all machines today (November 2000) use IEEE-754 floating point arithmetic, and almost all platforms map Python floats to IEEE-754 "double precision". 754 doubles contain 53 bits of precision, so on input the computer strives to convert 0.1 to the closest fraction it can of the form \(J/2^N\) where \(J\) is an integer containing exactly 53 bits. Rewriting

\[
1 / 10 \approx J / (2^N)
\]

as

\[
J \approx 2^N / 10
\]

and recalling that \(J\) has exactly 53 bits (is \(\geq 2^{52}\) but \(< 2^{53}\)), the best value for \(N\) is 56:

```
>>> 2**52
4503599627370496L
>>> 2**53
9007199254740992L
>>> 2**56/10
7205759403792793L
```

That is, 56 is the only value for \(N\) that leaves \(J\) with exactly 53 bits. The best possible value for \(J\) is then that quotient rounded:

```
>>> q, r = divmod(2**56, 10)
```
Since the remainder is more than half of 10, the best approximation is obtained by rounding up:

```python
>>> q+1
7205759403792794L
```

Therefore the best possible approximation to 1/10 in 754 double precision is that over 2**56, or

```latex
\frac{7205759403792794}{72057594037927936}
```

Note that since we rounded up, this is actually a little bit larger than 1/10; if we had not rounded up, the quotient would have been a little bit smaller than 1/10. But in no case can it be exactly 1/10!

So the computer never ``sees" 1/10: what it sees is the exact fraction given above, the best 754 double approximation it can get:

```python
>>> .1 * 2**56
7205759403792794.0
```

If we multiply that fraction by 10**30, we can see the (truncated) value of its 30 most significant decimal digits:

```python
>>> 7205759403792794 * 10**30 / 2**56
100000000000000005551115123125L
```

meaning that the exact number stored in the computer is approximately equal to the decimal value 0.100000000000000005551115123125. Rounding that to 17 significant digits gives the 0.10000000000000000000001 that Python displays (well, will display on any 754-conforming platform that does best-possible input and output conversions in its C library -- yours may not!).

C.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
C.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.4.4

1. This LICENSE AGREEMENT is between the Python Software Foundation (``PSF''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 2.4.4 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.4.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., ``Copyright © 2001-2006 Python Software Foundation; All Rights Reserved'' are retained in Python 2.4.4 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.4.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.4.4.

4. PSF is making Python 2.4.4 available to Licensee on an ``AS IS'' basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.4.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS
OF PYTHON 2.4.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.4.4, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.4.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (``BeOpen''), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (``Licensee'') accessing and otherwise using this software in source or binary form and its associated documentation (``the Software '').

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an ``AS IS'' basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT
LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the ``BeOpen Python'' logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

**CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1**

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (``CNRI''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to
reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013.''

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS'' basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual
property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

C.3.4 MD5 message digest algorithm

The source code for the md5 module contains the following notice:

Copyright (C) 1991-2, RSA Data Security, Inc. Created 1991. All rights reserved.

License to copy and use this software is granted provided that it is identified as the "RSA Data Security, Inc. MD5 Message-Digest Algorithm" in all material mentioning or referencing this software or this function.

License is also granted to make and use derivative works provided that such works are identified as "derived from the RSA Data Security, Inc. MD5 Message-Digest Algorithm" in all material mentioning or referencing the derived work.

RSA Data Security, Inc. makes no representations concerning either the merchantability of this software or the suitability of this software for any particular purpose. It is provided "as is" without express or implied warranty of any kind.

These notices must be retained in any copies of any part of this documentation and/or software.
C.3.5 Asynchronous socket services

The `asynchat` and `asyncore` modules contain the following notice:

Copyright 1996 by Sam Rushing

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3.6 Cookie management

The Cookie module contains the following notice:

Copyright 2000 by Timothy O'Malley <timo@alum.mit.edu>

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Timothy O'Malley not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

Timothy O'Malley DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL Timothy O'Malley BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3.7 Profiling

The profile and pstats modules contain the following notice:

Copyright 1994, by InfoSeek Corporation, all rights reserved.
Written by James Roskind

Permission to use, copy, modify, and distribute this Python software and its associated documentation for any purpose (subject to the restriction in the following sentence) without fee is hereby granted that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of InfoSeek Corporation not be used advertising or publicity pertaining to distribution of the software without specific, written prior permission.  This permission is explicitly restricted to the copying and modification of the software to remain in Python, compiled Python, or other languages (such as C wherein the modified or derived code is exclusively imported into a Python module.

INFOSEEK CORPORATION DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. and that both that copyright notice and this permission notice appe
supporting documentation, and that the name of neither Automatrix,
Bioreason or Mojam Media be used in advertising or publicity pertai
distribution of the software without specific, written prior permis
C.3.9 UUencode and UUdecode functions

The uu module contains the following notice:

Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and its
documentation for any purpose and without fee is hereby granted,
provided that the above copyright notice appear in all copies and that
both that copyright notice and this permission notice appear in
supporting documentation, and that the name of Lance Ellinghouse
not be used in advertising or publicity pertaining to distribution
of the software without specific, written prior permission.
LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO
THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY
FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE
FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES
WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion
  between ascii and binary. This results in a 1000-fold speedup. Th
  version is still 5 times faster, though.
- Arguments more compliant with python standard
C.3.10 XML Remote Procedure Calls

The `xmlrpclib` module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB

D. Glossary

>>> The typical Python prompt of the interactive shell. Often seen for code examples that can be tried right away in the interpreter.

... The typical Python prompt of the interactive shell when entering code for an indented code block.

BDFL
Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python's creator.

byte code
The internal representation of a Python program in the interpreter. The byte code is also cached in .pyc and .pyo files so that executing the same file is faster the second time (recompilation from source to byte code can be avoided). This ``intermediate language'' is said to run on a ``virtual machine'' that calls the subroutines corresponding to each bytecode.

classic class
Any class which does not inherit from object. See new-style class.

coection
The implicit conversion of an instance of one type to another during an operation which involves two arguments of the same type. For example, \texttt{int(3.15)} converts the floating point number to the integer 3, but in \texttt{3+4.5}, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a \texttt{TypeError}. Coercion between two operands can be performed with the \texttt{coerce} built-in function; thus, \texttt{3+4.5} is equivalent to calling \texttt{operator.add(*coerce(3, 4.5))} and results in \texttt{operator.add(3.0, 4.5)}. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., \texttt{float(3)+4.5} rather than just \texttt{3+4.5}.

complex number
An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of \(-1\)), often written \(i\) in mathematics or \(j\) in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a \(j\) suffix, e.g., \(3+1j\). To get access to complex equivalents of the \texttt{math} module, use \texttt{cmath}. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

**descriptor**

Any new-style object that defines the methods \texttt{__get__()}, \texttt{__set__()}, or \texttt{__delete__()}. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, writing \texttt{a.b} looks up the object \(b\) in the class dictionary for \(a\), but if \(b\) is a descriptor, the defined method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

**dictionary**

An associative array, where arbitrary keys are mapped to values. The use of \texttt{dict} much resembles that for \texttt{list}, but the keys can be any object with a \texttt{__hash__()} function, not just integers starting from zero. Called a hash in Perl.

**duck-typing**

Pythonic programming style that determines an object's type by inspection of its method or attribute signature rather than by explicit relationship to some type object ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using \texttt{type()} or \texttt{isinstance()}. Instead, it typically employs \texttt{hasattr()} tests or EAFP programming.

**EAFP**

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is
characterized by the presence of many try and except statements. The technique contrasts with the LBYL style that is common in many other languages such as C.

__future__
A pseudo module which programmers can use to enable new language features which are not compatible with the current interpreter. For example, the expression 11/4 currently evaluates to 2. If the module in which it is executed had enabled true division by executing:

```python
from __future__ import division
```
the expression 11/4 would evaluate to 2.75. By importing the __future__ module and evaluating its variables, you can see when a new feature was first added to the language and when it will become the default:

```python
>>> import __future__
>>> __future__.division
__Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha', 0), 8192)
```

generator
A function that returns an iterator. It looks like a normal function except that values are returned to the caller using a yield statement instead of a return statement. Generator functions often contain one or more for or while loops that yield elements back to the caller. The function execution is stopped at the yield keyword (returning the result) and is resumed there when the next element is requested by calling the next() method of the returned iterator.

generator expression
An expression that returns a generator. It looks like a normal expression followed by a for expression defining a loop variable, range, and an optional if expression. The combined expression generates values for an enclosing function:

```python
>>> sum(i*i for i in range(10))  # sum of squares 0, 1, 4, 9, ...
285
```

GIL
See global interpreter lock.
**global interpreter lock**
The lock used by Python threads to assure that only one thread can be run at a time. This simplifies Python by assuring that no two processes can access the same memory at the same time. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of some parallelism on multi-processor machines. Efforts have been made in the past to create a "free-threaded" interpreter (one which locks shared data at a much finer granularity), but performance suffered in the common single-processor case.

**IDLE**
An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment that ships with the standard distribution of Python. Good for beginners, it also serves as clear example code for those wanting to implement a moderately sophisticated, multi-platform GUI application.

**immutable**
An object with fixed value. Immutable objects are numbers, strings or tuples (and more). Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

**integer division**
Mathematical division discarding any remainder. For example, the expression \( 11/4 \) currently evaluates to 2 in contrast to the \( 2.75 \) returned by float division. Also called *floor division*. When dividing two integers the outcome will always be another integer (having the floor function applied to it). However, if one of the operands is another numeric type (such as a float), the result will be coerced (see coercion) to a common type. For example, an integer divided by a float will result in a float value, possibly with a decimal fraction. Integer division can be forced by using the // operator instead of the / operator. See also __future__.

**interactive**
Python has an interactive interpreter which means that you can try out things and immediately see their results. Just launch python with no arguments (possibly by selecting it from your computer's main menu). It is
a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

**interpreted**

Python is an interpreted language, as opposed to a compiled one. This means that the source files can be run directly without first creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also *interactive*.

**iterable**

A container object capable of returning its members one at a time. Examples of iterables include all sequence types (such as `list`, `str`, and `tuple`) and some non-sequence types like `dict` and `file` and objects of any classes you define with an `__iter__()` or `__getitem__()` method. Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, ...). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also *iterator*, *sequence*, and *generator*.

**iterator**

An object representing a stream of data. Repeated calls to the iterator's `next()` method return successive items in the stream. When no more data is available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `next()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code that attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty
container.

**LBYL**

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the *EAFP* approach and is characterized by the presence of many `if` statements.

**list comprehension**

A compact way to process all or a subset of elements in a sequence and return a list with the results. `result = ['0x%02x' % x for x in range(256) if x % 2 == 0]` generates a list of strings containing hex numbers (0x..) that are even and in the range from 0 to 255. The `if` clause is optional. If omitted, all elements in `range(256)` are processed.

**mapping**

A container object (such as `dict`) that supports arbitrary key lookups using the special method `__getitem__()`.

**metaclass**

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

**mutable**

Mutable objects can change their value but keep their `id()`. See also `immutable`.

**namespace**

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `__builtin__.open()` and `os.open()` are distinguished by their
namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.izip()` makes it clear that those functions are implemented by the `random` and `itertools` modules respectively.

**nested scope**

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes work only for reference and not for assignment which will always write to the innermost scope. In contrast, local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace.

**new-style class**

Any class that inherits from `object`. This includes all built-in types like `list` and `dict`. Only new-style classes can use Python's newer, versatile features like `__slots__`, descriptors, properties, `__getattribute__()`, class methods, and static methods.

**Python3000**

A mythical python release, not required to be backward compatible, with telepathic interface.

`__slots__`

A declaration inside a new-style class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

**sequence**

An iterable which supports efficient element access using integer indices via the `__getitem__()` and `__len__()` special methods. Some built-in sequence types are `list`, `str`, `tuple`, and `unicode`. Note that `dict` also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary `immutable` keys rather than integers.
Zen of Python

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing ``import this'' at the interactive prompt.

Release 2.4.4c1
11 October 2006

- Front Matter
- Contents
- 1. Introduction
- 2. Built-In Objects
  - 2.1 Built-in Functions
  - 2.2 Non-essential Built-in Functions
  - 2.3 Built-in Types
    - 2.3.1 Truth Value Testing
    - 2.3.2 Boolean Operations -- and, or, not
    - 2.3.3 Comparisons
    - 2.3.4 Numeric Types -- int, float, long, complex
    - 2.3.5 Iterator Types
    - 2.3.6 Sequence Types -- str, unicode, list, tuple, buffer, xrange
    - 2.3.7 Set Types -- set, frozenset
    - 2.3.8 Mapping Types -- classdict
    - 2.3.9 File Objects
    - 2.3.10 Other Built-in Types
    - 2.3.11 Special Attributes
  - 2.4 Built-in Exceptions
  - 2.5 Built-in Constants
- 3. Python Runtime Services
3.1 sys -- System-specific parameters and functions
3.2 gc -- Garbage Collector interface
3.3 weakref -- Weak references
   - 3.3.1 Weak Reference Objects
   - 3.3.2 Example
   - 3.3.3 Weak References in Extension Types
3.4 fpectl -- Floating point exception control
   - 3.4.1 Example
   - 3.4.2 Limitations and other considerations
3.5 atexit -- Exit handlers
   - 3.5.1 atexit Example
3.6 types -- Names for built-in types
3.7 UserDict -- Class wrapper for dictionary objects
3.8 UserList -- Class wrapper for list objects
3.9 UserString -- Class wrapper for string objects
3.10 operator -- Standard operators as functions
   - 3.10.1 Mapping Operators to Functions
3.11 inspect -- Inspect live objects
   - 3.11.1 Types and members
   - 3.11.2 Retrieving source code
   - 3.11.3 Classes and functions
   - 3.11.4 The interpreter stack
3.12 traceback -- Print or retrieve a stack traceback
   - 3.12.1 Traceback Example
3.13 linecache -- Random access to text lines
3.14 pickle -- Python object serialization
   - 3.14.1 Relationship to other Python modules
   - 3.14.2 Data stream format
   - 3.14.3 Usage
   - 3.14.4 What can be pickled and unpickled?
   - 3.14.5 The pickle protocol
   - 3.14.6 Subclassing Unpicklers
   - 3.14.7 Example
3.15 cPickle -- A faster pickle
3.16 copy_reg -- Register pickle support functions
3.17 shelve -- Python object persistence
   - 3.17.1 Restrictions
   - 3.17.2 Example
• **3.18 copy -- Shallow and deep copy operations**
• **3.19 marshal -- Internal Python object serialization**
• **3.20 warnings -- Warning control**
  • 3.20.1 Warning Categories
  • 3.20.2 The Warnings Filter
  • 3.20.3 Available Functions
• **3.21 imp -- Access the import internals**
  • 3.21.1 Examples
• **3.22 zipimport -- Import modules from Zip archives**
  • 3.22.1 zipimporter Objects
  • 3.22.2 Examples
• **3.23 pkgutil -- Package extension utility**
• **3.24 modulefinder -- Find modules used by a script**
• **3.25 code -- Interpreter base classes**
  • 3.25.1 Interactive Interpreter Objects
  • 3.25.2 Interactive Console Objects
• **3.26 codeop -- Compile Python code**
• **3.27 pprint -- Data pretty printer**
  • 3.27.1 PrettyPrinter Objects
• **3.28 repr -- Alternate repr() implementation**
  • 3.28.1 Repr Objects
  • 3.28.2 Subclassing Repr Objects
• **3.29 new -- Creation of runtime internal objects**
• **3.30 site -- Site-specific configuration hook**
• **3.31 user -- User-specific configuration hook**
• **3.32 __builtin__ -- Built-in objects**
• **3.33 __main__ -- Top-level script environment**
• **3.34 __future__ -- Future statement definitions**

• **4. String Services**
• **4.1 string -- Common string operations**
  • 4.1.1 String constants
  • 4.1.2 Template strings
  • 4.1.3 String functions
  • 4.1.4 Deprecated string functions
• **4.2 re -- Regular expression operations**
  • 4.2.1 Regular Expression Syntax
  • 4.2.2 Matching vs Searching
  • 4.2.3 Module Contents
4.2.4 Regular Expression Objects
4.2.5 Match Objects
4.2.6 Examples

4.3 struct -- Interpret strings as packed binary data
4.4 difflib -- Helpers for computing deltas
  4.4.1 SequenceMatcher Objects
  4.4.2 SequenceMatcher Examples
  4.4.3 Differ Objects
  4.4.4 Differ Example

4.5 fpformat -- Floating point conversions
4.6 StringIO -- Read and write strings as files
4.7 cStringIO -- Faster version of StringIO
4.8 textwrap -- Text wrapping and filling
4.9 codecs -- Codec registry and base classes
  4.9.1 Codec Base Classes
  4.9.2 Standard Encodings
  4.9.3 encodings.idna -- Internationalized Domain Names in Applications

4.10 unicodedata -- Unicode Database
4.11 stringprep -- Internet String Preparation

5. Miscellaneous Services
5.1 pydoc -- Documentation generator and online help system
5.2 doctest -- Test interactive Python examples
  5.2.1 Simple Usage: Checking Examples in Docstrings
  5.2.2 Simple Usage: Checking Examples in a Text File
  5.2.3 How It Works
  5.2.4 Basic API
  5.2.5 Unittest API
  5.2.6 Advanced API
  5.2.7 Debugging
  5.2.8 Soapbox

5.3 unittest -- Unit testing framework
  5.3.1 Basic example
  5.3.2 Organizing test code
  5.3.3 Re-using old test code
  5.3.4 Classes and functions
  5.3.5 TestCase Objects
  5.3.6 TestSuite Objects
5.3.7 TestResult Objects
5.3.8 TestLoader Objects

5.4 test -- Regression tests package for Python
  5.4.1 Writing Unit Tests for the test package
  5.4.2 Running tests using test.regrtest

5.5 test.test_support -- Utility functions for tests

5.6 decimal -- Decimal floating point arithmetic
  5.6.1 Quick-start Tutorial
  5.6.2 Decimal objects
  5.6.3 Context objects
  5.6.4 Signals
  5.6.5 Floating Point Notes
  5.6.6 Working with threads
  5.6.7 Recipes
  5.6.8 Decimal FAQ

5.7 math -- Mathematical functions

5.8 cmath -- Mathematical functions for complex numbers

5.9 random -- Generate pseudo-random numbers

5.10 whrandom -- Pseudo-random number generator

5.11 bisect -- Array bisection algorithm
  5.11.1 Examples

5.12 collections -- High-performance container datatypes
  5.12.1 Recipes

5.13 heapq -- Heap queue algorithm
  5.13.1 Theory

5.14 array -- Efficient arrays of numeric values

5.15 sets -- Unordered collections of unique elements
  5.15.1 Set Objects
  5.15.2 Example
  5.15.3 Protocol for automatic conversion to immutable
  5.15.4 Comparison to the built-in set types

5.16 itertools -- Functions creating iterators for efficient looping
  5.16.1 Itertool functions
  5.16.2 Examples
  5.16.3 Recipes

5.17 ConfigParser -- Configuration file parser
  5.17.1 RawConfigParser Objects
  5.17.2 ConfigParser Objects
5.17.3 SafeConfigParser Objects

5.18 fileinput -- Iterate over lines from multiple input streams

5.19 calendar -- General calendar-related functions

5.20 cmd -- Support for line-oriented command interpreters
  5.20.1 Cmd Objects

5.21 shlex -- Simple lexical analysis
  5.21.1 shlex Objects
  5.21.2 Parsing Rules

6. Generic Operating System Services

6.1 os -- Miscellaneous operating system interfaces
  6.1.1 Process Parameters
  6.1.2 File Object Creation
  6.1.3 File Descriptor Operations
  6.1.4 Files and Directories
  6.1.5 Process Management
  6.1.6 Miscellaneous System Information
  6.1.7 Miscellaneous Functions

6.2 os.path -- Common pathname manipulations

6.3 dircache -- Cached directory listings

6.4 stat -- Interpreting stat() results

6.5 statcache -- An optimization of os.stat()

6.6 statvfs -- Constants used with os.statvfs()

6.7 filecmp -- File and Directory Comparisons
  6.7.1 The dircmp class

6.8 subprocess -- Subprocess management
  6.8.1 Using the subprocess Module
  6.8.2 Popen Objects
  6.8.3 Replacing Older Functions with the subprocess Module

6.9 popen2 -- Subprocesses with accessible I/O streams
  6.9.1 Popen3 and Popen4 Objects
  6.9.2 Flow Control Issues

6.10 datetime -- Basic date and time types
  6.10.1 Available Types
  6.10.2 timedelta Objects
  6.10.3 date Objects
  6.10.4 datetime Objects
  6.10.5 time Objects
  6.10.6 tzinfo Objects
6.10.7 strftime() Behavior

6.11 time -- Time access and conversions

6.12 sched -- Event scheduler
   6.12.1 Scheduler Objects

6.13 mutex -- Mutual exclusion support
   6.13.1 Mutex Objects

6.14 getpass -- Portable password input

6.15 curses -- Terminal handling for character-cell displays
   6.15.1 Functions
   6.15.2 Window Objects
   6.15.3 Constants

6.16 curses.textpad -- Text input widget for curses programs
   6.16.1 Textbox objects

6.17 curses.wrapper -- Terminal handler for curses programs

6.18 curses.ascii -- Utilities for ASCII characters

6.19 curses.panel -- A panel stack extension for curses
   6.19.1 Functions
   6.19.2 Panel Objects

6.20 getopt -- Parser for command line options

6.21 optparse -- More powerful command line option parser
   6.21.1 Background
   6.21.2 Tutorial
   6.21.3 Reference Guide
   6.21.4 Option Callbacks
   6.21.5 Extending optparse

6.22 tempfile -- Generate temporary files and directories

6.23 errno -- Standard errno system symbols

6.24 glob -- UNIX style pathname pattern expansion

6.25 fnmatch -- UNIX filename pattern matching

6.26 shutil -- High-level file operations
   6.26.1 Example

6.27 locale -- Internationalization services
   6.27.1 Background, details, hints, tips and caveats
   6.27.2 For extension writers and programs that embed Python
   6.27.3 Access to message catalogs

6.28 gettext -- Multilingual internationalization services
   6.28.1 GNU gettext API
   6.28.2 Class-based API
6.28.3 Internationalizing your programs and modules
6.28.4 Acknowledgements

6.29 logging -- Logging facility for Python
6.29.1 Logger Objects
6.29.2 Basic example
6.29.3 Logging to multiple destinations
6.29.4 Sending and receiving logging events across a network
6.29.5 Handler Objects
6.29.6 Formatter Objects
6.29.7 Filter Objects
6.29.8 LogRecord Objects
6.29.9 Thread Safety
6.29.10 Configuration

6.30 platform -- Access to underlying platform's identifying data.
6.30.1 Cross Platform
6.30.2 Java Platform
6.30.3 Windows Platform
6.30.4 Mac OS Platform
6.30.5 UNIX Platforms

7. Optional Operating System Services
7.1 signal -- Set handlers for asynchronous events
7.1.1 Example

7.2 socket -- Low-level networking interface
7.2.1 Socket Objects
7.2.2 SSL Objects
7.2.3 Example

7.3 select -- Waiting for I/O completion
7.3.1 Polling Objects

7.4 thread -- Multiple threads of control

7.5 threading -- Higher-level threading interface
7.5.1 Lock Objects
7.5.2 RLock Objects
7.5.3 Condition Objects
7.5.4 Semaphore Objects
7.5.5 Event Objects
7.5.6 Thread Objects
7.5.7 Timer Objects

7.6 dummy_thread -- Drop-in replacement for the thread module
- **7.7 dummy_threading** -- Drop-in replacement for the threading module
- **7.8 Queue** -- A synchronized queue class
  - **7.8.1 Queue Objects**
- **7.9 mmap** -- Memory-mapped file support
- **7.10 anydbm** -- Generic access to DBM-style databases
- **7.11 dbhash** -- DBM-style interface to the BSD database library
  - **7.11.1 Database Objects**
- **7.12 whichdb** -- Guess which DBM module created a database
- **7.13 bsddb** -- Interface to Berkeley DB library
  - **7.13.1 Hash, BTree and Record Objects**
- **7.14 dumbdbm** -- Portable DBM implementation
  - **7.14.1 Dumbdbm Objects**
- **7.15 zlib** -- Compression compatible with gzip
- **7.16 gzip** -- Support for gzip files
- **7.17 bzip2** -- Compression compatible with bzip2
  - **7.17.1 (De)compression of files**
  - **7.17.2 Sequential (de)compression**
  - **7.17.3 One-shot (de)compression**
- **7.18 zipfile** -- Work with ZIP archives
  - **7.18.1 ZipFile Objects**
  - **7.18.2 PyZipFile Objects**
  - **7.18.3 ZipInfo Objects**
- **7.19 tarfile** -- Read and write tar archive files
  - **7.19.1 TarFile Objects**
  - **7.19.2 TarInfo Objects**
  - **7.19.3 Examples**
- **7.20 readline** -- GNU readline interface
  - **7.20.1 Example**
- **7.21 rlcompleter** -- Completion function for GNU readline
  - **7.21.1 Completer Objects**

### 8. Unix Specific Services
- **8.1 posix** -- The most common POSIX system calls
  - **8.1.1 Large File Support**
  - **8.1.2 Module Contents**
- **8.2 pwd** -- The password database
- **8.3 grp** -- The group database
- **8.4 crypt** -- Function to check UNIX passwords
8.5 dl -- Call C functions in shared objects
  8.5.1 Dl Objects
8.6 dbm -- Simple `database' interface
8.7 gdbm -- GNU's reinterpretation of dbm
8.8 termios -- POSIX style tty control
  8.8.1 Example
8.9 tty -- Terminal control functions
8.10 pty -- Pseudo-terminal utilities
8.11 fcntl -- The fcntl() and ioctl() system calls
8.12 pipes -- Interface to shell pipelines
  8.12.1 Template Objects
8.13 posixfile -- File-like objects with locking support
8.14 resource -- Resource usage information
  8.14.1 Resource Limits
  8.14.2 Resource Usage
8.15 nis -- Interface to Sun's NIS (Yellow Pages)
8.16 syslog -- UNIX syslog library routines
8.17 commands -- Utilities for running commands

9. The Python Debugger
  9.1 Debugger Commands
  9.2 How It Works

10. The Python Profiler
  10.1 Introduction to the profiler
  10.2 How Is This Profiler Different From The Old Profiler?
  10.3 Instant Users Manual
  10.4 What Is Deterministic Profiling?
  10.5 Reference Manual
    10.5.1 The Stats Class
  10.6 Limitations
  10.7 Calibration
  10.8 Extensions -- Deriving Better Profilers
  10.9 hotshot -- High performance logging profiler
    10.9.1 Profile Objects
    10.9.2 Using hotshot data
    10.9.3 Example Usage
  10.10 timeit -- Measure execution time of small code snippets
    10.10.1 Command Line Interface
    10.10.2 Examples
11. Internet Protocols and Support

11.1 webbrowser -- Convenient Web-browser controller
   11.1.1 Browser Controller Objects

11.2 cgi -- Common Gateway Interface support.
   11.2.1 Introduction
   11.2.2 Using the cgi module
   11.2.3 Higher Level Interface
   11.2.4 Old classes
   11.2.5 Functions
   11.2.6 Caring about security
   11.2.7 Installing your CGI script on a UNIX system
   11.2.8 Testing your CGI script
   11.2.9 Debugging CGI scripts
   11.2.10 Common problems and solutions

11.3 cgitb -- Traceback manager for CGI scripts

11.4 urllib -- Open arbitrary resources by URL
   11.4.1 URLopener Objects
   11.4.2 Examples

11.5 urllib2 -- extensible library for opening URLs
   11.5.1 Request Objects
   11.5.2 OpenerDirector Objects
   11.5.3 BaseHandler Objects
   11.5.4 HTTPRedirectHandler Objects
   11.5.5 HTTPCookieProcessor Objects
   11.5.6 ProxyHandler Objects
   11.5.7 HTTPPasswordMgr Objects
   11.5.8 AbstractBasicAuthHandler Objects
   11.5.9 HTTPBasicAuthHandler Objects
   11.5.10 ProxyBasicAuthHandler Objects
   11.5.11 AbstractDigestAuthHandler Objects
   11.5.12 HTTPDigestAuthHandler Objects
   11.5.13 ProxyDigestAuthHandler Objects
   11.5.14 HTTPHandler Objects
   11.5.15 HTTPSHandler Objects
   11.5.16 FileHandler Objects
   11.5.17 FTPHandler Objects
   11.5.18 CacheFTPHandler Objects
   11.5.19 GopherHandler Objects
- 11.5.20 UnknownHandler Objects
- 11.5.21 HTTPErrorProcessor Objects
- 11.5.22 Examples
- 11.6 httplib -- HTTP protocol client
  - 11.6.1 HTTPConnection Objects
  - 11.6.2 HTTPResponse Objects
  - 11.6.3 Examples
- 11.7 ftplib -- FTP protocol client
  - 11.7.1 FTP Objects
- 11.8 gopherlib -- Gopher protocol client
- 11.9 poplib -- POP3 protocol client
  - 11.9.1 POP3 Objects
  - 11.9.2 POP3 Example
- 11.10 imaplib -- IMAP4 protocol client
  - 11.10.1 IMAP4 Objects
  - 11.10.2 IMAP4 Example
- 11.11 nntplib -- NNTP protocol client
  - 11.11.1 NNTP Objects
- 11.12 smtplib -- SMTP protocol client
  - 11.12.1 SMTP Objects
  - 11.12.2 SMTP Example
- 11.13 smtplib -- SMTP Server
  - 11.13.1 SMTPServer Objects
  - 11.13.2 DebuggingServer Objects
  - 11.13.3 PureProxy Objects
  - 11.13.4 MailmanProxy Objects
- 11.14 telnetlib -- Telnet client
  - 11.14.1 Telnet Objects
  - 11.14.2 Telnet Example
- 11.15 urlparse -- Parse URLs into components
- 11.16 SocketServer -- A framework for network servers
  - 11.16.1 Server Creation Notes
  - 11.16.2 Server Objects
  - 11.16.3 RequestHandler Objects
- 11.17 BaseHTTPServer -- Basic HTTP server
- 11.18 SimpleHTTPServer -- Simple HTTP request handler
- 11.19 CGIHTTPServer -- CGI-capable HTTP request handler
- 11.20 cookielib -- Cookie handling for HTTP clients
11.20.1 CookieJar and FileCookieJar Objects
11.20.2 FileCookieJar subclasses and co-operation with web browsers
11.20.3 CookiePolicy Objects
11.20.4 DefaultCookiePolicy Objects
11.20.5 Cookie Objects
11.20.6 Examples

11.21 Cookie -- HTTP state management
11.21.1 Cookie Objects
11.21.2 Morsel Objects
11.21.3 Example

11.22 xmlrpclib -- XML-RPC client access
11.22.1 ServerProxy Objects
11.22.2 Boolean Objects
11.22.3 DateTime Objects
11.22.4 Binary Objects
11.22.5 Fault Objects
11.22.6 ProtocolError Objects
11.22.7 MultiCall Objects
11.22.8 Convenience Functions
11.22.9 Example of Client Usage

11.23 SimpleXMLRPCServer -- Basic XML-RPC server
11.23.1 SimpleXMLRPCServer Objects
11.23.2 CGIXMLRPCRequestHandler

11.24 DocXMLRPCServer -- Self-documenting XML-RPC server
11.24.1 DocXMLRPCServer Objects
11.24.2 DocCGIXMLRPCRequestHandler

11.25 asyncore -- Asynchronous socket handler
11.25.1 asyncore Example basic HTTP client

11.26 asynchat -- Asynchronous socket command/response handler
11.26.1 asynchat - Auxiliary Classes and Functions
11.26.2 asynchat Example

12. Internet Data Handling
12.1 formatter -- Generic output formatting
12.1.1 The Formatter Interface
12.1.2 Formatter Implementations
12.1.3 The Writer Interface
12.1.4 Writer Implementations
12.2 email -- An email and MIME handling package
   - 12.2.1 Representing an email message
   - 12.2.2 Parsing email messages
   - 12.2.3 Generating MIME documents
   - 12.2.4 Creating email and MIME objects from scratch
   - 12.2.5 Internationalized headers
   - 12.2.6 Representing character sets
   - 12.2.7 Encoders
   - 12.2.8 Exception and Defect classes
   - 12.2.9 Miscellaneous utilities
   - 12.2.10 Iterators
   - 12.2.11 Package History
   - 12.2.12 Differences from mimelib
   - 12.2.13 Examples

12.3 mailcap -- Mailcap file handling.

12.4 mailbox -- Read various mailbox formats
   - 12.4.1 Mailbox Objects

12.5 mhlib -- Access to MH mailboxes
   - 12.5.1 MH Objects
   - 12.5.2 Folder Objects
   - 12.5.3 Message Objects

12.6 mimetools -- Tools for parsing MIME messages
   - 12.6.1 Additional Methods of Message Objects

12.7 mimetypes -- Map filenames to MIME types
   - 12.7.1 MimeTypes Objects

12.8 MimeWriter -- Generic MIME file writer
   - 12.8.1 MimeWriter Objects

12.9 mimify -- MIME processing of mail messages

12.10 multifile -- Support for files containing distinct parts
   - 12.10.1 MultiFile Objects
   - 12.10.2 MultiFile Example

12.11 rfc822 -- Parse RFC 2822 mail headers
   - 12.11.1 Message Objects
   - 12.11.2 AddressList Objects

12.12 base64 -- RFC 3548: Base16, Base32, Base64 Data Encodings

12.13 binascii -- Convert between binary and ASCII

12.14 binhex -- Encode and decode binhex4 files
   - 12.14.1 Notes
- **12.15 quopri** -- Encode and decode MIME quoted-printable data
- **12.16 uu** -- Encode and decode uuencode files
- **12.17 xdrlib** -- Encode and decode XDR data
  - 12.17.1 Packer Objects
  - 12.17.2 Unpacker Objects
  - 12.17.3 Exceptions
- **12.18 netrc** -- netrc file processing
  - 12.18.1 netrc Objects
- **12.19 robotparser** -- Parser for robots.txt
- **12.20 csv** -- CSV File Reading and Writing
  - 12.20.1 Module Contents
  - 12.20.2 Dialects and Formatting Parameters
  - 12.20.3 Reader Objects
  - 12.20.4 Writer Objects
  - 12.20.5 Examples

- **13. Structured Markup Processing Tools**
  - **13.1 HTMLParser** -- Simple HTML and XHTML parser
    - 13.1.1 Example HTML Parser Application
  - **13.2 sgmllib** -- Simple SGML parser
  - **13.3 htmlllib** -- A parser for HTML documents
    - 13.3.1 HTMLParser Objects
  - **13.4 htmlentitydefs** -- Definitions of HTML general entities
  - **13.5 xml.parsers.expat** -- Fast XML parsing using Expat
    - 13.5.1 XMLParser Objects
    - 13.5.2 ExpatError Exceptions
    - 13.5.3 Example
    - 13.5.4 Content Model Descriptions

1. Introduction

The ``Python library'' contains several different kinds of components.

It contains data types that would normally be considered part of the ``core'' of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions -- objects that can be used by all Python code without the need of an import statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, such as access to specific hardware; others provide interfaces that are specific to a particular application domain, like the World Wide Web. Some modules are available in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized ``from the inside out:'' it first describes the built-in data types, then the built-in functions and exceptions, and finally the modules, grouped in chapters of related modules. The ordering of the chapters as well as the ordering of the modules within each chapter is roughly from most relevant to least important.

This means that if you start reading this manual from the start, and skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don't have to read it like a novel -- you can also browse the table
of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module random) and read a section or two. Regardless of the order in which you read the sections of this manual, it helps to start with chapter 2, "Built-in Types, Exceptions and Functions," as the remainder of the manual assumes familiarity with this material.

Let the show begin!
2. Built-In Objects

Names for built-in exceptions and functions and a number of constants are found in a separate symbol table. This table is searched last when the interpreter looks up the meaning of a name, so local and global user-defined names can override built-in names. Built-in types are described together here for easy reference.

The tables in this chapter document the priorities of operators by listing them in order of ascending priority (within a table) and grouping operators that have the same priority in the same box. Binary operators of the same priority group from left to right. (Unary operators group from right to left, but there you have no real choice.) See chapter 5 of the *Python Reference Manual* for the complete picture on operator priorities.

---

Footnotes

... reference

Most descriptions sorely lack explanations of the exceptions that may be raised -- this will be fixed in a future version of this manual.

---

• 2.4 Built-in Exceptions
• 2.5 Built-in Constants
2.1 Built-in Functions

The Python interpreter has a number of functions built into it that are always available. They are listed here in alphabetical order.

```python
__import__(name[, globals[, locals[, fromlist]]])
```

This function is invoked by the `import` statement. It mainly exists so that you can replace it with another function that has a compatible interface, in order to change the semantics of the `import` statement. For examples of why and how you would do this, see the standard library modules `ihooks` and `reexec`. See also the built-in module `imp`, which defines some useful operations out of which you can build your own `__import__()` function.

For example, the statement "import spam" results in the following call: `__import__('spam', globals(), locals(), [])`; the statement "from spam.ham import eggs" results in `__import__('spam.ham', globals(), locals(), ['eggs'])`. Note that even though `locals()` and `['eggs']` are passed in as arguments, the `__import__()` function does not set the local variable named `eggs`; this is done by subsequent code that is generated for the import statement. (In fact, the standard implementation does not use its `locals` argument at all, and uses its `globals` only to determine the package context of the `import` statement.)

When the `name` variable is of the form `package.module`, normally, the top-level package (the name up till the first dot) is returned, not the module named by `name`. However, when a non-empty `fromlist` argument is given, the module named by `name` is returned. This is done for compatibility with the bytecode generated for the different kinds of import statement; when using "import spam.ham.eggs", the top-level package `spam` must be placed in the importing namespace, but when using "from spam.ham import eggs", the `spam.ham` subpackage must be used to find the `eggs` variable. As a workaround for this behavior, use `getattr()` to extract the desired components. For example, you could define the following helper:
def my_import(name):
    mod = __import__(name)
    components = name.split('.')
    for comp in components[1:]:
        mod = getattr(mod, comp)
    return mod

abs(x)
Return the absolute value of a number. The argument may be a plain or long
integer or a floating point number. If the argument is a complex number, its
magnitude is returned.

basestring()
This abstract type is the superclass for str and unicode. It cannot be
called or instantiated, but it can be used to test whether an object is an
instance of str or unicode. isinstance(obj, basestring) is
equivalent to isinstance(obj, (str, unicode)). New in
version 2.3.

bool([x])
Convert a value to a Boolean, using the standard truth testing procedure. If
x is false or omitted, this returns False; otherwise it returns True. bool
is also a class, which is a subclass of int. Class bool cannot be
subclassed further. Its only instances are False and True.

    New in version 2.2.1. Changed in version 2.3: If no argument is given, this
    function returns False.

callable(object)
Return true if the object argument appears callable, false if not. If this
returns true, it is still possible that a call fails, but if it is false, calling object
will never succeed. Note that classes are callable (calling a class returns a
new instance); class instances are callable if they have a __call__() method.

chr(i)
Return a string of one character whose ASCII code is the integer i. For
example, chr(97) returns the string 'a'. This is the inverse of ord().
The argument must be in the range [0..255], inclusive; ValueError will
be raised if \( i \) is outside that range.

**classmethod**(*function*)

Return a class method for *function*.

A class method receives the class as implicit first argument, just like an instance method receives the instance. To declare a class method, use this idiom:

```python
class C:
    @classmethod
    def f(cls, arg1, arg2, ...):
        ...
```

The `@classmethod` form is a function decorator - see the description of function definitions in chapter 7 of the *Python Reference Manual* for details.

It can be called either on the class (such as `C.f()`) or on an instance (such as `C().f()`). The instance is ignored except for its class. If a class method is called for a derived class, the derived class object is passed as the implied first argument.

Class methods are different than C++ or Java static methods. If you want those, see `staticmethod()` in this section.

For more information on class methods, consult the documentation on the standard type hierarchy in chapter 3 of the *Python Reference Manual* (at the bottom). New in version 2.2. Changed in version 2.4: Function decorator syntax added.

**cmp**(*x, y*)

Compare the two objects \( x \) and \( y \) and return an integer according to the outcome. The return value is negative if \( x < y \), zero if \( x == y \) and strictly positive if \( x > y \).

**compile**(*string, filename, kind[, flags[, dont_inherit]])

Compile the *string* into a code object. Code objects can be executed by an `exec` statement or evaluated by a call to `eval()`. The *filename* argument should give the file from which the code was read; pass some recognizable
value if it wasn't read from a file ('<string>' is commonly used). The 
kind argument specifies what kind of code must be compiled; it can be 
'exec' if string consists of a sequence of statements, 'eval' if it 
consists of a single expression, or 'single' if it consists of a single 
interactive statement (in the latter case, expression statements that evaluate 
to something else than None will be printed).

When compiling multi-line statements, two caveats apply: line endings 
must be represented by a single newline character ('\n'), and the input 
must be terminated by at least one newline character. If line endings are 
represented by '\r\n', use the string replace() method to change 
them into '\n'.

The optional arguments flags and dont_inherit (which are new in Python 
2.2) control which future statements (see PEP 236) affect the compilation of 
string. If neither is present (or both are zero) the code is compiled with 
those future statements that are in effect in the code that is calling compile. 
If the flags argument is given and dont_inherit is not (or is zero) then the 
future statements specified by the flags argument are used in addition to 
those that would be used anyway. If dont_inherit is a non-zero integer then 
the flags argument is it - the future statements in effect around the call to 
compile are ignored.

Future statements are specified by bits which can be bitwise or-ed together 
to specify multiple statements. The bitfield required to specify a given 
feature can be found as the compiler_flag attribute on the _Feature 
instance in the __future__ module.

complex([real[, imag]])
Create a complex number with the value real + imag*j or convert a string 
or number to a complex number. If the first parameter is a string, it will be 
interpreted as a complex number and the function must be called without a 
second parameter. The second parameter can never be a string. Each 
argument may be any numeric type (including complex). If imag is omitted, 
it defaults to zero and the function serves as a numeric conversion function 
like int(), long() and float(). If both arguments are omitted, 
returns 0j.
**delattr**( *object, name*)

This is a relative of **setattr()**. The arguments are an object and a string. The string must be the name of one of the object's attributes. The function deletes the named attribute, provided the object allows it. For example, `delattr(x, 'foobar')` is equivalent to `del x.foobar`.

**dict**( *mapping-or-sequence*)

Return a new dictionary initialized from an optional positional argument or from a set of keyword arguments. If no arguments are given, return a new empty dictionary. If the positional argument is a mapping object, return a dictionary mapping the same keys to the same values as does the mapping object. Otherwise the positional argument must be a sequence, a container that supports iteration, or an iterator object. The elements of the argument must each also be of one of those kinds, and each must in turn contain exactly two objects. The first is used as a key in the new dictionary, and the second as the key's value. If a given key is seen more than once, the last value associated with it is retained in the new dictionary.

If keyword arguments are given, the keywords themselves with their associated values are added as items to the dictionary. If a key is specified both in the positional argument and as a keyword argument, the value associated with the keyword is retained in the dictionary. For example, these all return a dictionary equal to `{"one": 2, "two": 3}`:

- `dict({'one': 2, 'two': 3})`
- `dict({'one': 2, 'two': 3}.items())`
- `dict({'one': 2, 'two': 3}.iteritems())`
- `dict(zip(('one', 'two'), (2, 3)))`
- `dict([['two', 3], ['one', 2]])`
- `dict(one=2, two=3)`
- `dict([[['one', 'two'][i-2], i] for i in (2, 3)])`

New in version 2.2. Changed in version 2.3: Support for building a dictionary from keyword arguments added.

**dir**( *object*)

Without arguments, return the list of names in the current local symbol
table. With an argument, attempts to return a list of valid attributes for that object. This information is gleaned from the object's `__dict__` attribute, if defined, and from the class or type object. The list is not necessarily complete. If the object is a module object, the list contains the names of the module's attributes. If the object is a type or class object, the list contains the names of its attributes, and recursively of the attributes of its bases. Otherwise, the list contains the object's attributes' names, the names of its class's attributes, and recursively of the attributes of its class's base classes. The resulting list is sorted alphabetically. For example:

```python
>>> import struct
>>> dir()
['__builtins__', '__doc__', '__name__', 'struct']
>>> dir(struct)
['__doc__', '__name__', 'calcsizes', 'error', 'pack', 'unpack']
```

**Note:** Because `dir()` is supplied primarily as a convenience for use at an interactive prompt, it tries to supply an interesting set of names more than it tries to supply a rigorously or consistently defined set of names, and its detailed behavior may change across releases.

**divmod**

Take two (non complex) numbers as arguments and return a pair of numbers consisting of their quotient and remainder when using long division. With mixed operand types, the rules for binary arithmetic operators apply. For plain and long integers, the result is the same as \((a / b, a \% b)\). For floating point numbers the result is \((q, a \% b)\), where \(q\) is usually `math.floor(a / b)` but may be 1 less than that. In any case \(q * b + a \% b\) is very close to \(a\), if \(a \% b\) is non-zero it has the same sign as \(b\), and \(0 \leq abs(a \% b) < abs(b)\).

Changed in version 2.3: Using `divmod()` with complex numbers is deprecated.

**enumerate**

Return an enumerate object. `iterable` must be a sequence, an iterator, or some other object which supports iteration. The `next` method of the iterator returned by `enumerate()` returns a tuple containing a count (from zero) and the corresponding value obtained from iterating over `iterable`. `enumerate()` is useful for obtaining an indexed series: (0,
seq[0], (1, seq[1]), (2, seq[2]), ... New in version 2.3.

**eval**(expression[, globals[, locals]])

The arguments are a string and optional globals and locals. If provided, globals must be a dictionary. If provided, locals can be any mapping object. Changed in version 2.4: formerly locals was required to be a dictionary.

The expression argument is parsed and evaluated as a Python expression (technically speaking, a condition list) using the globals and locals dictionaries as global and local name space. If the globals dictionary is present and lacks '__builtins__', the current globals are copied into globals before expression is parsed. This means that expression normally has full access to the standard __builtins__ module and restricted environments are propagated. If the locals dictionary is omitted it defaults to the globals dictionary. If both dictionaries are omitted, the expression is executed in the environment where eval is called. The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```python
>>> x = 1
>>> print eval('x+1')
2
```

This function can also be used to execute arbitrary code objects (such as those created by compile()). In this case pass a code object instead of a string. The code object must have been compiled passing 'eval' as the kind argument.

Hints: dynamic execution of statements is supported by the exec statement. Execution of statements from a file is supported by the execfile() function. The globals() and locals() functions returns the current global and local dictionary, respectively, which may be useful to pass around for use by eval() or execfile().

**execfile**(filename[, globals[, locals]])

This function is similar to the exec statement, but parses a file instead of a string. It is different from the import statement in that it does not use the module administration -- it reads the file unconditionally and does not create a new module.
The arguments are a file name and two optional dictionaries. The file is parsed and evaluated as a sequence of Python statements (similarly to a module) using the `globals` and `locals` dictionaries as global and local namespace. If provided, `locals` can be any mapping object. Changed in version 2.4: formerly `locals` was required to be a dictionary. If the `locals` dictionary is omitted it defaults to the `globals` dictionary. If both dictionaries are omitted, the expression is executed in the environment where `execfile()` is called. The return value is `None`.

**Warning:** The default `locals` act as described for function `locals()` below: modifications to the default `locals` dictionary should not be attempted. Pass an explicit `locals` dictionary if you need to see effects of the code on `locals` after function `execfile()` returns. `execfile()` cannot be used reliably to modify a function's locals.

```python
file( filename[, mode[, bufsize]])
```
Return a new file object (described in section 2.3.9, `File Objects`). The first two arguments are the same as for `stdio's fopen()`: `filename` is the file name to be opened, `mode` indicates how the file is to be opened: 'r' for reading, 'w' for writing (truncating an existing file), and 'a' opens it for appending (which on some UNIX systems means that all writes append to the end of the file, regardless of the current seek position).

Modes 'r+', 'w+' and 'a+' open the file for updating (note that 'w+' truncates the file). Append 'b' to the mode to open the file in binary mode, on systems that differentiate between binary and text files (else it is ignored). If the file cannot be opened, `IOError` is raised.

In addition to the standard `fopen()` values `mode` may be 'U' or 'rU'. If Python is built with universal newline support (the default) the file is opened as a text file, but lines may be terminated by any of '\n', the Unix end-of-line convention, '\r', the Macintosh convention or '\r\n', the Windows convention. All of these external representations are seen as '\n' by the Python program. If Python is built without universal newline support `mode 'U' is the same as normal text mode. Note that file objects so opened also have an attribute called `newlines` which has a value of `None` (if no newlines have yet been seen), '\n', '\r', '\r\n', or a tuple containing all the newline types seen.
If mode is omitted, it defaults to 'r'. When opening a binary file, you should append 'b' to the mode value for improved portability. (It's useful even on systems which don't treat binary and text files differently, where it serves as documentation.) The optional bufsize argument specifies the file's desired buffer size: 0 means unbuffered, 1 means line buffered, any other positive value means use a buffer of (approximately) that size. A negative bufsize means to use the system default, which is usually line buffered for tty devices and fully buffered for other files. If omitted, the system default is used.

The file() constructor is new in Python 2.2 and is an alias for open(). Both spellings are equivalent. The intent is for open() to continue to be preferred for use as a factory function which returns a new file object. The spelling, file is more suited to type testing (for example, writing "isinstance(f, file)").

filter(function, list)
Construct a list from those elements of list for which function returns true. list may be either a sequence, a container which supports iteration, or an iterator. If list is a string or a tuple, the result also has that type; otherwise it is always a list. If function is None, the identity function is assumed, that is, all elements of list that are false are removed.

Note that filter(function, list) is equivalent to [item for item in list if function(item)] if function is not None and [item for item in list if item] if function is None.

float([x])
Convert a string or a number to floating point. If the argument is a string, it must contain a possibly signed decimal or floating point number, possibly embedded in whitespace. Otherwise, the argument may be a plain or long integer or a floating point number, and a floating point number with the same value (within Python's floating point precision) is returned. If no argument is given, returns 0.0.

Note: When passing in a string, values for NaN and Infinity may be returned, depending on the underlying C library. The specific set of strings accepted which cause these values to be returned depends entirely on the C
library and is known to vary.

**frozenset([iterable])**

Return a frozenset object whose elements are taken from *iterable*. Frozensets are sets that have no update methods but can be hashed and used as members of other sets or as dictionary keys. The elements of a frozenset must be immutable themselves. To represent sets of sets, the inner sets should also be *frozenset* objects. If *iterable* is not specified, returns a new empty set, *frozenset([ ])*. New in version 2.4.

**getattr(object, name[, default])**

Return the value of the named attributed of *object*. *name* must be a string. If the string is the name of one of the object's attributes, the result is the value of that attribute. For example, *getattr(x, 'foobar')* is equivalent to *x.foobar*. If the named attribute does not exist, *default* is returned if provided, otherwise *AttributeError* is raised.

**globals()**

Return a dictionary representing the current global symbol table. This is always the dictionary of the current module (inside a function or method, this is the module where it is defined, not the module from which it is called).

**hasattr(object, name)**

The arguments are an object and a string. The result is *True* if the string is the name of one of the object's attributes, *False* if not. (This is implemented by calling *getattr(object, name)* and seeing whether it raises an exception or not.)

**hash(object)**

Return the hash value of the object (if it has one). Hash values are integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, as is the case for 1 and 1.0).

**help([object])**

Invoke the built-in help system. (This function is intended for interactive
If no argument is given, the interactive help system starts on the interpreter console. If the argument is a string, then the string is looked up as the name of a module, function, class, method, keyword, or documentation topic, and a help page is printed on the console. If the argument is any other kind of object, a help page on the object is generated. New in version 2.2.

**hex(x)**
Convert an integer number (of any size) to a hexadecimal string. The result is a valid Python expression. Changed in version 2.4: Formerly only returned an unsigned literal.

**id(object)**
Return the ``identity'' of an object. This is an integer (or long integer) which is guaranteed to be unique and constant for this object during its lifetime. Two objects with non-overlapping lifetimes may have the same id() value. (Implementation note: this is the address of the object.)

**input([prompt])**
Equivalent to \texttt{eval(raw_input(prompt))}. \textbf{Warning:} This function is not safe from user errors! It expects a valid Python expression as input; if the input is not syntactically valid, a \texttt{SyntaxError} will be raised. Other exceptions may be raised if there is an error during evaluation. (On the other hand, sometimes this is exactly what you need when writing a quick script for expert use.)

If the \texttt{readline} module was loaded, then \texttt{input()} will use it to provide elaborate line editing and history features.

Consider using the \texttt{raw_input()} function for general input from users.

**int([x[, radix]])**
Convert a string or number to a plain integer. If the argument is a string, it must contain a possibly signed decimal number representable as a Python integer, possibly embedded in whitespace. The \texttt{radix} parameter gives the base for the conversion and may be any integer in the range [2, 36], or zero. If \texttt{radix} is zero, the proper radix is guessed based on the contents of string; the interpretation is the same as for integer literals. If \texttt{radix} is specified and
x is not a string, TypeError is raised. Otherwise, the argument may be a
plain or long integer or a floating point number. Conversion of floating
point numbers to integers truncates (towards zero). If the argument is
outside the integer range a long object will be returned instead. If no
arguments are given, returns 0.

isinstance( object, classinfo)
Return true if the object argument is an instance of the classinfo argument,
or of a (direct or indirect) subclass thereof. Also return true if classinfo is a
type object and object is an object of that type. If object is not a class
instance or an object of the given type, the function always returns false. If
classinfo is neither a class object nor a type object, it may be a tuple of class
or type objects, or may recursively contain other such tuples (other
sequence types are not accepted). If classinfo is not a class, type, or tuple of
classes, types, and such tuples, a TypeError exception is raised. Changed
in version 2.2: Support for a tuple of type information was added.

issubclass( class, classinfo)
Return true if class is a subclass (direct or indirect) of classinfo. A class is
considered a subclass of itself. classinfo may be a tuple of class objects, in
which case every entry in classinfo will be checked. In any other case, a
TypeError exception is raised. Changed in version 2.3: Support for a
tuple of type information was added.

iter( o[, sentinel])
Return an iterator object. The first argument is interpreted very differently
depending on the presence of the second argument. Without a second
argument, o must be a collection object which supports the iteration
protocol (the __iter__( ) method), or it must support the sequence
protocol (the __getitem__( ) method with integer arguments starting at
0). If it does not support either of those protocols, TypeError is raised. If
the second argument, sentinel, is given, then o must be a callable object.
The iterator created in this case will call o with no arguments for each call
to its next( ) method; if the value returned is equal to sentinel,
StopIteration will be raised, otherwise the value will be returned.
New in version 2.2.

len( s)
Return the length (the number of items) of an object. The argument may be a sequence (string, tuple or list) or a mapping (dictionary).

**list([sequence])**

Return a list whose items are the same and in the same order as sequence's items. sequence may be either a sequence, a container that supports iteration, or an iterator object. If sequence is already a list, a copy is made and returned, similar to sequence[:]. For instance, list('abc') returns ['a', 'b', 'c'] and list((1, 2, 3)) returns [1, 2, 3]. If no argument is given, returns a new empty list, [].

**locals()**

Update and return a dictionary representing the current local symbol table. **Warning:** The contents of this dictionary should not be modified; changes may not affect the values of local variables used by the interpreter.

**long([x[, radix]])**

Convert a string or number to a long integer. If the argument is a string, it must contain a possibly signed number of arbitrary size, possibly embedded in whitespace. The radix argument is interpreted in the same way as for int(), and may only be given when x is a string. Otherwise, the argument may be a plain or long integer or a floating point number, and a long integer with the same value is returned. Conversion of floating point numbers to integers truncates (towards zero). If no arguments are given, returns 0L.

**map(function, list, ...)**

Apply function to every item of list and return a list of the results. If additional list arguments are passed, function must take that many arguments and is applied to the items of all lists in parallel; if a list is shorter than another it is assumed to be extended with None items. If function is None, the identity function is assumed; if there are multiple list arguments, map() returns a list consisting of tuples containing the corresponding items from all lists (a kind of transpose operation). The list arguments may be any kind of sequence; the result is always a list.

**max(s[, args...])**

With a single argument s, return the largest item of a non-empty sequence
(such as a string, tuple or list). With more than one argument, return the largest of the arguments.

\textbf{min}( s[, \textit{args...}])

With a single argument \textit{s}, return the smallest item of a non-empty sequence (such as a string, tuple or list). With more than one argument, return the smallest of the arguments.

\textbf{object()}

Return a new featureless object. \textbf{object()} is a base for all new style classes. It has the methods that are common to all instances of new style classes. New in version 2.2.

Changed in version 2.3: This function does not accept any arguments. Formerly, it accepted arguments but ignored them.

\textbf{oct}( \textit{x})

Convert an integer number (of any size) to an octal string. The result is a valid Python expression. Changed in version 2.4: Formerly only returned an unsigned literal.

\textbf{open}( \textit{filename}[\textit{mode}[\textit{bufsize}]])

An alias for the \textbf{file()} function above.

\textbf{ord}( \textit{c})

Given a string of length one, return an integer representing the Unicode code point of the character when the argument is a unicode object, or the value of the byte when the argument is an 8-bit string. For example, \textbf{ord}('a') returns the integer 97, \textbf{ord}(u'\u2020') returns 8224. This is the inverse of \textbf{chr()} for 8-bit strings and of \textbf{unichr()} for unicode objects. If a unicode argument is given and Python was built with UCS2 Unicode, then the character's code point must be in the range [0..65535] inclusive; otherwise the string length is two, and a \texttt{TypeError} will be raised.

\textbf{pow}( \textit{x}, \textit{y}[\textit{, z}])

Return \textit{x} to the power \textit{y}; if \textit{z} is present, return \textit{x} to the power \textit{y}, modulo \textit{z}
(computed more efficiently than \( \texttt{pow}(x, y) \ % \ z \)). The arguments must have numeric types. With mixed operand types, the coercion rules for binary arithmetic operators apply. For \texttt{int} and \texttt{long int} operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, \( 10 ** 2 \) returns 100, but \( 10 ** -2 \) returns 0.01. (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised.) If the second argument is negative, the third argument must be omitted. If z is present, x and y must be of integer types, and y must be non-negative. (This restriction was added in Python 2.2. In Python 2.1 and before, floating 3-argument pow() returned platform-dependent results depending on floating-point rounding accidents.)

**property**( [\texttt{fget[, fset[, fdel[, doc]]]}])

Return a property attribute for new-style classes (classes that derive from \texttt{object}).

\texttt{fget} is a function for getting an attribute value, likewise \texttt{fset} is a function for setting, and \texttt{fdel} a function for del’ing, an attribute. Typical use is to define a managed attribute \texttt{x}:

```
class C(object):
    def \_init\_(self): self._x = None
    def getx(self): return self._x
    def setx(self, value): self._x = value
    def delx(self): del self._x
x = property(getx, setx, delx, "I'm the 'x' property.")
```

New in version 2.2.

**range**( [\texttt{start[, stop[, step]}])

This is a versatile function to create lists containing arithmetic progressions. It is most often used in \texttt{for} loops. The arguments must be plain integers. If the \texttt{step} argument is omitted, it defaults to 1. If the \texttt{start} argument is omitted, it defaults to 0. The full form returns a list of plain integers \([\texttt{start}, \texttt{start + step}, \texttt{start + 2 * step}, \ldots]\). If \texttt{step} is positive, the last element is the largest \( \texttt{start} + i \ * \ \texttt{step} \) less than \texttt{stop}; if \texttt{step} is negative, the last element is the smallest \( \texttt{start} + i \ * \ \texttt{step} \) greater than
stop. step must not be zero (or else ValueError is raised). Example:

```python
>>> range(10)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> range(1, 11)
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
>>> range(0, 30, 5)
[0, 5, 10, 15, 20, 25]
>>> range(0, 10, 3)
[0, 3, 6, 9]
>>> range(0, -10, -1)
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
>>> range(0)
[]
>>> range(1, 0)
[]
```

`raw_input([prompt])`

If the `prompt` argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that. When EOF is read, EOFError is raised. Example:

```python
>>> s = raw_input('-->

   --> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
```

If the `readline` module was loaded, then `raw_input()` will use it to provide elaborate line editing and history features.

`reduce(function, sequence[, initializer])`

Apply `function` of two arguments cumulatively to the items of `sequence`, from left to right, so as to reduce the sequence to a single value. For example, `reduce(lambda x, y: x+y, [1, 2, 3, 4, 5])` calculates (((1+2)+3)+4)+5. The left argument, `x`, is the accumulated value and the right argument, `y`, is the update value from the `sequence`. If the optional `initializer` is present, it is placed before the items of the sequence in the calculation, and serves as a default when the sequence is empty. If `initializer` is not given and `sequence` contains only one item, the first item is returned.

`reload(module)`
Reload a previously imported module. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the module argument).

When `reload(module)` is executed:

- Python modules' code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module's dictionary. The `init` function of extension modules is not called a second time.

- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.

- The names in the module namespace are updated to point to any new or changed objects.

- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

If a module is syntactically correct but its initialization fails, the first `import` statement for it does not bind its name locally, but does store a (partially initialized) module object in `sys.modules`. To reload the module you must first `import` it again (this will bind the name to the partially initialized module object) before you can `reload()` it.

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module's advantage if it maintains a global table or cache of objects -- with a `try` statement it can test for the table's presence and skip its initialization if desired:

```python
try:
```
cache
except NameError:
cache = {}

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for `sys`, `__main__` and `__builtin__`. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it -- one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.name`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances -- they continue to use the old class definition. The same is true for derived classes.

**`repr(object)`**
Return a string containing a printable representation of an object. This is the same value yielded by conversions (reverse quotes). It is sometimes useful to be able to access this operation as an ordinary function. For many types, this function makes an attempt to return a string that would yield an object with the same value when passed to `eval()`.

**`reversed(seq)`**
Return a reverse iterator. `seq` must be an object which supports the sequence protocol (the `__len__()` method and the `__getitem__()` method with integer arguments starting at 0). New in version 2.4.

**`round(x[, n])`**
Return the floating point value `x` rounded to `n` digits after the decimal point. If `n` is omitted, it defaults to zero. The result is a floating point number. Values are rounded to the closest multiple of 10 to the power minus `n`; if two multiples are equally close, rounding is done away from 0 (so for example, `round(0.5)` is `1.0` and `round(-0.5)` is `-1.0`).
**set([iterable])**

Return a set whose elements are taken from *iterable*. The elements must be immutable. To represent sets of sets, the inner sets should be `frozenset` objects. If *iterable* is not specified, returns a new empty set, `set([])`. New in version 2.4.

**setattr(object, name, value)**

This is the counterpart of `getattr()`. The arguments are an object, a string and an arbitrary value. The string may name an existing attribute or a new attribute. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

**slice([start,] stop[, step])**

Return a slice object representing the set of indices specified by `range(start, stop, step)`. The `start` and `step` arguments default to `None`. Slice objects have read-only data attributes `start`, `stop` and `step` which merely return the argument values (or their default). They have no other explicit functionality; however they are used by Numerical Python and other third party extensions. Slice objects are also generated when extended indexing syntax is used. For example: "a[start:stop:step]" or "a[start:stop, i]".

**sorted(iterable[, cmp[, key[, reverse]]]])**

Return a new sorted list from the items in *iterable*. The optional arguments `cmp`, `key`, and `reverse` have the same meaning as those for the `list.sort()` method (described in section 2.3.6).

`cmp` specifies a custom comparison function of two arguments (iterable elements) which should return a negative, zero or positive number depending on whether the first argument is considered smaller than, equal to, or larger than the second argument: "`cmp=lambda x,y: cmp(x.lower(), y.lower())""

`key` specifies a function of one argument that is used to extract a comparison key from each list element: "`key=str.lower""
reverse is a boolean value. If set to True, then the list elements are sorted as if each comparison were reversed.

In general, the key and reverse conversion processes are much faster than specifying an equivalent cmp function. This is because cmp is called multiple times for each list element while key and reverse touch each element only once.

New in version 2.4.

staticmethod(function)

Return a static method for function.

A static method does not receive an implicit first argument. To declare a static method, use this idiom:

```python
class C:
    @staticmethod
    def f(arg1, arg2, ...): ...
```

The @staticmethod form is a function decorator - see the description of function definitions in chapter 7 of the Python Reference Manual for details.

It can be called either on the class (such as C.f()) or on an instance (such as C().f()). The instance is ignored except for its class.

Static methods in Python are similar to those found in Java or C++. For a more advanced concept, see classmethod() in this section.

For more information on static methods, consult the documentation on the standard type hierarchy in chapter 3 of the Python Reference Manual (at the bottom). New in version 2.2. Changed in version 2.4: Function decorator syntax added.

str([object])

Return a string containing a nicely printable representation of an object. For strings, this returns the string itself. The difference with repr(object) is that str(object) does not always attempt to return a string that is acceptable to eval(); its goal is to return a printable string. If no
argument is given, returns the empty string, ' '.

**sum**(*sequence[, start]*)
Sums start and the items of a sequence, from left to right, and returns the total. start defaults to 0. The sequence's items are normally numbers, and are not allowed to be strings. The fast, correct way to concatenate sequence of strings is by calling ''.join(sequence). Note that sum(range(n), m) is equivalent to reduce(operator.add, range(n), m) New in version 2.3.

**super**(*type[, object-or-type]*)
Return the superclass of type. If the second argument is omitted the super object returned is unbound. If the second argument is an object, isinstance(obj, type) must be true. If the second argument is a type, issubclass(type2, type) must be true. super() only works for new-style classes.

A typical use for calling a cooperative superclass method is:

```python
class C(B):
    def meth(self, arg):
        super(C, self).meth(arg)
```

Note that super is implemented as part of the binding process for explicit dotted attribute lookups such as "super(C, self).__getitem__(name)". Accordingly, super is undefined for implicit lookups using statements or operators such as "super(C, self)[name]". New in version 2.2.

**tuple**(*sequence*)
Return a tuple whose items are the same and in the same order as sequence's items. sequence may be a sequence, a container that supports iteration, or an iterator object. If sequence is already a tuple, it is returned unchanged. For instance, tuple('abc') returns ('a', 'b', 'c') and tuple([1, 2, 3]) returns (1, 2, 3). If no argument is given, returns a new empty tuple, ()

**type**(*object*)
Return the type of an object. The return value is a type object. The `isinstance()` built-in function is recommended for testing the type of an object.

With three arguments, `type` functions as a constructor as detailed below.

**type( name, bases, dict)**
Return a new type object. This is essentially a dynamic form of the `class` statement. The `name` string is the class name and becomes the `__name__` attribute; the `bases` tuple itemizes the base classes and becomes the `__bases__` attribute; and the `dict` dictionary is the namespace containing definitions for class body and becomes the `__dict__` attribute. For example, the following two statements create identical type objects:

```python
>>> class X(object):
    ...
    a = 1
...
>>> X = type('X', (object,), dict(a=1))
```

New in version 2.2.

**unichr(i)**
Return the Unicode string of one character whose Unicode code is the integer `i`. For example, `unichr(97)` returns the string `u'a'`. This is the inverse of `ord()` for Unicode strings. The valid range for the argument depends how Python was configured - it may be either UCS2 `[0..0xFFFF]` or UCS4 `[0..0x10FFFF]`. `ValueError` is raised otherwise. New in version 2.0.

**unicode([object[, encoding [, errors]]])**
Return the Unicode string version of `object` using one of the following modes:

If `encoding` and/or `errors` are given, `unicode()` will decode the object which can either be an 8-bit string or a character buffer using the codec for `encoding`. The `encoding` parameter is a string giving the name of an encoding; if the encoding is not known, `LookupError` is raised. Error handling is done according to `errors`; this specifies the treatment of characters which are invalid in the input encoding. If `errors` is 'strict'
(the default), a ValueError is raised on errors, while a value of 'ignore' causes errors to be silently ignored, and a value of 'replace' causes the official Unicode replacement character, U+FFFD, to be used to replace input characters which cannot be decoded. See also the codecs module.

If no optional parameters are given, unicode() will mimic the behaviour of str() except that it returns Unicode strings instead of 8-bit strings. More precisely, if object is a Unicode string or subclass it will return that Unicode string without any additional decoding applied.

For objects which provide a __unicode__() method, it will call this method without arguments to create a Unicode string. For all other objects, the 8-bit string version or representation is requested and then converted to a Unicode string using the codec for the default encoding in 'strict' mode.

New in version 2.0. Changed in version 2.2: Support for __unicode__() added.

vars([object])
Without arguments, return a dictionary corresponding to the current local symbol table. With a module, class or class instance object as argument (or anything else that has a __dict__ attribute), returns a dictionary corresponding to the object's symbol table. The returned dictionary should not be modified: the effects on the corresponding symbol table are undefined.\[^{2.4}\]

xrange([start,] stop[, step])
This function is very similar to range(), but returns an "xrange object" instead of a list. This is an opaque sequence type which yields the same values as the corresponding list, without actually storing them all simultaneously. The advantage of xrange() over range() is minimal (since xrange() still has to create the values when asked for them) except when a very large range is used on a memory-starved machine or when all of the range's elements are never used (such as when the loop is usually terminated with break).
Note: \texttt{xrange()} is intended to be simple and fast. Implementations may impose restrictions to achieve this. The C implementation of Python restricts all arguments to native C longs ("short" Python integers), and also requires that the number of elements fit in a native C long.

\textbf{\texttt{zip([iterable, ...])}}

This function returns a list of tuples, where the \textit{i}-th tuple contains the \textit{i}-th element from each of the argument sequences or iterables. The returned list is truncated in length to the length of the shortest argument sequence. When there are multiple arguments which are all of the same length, \texttt{zip()} is similar to \texttt{map()} with an initial argument of \texttt{None}. With a single sequence argument, it returns a list of 1-tuples. With no arguments, it returns an empty list. New in version 2.0.

Changed in version 2.4: Formerly, \texttt{zip()} required at least one argument and \texttt{zip()} raised a \texttt{TypeError} instead of returning an empty list.

---

\textbf{Footnotes}

... module.\textsuperscript{2.2}

It is used relatively rarely so does not warrant being made into a statement.

... used.\textsuperscript{2.3}

Specifying a buffer size currently has no effect on systems that don't have \texttt{setvbuf()}. The interface to specify the buffer size is not done using a method that calls \texttt{setvbuf()}, because that may dump core when called after any I/O has been performed, and there's no reliable way to determine whether this is the case.

... undefined.\textsuperscript{2.4}

In the current implementation, local variable bindings cannot normally be affected this way, but variables retrieved from other scopes (such as modules) can be. This may change.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
2.2 Non-essential Built-in Functions

There are several built-in functions that are no longer essential to learn, know or use in modern Python programming. They have been kept here to maintain backwards compatibility with programs written for older versions of Python.

Python programmers, trainers, students and bookwriters should feel free to bypass these functions without concerns about missing something important.

apply( function, args[, keywords])

The function argument must be a callable object (a user-defined or built-in function or method, or a class object) and the args argument must be a sequence. The function is called with args as the argument list; the number of arguments is the length of the tuple. If the optional keywords argument is present, it must be a dictionary whose keys are strings. It specifies keyword arguments to be added to the end of the argument list. Calling apply() is different from just calling function(args), since in that case there is always exactly one argument. The use of apply() is equivalent to function(*args, **keywords). Use of apply() is not necessary since the ``extended call syntax,'' as used in the last example, is completely equivalent.

Deprecated since release 2.3. Use the extended call syntax instead, as described above.

buffer( object[, offset[, size]])

The object argument must be an object that supports the buffer call interface (such as strings, arrays, and buffers). A new buffer object will be created which references the object argument. The buffer object will be a slice from the beginning of object (or from the specified offset). The slice will extend to the end of object (or will have a length given by the size argument).

coerce( x, y)

Return a tuple consisting of the two numeric arguments converted to a common type, using the same rules as used by arithmetic operations. If coercion is not possible, raise TypeError.
**`intern`**

Enter `string` in the table of "interned" strings and return the interned string - which is `string` itself or a copy. Interning strings is useful to gain a little performance on dictionary lookup - if the keys in a dictionary are interned, and the lookup key is interned, the key comparisons (after hashing) can be done by a pointer compare instead of a string compare. Normally, the names used in Python programs are automatically interned, and the dictionaries used to hold module, class or instance attributes have interned keys. Changed in version 2.3: Interned strings are not immortal (like they used to be in Python 2.2 and before); you must keep a reference to the return value of `intern()` around to benefit from it.
2.3 Built-in Types

The following sections describe the standard types that are built into the interpreter. Historically, Python's built-in types have differed from user-defined types because it was not possible to use the built-in types as the basis for object-oriented inheritance. With the 2.2 release this situation has started to change, although the intended unification of user-defined and built-in types is as yet far from complete.

The principal built-in types are numerics, sequences, mappings, files classes, instances and exceptions.

Some operations are supported by several object types; in particular, practically all objects can be compared, tested for truth value, and converted to a string (with the `...` notation, the equivalent `repr()` function, or the slightly different `str()` function). The latter function is implicitly used when an object is written by the `print` statement. (Information on `print statement` and other language statements can be found in the `Python Reference Manual` and the `Python Tutorial`.)

  - 2.3.10.9 Boolean Values
  - 2.3.10.10 Internal Objects
- 2.3.11 Special Attributes
2.3.1 Truth Value Testing

Any object can be tested for truth value, for use in an if or while condition or as operand of the Boolean operations below. The following values are considered false:

- None
- False
- zero of any numeric type, for example, 0, 0L, 0.0, 0j.
- any empty sequence, for example, ' ', (), [].
- any empty mapping, for example, {}.
- instances of user-defined classes, if the class defines a __nonzero__() or __len__() method, when that method returns the integer zero or bool value False.\textsuperscript{2.5}

All other values are considered true -- so objects of many types are always true.

Operations and built-in functions that have a Boolean result always return 0 or False for false and 1 or True for true, unless otherwise stated. (Important exception: the Boolean operations "or" and "and" always return one of their operands.)

---

Footnotes

...False.\textsuperscript{2.5}

Additional information on these special methods may be found in the *Python Reference Manual*.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
2.3.2 Boolean Operations -- and, or, not

These are the Boolean operations, ordered by ascending priority:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>$x \text{ or } y$</td>
<td>if $x$ is false, then $y$, else $x$</td>
<td>(1)</td>
</tr>
<tr>
<td>$x \text{ and } y$</td>
<td>if $x$ is false, then $x$, else $y$</td>
<td>(1)</td>
</tr>
<tr>
<td>not $x$</td>
<td>if $x$ is false, then True, else False</td>
<td>(2)</td>
</tr>
</tbody>
</table>

Notes:

(1) These only evaluate their second argument if needed for their outcome.

(2) "not" has a lower priority than non-Boolean operators, so not $a == b$ is interpreted as not ($a == b$), and $a == \text{ not } b$ is a syntax error.
2.3.3 Comparisons

Comparison operations are supported by all objects. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily; for example, \( x < y <= z \) is equivalent to \( x < y \) and \( y <= z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

This table summarizes the comparison operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>strictly less than</td>
<td></td>
</tr>
<tr>
<td>&lt;=</td>
<td>less than or equal</td>
<td></td>
</tr>
<tr>
<td>&gt;</td>
<td>strictly greater than</td>
<td></td>
</tr>
<tr>
<td>&gt;=</td>
<td>greater than or equal</td>
<td></td>
</tr>
<tr>
<td>==</td>
<td>equal</td>
<td></td>
</tr>
<tr>
<td>!=</td>
<td>not equal</td>
<td>(1)</td>
</tr>
<tr>
<td>&lt;&gt;</td>
<td>not equal</td>
<td>(1)</td>
</tr>
<tr>
<td>is</td>
<td>object identity</td>
<td></td>
</tr>
<tr>
<td>is not</td>
<td>negated object identity</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) 

\( <> \) and \( != \) are alternate spellings for the same operator. \( != \) is the preferred spelling; \( <> \) is obsolescent.

Objects of different types, except different numeric types and different string types, never compare equal; such objects are ordered consistently but arbitrarily (so that sorting a heterogeneous array yields a consistent result). Furthermore, some types (for example, file objects) support only a degenerate notion of comparison where any two objects of that type are unequal. Again, such objects are ordered arbitrarily but consistently. The \( <, <=, > \) and \( >= \) operators will raise a \texttt{TypeError} exception when any operand is a complex number.

Instances of a class normally compare as non-equal unless the class defines the
__cmp__( ) method. Refer to the Python Reference Manual for information on the use of this method to effect object comparisons.

**Implementation note:** Objects of different types except numbers are ordered by their type names; objects of the same types that don't support proper comparison are ordered by their address.

Two more operations with the same syntactic priority, "in" and "not in", are supported only by sequence types (below).
2.3.4 Numeric Types -- int, float, long, complex

There are four distinct numeric types: plain integers, long integers, floating point numbers, and complex numbers. In addition, Booleans are a subtype of plain integers. Plain integers (also just called integers) are implemented using `long` in C, which gives them at least 32 bits of precision. Long integers have unlimited precision. Floating point numbers are implemented using `double` in C. All bets on their precision are off unless you happen to know the machine you are working with.

Complex numbers have a real and imaginary part, which are each implemented using `double` in C. To extract these parts from a complex number `z`, use `z.real` and `z.imag`.

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including hex and octal numbers) yield plain integers unless the value they denote is too large to be represented as a plain integer, in which case they yield a long integer. Integer literals with an "L" or "l" suffix yield long integers ("L" is preferred because "1l" looks too much like eleven!). Numeric literals containing a decimal point or an exponent sign yield floating point numbers. Appending "j" or "J" to a numeric literal yields a complex number with a zero real part. A complex numeric literal is the sum of a real and an imaginary part.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the ``narrower'' type is widened to that of the other, where plain integer is narrower than long integer is narrower than floating point is narrower than complex. Comparisons between numbers of mixed type use the same rule.\footnote{The constructors `int()`, `long()`, `float()`, and `complex()` can be used to produce numbers of a specific type.}

All numeric types (except complex) support the following operations, sorted by ascending priority (operations in the same box have the same priority; all numeric operations have a higher priority than comparison operations):

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Expression</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>------------</td>
<td>-------------</td>
<td></td>
</tr>
<tr>
<td>$x + y$</td>
<td>sum of $x$ and $y$</td>
<td></td>
</tr>
<tr>
<td>$x - y$</td>
<td>difference of $x$ and $y$</td>
<td></td>
</tr>
<tr>
<td>$x * y$</td>
<td>product of $x$ and $y$</td>
<td></td>
</tr>
<tr>
<td>$x / y$</td>
<td>quotient of $x$ and $y$</td>
<td>(1)</td>
</tr>
<tr>
<td>$x // y$</td>
<td>(floored) quotient of $x$ and $y$</td>
<td>(5)</td>
</tr>
<tr>
<td>$x % y$</td>
<td>remainder of $x / y$</td>
<td>(4)</td>
</tr>
<tr>
<td>$-x$</td>
<td>$x$ negated</td>
<td></td>
</tr>
<tr>
<td>$+x$</td>
<td>$x$ unchanged</td>
<td></td>
</tr>
<tr>
<td>$\text{abs}(x)$</td>
<td>absolute value or magnitude of $x$</td>
<td></td>
</tr>
<tr>
<td>$\text{int}(x)$</td>
<td>$x$ converted to integer</td>
<td>(2)</td>
</tr>
<tr>
<td>$\text{long}(x)$</td>
<td>$x$ converted to long integer</td>
<td>(2)</td>
</tr>
<tr>
<td>$\text{float}(x)$</td>
<td>$x$ converted to floating point</td>
<td></td>
</tr>
<tr>
<td>$\text{complex}(re, im)$</td>
<td>a complex number with real part $re$, imaginary part $im$. $im$ defaults to zero.</td>
<td></td>
</tr>
<tr>
<td>$c.\text{conjugate}()$</td>
<td>conjugate of the complex number $c$</td>
<td></td>
</tr>
<tr>
<td>$\text{divmod}(x, y)$</td>
<td>the pair $(x // y, x % y)$</td>
<td>(3)(4)</td>
</tr>
<tr>
<td>$\text{pow}(x, y)$</td>
<td>$x$ to the power $y$</td>
<td></td>
</tr>
<tr>
<td>$x ** y$</td>
<td>$x$ to the power $y$</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) For (plain or long) integer division, the result is an integer. The result is always rounded towards minus infinity: $1/2$ is $0$, $(-1)/2$ is $-1$, $1/(-2)$ is $-1$, and $(-1)/(-2)$ is $0$. Note that the result is a long integer if either operand is a long integer, regardless of the numeric value.

(2) Conversion from floating point to (long or plain) integer may round or truncate as in C; see functions $\text{floor}()$ and $\text{ceil}()$ in the $\text{math}$ module for well-defined conversions.

(3) See section 2.1, "Built-in Functions," for a full description.

(4)
Complex floor division operator, modulo operator, and `divmod()`.

**Deprecated since release 2.3.** Instead convert to float using `abs()` if appropriate.

(5)

Also referred to as integer division. The resultant value is a whole integer, though the result's type is not necessarily `int`.

---

**Footnotes**

... rule.\textsuperscript{2,6}

As a consequence, the list `[1, 2]` is considered equal to `[1.0, 2.0]`, and similarly for tuples.

---

**Subsections**

- [2.3.4.1 Bit-string Operations on Integer Types](2.3.4.1 Bit-string Operations on Integer Types)

---

Release 2.4.4c1, documentation updated on 11 October 2006. See [About this document...](About this document...) for information on suggesting changes.
2.3.5 Iterator Types

New in version 2.2.

Python supports a concept of iteration over containers. This is implemented using two distinct methods; these are used to allow user-defined classes to support iteration. Sequences, described below in more detail, always support the iteration methods.

One method needs to be defined for container objects to provide iteration support:

```python
__iter__(self)
```

Return an iterator object. The object is required to support the iterator protocol described below. If a container supports different types of iteration, additional methods can be provided to specifically request iterators for those iteration types. (An example of an object supporting multiple forms of iteration would be a tree structure which supports both breadth-first and depth-first traversal.) This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

The iterator objects themselves are required to support the following two methods, which together form the iterator protocol:

```python
__iter__(self)
```

Return the iterator object itself. This is required to allow both containers and iterators to be used with the `for` and `in` statements. This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

```python
next()
```

Return the next item from the container. If there are no further items, raise the `StopIteration` exception. This method corresponds to the `tp_iternext` slot of the type structure for Python objects in the Python/C API.

Python defines several iterator objects to support iteration over general and
specific sequence types, dictionaries, and other more specialized forms. The specific types are not important beyond their implementation of the iterator protocol.

The intention of the protocol is that once an iterator's `next()` method raises `StopIteration`, it will continue to do so on subsequent calls. Implementations that do not obey this property are deemed broken. (This constraint was added in Python 2.3; in Python 2.2, various iterators are broken according to this rule.)

Python's generators provide a convenient way to implement the iterator protocol. If a container object's `__iter__()` method is implemented as a generator, it will automatically return an iterator object (technically, a generator object) supplying the `__iter__()` and `next()` methods.
2.3.6 Sequence Types -- str, unicode, list, tuple, buffer, xrange

There are six sequence types: strings, Unicode strings, lists, tuples, buffers, and xrange objects.

String literals are written in single or double quotes: 'xyzzy', "frobozz". See chapter 2 of the Python Reference Manual for more about string literals. Unicode strings are much like strings, but are specified in the syntax using a preceding "u" character: u'abc', u"def". Lists are constructed with square brackets, separating items with commas: [a, b, c]. Tuples are constructed by the comma operator (not within square brackets), with or without enclosing parentheses, but an empty tuple must have the enclosing parentheses, such as a, b, c or (). A single item tuple must have a trailing comma, such as (d,).

Buffer objects are not directly supported by Python syntax, but can be created by calling the builtin function buffer(). They don't support concatenation or repetition.

Xrange objects are similar to buffers in that there is no specific syntax to create them, but they are created using the xrange() function. They don't support slicing, concatenation or repetition, and using in, not in, min() or max() on them is inefficient.

Most sequence types support the following operations. The "in" and "not in" operations have the same priorities as the comparison operations. The "+" and "*" operations have the same priority as the corresponding numeric operations.

This table lists the sequence operations sorted in ascending priority (operations in the same box have the same priority). In the table, s and t are sequences of the same type; n, i and j are integers:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x in s</td>
<td>True if an item of s is equal to x, else False</td>
<td>(1)</td>
</tr>
<tr>
<td>x not in s</td>
<td>False if an item of s is equal to x, else True</td>
<td>(1)</td>
</tr>
<tr>
<td>s + t</td>
<td>the concatenation of s and t</td>
<td></td>
</tr>
<tr>
<td>-------</td>
<td>-----------------------------</td>
<td></td>
</tr>
<tr>
<td>s * n , n * s</td>
<td>n shallow copies of s concatenated</td>
<td></td>
</tr>
<tr>
<td>s[i]</td>
<td>i'th item of s, origin 0</td>
<td></td>
</tr>
<tr>
<td>s[i:j]</td>
<td>slice of s from i to j</td>
<td></td>
</tr>
<tr>
<td>s[i:j:k]</td>
<td>slice of s from i to j with step k</td>
<td></td>
</tr>
<tr>
<td>len(s)</td>
<td>length of s</td>
<td></td>
</tr>
<tr>
<td>min(s)</td>
<td>smallest item of s</td>
<td></td>
</tr>
<tr>
<td>max(s)</td>
<td>largest item of s</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) When s is a string or Unicode string object the `in` and `not in` operations act like a substring test. In Python versions before 2.3, `x` had to be a string of length 1. In Python 2.3 and beyond, `x` may be a string of any length.

(2) Values of n less than 0 are treated as 0 (which yields an empty sequence of the same type as s). Note also that the copies are shallow; nested structures are not copied. This often haunts new Python programmers; consider:

```python
>>> lists = [[]] * 3
>>> lists
[[], [], []]
>>> lists[0].append(3)
>>> lists
[[3], [3], [3]]
```

What has happened is that `[]` is a one-element list containing an empty list, so all three elements of `[] * 3` are (pointers to) this single empty list. Modifying any of the elements of `lists` modifies this single list. You can create a list of different lists this way:

```python
>>> lists = [[] for i in range(3)]
>>> lists[0].append(3)
>>> lists[1].append(5)
>>> lists[2].append(7)
>>> lists
[[3], [5], [7]]
```
If \( i \) or \( j \) is negative, the index is relative to the end of the string: \( \text{len}(s) + i \) or \( \text{len}(s) + j \) is substituted. But note that \(-0\) is still \( 0 \).

(4)

The slice of \( s \) from \( i \) to \( j \) is defined as the sequence of items with index \( k \) such that \( i \leq k < j \). If \( i \) or \( j \) is greater than \( \text{len}(s) \), use \( \text{len}(s) \). If \( i \) is omitted or \( \text{None} \), use \( 0 \). If \( j \) is omitted or \( \text{None} \), use \( \text{len}(s) \). If \( i \) is greater than or equal to \( j \), the slice is empty.

(5)

The slice of \( s \) from \( i \) to \( j \) with step \( k \) is defined as the sequence of items with index \( x = i + n*k \) such that . In other words, the indices are \( i, i+k, i+2*k, i+3*k \) and so on, stopping when \( j \) is reached (but never including \( j \)). If \( i \) or \( j \) is greater than \( \text{len}(s) \), use \( \text{len}(s) \). If \( i \) or \( j \) are omitted or \( \text{None} \), they become ``end'' values (which end depends on the sign of \( k \)). Note, \( k \) cannot be zero. If \( k \) is \( \text{None} \), it is treated like \( 1 \).

(6)

If \( s \) and \( t \) are both strings, some Python implementations such as CPython can usually perform an in-place optimization for assignments of the form \( s=s+t \) or \( s+=t \). When applicable, this optimization makes quadratic run-time much less likely. This optimization is both version and implementation dependent. For performance sensitive code, it is preferable to use the \texttt{str.join()}\ method which assures consistent linear concatenation performance across versions and implementations. Changed in version 2.4: Formerly, string concatenation never occurred in-place.

Footnotes

... operations.\(^{2,7}\)

They must have since the parser can't tell the type of the operands.
2.3.7 Set Types -- set, frozenset

A set object is an unordered collection of immutable values. Common uses include membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference. New in version 2.4.

Like other collections, sets support \texttt{x in set}, \texttt{len(set)}, and \texttt{for x in set}. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

There are currently two builtin set types, \texttt{set} and \texttt{frozenset}. The \texttt{set} type is mutable -- the contents can be changed using methods like \texttt{add()} and \texttt{remove()}. Since it is mutable, it has no hash value and cannot be used as either a dictionary key or as an element of another set. The \texttt{frozenset} type is immutable and hashable -- its contents cannot be altered after is created; however, it can be used as a dictionary key or as an element of another set.

Instances of \texttt{set} and \texttt{frozenset} provide the following operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{len(s)}</td>
<td></td>
<td>cardinality of set \texttt{s}</td>
</tr>
<tr>
<td>\texttt{x in s}</td>
<td></td>
<td>test \texttt{x} for membership in \texttt{s}</td>
</tr>
<tr>
<td>\texttt{x not in s}</td>
<td></td>
<td>test \texttt{x} for non-membership in \texttt{s}</td>
</tr>
<tr>
<td>\texttt{s.issubset(t)}</td>
<td>\texttt{s &lt;= t}</td>
<td>test whether every element in \texttt{s} is in \texttt{t}</td>
</tr>
<tr>
<td>\texttt{s.issuperset(t)}</td>
<td>\texttt{s &gt;= t}</td>
<td>test whether every element in \texttt{t} is in \texttt{s}</td>
</tr>
<tr>
<td>\texttt{s.union(t)}</td>
<td>\texttt{s</td>

<td>Description</td>
<td></td>
</tr>
<tr>
<td>-----------------------------</td>
<td>--------------------------------------</td>
<td></td>
</tr>
<tr>
<td><code>s.symmetric_difference(t)</code></td>
<td>$s \Delta t$ new set with elements in either $s$ or $t$ but not both</td>
<td></td>
</tr>
<tr>
<td><code>s.copy()</code></td>
<td>new set with a shallow copy of $s$</td>
<td></td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `union()`, `intersection()`, `difference()`, and `symmetric_difference()`, `issubset()`, and `issuperset()` methods will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `set('abc') & 'cbs'` in favor of the more readable `set('abc').intersection('cbs')`.

Both `set` and `frozenset` support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

Instances of `set` are compared to instances of `frozenset` based on their members. For example, `"set('abc') == frozenset('abc')"` returns `True`.

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so all of the following return `False`: $a<b$, $a==b$, or $a>b$. Accordingly, sets do not implement the `__cmp__` method.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

Set elements are like dictionary keys; they need to define both `__hash__` and `__eq__` methods.

Binary operations that mix `set` instances with `frozenset` return the type of the first operand. For example: `"frozenset('ab') | set('bc')"` returns an instance of `frozenset`. 
The following table lists operations available for `set` that do not apply to immutable instances of `frozenset`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>s.update(t)</code></td>
<td>`s</td>
<td>= t`</td>
</tr>
<tr>
<td><code>s.intersection_update(t)</code></td>
<td><code>s &amp;= t</code></td>
<td>update set <code>s</code>, keeping only elements found in both <code>s</code> and <code>t</code></td>
</tr>
<tr>
<td><code>s.difference_update(t)</code></td>
<td><code>s -= t</code></td>
<td>update set <code>s</code>, removing elements found in <code>t</code></td>
</tr>
<tr>
<td><code>s.symmetric_difference_update(t)</code></td>
<td><code>s ^= t</code></td>
<td>update set <code>s</code>, keeping only elements found in either <code>s</code> or <code>t</code> but not in both</td>
</tr>
<tr>
<td><code>s.add(x)</code></td>
<td></td>
<td>add element <code>x</code> to set <code>s</code></td>
</tr>
<tr>
<td><code>s.remove(x)</code></td>
<td></td>
<td>remove <code>x</code> from set <code>s</code>; raises <code>KeyError</code> if not present</td>
</tr>
<tr>
<td><code>s.discard(x)</code></td>
<td></td>
<td>removes <code>x</code> from set <code>s</code> if present</td>
</tr>
<tr>
<td><code>s.pop()</code></td>
<td></td>
<td>remove and return an arbitrary element from <code>s</code>; raises <code>KeyError</code> if empty</td>
</tr>
</tbody>
</table>
s.clear()
remove all elements from set s

Note, the non-operator versions of the `update()`, `intersection_update()`, `difference_update()`, and `symmetric_difference_update()` methods will accept any iterable as an argument.

The design of the set types was based on lessons learned from the `sets` module.

Comparison to the built-in set types
Differences between the `sets` module and the built-in set types.
## 2.3.8 Mapping Types -- classdict

A *mapping* object maps immutable values to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the *dictionary*. A dictionary's keys are almost arbitrary values. Only values containing lists, dictionaries or other mutable types (that are compared by value rather than by object identity) may not be used as keys. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (such as 1 and 1.0) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are created by placing a comma-separated list of `key: value` pairs within braces, for example: `{'jack': 4098, 'sjoerd': 4127}` or `{4098: 'jack', 4127: 'sjoerd'}`.

The following operations are defined on mappings (where `a` and `b` are mappings, `k` is a key, and `v` and `x` are arbitrary objects):

<table>
<thead>

<td>return an iterator over the mapping's keys</td>
<td></td>
</tr>
<tr>
<td><code>a.itervalues()</code></td>
<td>return an iterator over the mapping's values</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) Raises a `KeyError` exception if `k` is not in the map.

(2) New in version 2.2.

(3) Keys and values are listed in an arbitrary order which is non-random, varies across Python implementations, and depends on the dictionary's history of insertions and deletions. If `items()`, `keys()`, `values()`, `iteritems()`, `iterkeys()`, and `itervalues()` are called with no intervening modifications to the dictionary, the lists will directly correspond. This allows the creation of `(value, key)` pairs using `zip()`:

```
pairs = zip(a.values(), a.keys())
```

The same relationship holds for the `iterkeys()` and `itervalues()` methods: "pairs = `zip(a.itervalues(), a.iterkeys())" provides the same value for pairs. Another way to create the same list is "pairs = `[(v, k) for (k, v) in a.iteritems()]".

(4) Never raises an exception if `k` is not in the map, instead it returns `x`. `x` is optional; when `x` is not provided and `k` is not in the map, `None` is returned.
(5) `setdefault()` is like `get()`, except that if `k` is missing, `x` is both returned and inserted into the dictionary as the value of `k`. `x` defaults to `None`.

(6) `popitem()` is useful to destructively iterate over a dictionary, as often used in set algorithms. If the dictionary is empty, calling `popitem()` raises a `KeyError`.

(7) `fromkeys()` is a class method that returns a new dictionary. `value` defaults to `None`. New in version 2.3.

(8) `pop()` raises a `KeyError` when no default value is given and the key is not found. New in version 2.3.

(9) `update()` accepts either another mapping object or an iterable of key/value pairs (as a tuple or other iterable of length two). If keyword arguments are specified, the mapping is then is updated with those key/value pairs: "d.update(red=1, blue=2)". Changed in version 2.4: Allowed the argument to be an iterable of key/value pairs and allowed keyword arguments.
2.3.9 File Objects

File objects are implemented using C's `stdio` package and can be created with the built-in constructor `file()` described in section 2.1, ``Built-in Functions``. File objects are also returned by some other built-in functions and methods, such as `os.popen()` and `os.fdopen()` and the `makefile()` method of socket objects.

When a file operation fails for an I/O-related reason, the exception `IOError` is raised. This includes situations where the operation is not defined for some reason, like `seek()` on a tty device or writing a file opened for reading.

Files have the following methods:

- **close()**
  Close the file. A closed file cannot be read or written any more. Any operation which requires that the file be open will raise a `ValueError` after the file has been closed. Calling `close()` more than once is allowed.

- **flush()**
  Flush the internal buffer, like `stdio's fflush()`. This may be a no-op on some file-like objects.

- **fileno()**
  Return the integer ``file descriptor'' that is used by the underlying implementation to request I/O operations from the operating system. This can be useful for other, lower level interfaces that use file descriptors, such as the `fcntl` module or `os.read()` and friends. **Note:** File-like objects which do not have a real file descriptor should not provide this method!

- **isatty()**
  Return `True` if the file is connected to a tty(-like) device, else `False`. **Note:** If a file-like object is not associated with a real file, this method should not be implemented.

- **next()**
A file object is its own iterator, for example `iter(f)` returns `f` (unless `f` is closed). When a file is used as an iterator, typically in a `for` loop (for example, `for line in f: print line`), the `next()` method is called repeatedly. This method returns the next input line, or raises `StopIteration` when EOF is hit. In order to make a `for` loop the most efficient way of looping over the lines of a file (a very common operation), the `next()` method uses a hidden read-ahead buffer. As a consequence of using a read-ahead buffer, combining `next()` with other file methods (like `readline()`) does not work right. However, using `seek()` to reposition the file to an absolute position will flush the read-ahead buffer. New in version 2.3.

**read( [size] )**

Read at most `size` bytes from the file (less if the read hits EOF before obtaining `size` bytes). If the `size` argument is negative or omitted, read all data until EOF is reached. The bytes are returned as a string object. An empty string is returned when EOF is encountered immediately. (For certain files, like ttys, it makes sense to continue reading after an EOF is hit.) Note that this method may call the underlying C function `fread()` more than once in an effort to acquire as close to `size` bytes as possible. Also note that when in non-blocking mode, less data than what was requested may be returned, even if no `size` parameter was given.

**readline( [size] )**

Read one entire line from the file. A trailing newline character is kept in the string (but may be absent when a file ends with an incomplete line). If the `size` argument is present and non-negative, it is a maximum byte count (including the trailing newline) and an incomplete line may be returned. An empty string is returned only when EOF is encountered immediately. **Note:** Unlike `stdio's` `fgets()`, the returned string contains null characters (`'\0'`) if they occurred in the input.

**readlines( [sizehint] )**

Read until EOF using `readline()` and return a list containing the lines thus read. If the optional `sizehint` argument is present, instead of reading up to EOF, whole lines totalling approximately `sizehint` bytes (possibly after rounding up to an internal buffer size) are read. Objects implementing a
file-like interface may choose to ignore sizehint if it cannot be implemented, or cannot be implemented efficiently.

xreadlines()
This method returns the same thing as iter(f). New in version 2.1. **Deprecated since release 2.3.** Use "for line in file" instead.

seek( offset[, whence])
Set the file's current position, like stdio's fseek(). The whence argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file's end). There is no return value. Note that if the file is opened for appending (mode 'a' or 'a+'), any seek() operations will be undone at the next write. If the file is only opened for writing in append mode (mode 'a'), this method is essentially a no-op, but it remains useful for files opened in append mode with reading enabled (mode 'a+'). If the file is opened in text mode (without 'b'), only offsets returned by tell() are legal. Use of other offsets causes undefined behavior.

Note that not all file objects are seekable.

tell()
Return the file's current position, like stdio's ftell().

**Note:** On Windows, tell() can return illegal values (after an fgets()) when reading files with UNIX-style line-endings. Use binary mode ('rb') to circumvent this problem.

truncate([size])
Truncate the file's size. If the optional size argument is present, the file is truncated to (at most) that size. The size defaults to the current position. The current file position is not changed. Note that if a specified size exceeds the file's current size, the result is platform-dependent: possibilities include that the file may remain unchanged, increase to the specified size as if zero-filled, or increase to the specified size with undefined new content. Availability: Windows, many UNIX variants.
**write**(str)
Write a string to the file. There is no return value. Due to buffering, the string may not actually show up in the file until the `flush()` or `close()` method is called.

**writelines**(sequence)
Write a sequence of strings to the file. The sequence can be any iterable object producing strings, typically a list of strings. There is no return value. (The name is intended to match `readlines(); writelines()` does not add line separators.)

Files support the iterator protocol. Each iteration returns the same result as `file.readline()`, and iteration ends when the `readline()` method returns an empty string.

File objects also offer a number of other interesting attributes. These are not required for file-like objects, but should be implemented if they make sense for the particular object.

**closed**
bool indicating the current state of the file object. This is a read-only attribute; the `close()` method changes the value. It may not be available on all file-like objects.

**encoding**
The encoding that this file uses. When Unicode strings are written to a file, they will be converted to byte strings using this encoding. In addition, when the file is connected to a terminal, the attribute gives the encoding that the terminal is likely to use (that information might be incorrect if the user has misconfigured the terminal). The attribute is read-only and may not be present on all file-like objects. It may also be `None`, in which case the file uses the system default encoding for converting Unicode strings.

New in version 2.3.

**mode**
The I/O mode for the file. If the file was created using the `open()` built-in function, this will be the value of the `mode` parameter. This is a read-only attribute and may not be present on all file-like objects.
name
If the file object was created using \texttt{open()}, the name of the file. Otherwise, some string that indicates the source of the file object, of the form "\texttt{<...>}". This is a read-only attribute and may not be present on all file-like objects.

newlines
If Python was built with the \texttt{--with-universal-newlines} option to \texttt{configure} (the default) this read-only attribute exists, and for files opened in universal newline read mode it keeps track of the types of newlines encountered while reading the file. The values it can take are \texttt{`'}, \texttt{`
'}, \texttt{`
'}, \texttt{None} (unknown, no newlines read yet) or a tuple containing all the newline types seen, to indicate that multiple newline conventions were encountered. For files not opened in universal newline read mode the value of this attribute will be \texttt{None}.

softspace
Boolean that indicates whether a space character needs to be printed before another value when using the \texttt{print} statement. Classes that are trying to simulate a file object should also have a writable \texttt{softspace} attribute, which should be initialized to zero. This will be automatic for most classes implemented in Python (care may be needed for objects that override attribute access); types implemented in C will have to provide a writable \texttt{softspace} attribute. \textbf{Note:} This attribute is not used to control the \texttt{print} statement, but to allow the implementation of \texttt{print} to keep track of its internal state.

Footnotes

... Functions."\textsuperscript{2.10}
\texttt{file()} is new in Python 2.2. The older built-in \texttt{open()} is an alias for \texttt{file()}.

... line).\textsuperscript{2.11}
The advantage of leaving the newline on is that returning an empty string is then an unambiguous EOF indication. It is also possible (in cases where it
might matter, for example, if you want to make an exact copy of a file while scanning its lines) to tell whether the last line of a file ended in a newline or not (yes this happens!).
2.3.10 Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

Subsections

- 2.3.10.1 Modules
- 2.3.10.2 Classes and Class Instances
- 2.3.10.3 Functions
- 2.3.10.4 Methods
- 2.3.10.5 Code Objects
- 2.3.10.6 Type Objects
- 2.3.10.7 The Null Object
- 2.3.10.8 The Ellipsis Object
- 2.3.10.9 Boolean Values
- 2.3.10.10 Internal Objects
2.3.11 Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant. Some of these are not reported by the \texttt{dir()} built-in function.

\texttt{__dict__}
A dictionary or other mapping object used to store an object's (writable) attributes.

\texttt{__methods__}
\textbf{Deprecated since release 2.2.} Use the built-in function \texttt{dir()} to get a list of an object's attributes. This attribute is no longer available.

\texttt{__members__}
\textbf{Deprecated since release 2.2.} Use the built-in function \texttt{dir()} to get a list of an object's attributes. This attribute is no longer available.

\texttt{__class__}
The class to which a class instance belongs.

\texttt{__bases__}
The tuple of base classes of a class object. If there are no base classes, this will be an empty tuple.

\texttt{__name__}
The name of the class or type.
2.4 Built-in Exceptions

Exceptions should be class objects. The exceptions are defined in the module `exceptions`. This module never needs to be imported explicitly: the exceptions are provided in the built-in namespace as well as the `exceptions` module.

**Note:** In past versions of Python string exceptions were supported. In Python 1.5 and newer versions, all standard exceptions have been converted to class objects and users are encouraged to do the same. String exceptions will raise a `PendingDeprecationWarning`. In future versions, support for string exceptions will be removed.

Two distinct string objects with the same value are considered different exceptions. This is done to force programmers to use exception names rather than their string value when specifying exception handlers. The string value of all built-in exceptions is their name, but this is not a requirement for user-defined exceptions or exceptions defined by library modules.

For class exceptions, in a `try` statement with an `except` clause that mentions a particular class, that clause also handles any exception classes derived from that class (but not exception classes from which it is derived). Two exception classes that are not related via subclassing are never equivalent, even if they have the same name.

The built-in exceptions listed below can be generated by the interpreter or built-in functions. Except where mentioned, they have an ``associated value'' indicating the detailed cause of the error. This may be a string or a tuple containing several items of information (e.g., an error code and a string explaining the code). The associated value is the second argument to the `raise` statement. For string exceptions, the associated value itself will be stored in the variable named as the second argument of the `except` clause (if any). For class
exceptions, that variable receives the exception instance. If the exception class is derived from the standard root class Exception, the associated value is present as the exception instance's args attribute, and possibly on other attributes as well.

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition ``just like'' the situation in which the interpreter raises the same exception; but beware that there is nothing to prevent user code from raising an inappropriate error.

The built-in exception classes can be sub-classed to define new exceptions; programmers are encouraged to at least derive new exceptions from the Exception base class. More information on defining exceptions is available in the Python Tutorial under the heading ``User-defined Exceptions.''

The following exceptions are only used as base classes for other exceptions.

**exception Exception**  
The root class for exceptions. All built-in exceptions are derived from this class. All user-defined exceptions should also be derived from this class, but this is not (yet) enforced. The str() function, when applied to an instance of this class (or most derived classes) returns the string value of the argument or arguments, or an empty string if no arguments were given to the constructor. When used as a sequence, this accesses the arguments given to the constructor (handy for backward compatibility with old code). The arguments are also available on the instance's args attribute, as a tuple.

**exception StandardError**  
The base class for all built-in exceptions except StopIteration and SystemExit. StandardError itself is derived from the root class Exception.

**exception ArithmeticError**  
The base class for those built-in exceptions that are raised for various arithmetic errors: OverflowError, ZeroDivisionError, FloatingPointError.

**exception LookupError**  
The base class for the exceptions that are raised when a key or index used
on a mapping or sequence is invalid: IndexError, KeyError. This can be raised directly by `sys.setdefaultencoding()`.

**Exception `EnvironmentError`**
The base class for exceptions that can occur outside the Python system: IOError, OSError. When exceptions of this type are created with a 2-tuple, the first item is available on the instance's `errno` attribute (it is assumed to be an error number), and the second item is available on the `strerror` attribute (it is usually the associated error message). The tuple itself is also available on the `args` attribute. New in version 1.5.2.

When an `EnvironmentError` exception is instantiated with a 3-tuple, the first two items are available as above, while the third item is available on the `filename` attribute. However, for backwards compatibility, the `args` attribute contains only a 2-tuple of the first two constructor arguments.

The `filename` attribute is `None` when this exception is created with other than 3 arguments. The `errno` and `strerror` attributes are also `None` when the instance was created with other than 2 or 3 arguments. In this last case, `args` contains the verbatim constructor arguments as a tuple.

The following exceptions are the exceptions that are actually raised.

**Exception `AssertionError`**
Raised when an `assert` statement fails.

**Exception `AttributeError`**
Raised when an attribute reference or assignment fails. (When an object does not support attribute references or attribute assignments at all, `TypeError` is raised.)

**Exception `EOFError`**
Raised when one of the built-in functions (input() or raw_input()) hits an end-of-file condition (EOF) without reading any data. (N.B.: the `read()` and `readline()` methods of file objects return an empty string when they hit EOF.)

**Exception `FloatingPointError`**
Raised when a floating point operation fails. This exception is always defined, but can only be raised when Python is configured with the \texttt{--with-fpectl} option, or the \texttt{WANT\_SIGFPE\_HANDLER} symbol is defined in the \texttt{pyconfig.h} file.

\textbf{exception IOError}

Raised when an I/O operation (such as a \texttt{print} statement, the built-in \texttt{open()} function or a method of a file object) fails for an I/O-related reason, e.g., ``file not found'' or ``disk full''.

This class is derived from \texttt{EnvironmentError}. See the discussion above for more information on exception instance attributes.

\textbf{exception ImportError}

Raised when an \texttt{import} statement fails to find the module definition or when a \texttt{from ... import} fails to find a name that is to be imported.

\textbf{exception IndexError}

Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not a plain integer, \texttt{TypeError} is raised.)

\textbf{exception KeyError}

Raised when a mapping (dictionary) key is not found in the set of existing keys.

\textbf{exception KeyboardInterrupt}

Raised when the user hits the interrupt key (normally \texttt{Control-C} or \texttt{Delete}). During execution, a check for interrupts is made regularly. Interrupts typed when a built-in function \texttt{input()} or \texttt{raw_input()} is waiting for input also raise this exception.

\textbf{exception MemoryError}

Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C's \texttt{malloc()} function), the interpreter may not always be able to completely recover from this situation; it nevertheless raises an exception so that a
stack traceback can be printed, in case a run-away program was the cause.

**exception NameError**
Raised when a local or global name is not found. This applies only to unqualified names. The associated value is an error message that includes the name that could not be found.

**exception NotImplemented OSError**
This exception is derived from RuntimeError. In user defined base classes, abstract methods should raise this exception when they require derived classes to override the method. New in version 1.5.2.

**exception OSError**
This class is derived from EnvironmentError and is used primarily as the os module's os.error exception. See EnvironmentError above for a description of the possible associated values. New in version 1.5.2.

**exception OverflowError**
Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for long integers (which would rather raise MemoryError than give up). Because of the lack of standardization of floating point exception handling in C, most floating point operations also aren't checked. For plain integers, all operations that can overflow are checked except left shift, where typical applications prefer to drop bits than raise an exception.

**exception ReferenceError**
This exception is raised when a weak reference proxy, created by the weakref.proxy() function, is used to access an attribute of the referent after it has been garbage collected. For more information on weak references, see the weakref module. New in version 2.2: Previously known as the weakref.REFERENCEERROR exception.

**exception RuntimeError**
Raised when an error is detected that doesn't fall in any of the other categories. The associated value is a string indicating what precisely went wrong. (This exception is mostly a relic from a previous version of the interpreter; it is not used very much any more.)
**exception StopIteration**
Raised by an iterator's `next()` method to signal that there are no further values. This is derived from Exception rather than StandardError, since this is not considered an error in its normal application. New in version 2.2.

**exception SyntaxError**
Raised when the parser encounters a syntax error. This may occur in an `import` statement, in an `exec` statement, in a call to the built-in function `eval()` or `input()`, or when reading the initial script or standard input (also interactively).

Instances of this class have attributes `filename`, `lineno`, `offset` and `text` for easier access to the details. `str()` of the exception instance returns only the message.

**exception SystemError**
Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-level terms).

You should report this to the author or maintainer of your Python interpreter. Be sure to report the version of the Python interpreter (`sys.version`; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

**exception SystemExit**
This exception is raised by the `sys.exit()` function. When it is not handled, the Python interpreter exits; no stack traceback is printed. If the associated value is a plain integer, it specifies the system exit status (passed to C's `exit()` function); if it is `None`, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

Instances have an attribute `code` which is set to the proposed exit status or error message (defaulting to `None`). Also, this exception derives directly from Exception and not StandardError, since it is not technically an error.
A call to `sys.exit()` is translated into an exception so that clean-up handlers (finally clauses of try statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The `os._exit()` function can be used if it is absolutely positively necessary to exit immediately (for example, in the child process after a call to `fork()`).

**exception TypeError**
Raised when an operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

**exception UnboundLocalError**
Raised when a reference is made to a local variable in a function or method, but no value has been bound to that variable. This is a subclass of `NameError`. New in version 2.0.

**exception UnicodeError**
Raised when a Unicode-related encoding or decoding error occurs. It is a subclass of `ValueError`. New in version 2.0.

**exception UnicodeEncodeError**
Raised when a Unicode-related error occurs during encoding. It is a subclass of `UnicodeError`. New in version 2.3.

**exception UnicodeDecodeError**
Raised when a Unicode-related error occurs during decoding. It is a subclass of `UnicodeError`. New in version 2.3.

**exception UnicodeTranslateError**
Raised when a Unicode-related error occurs during translating. It is a subclass of `UnicodeError`. New in version 2.3.

**exception ValueError**
Raised when a built-in operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as `IndexError`.

**exception WindowsError**
Raised when a Windows-specific error occurs or when the error number does not correspond to an `errno` value. The `errno` and `strerror` values are created from the return values of the `GetLastError()` and `FormatMessage()` functions from the Windows Platform API. This is a subclass of `OSError`. New in version 2.0.

**exception ZeroDivisionError**
Raised when the second argument of a division or modulo operation is zero. The associated value is a string indicating the type of the operands and the operation.

The following exceptions are used as warning categories; see the `warnings` module for more information.

**exception Warning**
Base class for warning categories.

**exception UserWarning**
Base class for warnings generated by user code.

**exception DeprecationWarning**
Base class for warnings about deprecated features.

**exception PendingDeprecationWarning**
Base class for warnings about features which will be deprecated in the future.

**exception SyntaxWarning**
Base class for warnings about dubious syntax.

**exception RuntimeWarning**
Base class for warnings about dubious runtime behavior.

**exception FutureWarning**
Base class for warnings about constructs that will change semantically in the future.

The class hierarchy for built-in exceptions is:

```
Exception
```
++-- SystemExit
++-- StopIteration
++-- StandardError
    | ++-- KeyboardInterrupt
    | ++-- ImportError
    | ++-- EnvironmentError
    |    | ++-- IOError
    |    | ++-- OSError
    |    |    | ++-- WindowsError
    | ++-- EOFError
    | ++-- RuntimeError
    |    | ++-- NotImplemented
    | ++-- NameError
    |    | ++-- UnboundLocalError
    | ++-- AttributeError
    | ++-- SyntaxError
    |    | ++-- IndentationError
    |    |    | ++-- TabError
    | ++-- TypeError
    | ++-- AssertionError
    | ++-- LookupError
    |    | ++-- IndexError
    |    | ++-- KeyError
    | ++-- ArithmeticError
    |    | ++-- OverflowError
    |    | ++-- ZeroDivisionError
    | ++-- FloatingPointError
    | ++-- ValueError
    |    | ++-- UnicodeError
    |    |    | ++-- UnicodeEncodeError
    |    |    | ++-- UnicodeDecodeError
    |    |    | ++-- UnicodeTranslateError

2.5 Built-in Constants

A small number of constants live in the built-in namespace. They are:

**False**
The false value of the `bool` type. New in version 2.3.

**True**
The true value of the `bool` type. New in version 2.3.

**None**
The sole value of `types.NoneType`. `None` is frequently used to represent the absence of a value, as when default arguments are not passed to a function.

**NotImplemented**
Special value which can be returned by the ``rich comparison`` special methods (`__eq__()` , `__lt__()` , and friends), to indicate that the comparison is not implemented with respect to the other type.

**Ellipsis**
Special value used in conjunction with extended slicing syntax.

**Python Library Reference**

Previous: 2.4 Built-in Exceptions  Up: 2. Built-In Objects  Next: 3. Python Runtime Services

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3. Python Runtime Services

The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here's an overview:

- **sys**
  Access system-specific parameters and functions.

- **gc**
  Interface to the cycle-detecting garbage collector.

- **weakref**
  Support for weak references and weak dictionaries.

- **fpectl**
  Provide control for floating point exception handling.

- **atexit**
  Register and execute cleanup functions.

- **types**
  Names for built-in types.

- **UserDict**
  Class wrapper for dictionary objects.

- **UserList**
  Class wrapper for list objects.

- **UserString**
  Class wrapper for string objects.

- **operator**
  All Python's standard operators as built-in functions.

- **inspect**
  Extract information and source code from live objects.

- **traceback**
  Print or retrieve a stack traceback.

- **linecache**
  This module provides random access to individual lines from text files.

- **pickle**
  Convert Python objects to streams of bytes and back.

- **cPickle**
  Faster version of **pickle**, but not subclassable.

- **copy_reg**
  Register pickle support functions.

- **shelve**
  Python object persistence.

- **copy**
  Shallow and deep copy operations.

- **marshal**
  Convert Python objects to streams of bytes and back (with different constraints).

- **warnings**
  Issue warning messages and control their disposition.

- **imp**
  Access the implementation of the import statement.

- **zipimport**
  Support for importing Python modules from ZIP archives.

- **pkgutil**
  Utilities to support extension of packages.

- **modulefinder**
  Find modules used by a script.
code
Base classes for interactive Python interpreters.

codeop
Compile (possibly incomplete) Python code.

pprint
Data pretty printer.

repr
Alternate repr() implementation with size limits.

new
Interface to the creation of runtime implementation objects.

site
A standard way to reference site-specific modules.

user
A standard way to reference user-specific modules.

__builtin__
The module that provides the built-in namespace.

__main__
The environment where the top-level script is run.

__future__
Future statement definitions
3.1 sys -- System-specific parameters and functions

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

argv
The list of command line arguments passed to a Python script. argv[0] is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the -c command line option to the interpreter, argv[0] is set to the string '-c'. If no script name was passed to the Python interpreter, argv has zero length.

byteorder
An indicator of the native byte order. This will have the value 'big' on big-endian (most-significant byte first) platforms, and 'little' on little-endian (least-significant byte first) platforms. New in version 2.0.

builtin_module_names
A tuple of strings giving the names of all modules that are compiled into this Python interpreter. (This information is not available in any other way -- modules.keys() only lists the imported modules.)

copyright
A string containing the copyright pertaining to the Python interpreter.

dllhandle
Integer specifying the handle of the Python DLL. Availability: Windows.

displayhook(value)
If value is not None, this function prints it to sys.stdout, and saves it in __builtin___.
	sys.displayhook is called on the result of evaluating an expression entered in an interactive Python session. The display of these values can be
customized by assigning another one-argument function to sys.displayhook.

```
excepthook( type, value, traceback)
```

This function prints out a given traceback and exception to sys.stderr.

When an exception is raised and uncaught, the interpreter calls sys.excepthook with three arguments, the exception class, exception instance, and a traceback object. In an interactive session this happens just before control is returned to the prompt; in a Python program this happens just before the program exits. The handling of such top-level exceptions can be customized by assigning another three-argument function to sys.excepthook.

```
__displayhook__
__excepthook__
```

These objects contain the original values of displayhook and excepthook at the start of the program. They are saved so that displayhook and excepthook can be restored in case they happen to get replaced with broken objects.

```
exc_info()
```

This function returns a tuple of three values that give information about the exception that is currently being handled. The information returned is specific both to the current thread and to the current stack frame. If the current stack frame is not handling an exception, the information is taken from the calling stack frame, or its caller, and so on until a stack frame is found that is handling an exception. Here, ``handling an exception'' is defined as ``executing or having executed an except clause.'' For any stack frame, only information about the most recently handled exception is accessible.

If no exception is being handled anywhere on the stack, a tuple containing three None values is returned. Otherwise, the values returned are (type, value, traceback). Their meaning is: type gets the exception type of the exception being handled (a class object); value gets the exception parameter (its associated value or the second argument to raise, which is always a class instance if the exception type is a class object); traceback gets a
traceback object (see the Reference Manual) which encapsulates the call stack at the point where the exception originally occurred.

If `exc_clear()` is called, this function will return three `None` values until either another exception is raised in the current thread or the execution stack returns to a frame where another exception is being handled.

**Warning:** Assigning the `traceback` return value to a local variable in a function that is handling an exception will cause a circular reference. This will prevent anything referenced by a local variable in the same function or by the traceback from being garbage collected. Since most functions don't need access to the traceback, the best solution is to use something like `exc_type, value = sys.exc_info()[:2]` to extract only the exception type and value. If you do need the traceback, make sure to delete it after use (best done with a `try ... finally` statement) or to call `exc_info()` in a function that does not itself handle an exception. **Note:** Beginning with Python 2.2, such cycles are automatically reclaimed when garbage collection is enabled and they become unreachable, but it remains more efficient to avoid creating cycles.

**exc_clear()**

This function clears all information relating to the current or last exception that occurred in the current thread. After calling this function, `exc_info()` will return three `None` values until another exception is raised in the current thread or the execution stack returns to a frame where another exception is being handled.

This function is only needed in only a few obscure situations. These include logging and error handling systems that report information on the last or current exception. This function can also be used to try to free resources and trigger object finalization, though no guarantee is made as to what objects will be freed, if any. New in version 2.3.

**exc_type**
**exc_value**
**exc_traceback**

*Deprecated since release 1.5.* Use `exc_info()` instead.

Since they are global variables, they are not specific to the current thread,
so their use is not safe in a multi-threaded program. When no exception is being handled, exc_type is set to `None` and the other two are undefined.

**exec_prefix**

A string giving the site-specific directory prefix where the platform-dependent Python files are installed; by default, this is also `/usr/local`. This can be set at build time with the `--exec-prefix` argument to the `configure` script. Specifically, all configuration files (e.g. the `pyconfig.h` header file) are installed in the directory `exec_prefix + '/lib/pythonversion/config'`, and shared library modules are installed in `exec_prefix + '/lib/pythonversion/lib-dynload'`, where `version` is equal to `version[:3]`.

**executable**

A string giving the name of the executable binary for the Python interpreter, on systems where this makes sense.

**exit([arg])**

Exit from Python. This is implemented by raising the `SystemExit` exception, so cleanup actions specified by finally clauses of `try` statements are honored, and it is possible to intercept the exit attempt at an outer level. The optional argument arg can be an integer giving the exit status (defaulting to zero), or another type of object. If it is an integer, zero is considered "successful termination" and any nonzero value is considered "abnormal termination" by shells and the like. Most systems require it to be in the range 0-127, and produce undefined results otherwise. Some systems have a convention for assigning specific meanings to specific exit codes, but these are generally underdeveloped; Unix programs generally use 2 for command line syntax errors and 1 for all other kind of errors. If another type of object is passed, `None` is equivalent to passing zero, and any other object is printed to `sys.stderr` and results in an exit code of 1. In particular, `sys.exit("some error message")` is a quick way to exit a program when an error occurs.

**exitfunc**

This value is not actually defined by the module, but can be set by the user (or by a program) to specify a clean-up action at program exit. When set, it should be a parameterless function. This function will be called when the
interpreter exits. Only one function may be installed in this way; to allow multiple functions which will be called at termination, use the `atexit` module. **Note:** The exit function is not called when the program is killed by a signal, when a Python fatal internal error is detected, or when `os._exit()` is called. 

**Deprecated since release 2.4.** Use `atexit` instead.

`getcheckinterval()`
Return the interpreter's ``check interval``; see `setcheckinterval()`. New in version 2.3.

`getdefaultencoding()`
Return the name of the current default string encoding used by the Unicode implementation. New in version 2.0.

`getdlopenflags()`
Return the current value of the flags that are used for `dlopen()` calls. The flag constants are defined in the `dl` and `DLFCN` modules. Availability: UNIX. New in version 2.2.

`getfilesystemencoding()`
Return the name of the encoding used to convert Unicode filenames into system file names, or None if the system default encoding is used. The result value depends on the operating system:

- On Windows 9x, the encoding is ``mbcs``.
- On Mac OS X, the encoding is ``utf-8``.
- On Unix, the encoding is the user's preference according to the result of `nl_langinfo(CODESET)`, or None if the `nl_langinfo(CODESET)` failed.
- On Windows NT+, file names are Unicode natively, so no conversion is performed. `getfilesystemencoding` still returns ``mbcs``, as this is the encoding that applications should use when they explicitly want to convert Unicode strings to byte strings that are equivalent when used as file names.

New in version 2.3.

`getrefcount`(object)
Return the reference count of the object. The count returned is generally one higher than you might expect, because it includes the (temporary) reference as an argument to `getrefcount()`.

**getrecursionlimit()**

Return the current value of the recursion limit, the maximum depth of the Python interpreter stack. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python. It can be set by `setrecursionlimit()`.

**_getframe([depth])**

Return a frame object from the call stack. If optional integer `depth` is given, return the frame object that many calls below the top of the stack. If that is deeper than the call stack, `ValueError` is raised. The default for `depth` is zero, returning the frame at the top of the call stack.

This function should be used for internal and specialized purposes only.

**getwindowsversion()**

Return a tuple containing five components, describing the Windows version currently running. The elements are `major`, `minor`, `build`, `platform`, and `text`. `text` contains a string while all other values are integers.

`platform` may be one of the following values:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Platform</th>
</tr>
</thead>
<tbody>
<tr>
<td>0 (VER_PLATFORM_WIN32s)</td>
<td>Win32s on Windows 3.1</td>
</tr>
<tr>
<td>1 (VER_PLATFORM_WIN32_WINDOWS)</td>
<td>Windows 95/98/ME</td>
</tr>
<tr>
<td>2 (VER_PLATFORM_WIN32_NT)</td>
<td>Windows NT/2000/XP</td>
</tr>
<tr>
<td>3 (VER_PLATFORM_WIN32_CE)</td>
<td>Windows CE</td>
</tr>
</tbody>
</table>

This function wraps the Win32 `GetVersionEx()` function; see the Microsoft documentation for more information about these fields.

Availability: Windows. New in version 2.3.

**hexversion**

The version number encoded as a single integer. This is guaranteed to
increase with each version, including proper support for non-production releases. For example, to test that the Python interpreter is at least version 1.5.2, use:

```python
if sys.hexversion >= 0x010502F0:
    # use some advanced feature
    ...
else:
    # use an alternative implementation or warn the user
    ...
```

This is called "hexversion" since it only really looks meaningful when viewed as the result of passing it to the built-in `hex()` function. The `version_info` value may be used for a more human-friendly encoding of the same information. New in version 1.5.2.

`last_type`
`last_value`
`last_traceback`
These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error. (Typical use is "import pdb; pdb.pm()" to enter the post-mortem debugger; see chapter 9, "The Python Debugger," for more information.)

The meaning of the variables is the same as that of the return values from `exc_info()` above. (Since there is only one interactive thread, thread-safety is not a concern for these variables, unlike for `exc_type` etc.)

`maxint`
The largest positive integer supported by Python's regular integer type. This is at least 2**31-1. The largest negative integer is `-maxint -1` -- the asymmetry results from the use of 2's complement binary arithmetic.

`maxunicode`
An integer giving the largest supported code point for a Unicode character. The value of this depends on the configuration option that specifies whether Unicode characters are stored as UCS-2 or UCS-4.
**modules**
This is a dictionary that maps module names to modules which have already been loaded. This can be manipulated to force reloading of modules and other tricks. Note that removing a module from this dictionary is *not* the same as calling `reload()` on the corresponding module object.

**path**
A list of strings that specifies the search path for modules. Initialized from the environment variable `PYTHONPATH`, plus an installation-dependent default.

As initialized upon program startup, the first item of this list, `path[0]`, is the directory containing the script that was used to invoke the Python interpreter. If the script directory is not available (e.g. if the interpreter is invoked interactively or if the script is read from standard input), `path[0]` is the empty string, which directs Python to search modules in the current directory first. Notice that the script directory is inserted *before* the entries inserted as a result of `PYTHONPATH`.

A program is free to modify this list for its own purposes.

Changed in version 2.3: Unicode strings are no longer ignored.

**platform**
This string contains a platform identifier, e.g. 'sunos5' or 'linux1'. This can be used to append platform-specific components to `path`, for instance.

**prefix**
A string giving the site-specific directory prefix where the platform independent Python files are installed; by default, this is the string '/usr/local'. This can be set at build time with the `--prefix` argument to the `configure` script. The main collection of Python library modules is installed in the directory `prefix + '/lib/pythonversion'` while the platform independent header files (all except `pyconfig.h`) are stored in `prefix + '/include/pythonversion'`, where `version` is equal to `version[:3]`.

**ps1**
Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are '>>>' and '... '. If a non-string object is assigned to either variable, its \texttt{str()} is re-evaluated each time the interpreter prepares to read a new interactive command; this can be used to implement a dynamic prompt.

\texttt{setcheckinterval( interval)}

Set the interpreter's `check interval`. This integer value determines how often the interpreter checks for periodic things such as thread switches and signal handlers. The default is \texttt{100}, meaning the check is performed every 100 Python virtual instructions. Setting it to a larger value may increase performance for programs using threads. Setting it to a value <= 0 checks every virtual instruction, maximizing responsiveness as well as overhead.

\texttt{setdefaultencoding( name)}

Set the current default string encoding used by the Unicode implementation. If \texttt{name} does not match any available encoding, \texttt{LookupError} is raised. This function is only intended to be used by the \texttt{site} module implementation and, where needed, by \texttt{sitecustomize}. Once used by the \texttt{site} module, it is removed from the \texttt{sys} module's namespace. New in version 2.0.

\texttt{setdlopenflags( n)}

Set the flags used by the interpreter for \texttt{dlopen()} calls, such as when the interpreter loads extension modules. Among other things, this will enable a lazy resolving of symbols when importing a module, if called as \texttt{sys.setdlopenflags(0)}. To share symbols across extension modules, call as \texttt{sys.setdlopenflags(d1.RTLD_NOW | d1.RTLD_GLOBAL)}. Symbolic names for the flag modules can be either found in the \texttt{dl} module, or in the DLFCN module. If DLFCN is not available, it can be generated from \texttt{/usr/include/dlfcn.h} using the \texttt{h2py} script. Availability: UNIX. New in version 2.2.

\texttt{setprofile( profilefunc)}

Set the system's profile function, which allows you to implement a Python
source code profiler in Python. See chapter 10 for more information on the Python profiler. The system's profile function is called similarly to the system's trace function (see settrace()), but it isn't called for each executed line of code (only on call and return, but the return event is reported even when an exception has been set). The function is thread-specific, but there is no way for the profiler to know about context switches between threads, so it does not make sense to use this in the presence of multiple threads. Also, its return value is not used, so it can simply return None.

setrecursionlimit( limit)
Set the maximum depth of the Python interpreter stack to limit. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python.

The highest possible limit is platform-dependent. A user may need to set the limit higher when she has a program that requires deep recursion and a platform that supports a higher limit. This should be done with care, because a too-high limit can lead to a crash.

settrace( tracefunc)
Set the system's trace function, which allows you to implement a Python source code debugger in Python. See section 9.2, "How It Works," in the chapter on the Python debugger. The function is thread-specific; for a debugger to support multiple threads, it must be registered using settrace() for each thread being debugged. Note: The settrace() function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

settscdump( on_flag)
Activate dumping of VM measurements using the Pentium timestamp counter, if on_flag is true. Deactivate these dumps if on_flag is off. The function is available only if Python was compiled with --with-tsc. To understand the output of this dump, read Python/ceval.c in the Python sources. New in version 2.4.
stdin
stdout
stderr

File objects corresponding to the interpreter's standard input, output and error streams. stdin is used for all interpreter input except for scripts but including calls to input() and raw_input(). stdout is used for the output of print and expression statements and for the prompts of input() and raw_input(). The interpreter's own prompts and (almost all of) its error messages go to stderr. stdout and stderr needn't be built-in file objects: any object is acceptable as long as it has a write() method that takes a string argument. (Changing these objects doesn't affect the standard I/O streams of processes executed by os.popen(), os.system() or the exec*() family of functions in the os module.)

__stdin__
__stdout__
__stderr__

These objects contain the original values of stdin, stderr and stdout at the start of the program. They are used during finalization, and could be useful to restore the actual files to known working file objects in case they have been overwritten with a broken object.

tracebacklimit

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is 1000. When set to 0 or less, all traceback information is suppressed and only the exception type and value are printed.

version

A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. It has a value of the form 'version (#build_number, build_date, build_time) [compiler]'. The first three characters are used to identify the version in the installation directories (where appropriate on each platform). An example:

```python
>>> import sys
>>> sys.version
'1.5.2 (#0 Apr 13 1999, 10:51:12) [MSC 32 bit (Intel)]'
```
**api_version**

The C API version for this interpreter. Programmers may find this useful when debugging version conflicts between Python and extension modules. New in version 2.3.

**version_info**

A tuple containing the five components of the version number: major, minor, micro, releaselevel, and serial. All values except releaselevel are integers; the release level is 'alpha', 'beta', 'candidate', or 'final'. The version_info value corresponding to the Python version 2.0 is (2, 0, 0, 'final', 0). New in version 2.0.

**warnoptions**

This is an implementation detail of the warnings framework; do not modify this value. Refer to the warnings module for more information on the warnings framework.

**winver**

The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python DLL. The value is normally the first three characters of version. It is provided in the sys module for informational purposes; modifying this value has no effect on the registry keys used by Python. Availability: Windows.

Module [site]:

This describes how to use .pth files to extend sys.path.

---

Release 2.4.4c1, documentation updated on 11 October 2006. See [About this document...](#) for information on suggesting changes.
3.2 gc -- Garbage Collector interface

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling `gc.disable()`. To debug a leaking program call `gc.set_debug(gc.DEBUG_LEAK)`. Notice that this includes `gc.DEBUG_SAVEALL`, causing garbage-collected objects to be saved in `gc.garbage` for inspection.

The `gc` module provides the following functions:

- **enable()**
  Enable automatic garbage collection.

- **disable()**
  Disable automatic garbage collection.

- **isenabled()**
  Returns true if automatic collection is enabled.

- **collect()**
  Run a full collection. All generations are examined and the number of unreachable objects found is returned.

- **set_debug(flags)**
  Set the garbage collection debugging flags. Debugging information will be written to `sys.stderr`. See below for a list of debugging flags which can be combined using bit operations to control debugging.

- **get_debug()**
  Return the debugging flags currently set.
get_objects()
Returns a list of all objects tracked by the collector, excluding the list returned. New in version 2.2.

set_threshold( threshold0[, threshold1[, threshold2]])
Set the garbage collection thresholds (the collection frequency). Setting threshold0 to zero disables collection.

The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide when to run, the collector keeps track of the number of object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds threshold0, collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than threshold1 times since generation 1 has been examined, then generation 1 is examined as well. Similarly, threshold2 controls the number of collections of generation 1 before collecting generation 2.

get_threshold()
Return the current collection thresholds as a tuple of (threshold0, threshold1, threshold2).

get_referrers( *objs)
Return the list of objects that directly refer to any of objs. This function will only locate those containers which support garbage collection; extension types which do refer to other objects but do not support garbage collection will not be found.

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referrers. To get only currently live objects, call collect() before calling get_referrers().

Care must be taken when using objects returned by get_referrers()
because some of them could still be under construction and hence in a temporarily invalid state. Avoid using `get_referrers()` for any purpose other than debugging.

New in version 2.2.

**get_referents( *objs)**

Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments' C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable. `tp_traverse` methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

New in version 2.3.

The following variable is provided for read-only access (you can mutate its value but should not rebind it):

**garbage**

A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). By default, this list contains only objects with `__del__()` methods. Objects that have `__del__()` methods and are part of a reference cycle cause the entire reference cycle to be uncollectable, including objects not necessarily in the cycle but reachable only from it. Python doesn't collect such cycles automatically because, in general, it isn't possible for Python to guess a safe order in which to run the `__del__()` methods. If you know a safe order, you can force the issue by examining the `garbage` list, and explicitly breaking cycles due to your objects within the list. Note that these objects are kept alive even so by virtue of being in the `garbage` list, so they should be removed from `garbage` too. For example, after breaking cycles, do `del gc.garbage[:]` to empty the list. It's generally better to avoid the issue by not creating cycles containing objects with `__del__()` methods, and `garbage` can be examined in that case to verify that no such cycles are being created.

If `DEBUG_SAVEALL` is set, then all unreachable objects will be added to
this list rather than freed.

The following constants are provided for use with `set_debug()`:

**DEBUG_STATS**
Print statistics during collection. This information can be useful when tuning the collection frequency.

**DEBUG_COLLECTABLE**
Print information on collectable objects found.

**DEBUG_UNCOLLECTABLE**
Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These objects will be added to the garbage list.

**DEBUG_INSTANCES**
When `DEBUG_COLLECTABLE` or `DEBUG_UNCOLLECTABLE` is set, print information about instance objects found.

**DEBUG_OBJECTS**
When `DEBUG_COLLECTABLE` or `DEBUG_UNCOLLECTABLE` is set, print information about objects other than instance objects found.

**DEBUG_SAVEALL**
When set, all unreachable objects found will be appended to `garbage` rather than being freed. This can be useful for debugging a leaking program.

**DEBUG_LEAK**
The debugging flags necessary for the collector to print information about a leaking program (equal to `DEBUG_COLLECTABLE` | `DEBUG_UNCOLLECTABLE` | `DEBUG_INSTANCES` | `DEBUG_OBJECTS` | `DEBUG_SAVEALL`).

---

**Footnotes**

... methods.\footnote{3.1}
Prior to Python 2.2, the list contained all instance objects in unreachable
cycles, not only those with `__del__()` methods.
3.3 weakref -- Weak references

New in version 2.1.

The weakref module allows the Python programmer to create *weak references* to objects.

In the following, the term *referent* means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, garbage collection is free to destroy the referent and reuse its memory for something else. A primary use for weak references is to implement caches or mappings holding large objects, where it's desired that a large object not be kept alive solely because it appears in a cache or mapping. For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The WeakKeyDictionary and WeakValueDictionary classes supplied by the weakref module are an alternative, using weak references to construct mappings that don't keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a WeakValueDictionary, then when the last remaining references to that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

WeakKeyDictionary and WeakValueDictionary use weak references in their implementation, setting up callback functions on the weak references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. Most programs should find that using one of these weak dictionary types is all they need - it's not usually necessary to create your own weak references directly. The low-level machinery used by the weak dictionary implementations is exposed by the weakref module for the benefit of advanced uses.
Not all objects can be weakly referenced; those objects which can include class instances, functions written in Python (but not in C), methods (both bound and unbound), sets, frozensets, file objects, generators, type objects, DBcursor objects from the `bsddb` module, sockets, arrays, deques, and regular expression pattern objects. Changed in version 2.4: Added support for files, sockets, arrays, and patterns.

Several built-in types such as `list` and `dict` do not directly support weak references but can add support through subclassing:

```python
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3)  # this object is weak referencable
```

Extension types can easily be made to support weak references; see section 3.3.3, "Weak References in Extension Types," for more information.

```python
class ref(object[, callback])
```

Return a weak reference to `object`. The original object can be retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause `None` to be returned. If `callback` is provided and not `None`, it will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object's `__del__()` method.

Weak references are hashable if the `object` is hashable. They will maintain their hash value even after the `object` was deleted. If `hash()` is called the first time only after the `object` was deleted, the call will raise `TypeError`.

Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their
referents (regardless of the `callback`). If either referent has been deleted, the references are equal only if the reference objects are the same object.

Changed in version 2.4: This is now a subclassable type rather than a factory function; it derives from `object`.

```python
proxy(object[, callback])
```

Return a proxy to `object` which uses a weak reference. This supports use of the proxy in most contexts instead of requiring the explicit dereferencing used with weak reference objects. The returned object will have a type of either `ProxyType` or `CallableProxyType`, depending on whether `object` is callable. Proxy objects are not hashable regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevent their use as dictionary keys. `callback` is the same as the parameter of the same name to the `ref()` function.

```python
getweakrefcount(object)
```

Return the number of weak references and proxies which refer to `object`.

```python
getweakrefs(object)
```

Return a list of all weak reference and proxy objects which refer to `object`.

```python
class WeakKeyDictionary([dict])
```

Mapping class that references keys weakly. Entries in the dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

**Note:** Caution: Because a `WeakKeyDictionary` is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a `WeakKeyDictionary` because actions performed by the program during iteration may cause items in the dictionary to vanish "by magic" (as a side effect of garbage collection).

```python
class WeakValueDictionary([dict])
```

Mapping class that references values weakly. Entries in the dictionary will
be discarded when no strong reference to the value exists any more.

**Note:** Caution: Because a `WeakValueDictionary` is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a `WeakValueDictionary` because actions performed by the program during iteration may cause items in the dictionary to vanish "by magic" (as a side effect of garbage collection).

**ReferenceType**
The type object for weak references objects.

**ProxyType**
The type object for proxies of objects which are not callable.

**CallableProxyType**
The type object for proxies of callable objects.

**ProxyTypes**
Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

**exception ReferenceError**
Exception raised when a proxy object is used but the underlying object has been collected. This is the same as the standard `ReferenceError` exception.

**Subsections**

- [3.3.1 Weak Reference Objects](#)
3.3.2 Example
3.3.3 Weak References in Extension Types
3.3.1 Weak Reference Objects

Weak reference objects have no attributes or methods, but do allow the referent to be obtained, if it still exists, by calling it:

```python
>>> import weakref
>>> class Object:
...     pass
...
>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns `None`:

```python
>>> del o, o2
>>> print r()
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```python
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print "Object has been deallocated; can't frobnicate."
else:
    print "Object is still live!"
    o.do_something_useful()
```

Using a separate test for "liveness" creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom shown above is safe in threaded applications as well as single-threaded applications.

Specialized versions of `ref` objects can be created through subclassing. This is used in the implementation of the `WeakValueDictionary` to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert
additional processing on calls to retrieve the referent.

This example shows how a subclass of `ref` can be used to store additional information about an object and affect the value that's returned when the referent is accessed:

```python
text
import weakref

class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, **annotations):
        super(ExtendedRef, self).__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.iteritems():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the number of times the reference has been called."
        ob = super(ExtendedRef, self).__call__()
        if ob is not None:
            self.__counter += 1
            ob = (ob, self.__counter)
        return ob
```

3.3.2 Example

This simple example shows how an application can use objects IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```python
import weakref

_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```

See About this document... for information on suggesting changes.
3.3.3 Weak References in Extension Types

One of the goals of the implementation is to allow any type to participate in the weak reference mechanism without incurring the overhead on those objects which do not benefit by weak referencing (such as numbers).

For an object to be weakly referencable, the extension must include a PyObject* field in the instance structure for the use of the weak reference mechanism; it must be initialized to NULL by the object's constructor. It must also set the tp_weaklistoffset field of the corresponding type object to the offset of the field. Also, it needs to add Py_TPFLAGS_HAVE_WEAKREFS to the tp_flags slot. For example, the instance type is defined with the following structure:

```c
typedef struct {
    PyObject_HEAD
    PyClassObject *in_class; /* The class object */
    PyObject *in_dict;    /* A dictionary */
    PyObject *in_weakreflist; /* List of weak references */
} PyInstanceObject;
```

The statically-declared type object for instances is defined this way:

```c
PyTypeObject PyInstance_Type = {
    PyObject_HEAD_INIT(&PyType_Type)
    0,
    "module.instance",
    /* Lots of stuff omitted for brevity... */
    Py_TPFLAGS_DEFAULT | Py_TPFLAGS_HAVE_WEAKREFS /* tp_flags */
    0, /* tp_doc */
    0, /* tp_traverse */
    0, /* tp_clear */
    0, /* tp_richcompare */
    offsetof(PyInstanceObject, in_weakreflist), /* tp_weaklistoffset */
};
```

The type constructor is responsible for initializing the weak reference list to NULL:

```c
static PyObject *
instance_new() {
    /* Other initialization stuff omitted for brevity */
```
self->in_weakreflist = NULL;
return (PyObject *) self;
}

The only further addition is that the destructor needs to call the weak reference manager to clear any weak references. This should be done before any other parts of the destruction have occurred, but is only required if the weak reference list is non-NULL:

```c
static void instance_dealloc(PyInstanceObject *inst)
{
    /* Allocate temporaries if needed, but do not begin destruction just yet. */

    if (inst->in_weakreflist != NULL)
        PyObject_ClearWeakRefs((PyObject *) inst);

    /* Proceed with object destruction normally. */
}
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.4 fpectl -- Floating point exception control

Availability: Unix.

Most computers carry out floating point operations in conformance with the so-called IEEE-754 standard. On any real computer, some floating point operations produce results that cannot be expressed as a normal floating point value. For example, try

```python
>>> import math
>>> math.exp(1000)
inf
>>> math.exp(1000) / math.exp(1000)
nan
```

(The example above will work on many platforms. DEC Alpha may be one exception.) "Inf" is a special, non-numeric value in IEEE-754 that stands for "infinity", and "nan" means "not a number." Note that, other than the non-numeric results, nothing special happened when you asked Python to carry out those calculations. That is in fact the default behaviour prescribed in the IEEE-754 standard, and if it works for you, stop reading now.

In some circumstances, it would be better to raise an exception and stop processing at the point where the faulty operation was attempted. The `fpectl` module is for use in that situation. It provides control over floating point units from several hardware manufacturers, allowing the user to turn on the generation of SIGFPE whenever any of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid Operation occurs. In tandem with a pair of wrapper macros that are inserted into the C code comprising your python system, SIGFPE is trapped and converted into the Python `FloatingPointError` exception.

The `fpectl` module defines the following functions and may raise the given exception:

```python
turnon_sigfpe()
```

Turn on the generation of SIGFPE, and set up an appropriate signal
**handler.**

**turnoff_sigfpe()**
Reset default handling of floating point exceptions.

**exception FloatingPointError**
After `turnon_sigfpe()` has been executed, a floating point operation that raises one of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid operation will in turn raise this standard Python exception.

**Python Library Reference**

*Previous:* [3.3.3 Weak References in](#)  *Up:* [3. Python Runtime Services](#)  *Next:* [3.4.1 Example](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.*

*See [About this document...](#) for information on suggesting changes.*
3.4.1 Example

The following example demonstrates how to start up and test operation of the `fpectl` module.

```python
>>> import fpectl
>>> import fpetest
>>> fpectl.turnon_sigfpe()
>>> fpetest.test()
overflow        PASS
FloatingPointError: Overflow

div by 0         PASS
FloatingPointError: Division by zero
    [ more output from test elided ]
>>> import math
>>> math.exp(1000)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
FloatingPointError: in math_1
```
3.4.2 Limitations and other considerations

Setting up a given processor to trap IEEE-754 floating point errors currently requires custom code on a per-architecture basis. You may have to modify fpectl to control your particular hardware.

Conversion of an IEEE-754 exception to a Python exception requires that the wrapper macros PyFPE_START_PROTECT and PyFPE_END_PROTECT be inserted into your code in an appropriate fashion. Python itself has been modified to support the fpectl module, but many other codes of interest to numerical analysts have not.

The fpectl module is not thread-safe.

See Also:

Some files in the source distribution may be interesting in learning more about how this module operates. The include file Include/pyfpe.h discusses the implementation of this module at some length. Modules/fpetestmodule.c gives several examples of use. Many additional examples can be found in Objects/floatobject.c.
3.5 atexit -- Exit handlers

New in version 2.0.

The `atexit` module defines a single function to register cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination.

Note: the functions registered via this module are not called when the program is killed by a signal, when a Python fatal internal error is detected, or when `os._exit()` is called.

This is an alternate interface to the functionality provided by the `sys.exitfunc` variable.

Note: This module is unlikely to work correctly when used with other code that sets `sys.exitfunc`. In particular, other core Python modules are free to use `atexit` without the programmer's knowledge. Authors who use `sys.exitfunc` should convert their code to use `atexit` instead. The simplest way to convert code that sets `sys.exitfunc` is to import `atexit` and register the function that had been bound to `sys.exitfunc`.

```python
register(func[, *args[, **kargs]])
```

Register `func` as a function to be executed at termination. Any optional arguments that are to be passed to `func` must be passed as arguments to `register()`.

At normal program termination (for instance, if `sys.exit()` is called or the main module's execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.

If an exception is raised during execution of the exit handlers, a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run the last exception to
be raised is re-raised.

Module `readline`:
Useful example of `atexit` to read and write `readline` history files.

Subsections

- 3.5.1 `atexit` Example

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.5.1 atexit Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter's updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```python
try:
    _count = int(open("/tmp/counter").read())
except IOError:
    _count = 0

def incrcounter(n):
    global _count
    _count = _count + n

def savecounter():
    open("/tmp/counter", "w").write("%d" % _count)

import atexit
atexit.register(savecounter)
```

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

```python
def goodbye(name, adjective):
    print 'Goodbye, %s, it was %s to meet you.' % (name, adjective)

import atexit
atexit.register(goodbye, 'Donny', 'nice')

# or:
atexit.register(goodbye, adjective='nice', name='Donny')
```
3.6 types -- Names for built-in types

This module defines names for some object types that are used by the standard Python interpreter, but not for the types defined by various extension modules. Also, it does not include some of the types that arise during processing such as the listiterator type. It is safe to use "from types import *" -- the module does not export any names besides the ones listed here. New names exported by future versions of this module will all end in "Type".

Typical use is for functions that do different things depending on their argument types, like the following:

```python
from types import *

def delete(mylist, item):
    if type(item) is IntType:
        del mylist[item]
    else:
        mylist.remove(item)
```

Starting in Python 2.2, built-in factory functions such as int() and str() are also names for the corresponding types. This is now the preferred way to access the type instead of using the types module. Accordingly, the example above should be written as follows:

```python
def delete(mylist, item):
    if isinstance(item, int):
        del mylist[item]
    else:
        mylist.remove(item)
```

The module defines the following names:

**NoneType**

The type of None.

**TypeType**

The type of type objects (such as returned by type()).

**BooleanType**

The type of the bool values True and False; this is an alias of the built-
in `bool()` function. New in version 2.3.

**IntType**
The type of integers (e.g. 1).

**LongType**
The type of long integers (e.g. 1L).

**FloatType**
The type of floating point numbers (e.g. 1.0).

**ComplexType**
The type of complex numbers (e.g. 1.0j). This is not defined if Python was built without complex number support.

**StringType**
The type of character strings (e.g. 'Spam').

**UnicodeType**
The type of Unicode character strings (e.g. u'Spam'). This is not defined if Python was built without Unicode support.

**TupleType**
The type of tuples (e.g. (1, 2, 3, 'Spam')).

**ListType**
The type of lists (e.g. [0, 1, 2, 3]).

**DictType**
The type of dictionaries (e.g. {'Bacon': 1, 'Ham': 0}).

**DictionaryType**
An alternate name for DictType.

**FunctionType**
The type of user-defined functions and lambdas.

**LambdaType**
An alternate name for FunctionType.
**GeneratorType**
The type of generator-iterator objects, produced by calling a generator function. New in version 2.2.

**CodeType**
The type for code objects such as returned by `compile()`.

**ClassType**
The type of user-defined classes.

**InstanceType**
The type of instances of user-defined classes.

**MethodType**
The type of methods of user-defined class instances.

**UnboundMethodType**
An alternate name for `MethodType`.

**BuiltinFunctionType**
The type of built-in functions like `len()` or `sys.exit()`.

**BuiltinMethodType**
An alternate name for `BuiltinFunction`.

**ModuleType**
The type of modules.

**FileType**
The type of open file objects such as `sys.stdout`.

**XRangeType**
The type of range objects returned by `xrange()`.

**SliceType**
The type of objects returned by `slice()`.

**EllipsisType**
The type of `Ellipsis`. 
TracebackType
The type of traceback objects such as found in `sys.exc_traceback`.

FrameType
The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

BufferType
The type of buffer objects created by the `buffer()` function.

StringTypes
A sequence containing `StringType` and `UnicodeType` used to facilitate easier checking for any string object. Using this is more portable than using a sequence of the two string types constructed elsewhere since it only contains `UnicodeType` if it has been built in the running version of Python. For example: `isinstance(s, types.StringTypes)`. New in version 2.2.
3.7 UserDict -- Class wrapper for dictionary objects

The module defines a mixin, DictMixin, defining all dictionary methods for classes that already have a minimum mapping interface. This greatly simplifies writing classes that need to be substitutable for dictionaries (such as the shelve module).

This also module defines a class, UserDict, that acts as a wrapper around dictionary objects. The need for this class has been largely supplanted by the ability to subclass directly from dict (a feature that became available starting with Python version 2.2). Prior to the introduction of dict, the UserDict class was used to create dictionary-like sub-classes that obtained new behaviors by overriding existing methods or adding new ones.

The UserDict module defines the UserDict class and DictMixin:

```python
class UserDict([initialdata])
    Class that simulates a dictionary. The instance's contents are kept in a regular dictionary, which is accessible via the data attribute of UserDict instances. If initialdata is provided, data is initialized with its contents; note that a reference to initialdata will not be kept, allowing it be used for other purposes. Note: For backward compatibility, instances of UserDict are not iterable.
```

```python
class IterableUserDict([initialdata])
    Subclass of UserDict that supports direct iteration (e.g. for key in myDict).
```

In addition to supporting the methods and operations of mappings (see section 2.3.8), UserDict and IterableUserDict instances provide the following attribute:

```python
data
    A real dictionary used to store the contents of the UserDict class.
```
class DictMixin()

Mixin defining all dictionary methods for classes that already have a minimum dictionary interface including \_\_getitem\_\_(), \_\_setitem\_\_(), \_\_delitem\_\_(), and keys().

This mixin should be used as a superclass. Adding each of the above methods adds progressively more functionality. For instance, defining all but \_\_delitem\_\_ will preclude only pop and popitem from the full interface.

In addition to the four base methods, progressively more efficiency comes with defining \_\_contains\_\_(), \_\_iter\_\_(), and iteritems().

Since the mixin has no knowledge of the subclass constructor, it does not define \_\_init\_\_() or copy().

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.8 UserList -- Class wrapper for list objects

**Note:** This module is available for backward compatibility only. If you are writing code that does not need to work with versions of Python earlier than Python 2.2, please consider subclassing directly from the built-in list type.

This module defines a class that acts as a wrapper around list objects. It is a useful base class for your own list-like classes, which can inherit from them and override existing methods or add new ones. In this way one can add new behaviors to lists.

The UserList module defines the UserList class:

```python
class UserList([list])
    Class that simulates a list. The instance's contents are kept in a regular list, which is accessible via the data attribute of UserList instances. The instance's contents are initially set to a copy of list, defaulting to the empty list[]. list can be either a regular Python list, or an instance of UserList (or a subclass).
```

In addition to supporting the methods and operations of mutable sequences (see section 2.3.6), UserList instances provide the following attribute:

**data**

A real Python list object used to store the contents of the UserList class.

**Subclassing requirements:** Subclasses of UserList are expect to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.

If a derived class does not wish to comply with this requirement, all of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided
in that case.

Changed in version 2.0: Python versions 1.5.2 and 1.6 also required that the constructor be callable with no parameters, and offer a mutable `data` attribute. Earlier versions of Python did not attempt to create instances of the derived class.
3.9 UserString -- Class wrapper for string objects

Note: This UserString class from this module is available for backward compatibility only. If you are writing code that does not need to work with versions of Python earlier than Python 2.2, please consider subclassing directly from the built-in str type instead of using UserString (there is no built-in equivalent to MutableString).

This module defines a class that acts as a wrapper around string objects. It is a useful base class for your own string-like classes, which can inherit from them and override existing methods or add new ones. In this way one can add new behaviors to strings.

It should be noted that these classes are highly inefficient compared to real string or Unicode objects; this is especially the case for MutableString.

The UserString module defines the following classes:

class UserString([sequence])
Class that simulates a string or a Unicode string object. The instance's content is kept in a regular string or Unicode string object, which is accessible via the data attribute of UserString instances. The instance's contents are initially set to a copy of sequence. sequence can be either a regular Python string or Unicode string, an instance of UserString (or a subclass) or an arbitrary sequence which can be converted into a string using the built-in str() function.

class MutableString([sequence])
This class is derived from the UserString above and redefines strings to be mutable. Mutable strings can't be used as dictionary keys, because dictionaries require immutable objects as keys. The main intention of this class is to serve as an educational example for inheritance and necessity to remove (override) the __hash__() method in order to trap attempts to use a mutable object as dictionary key, which would be otherwise very error
prone and hard to track down.

In addition to supporting the methods and operations of string and Unicode objects (see section 2.3.6, "String Methods"), UserString instances provide the following attribute:

**data**

A real Python string or Unicode object used to store the content of the UserString class.
3.10 operator -- Standard operators as functions.

The operator module exports a set of functions implemented in C corresponding to the intrinsic operators of Python. For example, `operator.add(x, y)` is equivalent to the expression `x+y`. The function names are those used for special class methods; variants without leading and trailing "__" are also provided for convenience.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations, sequence operations, and abstract type tests.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

```python
lt(a, b)
le(a, b)
eq(a, b)
ne(a, b)
ge(a, b)
gt(a, b)
__lt__(a, b)
__le__(a, b)
__eq__(a, b)
__ne__(a, b)
__ge__(a, b)
__gt__(a, b)
```

Perform "rich comparisons" between `a` and `b`. Specifically, `lt(a, b)` is equivalent to `a < b`, `le(a, b)` is equivalent to `a <= b`, `eq(a, b)` is equivalent to `a == b`, `ne(a, b)` is equivalent to `a != b`, `gt(a, b)` is equivalent to `a > b` and `ge(a, b)` is equivalent to `a >= b`. Note that
unlike the built-in `cmp()`, these functions can return any value, which may or may not be interpretable as a Boolean value. See the Python Reference Manual for more information about rich comparisons. New in version 2.2.

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

```python
not_(o)
__not__(o)
Return the outcome of `not o`. (Note that there is no `__not__(o)` method for object instances; only the interpreter core defines this operation. The result is affected by the `__nonzero__(o)` and `__len__(o)` methods.)
```

```python
truth(o)
Return `True` if `o` is true, and `False` otherwise. This is equivalent to using the `bool` constructor.
```

```python
is_(a, b)
Return `a is b`. Tests object identity. New in version 2.3.
```

```python
is_not(a, b)
Return `a is not b`. Tests object identity. New in version 2.3.
```

The mathematical and bitwise operations are the most numerous:

```python
abs(o)
__abs__(o)
Return the absolute value of `o`.
```

```python
add(a, b)
__add__(a, b)
Return `a + b`, for `a` and `b` numbers.
```

```python
and_(a, b)
__and__(a, b)
Return the bitwise and of `a` and `b`.
```
\texttt{div}(a, b)
\texttt{\_\_div\_\_}(a, b)
    \text{Return } a / b \text{ when } \texttt{\_\_future\_.division} \text{ is not in effect. This is also}
    \text{known as ``classic'' division.}

\texttt{floordiv}(a, b)
\texttt{\_\_floordiv\_\_}(a, b)
    \text{Return } a \mathord{//} b. New in version 2.2.

\texttt{inv}(o)
\texttt{invert}(o)
\texttt{\_\_inv\_\_}(o)
\texttt{\_\_invert\_\_}(o)
    \text{Return the bitwise inverse of the number } o. \text{ This is equivalent to } \sim o. \text{ The}
    \text{names } \texttt{invert()} \text{ and } \texttt{\_\_invert\_\_()} \text{ were added in Python 2.0.}

\texttt{lshift}(a, b)
\texttt{\_\_lshift\_\_}(a, b)
    \text{Return } a \text{ shifted left by } b.

\texttt{mod}(a, b)
\texttt{\_\_mod\_\_}(a, b)
    \text{Return } a \% b.

\texttt{mul}(a, b)
\texttt{\_\_mul\_\_}(a, b)
    \text{Return } a \ast b, \text{ for } a \text{ and } b \text{ numbers.}

\texttt{neg}(o)
\texttt{\_\_neg\_\_}(o)
    \text{Return } o \text{ negated.}

\texttt{or\_\_}(a, b)
\texttt{\_\_or\_\_}(a, b)
Return the bitwise or of $a$ and $b$.

```python
pos(o)
__pos__(o)
    Return $o$ positive.
```

```python
pow(a, b)
__pow__(a, b)
    Return $a ** b$, for $a$ and $b$ numbers. New in version 2.3.
```

```python
rshift(a, b)
__rshift__(a, b)
    Return $a$ shifted right by $b$.
```

```python
sub(a, b)
__sub__(a, b)
    Return $a - b$.
```

```python
truediv(a, b)
__truediv__(a, b)
    Return $a / b$ when `__future__.division` is in effect. This is also known as division. New in version 2.2.
```

```python
xor(a, b)
__xor__(a, b)
    Return the bitwise exclusive or of $a$ and $b$.
```

Operations which work with sequences include:

```python
concat(a, b)
__concat__(a, b)
    Return $a + b$ for $a$ and $b$ sequences.
```

```python
contains(a, b)
__contains__(a, b)
```
Return the outcome of the test $b$ in $a$. Note the reversed operands. The name `__contains__()` was added in Python 2.0.

`countOf(a, b)`

Return the number of occurrences of $b$ in $a$.

`delitem(a, b)`

`__delitem__(a, b)`

Remove the value of $a$ at index $b$.

`delslice(a, b, c)`

`__delslice__(a, b, c)`

Delete the slice of $a$ from index $b$ to index $c - 1$.

`getitem(a, b)`

`__getitem__(a, b)`

Return the value of $a$ at index $b$.

`getslice(a, b, c)`

`__getslice__(a, b, c)`

Return the slice of $a$ from index $b$ to index $c - 1$.

`indexOf(a, b)`

Return the index of the first of occurrence of $b$ in $a$.

`repeat(a, b)`

`__repeat__(a, b)`

Return $a \times b$ where $a$ is a sequence and $b$ is an integer.

`sequenceIncludes(...)`

Deprecated since release 2.0. Use `contains()` instead.

Alias for `contains()`.

`setitem(a, b, c)`
__setitem__(a, b, c)
    Set the value of a at index b to c.

setslice(a, b, c, v)
__setslice__(a, b, c, v)
    Set the slice of a from index b to index c-1 to the sequence v.

The operator module also defines a few predicates to test the type of objects.

Note: Be careful not to misinterpret the results of these functions; only isCallable() has any measure of reliability with instance objects. For example:

```python
>>> class C:
...     pass
...
>>> import operator
>>> o = C()
>>> operator.isMappingType(o)
True
```

isCallable(o)
    Deprecated since release 2.0. Use the callable() built-in function instead.

    Returns true if the object o can be called like a function, otherwise it returns false. True is returned for functions, bound and unbound methods, class objects, and instance objects which support the __call__() method.

isMappingType(o)
    Returns true if the object o supports the mapping interface. This is true for dictionaries and all instance objects defining __getitem__. Warning: There is no reliable way to test if an instance supports the complete mapping protocol since the interface itself is ill-defined. This makes this test less useful than it otherwise might be.

isNumberType(o)
    Returns true if the object o represents a number. This is true for all numeric types implemented in C. Warning: There is no reliable way to test if an instance supports the complete numeric interface since the interface itself is
ill-defined. This makes this test less useful than it otherwise might be.

**isSequenceType**(*o*)

Returns true if the object *o* supports the sequence protocol. This returns true for all objects which define sequence methods in C, and for all instance objects defining **__getitem__**. **Warning:** There is no reliable way to test if an instance supports the complete sequence interface since the interface itself is ill-defined. This makes this test less useful than it otherwise might be.

Example: Build a dictionary that maps the ordinals from 0 to 255 to their character equivalents.

```python
>>> import operator
>>> d = {}
>>> keys = range(256)
>>> vals = map(chr, keys)
>>> map(operator.setitem, [d]*len(keys), keys, vals)
```

The **operator** module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for **map()**, **sorted()**, **itertools.groupby()**, or other functions that expect a function argument.

**attrgetter**( *attr*)

Return a callable object that fetches *attr* from its operand. After, "f=attrgetter('name')", the call "f(b)" returns "b.name". New in version 2.4.

**itemgetter**( *item*)

Return a callable object that fetches *item* from its operand. After, "f=itemgetter(2)", the call "f(b)" returns "b[2]". New in version 2.4.

Examples:

```python
>>> from operator import *
>>> inventory = [('apple', 3), ('banana', 2), ('pear', 5), ('orange', 1)]
>>> getcount = itemgetter(1)
>>> map(getcount, inventory)
[3, 2, 5, 1]
```
>>> sorted(inventory, key=getcount)
[('orange', 1), ('banana', 2), ('apple', 3), ('pear', 5)]
# 3.10.1 Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the `operator` module.

<table>

</tbody>
</table>
3.11 inspect -- Inspect live objects

New in version 2.1.

The inspect module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.

Subsections

- 3.11.1 Types and members
- 3.11.2 Retrieving source code
- 3.11.3 Classes and functions
- 3.11.4 The interpreter stack
3.11.1 Types and members

The `getmembers()` function retrieves the members of an object such as a class or module. The eleven functions whose names begin with `''is''` are mainly provided as convenient choices for the second argument to `getmembers()`. They also help you determine when you can expect to find the following special attributes:

<table>
<thead>
<tr>
<th>Type</th>
<th>Attribute</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>module</td>
<td><strong>doc</strong></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><strong>file</strong></td>
<td>filename (missing for built-in modules)</td>
<td></td>
</tr>
<tr>
<td>class</td>
<td><strong>doc</strong></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><strong>module</strong></td>
<td>name of module in which this class was defined</td>
<td></td>
</tr>
<tr>
<td>method</td>
<td><strong>doc</strong></td>

<tr>
<td></td>
<td><strong>name</strong></td>
<td>original name of this function or method</td>
<td></td>
</tr>
<tr>
<td></td>
<td><strong>self</strong></td>
<td>instance to which a method is bound, or None</td>
<td></td>
</tr>
</tbody>
</table>

Note:

(1) Changed in version 2.2: im_class used to refer to the class that defined the method.

getmembers( object[, predicate])

Return all the members of an object in a list of (name, value) pairs sorted by name. If the optional predicate argument is supplied, only members for which the predicate returns a true value are included.

getmoduleinfo( path)

Return a tuple of values that describe how Python will interpret the file identified by path if it is a module, or None if it would not be identified as a module. The return tuple is (name, suffix, mode, mtype), where name is the name of the module without the name of any enclosing package, suffix is the trailing part of the file name (which may not be a dot-delimited extension), mode is the open() mode that would be used ('r' or 'rb'), and mtype is an integer giving the type of the module. mtype will have a value which can be compared to the constants defined in the imp
module; see the documentation for that module for more information on module types.

\texttt{getmodulename(path)}
Return the name of the module named by the file \textit{path}, without including the names of enclosing packages. This uses the same algorithm as the interpreter uses when searching for modules. If the name cannot be matched according to the interpreter's rules, \texttt{None} is returned.

\texttt{ismodule(object)}
Return true if the object is a module.

\texttt{isclass(object)}
Return true if the object is a class.

\texttt{ismethod(object)}
Return true if the object is a method.

\texttt{isfunction(object)}
Return true if the object is a Python function or unnamed (lambda) function.

\texttt{istraceback(object)}
Return true if the object is a traceback.

\texttt{isframe(object)}
Return true if the object is a frame.

\texttt{iscode(object)}
Return true if the object is a code.

\texttt{isbuiltin(object)}
Return true if the object is a built-in function.

\texttt{isroutine(object)}
Return true if the object is a user-defined or built-in function or method.
ismethoddescriptor( object)
Return true if the object is a method descriptor, but not if ismethod() or isclass() or isfunction() are true.

This is new as of Python 2.2, and, for example, is true of int.__add__. An object passing this test has a __get__ attribute but not a __set__ attribute, but beyond that the set of attributes varies. __name__ is usually sensible, and __doc__ often is.

Methods implemented via descriptors that also pass one of the other tests return false from the ismethoddescriptor() test, simply because the other tests promise more - you can, e.g., count on having the im_func attribute (etc) when an object passes ismethod().

isdatadescriptor( object)
Return true if the object is a data descriptor.

Data descriptors have both a __get__ and a __set__ attribute. Examples are properties (defined in Python) and getsets and members (defined in C). Typically, data descriptors will also have __name__ and __doc__ attributes (properties, getsets, and members have both of these attributes), but this is not guaranteed. New in version 2.3.
3.11.2 Retrieving source code

getdoc(object)
Get the documentation string for an object. All tabs are expanded to spaces. To clean up docstrings that are indented to line up with blocks of code, any whitespace than can be uniformly removed from the second line onwards is removed.

getcomments(object)
Return in a single string any lines of comments immediately preceding the object's source code (for a class, function, or method), or at the top of the Python source file (if the object is a module).

getfile(object)
Return the name of the (text or binary) file in which an object was defined. This will fail with a TypeError if the object is a built-in module, class, or function.

getmodule(object)
Try to guess which module an object was defined in.

getsourcefile(object)
Return the name of the Python source file in which an object was defined. This will fail with a TypeError if the object is a built-in module, class, or function.

getsourcelines(object)
Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An IOError is raised if the source code cannot be retrieved.

getsource(object)
Return the text of the source code for an object. The argument may be a
module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An IOError is raised if the source code cannot be retrieved.
3.11.3 Classes and functions

getclasstree(classes[, unique])

Arrange the given list of classes into a hierarchy of nested lists. Where a
nested list appears, it contains classes derived from the class whose entry
immediately precedes the list. Each entry is a 2-tuple containing a class and
a tuple of its base classes. If the unique argument is true, exactly one entry
appears in the returned structure for each class in the given list. Otherwise,
classes using multiple inheritance and their descendants will appear
multiple times.

getargspec(func)

Get the names and default values of a function's arguments. A tuple of four
things is returned: (args, varargs, varkw, defaults). args is a list of
the argument names (it may contain nested lists). varargs and varkw are the
names of the * and ** arguments or None. defaults is a tuple of default
argument values or None if there are no default arguments; if this tuple has
n elements, they correspond to the last n elements listed in args.

getargvalues(frame)

Get information about arguments passed into a particular frame. A tuple of
four things is returned: (args, varargs, varkw, locals). args is a list of
the argument names (it may contain nested lists). varargs and varkw are the
names of the * and ** arguments or None. locals is the locals dictionary of
the given frame.

formatargspec(args[, varargs, varkw, defaults, argformat, varargsformat,

varkwformat, defaultformat])

Format a pretty argument spec from the four values returned by
getargspec(). The other four arguments are the corresponding optional
formatting functions that are called to turn names and values into strings.

formatargvalues(args[, varargs, varkw, locals, argformat, varargsformat,
varkwformat, valueformat])
Format a pretty argument spec from the four values returned by `getargvalues()`. The other four arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

`getmro(cls)`

Return a tuple of class cls's base classes, including cls, in method resolution order. No class appears more than once in this tuple. Note that the method resolution order depends on cls's type. Unless a very peculiar user-defined metatype is in use, cls will be the first element of the tuple.
3.11.4 The interpreter stack

When the following functions return ``frame records,'' each record is a tuple of six items: the frame object, the filename, the line number of the current line, the function name, a list of lines of context from the source code, and the index of the current line within that list.

**Warning:** Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python's optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a `finally` clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```python
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
        del frame
```

The optional `context` argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.

`getframeinfo(frame[, context])`

Get information about a frame or traceback object. A 5-tuple is returned, the last five elements of the frame's frame record.
getouterframes(frame[, context])
Get a list of frame records for a frame and all outer frames. These frames represent the calls that lead to the creation of frame. The first entry in the returned list represents frame; the last entry represents the outermost call on frame's stack.

currentframe()
Return the frame object for the caller's stack frame.

getinnerframes(traceback[, context])
Get a list of frame records for a traceback's frame and all inner frames. These frames represent calls made as a consequence of frame. The first entry in the list represents traceback; the last entry represents where the exception was raised.

stack([context])
Return a list of frame records for the caller's stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.

trace([context])
Return a list of frame records for the stack between the current frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.
3.12 traceback -- Print or retrieve a stack traceback

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a "wrapper" around the interpreter.

The module uses traceback objects -- this is the object type that is stored in the variables \texttt{sys.exc_traceback} (deprecated) and \texttt{sys.last_traceback} and returned as the third item from \texttt{sys.exc_info()}.

The module defines the following functions:

\begin{verbatim}
print_tb(traceback[, limit[, file]])
\end{verbatim}

Print up to \texttt{limit} stack trace entries from \texttt{traceback}. If \texttt{limit} is omitted or \texttt{None}, all entries are printed. If \texttt{file} is omitted or \texttt{None}, the output goes to \texttt{sys.stderr}; otherwise it should be an open file or file-like object to receive the output.

\begin{verbatim}
print_exception(type, value, traceback[, limit[, file]])
\end{verbatim}

Print exception information and up to \texttt{limit} stack trace entries from \texttt{traceback} to \texttt{file}. This differs from \texttt{print_tb()} in the following ways:

1. if \texttt{traceback} is not \texttt{None}, it prints a header "Traceback (most recent call last):";
2. it prints the exception \texttt{type} and \texttt{value} after the stack trace;
3. if \texttt{type} is \texttt{SyntaxError} and \texttt{value} has the appropriate format, it prints the line where the syntax error occurred with a caret indicating the approximate position of the error.

\begin{verbatim}
print_exc([limit[, file]])
\end{verbatim}

This is a shorthand for \texttt{print_exception(sys.exc_type, sys.exc_value, sys.exc_traceback, limit, file)}. (In fact, it uses \texttt{sys.exc_info()} to retrieve the same information in a thread-safe
way instead of using the deprecated variables.)

**format_exc([limit])**

This is like `print_exc(limit)` but returns a string instead of printing to a file. New in version 2.4.

**print_last([limit[, file]])**

This is a shorthand for `print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file)`.

**print_stack([f[, limit[, file]]])**

This function prints a stack trace from its invocation point. The optional `f` argument can be used to specify an alternate stack frame to start. The optional `limit` and `file` arguments have the same meaning as for `print_exception()`.

**extract_tb(traceback[, limit])**

Return a list of up to `limit``pre-processed" stack trace entries extracted from the traceback object `traceback`. It is useful for alternate formatting of stack traces. If `limit` is omitted or `None`, all entries are extracted. A "pre-processed" stack trace entry is a quadruple `(filename, line number, function name, text)` representing the information that is usually printed for a stack trace. The `text` is a string with leading and trailing whitespace stripped; if the source is not available it is `None`.

**extract_stack([f[, limit]])**

Extract the raw traceback from the current stack frame. The return value has the same format as for `extract_tb()`. The optional `f` and `limit` arguments have the same meaning as for `print_stack()`.

**format_list(list)**

Given a list of tuples as returned by `extract_tb()` or `extract_stack()`, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not
None.

format_exception_only(type, value)
Format the exception part of a traceback. The arguments are the exception type and value such as given by `sys.last_type` and `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

format_exception(type, value, tb[, limit])
Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`. The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.

format_tb(tb[, limit])
A shorthand for `format_list(extract_tb(tb, limit))`.

format_stack([f[, limit]])
A shorthand for `format_list(extract_stack(f, limit))`.

tb_lineno(tb)
This function returns the current line number set in the traceback object. This function was necessary because in versions of Python prior to 2.3 when the `-O` flag was passed to Python the `tb.tb_lineno` was not updated correctly. This function has no use in versions past 2.3.

Subsections

- [3.12.1 Traceback Example](#)
3.12.1 Traceback Example

This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the code module.

```python
import sys, traceback

def run_user_code(envdir):
    source = raw_input(">>> ")
    try:
        exec source in envdir
    except:
        print "Exception in user code:"
        print '-'*60
        traceback.print_exc(file=sys.stdout)
        print '-'*60

envdir = {}
while 1:
    run_user_code(envdir)
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.13 linecache -- Random access to text lines

The linecache module allows one to get any line from any file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the traceback module to retrieve source lines for inclusion in the formatted traceback.

The linecache module defines the following functions:

**getline**(filename, lineno)
Get line lineno from file named filename. This function will never throw an exception -- it will return '' on errors (the terminating newline character will be included for lines that are found).

If a file named filename is not found, the function will look for it in the module search path, sys.path.

**clearcache()**
Clear the cache. Use this function if you no longer need lines from files previously read using getline().

**checkcache**(filename)
Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If filename is omitted, it will check all the entries in the cache.

Example:

```python
>>> import linecache
>>> linecache.getline('/etc/passwd', 4)
'sys:x:3:3:sys:/dev:/bin/sh
'
```
3.14 pickle

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
3.14 pickle -- Python object serialization

The pickle module implements a fundamental, but powerful algorithm for serializing and de-serializing a Python object structure. `Pickling` is the process whereby a Python object hierarchy is converted into a byte stream, and `unpickling` is the inverse operation, whereby a byte stream is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as `serialization`, `marshalling`, or `flattening`, however, to avoid confusion, the terms used here are `pickling` and `unpickling`.

This documentation describes both the pickle module and the cPickle module.

Footnotes

... `marshalling`, Don't confuse this with the marshal module

3.14.1 Relationship to other Python modules

The pickle module has an optimized cousin called the cPickle module. As its name implies, cPickle is written in C, so it can be up to 1000 times faster than pickle. However it does not support subclassing of the Pickler() and Unpickler() classes, because in cPickle these are functions, not classes. Most applications have no need for this functionality, and can benefit from the improved performance of cPickle. Other than that, the interfaces of the two modules are nearly identical; the common interface is described in this manual and differences are pointed out where necessary. In the following discussions, we use the term ``pickle'' to collectively describe the pickle and cPickle modules.

The data streams the two modules produce are guaranteed to be interchangeable.

Python has a more primitive serialization module called marshal, but in general pickle should always be the preferred way to serialize Python objects. marshal exists primarily to support Python's .pyc files.

The pickle module differs from marshal several significant ways:

- The pickle module keeps track of the objects it has already serialized, so that later references to the same object won't be serialized again. marshal doesn't do this.

  This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by marshal, and in fact, attempting to marshal recursive objects will crash your Python interpreter. Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. pickle stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- marshal cannot be used to serialize user-defined classes and their instances. pickle can save and restore class instances transparently, however the class definition must be importable and live in the same
module as when the object was stored.

- The **marshal** serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support `.pyc` files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The **pickle** serialization format is guaranteed to be backwards compatible across Python releases.

  **Warning:** The **pickle** module is not intended to be secure against erroneous or maliciously constructed data. Never unpickle data received from an untrusted or unauthenticated source.

Note that serialization is a more primitive notion than persistence; although **pickle** reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The **pickle** module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The module **shelve** provides a simple interface to pickle and unpickle objects on DBM-style database files.
3.14.2 Data stream format

The data format used by pickle is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as XDR (which can't represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the pickle data format uses a printable ASCII representation. This is slightly more voluminous than a binary representation. The big advantage of using printable ASCII (and of some other characteristics of pickle's representation) is that for debugging or recovery purposes it is possible for a human to read the pickled file with a standard text editor.

There are currently 3 different protocols which can be used for pickling.

- Protocol version 0 is the original ASCII protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is the old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of new-style classes.

Refer to PEP 307 for more information.

If a protocol is not specified, protocol 0 is used. If protocol is specified as a negative value or HIGHEST_PROTOCOL, the highest protocol version available will be used.

Changed in version 2.3: The bin parameter is deprecated and only provided for backwards compatibility. You should use the protocol parameter instead.

A binary format, which is slightly more efficient, can be chosen by specifying a true value for the bin argument to the Pickler constructor or the dump() and dumps() functions. A protocol version >= 1 implies use of a binary format.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.14.3 Usage

To serialize an object hierarchy, you first create a pickler, then you call the pickler’s `dump()` method. To de-serialize a data stream, you first create an unpickler, then you call the unpickler’s `load()` method. The pickle module provides the following constant:

**HIGHEST_PROTOCOL**

The highest protocol version available. This value can be passed as a `protocol` value. New in version 2.3.

**Note:** Be sure to always open pickle files created with protocols >= 1 in binary mode. For the old ASCII-based pickle protocol 0 you can use either text mode or binary mode as long as you stay consistent.

A pickle file written with protocol 0 in binary mode will contain lone linefeeds as line terminators and therefore will look ``funny'' when viewed in Notepad or other editors which do not support this format.

The pickle module provides the following functions to make the pickling process more convenient:

```
dump(obj, file[, protocol[, bin]])
```

Write a pickled representation of `obj` to the open file object `file`. This is equivalent to `Pickler(file, protocol, bin).dump(obj)`.

If the `protocol` parameter is omitted, protocol 0 is used. If `protocol` is specified as a negative value or `HIGHEST_PROTOCOL`, the highest protocol version will be used.

Changed in version 2.3: The `protocol` parameter was added. The `bin` parameter is deprecated and only provided for backwards compatibility. You should use the `protocol` parameter instead.

If the optional `bin` argument is true, the binary pickle format is used; otherwise the (less efficient) text pickle format is used (for backwards compatibility, this is the default).
file must have a write() method that accepts a single string argument. It can thus be a file object opened for writing, a StringIO object, or any other custom object that meets this interface.

load(file)
Read a string from the open file object file and interpret it as a pickle data stream, reconstructing and returning the original object hierarchy. This is equivalent to Unpickler(file).load().

file must have two methods, a read() method that takes an integer argument, and a readline() method that requires no arguments. Both methods should return a string. Thus file can be a file object opened for reading, a StringIO object, or any other custom object that meets this interface.

This function automatically determines whether the data stream was written in binary mode or not.

dumps(obj[, protocol[, bin]])
Return the pickled representation of the object as a string, instead of writing it to a file.

If the protocol parameter is omitted, protocol 0 is used. If protocol is specified as a negative value or HIGHEST_PROTOCOL, the highest protocol version will be used.

Changed in version 2.3: The protocol parameter was added. The bin parameter is deprecated and only provided for backwards compatibility. You should use the protocol parameter instead.

If the optional bin argument is true, the binary pickle format is used; otherwise the (less efficient) text pickle format is used (this is the default).

loads(string)
Read a pickled object hierarchy from a string. Characters in the string past the pickled object's representation are ignored.

The pickle module also defines three exceptions:
exception PickleError
    A common base class for the other exceptions defined below. This inherits from Exception.

exception PicklingError
    This exception is raised when an unpicklable object is passed to the dump() method.

exception UnpicklingError
    This exception is raised when there is a problem unpickling an object. Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) AttributeError, EOFError, ImportError, and IndexError.

The pickle module also exports two callables, Pickler and Unpickler:

class Pickler( file[, protocol[, bin]])
    This takes a file-like object to which it will write a pickle data stream.

    If the protocol parameter is omitted, protocol 0 is used. If protocol is specified as a negative value, the highest protocol version will be used.

    Changed in version 2.3: The bin parameter is deprecated and only provided for backwards compatibility. You should use the protocol parameter instead.

    Optional bin if true, tells the pickler to use the more efficient binary pickle format, otherwise the ASCII format is used (this is the default).

    file must have a write() method that accepts a single string argument. It can thus be an open file object, a StringIO object, or any other custom object that meets this interface.

Pickler objects define one (or two) public methods:

dump( obj)
    Write a pickled representation of obj to the open file object given in the constructor. Either the binary or ASCII format will be used, depending on the value of the bin flag passed to the constructor.
**clear_memo()**

Clears the pickler's ``memo``. The memo is the data structure that remembers which objects the pickler has already seen, so that shared or recursive objects pickled by reference and not by value. This method is useful when re-using picklers.

---

**Note:** Prior to Python 2.3, `clear_memo()` was only available on the picklers created by `cPickle`. In the `pickle` module, picklers have an instance variable called `memo` which is a Python dictionary. So to clear the memo for a `pickle` module pickler, you could do the following:

```python
mypickler.memo.clear()
```

Code that does not need to support older versions of Python should simply use `clear_memo()`.

---

It is possible to make multiple calls to the `dump()` method of the same `Pickler` instance. These must then be matched to the same number of calls to the `load()` method of the corresponding `Unpickler` instance. If the same object is pickled by multiple `dump()` calls, the `load()` will all yield references to the same object.\(^3\)\(^4\)

**Unpickler** objects are defined as:

**class Unpickler(file)**

This takes a file-like object from which it will read a pickle data stream. This class automatically determines whether the data stream was written in binary mode or not, so it does not need a flag as in the `Pickler` factory.

`file` must have two methods, a `read()` method that takes an integer argument, and a `readline()` method that requires no arguments. Both methods should return a string. Thus `file` can be a file object opened for reading, a `StringIO` object, or any other custom object that meets this interface.
Unpickler objects have one (or two) public methods:

**load()**

Read a pickled object representation from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein.

**noload()**

This is just like `load()` except that it doesn't actually create any objects. This is useful primarily for finding what's called ``persistent ids'' that may be referenced in a pickle data stream. See section 3.14.5 below for more details.

**Note:** the `noload()` method is currently only available on Unpickler objects created with the `cPickle` module. `pickle` module Unpicklers do not have the `noload()` method.

---

Footnotes

... callables\[^3\,^3\] In the `pickle` module these callables are classes, which you could subclass to customize the behavior. However, in the `cPickle` module these callables are factory functions and so cannot be subclassed. One common reason to subclass is to control what objects can actually be unpickled. See section 3.14.6 for more details.

... object.\[^3\,^4\] Warning: this is intended for pickling multiple objects without intervening modifications to the objects or their parts. If you modify an object and then pickle it again using the same `Pickler` instance, the object is not pickled again -- a reference to it is pickled and the `Unpickler` will return the old value, not the modified one. There are two problems here: (1) detecting changes, and (2) marshalling a minimal set of changes. Garbage Collection may also become a problem here.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
3.14.4 What can be pickled and unpickled?

The following types can be pickled:

- None, True, and False
- integers, long integers, floating point numbers, complex numbers
- normal and Unicode strings
- tuples, lists, sets, and dictionaries containing only picklable objects
- functions defined at the top level of a module
- built-in functions defined at the top level of a module
- classes that are defined at the top level of a module
- instances of such classes whose `__dict__` or `__setstate__()` is picklable (see section 3.14.5 for details)

Attempts to pickle unpicklable objects will raise the `PicklingError` exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a `RuntimeError` will be raised in this case. You can carefully raise this limit with `sys.setrecursionlimit()`.

Note that functions (built-in and user-defined) are pickled by ```fully qualified``` name reference, not by value. This means that only the function name is pickled, along with the name of module the function is defined in. Neither the function's code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised.\(^\text{3.5}\)

Similarly, classes are pickled by named reference, so the same restrictions in the unpickling environment apply. Note that none of the class's code or data is pickled, so in the following example the class attribute `attr` is not restored
the unpickling environment:

```python
class Foo:
    attr = 'a class attr'

picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined in the top level of a module.

Similarly, when class instances are pickled, their class's code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class's `__setstate__() method.

---

**Footnotes**

... raised.³⁵

The exception raised will likely be an `ImportError` or an `AttributeError` but it could be something else.

---

*See [About this document...](#) for information on suggesting changes.*
Previous: 3.14.4 What can be  Up: 3.14 pickle  Next: 3.14.5.1 Pickling and unpickling
3.14.5 The pickle protocol

This section describes the "pickling protocol" that defines the interface between the pickler/unpickler and the objects that are being serialized. This protocol provides a standard way for you to define, customize, and control how your objects are serialized and de-serialized. The description in this section doesn't cover specific customizations that you can employ to make the unpickling environment slightly safer from untrusted pickle data streams; see section 3.14.6 for more details.

Subsections

• 3.14.5.1 Pickling and unpickling normal class instances
• 3.14.5.2 Pickling and unpickling extension types
• 3.14.5.3 Pickling and unpickling external objects
3.14.6 Subclassing Unpicklers

By default, unpickling will import any class that it finds in the pickle data. You can control exactly what gets unpickled and what gets called by customizing your unpickler. Unfortunately, exactly how you do this is different depending on whether you're using pickle or cPickle.\footnote{3.10}

In the pickle module, you need to derive a subclass from Unpickler, overriding the `load_global()` method. `load_global()` should read two lines from the pickle data stream where the first line will be the name of the module containing the class and the second line will be the name of the instance's class. It then looks up the class, possibly importing the module and digging out the attribute, then it appends what it finds to the unpickler's stack. Later on, this class will be assigned to the `__class__` attribute of an empty class, as a way of magically creating an instance without calling its class's `__init__()`. Your job (should you choose to accept it), would be to have `load_global()` push onto the unpickler's stack, a known safe version of any class you deem safe to unpickle. It is up to you to produce such a class. Or you could raise an error if you want to disallow all unpickling of instances. If this sounds like a hack, you're right. Refer to the source code to make this work.

Things are a little cleaner with cPickle, but not by much. To control what gets unpickled, you can set the unpickler's `find_global` attribute to a function or `None`. If it is `None` then any attempts to unpickle instances will raise an `UnpicklingError`. If it is a function, then it should accept a module name and a class name, and return the corresponding class object. It is responsible for looking up the class and performing any necessary imports, and it may raise an error to prevent instances of the class from being unpickled.

The moral of the story is that you should be really careful about the source of the strings your application unpickles.

---

Footnotes
A word of caution: the mechanisms described here use internal attributes and methods, which are subject to change in future versions of Python. We intend to someday provide a common interface for controlling this behavior, which will work in either pickle or cPickle.
3.14.7 Example

Here's a simple example of how to modify pickling behavior for a class. The TextReader class opens a text file, and returns the line number and line contents each time its readline() method is called. If a TextReader instance is pickled, all attributes except the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The __setstate__() and __getstate__() methods are used to implement this behavior.

class TextReader:
    """Print and number lines in a text file."""
    def __init__(self, file):
        self.file = file
        self.fh = open(file)
        self.lineno = 0

    def readline(self):
        self.lineno = self.lineno + 1
        line = self.fh.readline()
        if not line:
            return None
        if line.endswith("\n"):
            line = line[:-1]
        return "%d: %s" % (self.lineno, line)

    def __getstate__(self):
        odict = self.__dict__.copy()  # copy the dict since we change
        del odict['fh']  # remove filehandle entry
        return odict

    def __setstate__(self,dict):
        fh = open(dict['file'])  # reopen file
        count = dict['lineno']  # read from file...
        while count:
            fh.readline()  # until line count is restored
            count = count - 1
        self.__dict__.update(dict)  # update attributes
        self.fh = fh  # save the file object

A sample usage might be something like this:

    >>> import TextReader
    >>> obj = TextReader.TextReader("TextReader.py")
    >>> obj.readline()
    '1: #!/usr/local/bin/python'
>>> # (more invocations of obj.readline() here)
... obj.readline()
'7: class TextReader:'
>>> import pickle
>>> pickle.dump(obj,open('save.p','w'))

If you want to see that pickle works across Python processes, start another Python session, before continuing. What follows can happen from either the same process or a new process.

>>> import pickle
>>> reader = pickle.load(open('save.p'))
>>> reader.readline()
'8: "Print and number lines in a text file."

Module copy_reg:
    Pickle interface constructor registration for extension types.

Module shelve:
    Indexed databases of objects; uses pickle.

Module copy:
    Shallow and deep object copying.

Module marshal:
    High-performance serialization of built-in types.
3.15 cPickle -- A faster pickle

The cPickle module supports serialization and de-serialization of Python objects, providing an interface and functionality nearly identical to the pickle module. There are several differences, the most important being performance and subclassability.

First, cPickle can be up to 1000 times faster than pickle because the former is implemented in C. Second, in the cPickle module the callables Pickler() and Unpickler() are functions, not classes. This means that you cannot use them to derive custom pickling and unpickling subclasses. Most applications have no need for this functionality and should benefit from the greatly improved performance of the cPickle module.

The pickle data stream produced by pickle and cPickle are identical, so it is possible to use pickle and cPickle interchangeably with existing pickles.3.11

There are additional minor differences in API between cPickle and pickle, however for most applications, they are interchangeable. More documentation is provided in the pickle module documentation, which includes a list of the documented differences.

Footnotes

... pickles.3.11

Since the pickle data format is actually a tiny stack-oriented programming language, and some freedom is taken in the encodings of certain objects, it is possible that the two modules produce different data streams for the same input objects. However it is guaranteed that they will always be able to read each other's data streams.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.16 copy_reg -- Register pickle support functions

The copy_reg module provides support for the pickle and cPickle modules. The copy module is likely to use this in the future as well. It provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

**constructor**( **object**)

Declares **object** to be a valid constructor. If **object** is not callable (and hence not valid as a constructor), raises TypeError.

**pickle**( **type**, **function**, [**, constructor**])**

Declares that **function** should be used as a "reduction" function for objects of type **type**; **type** must not be a "classic" class object. (Classic classes are handled differently; see the documentation for the pickle module for details.) **function** should return either a string or a tuple containing two or three elements.

The optional **constructor** parameter, if provided, is a callable object which can be used to reconstruct the object when called with the tuple of arguments returned by **function** at pickling time. TypeError will be raised if **object** is a class or **constructor** is not callable.

See the pickle module for more details on the interface expected of **function** and **constructor**.
3.17 \texttt{shelf} -- Python object persistence

A ```shelf''` is a persistent, dictionary-like object. The difference with ```dbm''` databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects -- anything that the \texttt{pickle} module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

\begin{verbatim}
open( filename[,flag='c',protocol=\texttt{None},writeback=\texttt{False},binary=\texttt{None}])
\end{verbatim}

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional \texttt{flag} parameter has the same interpretation as the \texttt{flag} parameter of any\texttt{dbm}.\texttt{open}.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the \texttt{protocol} parameter. Changed in version 2.3: The \texttt{protocol} parameter was added. The \texttt{binary} parameter is deprecated and provided for backwards compatibility only.

By default, mutations to persistent-dictionary mutable entries are not automatically written back. If the optional \texttt{writeback} parameter is set to \texttt{True}, all entries accessed are cached in memory, and written back at close time; this can make it handier to mutate mutable entries in the persistent dictionary, but, if many entries are accessed, it can consume vast amounts of memory for the cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were actually mutated).

Shelve objects support all methods supported by dictionaries. This eases the transition from dictionary based scripts to those requiring persistent storage.

One additional method is supported:

\begin{verbatim}
sync()
\end{verbatim}
Write back all entries in the cache if the shelf was opened with `writeback` set to `True`. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with `close()`.

Subsections

- [3.17.1 Restrictions](#)
- [3.17.2 Example](#)

Release 2.4.4c1, documentation updated on 11 October 2006. See [About this document...](#) for information on suggesting changes.
3.17.1 Restrictions

- The choice of which database package will be used (such as `dbm`, `gdbm`, or `bsddb`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used -- this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.

- Depending on the implementation, closing a persistent dictionary may or may not be necessary to flush changes to disk. The `__del__` method of the `Shelf` class calls the `close` method, so the programmer generally need not do this explicitly.

- The `shelve` module does not support *concurrent* read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. UNIX file locking can be used to solve this, but this differs across UNIX versions and requires knowledge about the database implementation used.

```python
class Shelf(dict, protocol=None, writeback=False, binary=None)
```

A subclass of `UserDict.DictMixin` which stores pickled values in the `dict` object.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the `protocol` parameter. See the `pickle` documentation for a discussion of the pickle protocols. Changed in version 2.3: The `protocol` parameter was added. The `binary` parameter is deprecated and provided for backwards compatibility only.

If the `writeback` parameter is `True`, the object will hold a cache of all entries accessed and write them back to the `dict` at sync and close times. This allows natural operations on mutable entries, but can consume much more memory and make sync and close take a long time.
class BsdDbShelf(binary=None):

A subclass of Shelf which exposes first, next, previous, last and set_location which are available in the bsddb module but not in other database modules. The dict object passed to the constructor must support those methods. This is generally accomplished by calling one of bsddb.hashopen, bsddb.btopen or bsddb.rnopen. The optional protocol, writeback, and binary parameters have the same interpretation as for the Shelf class.

class DbfilenameShelf(filename[, flag='c', protocol=None[, writeback=False[, binary=None]]]])

A subclass of Shelf which accepts a filename instead of a dict-like object. The underlying file will be opened using anydbm.open. By default, the file will be created and opened for both read and write. The optional flag parameter has the same interpretation as for the open function. The optional protocol, writeback, and binary parameters have the same interpretation as for the Shelf class.
3.17.2 Example

To summarize the interface (key is a string, data is an arbitrary object):

```python
import shelve

d = shelve.open(filename)  # open -- file may get suffix added by low
# library

_d[key] = data  # store data at key (overwrites old data if
# using an existing key)
data = d[key]  # retrieve a COPY of data at key (raise KeyError if
# such key)
del d[key]  # delete data stored at key (raises KeyError
# if no such key)
flag = d.has_key(key)  # true if the key exists
list = d.keys()  # a list of all existing keys (slow!)

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = range(4)  # this works as expected, but...
d['xx'].append(5)  # *this doesn't!* -- d['xx'] is STILL range(4)!!
# having opened d without writeback=True, you need to code carefully
temp = d['xx']  # extracts the copy
temp.append(5)  # mutates the copy
d['xx'] = temp  # stores the copy right back, to persist it
# or, d=shelve.open(filename,writeback=True) would let you just code
# d['xx'].append(5) and have it work as expected, BUT it would also
# consume more memory and make the d.close() operation slower.

d.close()  # close it
```

High-performance version of pickle.
3.18 copy -- Shallow and deep copy operations

This module provides generic (shallow and deep) copying operations.

Interface summary:

```python
import copy

x = copy.copy(y)  # make a shallow copy of y
x = copy.deepcopy(y)  # make a deep copy of y
```

For module specific errors, `copy.error` is raised.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A **shallow copy** constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.

- A **deep copy** constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don't exist with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.

- Because deep copy copies *everything* it may copy too much, e.g., administrative data structures that should be shared even between copies.

The `deepcopy()` function avoids these problems by:

- keeping a "memo" dictionary of objects already copied during the current copying pass; and

- letting user-defined classes override the copying operation or the set of
components copied.

This version does not copy types like module, class, function, method, stack trace, stack frame, file, socket, window, array, or any similar types.

Classes can use the same interfaces to control copying that they use to control pickling. See the description of module `pickle` for information on these methods. The `copy` module does not use the `copy_reg` registration module.

In order for a class to define its own copy implementation, it can define special methods `__copy__()` and `__deepcopy__()`. The former is called to implement the shallow copy operation; no additional arguments are passed. The latter is called to implement the deep copy operation; it is passed one argument, the memo dictionary. If the `__deepcopy__()` implementation needs to make a deep copy of a component, it should call the `deepcopy()` function with the component as first argument and the memo dictionary as second argument.

Module `pickle`:
Discussion of the special methods used to support object state retrieval and restoration.
3.19 marshal -- Internal Python object serialization

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does).\[3.12\]

This is not a general `\`persistence\"` module. For general persistence and transfer of Python objects through RPC calls, see the modules \pickle\ and \shelve\. The \marshal\ module exists mainly to support reading and writing the `\`pseudo-compiled\"` code for Python modules of .\pyc\ files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you're serializing and de-serializing Python objects, use the \pickle\ module instead.

**Warning:** The \marshal\ module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: \none\, integers, long integers, floating point numbers, strings, Unicode objects, tuples, lists, dictionaries, and code objects, where it should be understood that tuples, lists and dictionaries are only supported as long as the values contained therein are themselves supported; and recursive lists and dictionaries should not be written (they will cause infinite loops).

**Caveat:** On machines where C's \long int\ type has more than 32 bits (such as the DEC Alpha), it is possible to create plain Python integers that are longer than 32 bits. If such an integer is marshaled and read back in on a machine where C's
long int type has only 32 bits, a Python long integer object is returned instead. While of a different type, the numeric value is the same. (This behavior is new in Python 2.2. In earlier versions, all but the least-significant 32 bits of the value were lost, and a warning message was printed.)

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

**dump** *(value, file[, version]*)
Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `posix.popen()`. It must be opened in binary mode ('wb' or 'w+b').

If the value has (or contains an object that has) an unsupported type, a `ValueError` exception is raised -- but garbage data will also be written to the file. The object will not be properly read back by `load()`.

New in version 2.4: The `version` argument indicates the data format that `dump` should use (see below).

**load** *(file)*
Read one value from the open file and return it. If no valid value is read, raise `EOFError`, `ValueError` or `TypeError`. The file must be an open file object opened in binary mode ('rb' or 'r+b').

**Warning:** If an object containing an unsupported type was marshalled with `dump()`, `load()` will substitute `None` for the unmarshallable type.

**dumps** *(value[, version]*)
Return the string that would be written to a file by `dump(value, file)`. The value must be a supported type. Raise a `ValueError` exception if value has (or contains an object that has) an unsupported type.

New in version 2.4: The `version` argument indicates the data format that `dumps` should use (see below).
**loads** (*string*)

Convert the string to a value. If no valid value is found, raise `EOFError`, `ValueError` or `TypeError`. Extra characters in the string are ignored.

In addition, the following constants are defined:

**version**

Indicates the format that the module uses. Version 0 is the historical format, version 1 (added in Python 2.4) shares interned strings. The current version is 1.

New in version 2.4.

---

**Footnotes**

... does). 3.12

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term ``marshalling`` for shipping of data around in a self-contained form. Strictly speaking, ``to marshal`` means to convert some data from internal to external form (in an RPC buffer for instance) and ``unmarshalling`` for the reverse process.
3.20 warnings -- Warning control

New in version 2.1.

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn't warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module. (C programmers use `PyErr_Warn();` see the [Python/C API Reference Manual](https://docs.python.org/3/extending/c-api/err.html) for details).

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the warning category (see below), the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the warning filter, which is a sequence of matching rules and actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`, which may be overridden; the default implementation of this function formats the message by calling `formatwarning()`, which is also available for use by custom implementations.

---

**Subsections**

- [3.20.1 Warning Categories](#)
3.20.2 The Warnings Filter

3.20.3 Available Functions
3.20.1 Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings. The following warnings category classes are currently defined:

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Warning</td>
<td>This is the base class of all warning category classes. It is a subclass of Exception.</td>
</tr>
<tr>
<td>UserWarning</td>
<td>The default category for warn().</td>
</tr>
<tr>
<td>DeprecationWarning</td>
<td>Base category for warnings about deprecated features.</td>
</tr>
<tr>
<td>SyntaxWarning</td>
<td>Base category for warnings about dubious syntactic features.</td>
</tr>
<tr>
<td>RuntimeWarning</td>
<td>Base category for warnings about dubious runtime features.</td>
</tr>
<tr>
<td>FutureWarning</td>
<td>Base category for warnings about constructs that will change semantically in the future.</td>
</tr>
</tbody>
</table>

While these are technically built-in exceptions, they are documented here, because conceptually they belong to the warnings mechanism.

User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the Warning class.
3.20.2 The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the match determines the disposition of the match. Each entry is a tuple of the form (action, message, category, module, lineno), where:

- **action** is one of the following strings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Disposition</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;error&quot;</td>
<td>turn matching warnings into exceptions</td>
</tr>
<tr>
<td>&quot;ignore&quot;</td>
<td>never print matching warnings</td>
</tr>
<tr>
<td>&quot;always&quot;</td>
<td>always print matching warnings</td>
</tr>
<tr>
<td>&quot;default&quot;</td>
<td>print the first occurrence of matching warnings for each location where the warning is issued</td>
</tr>
<tr>
<td>&quot;module&quot;</td>
<td>print the first occurrence of matching warnings for each module where the warning is issued</td>
</tr>
<tr>
<td>&quot;once&quot;</td>
<td>print only the first occurrence of matching warnings, regardless of location</td>
</tr>
</tbody>
</table>

- **message** is a string containing a regular expression that the warning message must match (the match is compiled to always be case-insensitive)

- **category** is a class (a subclass of Warning) of which the warning category must be a subclass in order to match

- **module** is a string containing a regular expression that the module name must match (the match is compiled to be case-sensitive)

- **lineno** is an integer that the line number where the warning occurred must match, or 0 to match all line numbers

Since the Warning class is derived from the built-in Exception class, to turn a warning into an error we simply raise category(message).
The warnings filter is initialized by -W options passed to the Python interpreter command line. The interpreter saves the arguments for all -W options without interpretation in sys.warnoptions; the warnings module parses these when it is first imported (invalid options are ignored, after printing a message to sys.stderr).
3.20.3 Available Functions

**warn** *(message[, category[, stacklevel]])*

Issue a warning, or maybe ignore it or raise an exception. The *category* argument, if given, must be a warning category class (see above); it defaults to **UserWarning**. Alternatively *message* can be a **Warning** instance, in which case *category* will be ignored and *message.__class__* will be used. In this case the message text will be `str(message)`. This function raises an exception if the particular warning issued is changed into an error by the warnings filter see above. The *stacklevel* argument can be used by wrapper functions written in Python, like this:

```python
def deprecation(message):
    warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to `deprecation()`'s caller, rather than to the source of `deprecation()` itself (since the latter would defeat the purpose of the warning message).

**warn_explicit** *(message, category, filename, lineno[, module[, registry]])*

This is a low-level interface to the functionality of `warn()`, passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the **__warningregistry__** dictionary of the module). The module name defaults to the filename with `.py` stripped; if no registry is passed, the warning is never suppressed. *message* must be a string and *category* a subclass of **Warning** or *message* may be a **Warning** instance, in which case *category* will be ignored.

**showwarning** *(message, category, filename, lineno[, file])*

Write a warning to a file. The default implementation calls **formatwarning**(message, category, filename, lineno) and writes the resulting string to *file*, which defaults to **sys.stderr**. You may replace this function with an alternative implementation by assigning to **warnings.showwarning**.
**formatwarning**(*message, category, filename, lineno*)  
Format a warning the standard way. This returns a string which may contain embedded newlines and ends in a newline.

**filterwarnings**(*action[, message[, category[, module[, lineno[, append]]]]]*)  
Insert an entry into the list of warnings filters. The entry is inserted at the front by default; if *append* is true, it is inserted at the end. This checks the types of the arguments, compiles the message and module regular expressions, and inserts them as a tuple in front of the warnings filter. Entries inserted later override entries inserted earlier, if both match a particular warning. Omitted arguments default to a value that matches everything.

**resetwarnings()**  
Reset the warnings filter. This discards the effect of all previous calls to *filterwarnings()*, including that of the -W command line options.
3.21 imp -- Access the import internals

This module provides an interface to the mechanisms used to implement the import statement. It defines the following constants and functions:

get_magic()
Return the magic string value used to recognize byte-compiled code files (.pyc files). (This value may be different for each Python version.)

get_suffixes()
Return a list of triples, each describing a particular type of module. Each triple has the form (suffix, mode, type), where suffix is a string to be appended to the module name to form the filename to search for, mode is the mode string to pass to the built-in open() function to open the file (this can be 'r' for text files or 'rb' for binary files), and type is the file type, which has one of the values PY_SOURCE, PY_COMPILLED, or C_EXTENSION, described below.

find_module(name[, path])
Try to find the module name on the search path path. If path is a list of directory names, each directory is searched for files with any of the suffixes returned by get_suffixes() above. Invalid names in the list are silently ignored (but all list items must be strings). If path is omitted or None, the list of directory names given by sys.path is searched, but first it searches a few special places: it tries to find a built-in module with the given name (C_BUILTIN), then a frozen module (PY_FROZEN), and on some systems some other places are looked in as well (on the Mac, it looks for a resource (PY_RESOURCE); on Windows, it looks in the registry which may point to a specific file).

If search is successful, the return value is a triple (file, pathname, description) where file is an open file object positioned at the beginning, pathname is the pathname of the file found, and description is a triple as
contained in the list returned by \texttt{get_suffixes()} describing the kind of module found. If the module does not live in a file, the returned \texttt{file} is \texttt{None}, \texttt{filename} is the empty string, and the \texttt{description} tuple contains empty strings for its suffix and mode; the module type is as indicate in parentheses above. If the search is unsuccessful, \texttt{ImportError} is raised. Other exceptions indicate problems with the arguments or environment.

This function does not handle hierarchical module names (names containing dots). In order to find $P.M$, that is, submodule $M$ of package $P$, use \texttt{find_module()} and \texttt{load_module()} to find and load package $P$, and then use \texttt{find_module()} with the \texttt{path} argument set to $P.__path__$. When $P$ itself has a dotted name, apply this recipe recursively.

\begin{verbatim}
load_module(name, file, filename, description)
\end{verbatim}

Load a module that was previously found by \texttt{find_module()} (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was already imported, it is equivalent to a \texttt{reload()}! The \texttt{name} argument indicates the full module name (including the package name, if this is a submodule of a package). The \texttt{file} argument is an open file, and \texttt{filename} is the corresponding file name; these can be \texttt{None} and '', respectively, when the module is not being loaded from a file. The \texttt{description} argument is a tuple, as would be returned by \texttt{get_suffixes()}, describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually \texttt{ImportError}) is raised.

\textbf{Important:} the caller is responsible for closing the \texttt{file} argument, if it was not \texttt{None}, even when an exception is raised. This is best done using a \texttt{try} ... \texttt{finally} statement.

\begin{verbatim}
new_module(name)
\end{verbatim}

Return a new empty module object called \texttt{name}. This object is \texttt{not} inserted in \texttt{sys.modules}.

\begin{verbatim}
lock_held()
\end{verbatim}
Return True if the import lock is currently held, else False. On platforms without threads, always return False.

On platforms with threads, a thread executing an import holds an internal lock until the import is complete. This lock blocks other threads from doing an import until the original import completes, which in turn prevents other threads from seeing incomplete module objects constructed by the original thread while in the process of completing its import (and the imports, if any, triggered by that).

**acquire_lock()**
Acquires the interpreter's import lock for the current thread. This lock should be used by import hooks to ensure thread-safety when importing modules. On platforms without threads, this function does nothing. New in version 2.3.

**release_lock()**
Release the interpreter's import lock. On platforms without threads, this function does nothing. New in version 2.3.

The following constants with integer values, defined in this module, are used to indicate the search result of `find_module()`.

**PY_SOURCE**
The module was found as a source file.

**PY_COMPILE**
The module was found as a compiled code object file.

**C_EXTENSION**
The module was found as a dynamically loadable shared library.

**PY_RESOURCE**
The module was found as a Mac OS 9 resource. This value can only be returned on a Mac OS 9 or earlier Macintosh.

**PKG_DIRECTORY**
The module was found as a package directory.
C_BUILTIN
The module was found as a built-in module.

PY_FROZEN
The module was found as a frozen module (see init_frozen()).

The following constant and functions are obsolete; their functionality is available through find_module() or load_module(). They are kept around for backward compatibility:

SEARCH_ERROR
Unused.

init_builtin(name)
Initialize the built-in module called name and return its module object. If the module was already initialized, it will be initialized again. A few modules cannot be initialized twice -- attempting to initialize these again will raise an ImportError exception. If there is no built-in module called name, None is returned.

init_frozen(name)
Initialize the frozen module called name and return its module object. If the module was already initialized, it will be initialized again. If there is no frozen module called name, None is returned. (Frozen modules are modules written in Python whose compiled byte-code object is incorporated into a custom-built Python interpreter by Python's freeze utility. See Tools/freeze/ for now.)

is_builtin(name)
Return 1 if there is a built-in module called name which can be initialized again. Return -1 if there is a built-in module called name which cannot be initialized again (see init_builtin()). Return 0 if there is no built-in module called name.

is_frozen(name)
Return True if there is a frozen module (see init_frozen()) called name, or False if there is no such module.
**load_compiled**( *name, pathname, [file]*)

Load and initialize a module implemented as a byte-compiled code file and return its module object. If the module was already initialized, it will be initialized again. The *name* argument is used to create or access a module object. The *pathname* argument points to the byte-compiled code file. The *file* argument is the byte-compiled code file, open for reading in binary mode, from the beginning. It must currently be a real file object, not a user-defined class emulating a file.

**load_dynamic**( *name, pathname[, file]*)

Load and initialize a module implemented as a dynamically loadable shared library and return its module object. If the module was already initialized, it will be initialized again. Some modules don't like that and may raise an exception. The *pathname* argument must point to the shared library. The *name* argument is used to construct the name of the initialization function: an external C function called "*initname()*" in the shared library is called. The optional *file* argument is ignored. (Note: using shared libraries is highly system dependent, and not all systems support it.)

**load_source**( *name, pathname[, file]*)

Load and initialize a module implemented as a Python source file and return its module object. If the module was already initialized, it will be initialized again. The *name* argument is used to create or access a module object. The *pathname* argument points to the source file. The *file* argument is the source file, open for reading as text, from the beginning. It must currently be a real file object, not a user-defined class emulating a file. Note that if a properly matching byte-compiled file (with suffix .pyc or .pyo) exists, it will be used instead of parsing the given source file.
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
3.21.1 Examples

The following function emulates what was the standard import statement up to Python 1.4 (no hierarchical module names). (This implementation wouldn't work in that version, since find_module() has been extended and load_module() has been added in 1.4.)

```python
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=None):
    # Fast path: see if the module has already been imported.
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller handle it.

    fp, pathname, description = imp.find_module(name)

    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close fp explicitly.
        if fp:
            fp.close()
```

A more complete example that implements hierarchical module names and includes a reload() function can be found in the module knee. The knee module can be found in Demo/imputil/ in the Python source distribution.
3.22 zipimport -- Import modules from Zip archives

New in version 2.3.

This module adds the ability to import Python modules (*.py, *.py[co]) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the built-in `import` mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `/tmp/example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but only files `.py` and `.py[co]` are available for import. ZIP import of dynamic modules (.pyd, .so) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` or `.pyo` file, meaning that if a ZIP archive doesn't contain `.pyc` files, importing may be rather slow.

Using the built-in `reload()` function will fail if called on a module loaded from a ZIP archive; it is unlikely that `reload()` would be needed, since this would imply that the ZIP has been altered during runtime.

The available attributes of this module are:

**exception ZipImporterError**

Exception raised by `zipimporter` objects. It's a subclass of `ImportError`, so it can be caught as `ImportError`, too.

**class zipimporter**

The class for importing ZIP files. See ```zipimporter Objects``" (section 3.22.1) for constructor details.

Python Library Reference

Previous: 3.21.1 Examples  Up: 3. Python Runtime Services  Next: 3.22.1 zipimporter Objects

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
3.22.1 zipimporter Objects

class zipimporter(archivepath)
    Create a new zipimporter instance. archivepath must be a path to a zipfile. ZipImportError is raised if archivepath doesn't point to a valid ZIP archive.

find_module(fullname[, path])
    Search for a module specified by fullname. fullname must be the fully qualified (dotted) module name. It returns the zipimporter instance itself if the module was found, or None if it wasn't. The optional path argument is ignored--it's there for compatibility with the importer protocol.

get_code(fullname)
    Return the code object for the specified module. Raise ZipImportError if the module couldn't be found.

get_data(pathname)
    Return the data associated with pathname. Raise IOError if the file wasn't found.

get_source(fullname)
    Return the source code for the specified module. Raise ZipImportError if the module couldn't be found, return None if the archive does contain the module, but has no source for it.

is_package(fullname)
    Return True if the module specified by fullname is a package. Raise ZipImportError if the module couldn't be found.

load_module(fullname)
    Load the module specified by fullname. fullname must be the fully qualified (dotted) module name. It returns the imported module, or raises ZipImportError if it wasn't found.
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
3.22.2 Examples

Here is an example that imports a module from a ZIP archive - note that the `zipimport` module is not explicitly used.

```
$ unzip -l /tmp/example.zip
Archive:  /tmp/example.zip
         Length   Date    Time   Name
          ----   -------   -----   -----
        8467 11-26-02 22:30  jwzthreading.py
        -------             -------
          8467                1 file
$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, '/tmp/example.zip')  # Add .zip file to front
>>> import jwzthreading
>>> jwzthreading.__file__
'/tmp/example.zip/jwzthreading.py'
```
3.23 pkgutil -- Package extension utility

New in version 2.3.

This module provides a single function:

**extend_path**(*path*, *name*)

Extend the search path for the modules which comprise a package. Intended use is to place the following code in a package's __init__.py:

```python
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

This will add to the package's __path__ all subdirectories of directories on sys.path named after the package. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for *.pkg files beginning where * matches the *name* argument. This feature is similar to *.pth files (see the site module for more information), except that it doesn't special-case lines starting with import. A *.pkg file is trusted at face value: apart from checking for duplicates, all entries found in a *.pkg file are added to the path, regardless of whether they exist the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not modified; an extended copy is returned. Items are only appended to the copy at the end.

It is assumed that sys.path is a sequence. Items of sys.path that are not (Unicode or 8-bit) strings referring to existing directories are ignored. Unicode items on sys.path that cause errors when used as filenames may cause this function to raise an exception (in line with os.path.isdir() behavior).
3.24 modulefinder -- Find modules used by a script

This module provides a ModuleFinder class that can be used to determine the set of modules imported by a script. modulefinder.py can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

**AddPackagePath**( pkg_name, path)

Record that the package named pkg_name can be found in the specified path.

**ReplacePackage**( oldname, newname)

Allows specifying that the module named oldname is in fact the package named newname. The most common usage would be to handle how the _xmlplus package replaces the xml package.

**class ModuleFinder**

This class provides run_script() and report() methods to determine the set of modules imported by a script. path can be a list of directories to search for modules; if not specified, sys.path is used. debug sets the debugging level; higher values make the class print debugging messages about what it's doing. excludes is a list of module names to exclude from the analysis. replace_paths is a list of (oldpath, newpath) tuples that will be replaced in module paths.

**report()**

Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.

**run_script**( pathname)
Analyze the contents of the `pathname` file, which must contain Python code.
3.25 code -- Interpreter base classes

The code module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

**class InteractiveInterpreter([locals])**

This class deals with parsing and interpreter state (the user's namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional *locals* argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key '__name__' set to '__console__' and key '__doc__' set to None.

**class InteractiveConsole([locals[, filename]])**

Closely emulate the behavior of the interactive Python interpreter. This class builds on InteractiveInterpreter and adds prompting using the familiar sys.ps1 and sys.ps2, and input buffering.

**interact([banner[, readfunc[, local]]])**

Convenience function to run a read-eval-print loop. This creates a new instance of InteractiveConsole and sets *readfunc* to be used as the raw_input() method, if provided. If *local* is provided, it is passed to the InteractiveConsole constructor for use as the default namespace for the interpreter loop. The *interact()* method of the instance is then run with *banner* passed as the banner to use, if provided. The console object is discarded after use.

**compile_command(source[, filename[, symbol]])**

This function is useful for programs that want to emulate Python's interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function *almost* always makes the same decision as the real interpreter main loop.
source is the source string; filename is the optional filename from which source was read, defaulting to '<input>'; and symbol is the optional grammar start symbol, which should be either 'single' (the default) or 'eval'.

Returns a code object (the same as compile(source, filename, symbol)) if the command is complete and valid; None if the command is incomplete; raises SyntaxError if the command is complete and contains a syntax error, or raises OverflowError or ValueError if the command contains an invalid literal.
3.25.1 Interactive Interpreter Objects

\texttt{runsource}( source[, filename[, symbol]])

Compile and run some source in the interpreter. Arguments are the same as for \texttt{compile\_command()}; the default for \texttt{filename} is '\texttt{<input>}' , and for \texttt{symbol} is '\texttt{single}'. One several things can happen:

- The input is incorrect; \texttt{compile\_command()} raised an exception (\texttt{SyntaxError} or \texttt{OverflowError}). A syntax traceback will be printed by calling the \texttt{showsyntaxerror()} method. \texttt{runsource()} returns False.
- The input is incomplete, and more input is required; \texttt{compile\_command()} returned None. \texttt{runsource()} returns True.
- The input is complete; \texttt{compile\_command()} returned a code object. The code is executed by calling the \texttt{runcode()} (which also handles run-time exceptions, except for \texttt{SystemExit}). \texttt{runsource()} returns False.

The return value can be used to decide whether to use \texttt{sys.ps1} or \texttt{sys.ps2} to prompt the next line.

\texttt{runcode}( code)

Execute a code object. When an exception occurs, \texttt{showtraceback()} is called to display a traceback. All exceptions are caught except \texttt{SystemExit}, which is allowed to propagate.

A note about \texttt{KeyboardInterrupt}: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.

\texttt{showsyntaxerror}([filename])

Display the syntax error that just occurred. This does not display a stack trace because there isn't one for syntax errors. If \texttt{filename} is given, it is
stuffed into the exception instead of the default filename provided by Python's parser, because it always uses '<string>' when reading from a string. The output is written by the `write()` method.

**showtraceback()**
Display the exception that just occurred. We remove the first stack item because it is within the interpreter object implementation. The output is written by the `write()` method.

**write(data)**
Write a string to the standard error stream (`sys.stderr`). Derived classes should override this to provide the appropriate output handling as needed.
3.25.2 Interactive Console Objects

The `InteractiveConsole` class is a subclass of `InteractiveInterpreter`, and so offers all the methods of the interpreter objects as well as the following additions.

`interact([banner])`
Closely emulate the interactive Python console. The optional banner argument specify the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter - since it's so close!).

`push(line)`
Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter's `runsource()` method is called with the concatenated contents of the buffer as source. If this indicates that the command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was appended. The return value is `True` if more input is required, `False` if the line was dealt with in some way (this is the same as `runsource()`).

`resetbuffer()`
Remove any unhandled source text from the input buffer.

`raw_input([prompt])`
Write a prompt and read a line. The returned line does not include the trailing newline. When the user enters the EOF key sequence, `EOFError` is raised. The base implementation uses the built-in function `raw_input();` a subclass may replace this with a different implementation.
codeop

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
3.26 codeop -- Compile Python code

The codeop module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the code module. As a result, you probably don't want to use the module directly; if you want to include such a loop in your program you probably want to use the code module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print `>>> ` or `... ` next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The codeop module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

```python
compile_command(source[, filename[, symbol]])
```

Tries to compile source, which should be a string of Python code and return a code object if source is valid Python code. In that case, the filename attribute of the code object will be filename, which defaults to '<input>'. Returns None if source is not valid Python code, but is a prefix of valid Python code.

If there is a problem with source, an exception will be raised. SyntaxError is raised if there is invalid Python syntax, and OverflowError or ValueError if there is an invalid literal.

The symbol argument determines whether source is compiled as a statement ('single', the default) or as an expression ('eval'). Any other value will cause ValueError to be raised.

**Caveat:** It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a
backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

**class Compile()**

Instances of this class have `__call__()` methods identical in signature to the built-in function `compile()`, but with the difference that if the instance compiles program text containing a `__future__` statement, the instance 'remembers' and compiles all subsequent program texts with the statement in force.

**class CommandCompiler()**

Instances of this class have `__call__()` methods identical in signature to `compile_command()`; the difference is that if the instance compiles program text containing a `__future__` statement, the instance 'remembers' and compiles all subsequent program texts with the statement in force.

A note on version compatibility: the `Compile` and `CommandCompiler` are new in Python 2.2. If you want to enable the future-tracking features of 2.2 but also retain compatibility with 2.1 and earlier versions of Python you can either write

```python
try:
    from codeop import CommandCompiler
    compile_command = CommandCompiler()
    del CommandCompiler
except ImportError:
    from codeop import compile_command
```

which is a low-impact change, but introduces possibly unwanted global state into your program, or you can write:

```python
try:
    from codeop import CommandCompiler
except ImportError:
    def CommandCompiler():
        from codeop import compile_command
        return compile_command
```

and then call `CommandCompiler` every time you need a fresh compiler object.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.27 pprint -- Data pretty printer

The pprint module provides a capability to `"pretty-print" arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets, classes, or instances are included, as well as many other builtin objects which are not representable as Python constants.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don't fit within the allowed width. Construct PrettyPrinter objects explicitly if you need to adjust the width constraint.

The pprint module defines one class:

```
class PrettyPrinter(...)

Construct a PrettyPrinter instance. This constructor understands several keyword parameters. An output stream may be set using the stream keyword; the only method used on the stream object is the file protocol's write() method. If not specified, the PrettyPrinter adopts sys.stdout. Three additional parameters may be used to control the formatted representation. The keywords are indent, depth, and width. The amount of indentation added for each recursive level is specified by indent; the default is one. Other values can cause output to look a little odd, but can make nesting easier to spot. The number of levels which may be printed is controlled by depth; if the data structure being printed is too deep, the next contained level is replaced by "...". By default, there is no constraint on the depth of the objects being formatted. The desired output width is constrained using the width parameter; the default is eighty characters. If a structure cannot be formatted within the constrained width, a best effort will be made.
```

```python
>>> import pprint, sys
>>> stuff = sys.path[:]
>>> stuff.insert(0, stuff[:])
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
[   [   ',
```
The **PrettyPrinter** class supports several derivative functions:

**pformat**(object[, indent[, width[, depth]]])
Return the formatted representation of `object` as a string. `indent`, `width` and `depth` will be passed to the **PrettyPrinter** constructor as formatting parameters. Changed in version 2.4: The parameters `indent`, `width` and `depth` were added.

**pprint**(object[, stream[, indent[, width[, depth]]]])
Prints the formatted representation of `object` on `stream`, followed by a newline. If `stream` is omitted, `sys.stdout` is used. This may be used in the interactive interpreter instead of a `print` statement for inspecting values. `indent`, `width` and `depth` will be passed to the **PrettyPrinter** constructor as formatting parameters.

```python
>>> stuff = sys.path[:]
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=869440>,
 '',
 '/usr/local/lib/python1.5',
 '/usr/local/lib/python1.5/test',
 '/usr/local/lib/python1.5/sunos5',
 '/usr/local/lib/python1.5/sharedmodules',
 '/usr/local/lib/python1.5/tkinter']
```

Changed in version 2.4: The parameters `indent`, `width` and `depth` were
isreadable( object)
Determine if the formatted representation of object is ``readable,'' or can be used to reconstruct the value using eval(). This always returns false for recursive objects.

```python
>>> pprint.isreadable(stuff)
False
```

isrecursive( object)
Determine if object requires a recursive representation.

One more support function is also defined:

saferepr( object)
Return a string representation of object, protected against recursive data structures. If the representation of object exposes a recursive entry, the recursive reference will be represented as "<Recursion on typename with id=number>". The representation is not otherwise formatted.

```python
>>> pprint.saferepr(stuff)
"[<Recursion on list with id=682968>, '', '/usr/local/lib/python1.5/lib/python1.5/test', '/usr/local/lib/python1.5/sunos5', '/usr/local/lib/python1.5/sharedmodules', '/usr/local/lib/python1.5/tkinter']"
```
3.27.1 PrettyPrinter Objects

PrettyPrinter instances have the following methods:

**pformat**(object)
   Return the formatted representation of object. This takes into Account the options passed to the PrettyPrinter constructor.

**pprint**(object)
   Print the formatted representation of object on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new PrettyPrinter objects don't need to be created.

**isreadable**(object)
   Determine if the formatted representation of the object is ``readable,'' or can be used to reconstruct the value using eval(). Note that this returns false for recursive objects. If the depth parameter of the PrettyPrinter is set and the object is deeper than allowed, this returns false.

**isrecursive**(object)
   Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the saferrepr() implementation.

**format**(object, context, maxlevels, level)
   Returns three values: the formatted version of object as a string, a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the id() of objects that are part of the current presentation context (direct and indirect containers for object that are affecting the presentation) as the keys; if an object needs to be
presented which is already represented in `context`, the third return value should be true. Recursive calls to the `format()` method should add additional entries for containers to this dictionary. The fourth argument, `maxlevels`, gives the requested limit to recursion; this will be 0 if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, `level` gives the current level; recursive calls should be passed a value less than that of the current call. New in version 2.3.
3.28 repr -- Alternate repr() implementation

The `repr` module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

**class Repr()**

Class which provides formatting services useful in implementing functions similar to the built-in `repr()`; size limits for different object types are added to avoid the generation of representations which are excessively long.

**aRepr**

This is an instance of Repr which is used to provide the `repr()` function described below. Changing the attributes of this object will affect the size limits used by `repr()` and the Python debugger.

**repr(obj)**

This is the `repr()` method of `aRepr`. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.

Subsections

- 3.28.1 Repr Objects
- 3.28.2 Subclassing Repr Objects
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
3.28.1 Repr Objects

Repr instances provide several members which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

maxlevel
Depth limit on the creation of recursive representations. The default is 6.

maxdict
maxlist
maxtuple
maxset
maxfrozenset
maxdeque
maxarray
Limits on the number of entries represented for the named object type. The default is 4 for maxdict, 5 for maxarray, and 6 for the others. New in version 2.4: maxset, maxfrozenset, and set.

maxlong
Maximum number of characters in the representation for a long integer. Digits are dropped from the middle. The default is 40.

maxstring
Limit on the number of characters in the representation of the string. Note that the `"normal"` representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is 30.

maxother
This limit is used to control the size of object types for which no specific formatting method is available on the Repr object. It is applied in a similar manner as maxstring. The default is 20.

repr(obj)
The equivalent to the built-in repr() that uses the formatting imposed by
the instance.

**repr1**(obj, level)
Recursive implementation used by **repr()**. This uses the type of obj to determine which formatting method to call, passing it obj and level. The type-specific methods should call **repr1()** to perform recursive formatting, with level - 1 for the value of level in the recursive call.

**repr_type**(obj, level)
Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, type is replaced by `string.join(string.split(type(obj).__name__, '_'))`. Dispatch to these methods is handled by **repr1()**. Type-specific methods which need to recursively format a value should call "self.repr1(subobj, level - 1)".
3.28.2 Subclassing Repr Objects

The use of dynamic dispatching by `Repr.repr1()` allows subclasses of `Repr` to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```python
import repr
import sys

class MyRepr(repr.Repr):
    def repr_file(self, obj, level):
        if obj.name in ['<stdin>', '<stdout>', '<stderr>']:
            return obj.name
        else:
            return `obj`

aRepr = MyRepr()
print aRepr.repr(sys.stdin)  # prints '<stdin>'
```

Python Library Reference

Previous: 3.28.1 Repr Objects  Up: 3.28 repr  Next: 3.29 new

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.29 new -- Creation of runtime internal objects

The new module allows an interface to the interpreter object creation functions. This is for use primarily in marshal-type functions, when a new object needs to be created ``magically'' and not by using the regular creation functions. This module provides a low-level interface to the interpreter, so care must be exercised when using this module. It is possible to supply non-sensical arguments which crash the interpreter when the object is used.

The new module defines the following functions:

**instance**( class[, dict])

This function creates an instance of class with dictionary dict without calling the __init__() constructor. If dict is omitted or None, a new, empty dictionary is created for the new instance. Note that there are no guarantees that the object will be in a consistent state.

**instancemethod**( function, instance, class)

This function will return a method object, bound to instance, or unbound if instance is None. function must be callable.

**function**( code, globals[, name[, argdefs[, closure]]]])

Returns a (Python) function with the given code and globals. If name is given, it must be a string or None. If it is a string, the function will have the given name, otherwise the function name will be taken from code.co_name. If argdefs is given, it must be a tuple and will be used to determine the default values of parameters. If closure is given, it must be None or a tuple of cell objects containing objects to bind to the names in code.co_freevars.

**code**( argcount, nlocals, stacksize, flags, codestring, constants, names, varnames, filename, name, firstlineno, inotab)

This function is an interface to the PyCode_New() C function.
**module**(*name[, doc]*)

This function returns a new module object with name *name*. *name* must be a string. The optional *doc* argument can have any type.

**classobj**(*name, baseclasses, dict*)

This function returns a new class object, with name *name*, derived from *baseclasses* (which should be a tuple of classes) and with namespace *dict*. 
3.30 site -- Site-specific configuration hook

This module is automatically imported during initialization. The automatic import can be suppressed using the interpreter's -S option.

Importing this module will append site-specific paths to the module search path.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses sys.prefix and sys.exec_prefix; empty heads are skipped. For the tail part, it uses the empty string (on Windows) or lib/python2.4/site-packages (on Unix and Macintosh) and then lib/site-python. For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to sys.path and also inspects the newly added path for configuration files.

A path configuration file is a file whose name has the form package.pth and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to sys.path. Non-existing items are never added to sys.path, but no check is made that the item refers to a directory (rather than a file). No item is added to sys.path more than once. Blank lines and lines beginning with # are skipped. Lines starting with import are executed.

For example, suppose sys.prefix and sys.exec_prefix are set to /usr/local. The Python 2.4.4 library is then installed in /usr/local/lib/python2.4 (where only the first three characters of sys.version are used to form the installation path name). Suppose this has a subdirectory /usr/local/lib/python2.4/site-packages with three subdirectories, foo, bar and spam, and two path configuration files, foo.pth and bar.pth. Assume foo.pth contains the following:

```bash
# foo package configuration
foo
bar
bletch
```
and `bar.pth` contains:

```
# bar package configuration

bar
```

Then the following directories are added to `sys.path`, in this order:

```
/usr/local/lib/python2.3/site-packages/bar
/usr/local/lib/python2.3/site-packages/foo
```

Note that `bletch` is omitted because it doesn't exist; the `bar` directory precedes the `foo` directory because `bar.pth` comes alphabetically before `foo.pth`; and `spam` is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named `sitecustomize`, which can perform arbitrary site-specific customizations. If this import fails with an `ImportError` exception, it is silently ignored.

Note that for some non-UNIX systems, `sys.prefix` and `sys.exec_prefix` are empty, and the path manipulations are skipped; however the import of `sitecustomize` is still attempted.
3.31 user -- User-specific configuration hook

As a policy, Python doesn't run user-specified code on startup of Python programs. (Only interactive sessions execute the script specified in the PYTHONSTARTUP environment variable if it exists).

However, some programs or sites may find it convenient to allow users to have a standard customization file, which gets run when a program requests it. This module implements such a mechanism. A program that wishes to use the mechanism must execute the statement

```
import user
```

The `user` module looks for a file `.pythonrc.py` in the user's home directory and if it can be opened, executes it (using `execfile()`) in its own (the module `user`'s) global namespace. Errors during this phase are not caught; that's up to the program that imports the `user` module, if it wishes. The home directory is assumed to be named by the HOME environment variable; if this is not set, the current directory is used.

The user's `.pythonrc.py` could conceivably test for `sys.version` if it wishes to do different things depending on the Python version.

A warning to users: be very conservative in what you place in your `.pythonrc.py` file. Since you don't know which programs will use it, changing the behavior of standard modules or functions is generally not a good idea.

A suggestion for programmers who wish to use this mechanism: a simple way to let users specify options for your package is to have them define variables in their `.pythonrc.py` file that you test in your module. For example, a module `spam` that has a verbosity level can look for a variable `user.spam_verbose`, as follows:

```
import user

verbose = bool(getattr(user, "spam_verbose", 0))
```
(The three-argument form of `getattr()` is used in case the user has not defined `spam_verbose` in their `.pythonrc.py` file.)

Programs with extensive customization needs are better off reading a program-specific customization file.

Programs with security or privacy concerns should *not* import this module; a user can easily break into a program by placing arbitrary code in the `.pythonrc.py` file.

Modules for general use should *not* import this module; it may interfere with the operation of the importing program.

*Release 2.4.4c1, documentation updated on 11 October 2006.*

See [About this document...] for information on suggesting changes.
This module provides direct access to all `built-in' identifiers of Python; for example, `__builtin__.open' is the full name for the built-in function `open()'. See chapter 2, "Built-in Objects."

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an `open()' function that wraps the built-in `open()', this module can be used directly:

```python
import __builtin__

def open(path):
    f = __builtin__.open(path, 'r')
    return UpperCaser(f)

class UpperCaser:
    '''Wrapper around a file that converts output to upper-case.''
    def __init__(self, f):
        self._f = f
    def read(self, count=-1):
        return self._f.read(count).upper()
    # ...
```

As an implementation detail, most modules have the name `__builtins__' (note the "s") made available as part of their globals. The value of `__builtins__' is normally either this module or the value of this module's `__dict__' attribute. Since this is an implementation detail, it may not be used by alternate implementations of Python.
3.33 __main__ -- Top-level script environment

This module represents the (otherwise anonymous) scope in which the interpreter's main program executes -- commands read either from standard input, from a script file, or from an interactive prompt. It is this environment in which the idiomatic ``conditional script'' stanza causes a script to run:

```python
if __name__ == "__main__":
    main()
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
3.34 __future__ -- Future statement definitions

__future__ is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they're importing.

- To ensure that future_statements run under releases prior to 2.1 at least yield runtime exceptions (the import of __future__ will fail, because there was no module of that name prior to 2.1).

- To document when incompatible changes were introduced, and when they will be -- or were -- made mandatory. This is a form of executable documentation, and can be inspected programatically via importing __future__ and examining its contents.

Each statement in __future__.py is of the form:

```
FeatureName = "_Feature(" OptionalRelease "," MandatoryRelease ","
       CompilerFlag ")"
```

where, normally, OptionalRelease is less than MandatoryRelease, and both are 5-tuples of the same form as sys.version_info:

```
(PY_MAJOR_VERSION, # the 2 in 2.1.0a3; an int
 PY_MINOR_VERSION, # the 1; an int
 PY_MICRO_VERSION, # the 0; an int
 PY_RELEASE_LEVEL, # "alpha", "beta", "candidate" or "final"; st
 PY_RELEASE_SERIAL # the 3; an int
 )
```

OptionalRelease records the first release in which the feature was accepted.

In the case of a MandatoryRelease that has not yet occurred, MandatoryRelease predicts the release in which the feature will become part of the language.
Else *MandatoryRelease* records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

*MandatoryRelease* may also be *None*, meaning that a planned feature got dropped.

Instances of class *_Feature* have two corresponding methods, *getOptionalRelease()* and *getMandatoryRelease()*.

*CompilerFlag* is the (bitfield) flag that should be passed in the fourth argument to the builtin function *compile()* to enable the feature in dynamically compiled code. This flag is stored in the *compiler_flag* attribute on *_Feature* instances.

No feature description will ever be deleted from *__future__*.
4. String Services

The modules described in this chapter provide a wide range of string manipulation operations. Here's an overview:

- **string**: Common string operations.
- **re**: Regular expression search and match operations with a Perl-style expression syntax.
- **struct**: Interpret strings as packed binary data.
- **difflib**: Helpers for computing differences between objects.
- **fpformat**: General floating point formatting functions.
- **StringIO**: Read and write strings as if they were files.
- **cStringIO**: Faster version of StringIO, but not subclassable.
- **textwrap**: Text wrapping and filling
- **codecs**: Encode and decode data and streams.
- **encodings.idna**: Internationalized Domain Names implementation
- **unicodedata**: Access the Unicode Database.
- **stringprep**: String preparation, as per RFC 3453

Information on the methods of string objects can be found in section 2.3.6, `\`String Methods.``
4.1 string -- Common string operations

The string module contains a number of useful constants and classes, as well as some deprecated legacy functions that are also available as methods on strings. See the module re for string functions based on regular expressions.

Subsections

- 4.1.1 String constants
- 4.1.2 Template strings
- 4.1.3 String functions
- 4.1.4 Deprecated string functions
4.1.1 String constants

The constants defined in this module are:

**ascii_letters**
The concatenation of the `ascii_lowercase` and `ascii_uppercase` constants described below. This value is not locale-dependent.

**ascii_lowercase**
The lowercase letters 'abcdefghijklmnopqrstuvwxyz'. This value is not locale-dependent and will not change.

**ascii_uppercase**
The uppercase letters 'ABCDEFGHIJKLMNOPQRSTUVWXYZ'. This value is not locale-dependent and will not change.

**digits**
The string '0123456789'.

**hexdigits**
The string '0123456789abcdefABCDEF'.

**letters**
The concatenation of the strings `lowercase` and `uppercase` described below. The specific value is locale-dependent, and will be updated when `locale.setlocale()` is called.

**lowercase**
A string containing all the characters that are considered lowercase letters. On most systems this is the string 'abcdefghijklmnopqrstuvwxyz'. Do not change its definition -- the effect on the routines `upper()` and `swapcase()` is undefined. The specific value is locale-dependent, and will be updated when `locale.setlocale()` is called.

**octdigits**
The string '01234567'.
punctuation
String of ASCII characters which are considered punctuation characters in the "C" locale.

printable
String of characters which are considered printable. This is a combination of digits, letters, punctuation, and whitespace.

uppercase
A string containing all the characters that are considered uppercase letters. On most systems this is the string
'ABCDEFHGIJKLMNOPQRSTUVWXYZ'. Do not change its definition -- the effect on the routines `lower()` and `swapcase()` is undefined. The specific value is locale-dependent, and will be updated when `locale.setlocale()` is called.

whitespace
A string containing all characters that are considered whitespace. On most systems this includes the characters space, tab, linefeed, return, formfeed, and vertical tab. Do not change its definition -- the effect on the routines `strip()` and `split()` is undefined.
4.1.2 Template strings

Templates provide simpler string substitutions as described in PEP 292. Instead of the normal "%"-based substitutions, Templates support "$"-based substitutions, using the following rules:

- "$$" is an escape; it is replaced with a single "$".

- "$identifier" names a substitution placeholder matching a mapping key of "identifier". By default, "identifier" must spell a Python identifier. The first non-identifier character after the "$" character terminates this placeholder specification.

- "${identifier}" is equivalent to "$identifier". It is required when valid identifier characters follow the placeholder but are not part of the placeholder, such as "${noun}ification".

Any other appearance of "$" in the string will result in a ValueError being raised.

New in version 2.4.

The string module provides a Template class that implements these rules. The methods of Template are:

class Template( template)

    The constructor takes a single argument which is the template string.

substitute( mapping[, **kws])

    Performs the template substitution, returning a new string. mapping is any dictionary-like object with keys that match the placeholders in the template. Alternatively, you can provide keyword arguments, where the keywords are the placeholders. When both mapping and kws are given and there are duplicates, the placeholders from kws take precedence.

safe_substitute( mapping[, **kws])

    Like substitute(), except that if placeholders are missing from
*mapping* and *kws*, instead of raising a *KeyError* exception, the original placeholder will appear in the resulting string intact. Also, unlike with *substitute()* , any other appearances of the "$" will simply return "$" instead of raising *ValueError* .

While other exceptions may still occur, this method is called ``safe" because substitutions always tries to return a usable string instead of raising an exception. In another sense, *safe_substitute()* may be anything other than safe, since it will silently ignore malformed templates containing dangling delimiters, unmatched braces, or placeholders that are not valid Python identifiers.

*Template* instances also provide one public data attribute:

**template**

This is the object passed to the constructor's *template* argument. In general, you shouldn't change it, but read-only access is not enforced.

Here is an example of how to use a Template:

```python
>>> from string import Template
>>> s = Template('$who likes $what')
>>> s.substitute(who='tim', what='kung pao')
'tim likes kung pao'
>>> d = dict(who='tim')
>>> Template('Give $who $100').substitute(d)
Traceback (most recent call last):
[...]
ValueError: Invalid placeholder in string: line 1, col 10
>>> Template('$who likes $what').substitute(d)
Traceback (most recent call last):
[...]
KeyError: 'what'
>>> Template('$who likes $what').safe_substitute(d)
'tim likes $what'
```

Advanced usage: you can derive subclasses of *Template* to customize the placeholder syntax, delimiter character, or the entire regular expression used to parse template strings. To do this, you can override these class attributes:

- **delimiter** - This is the literal string describing a placeholder introducing delimiter. The default value "$". Note that this should *not* be a regular expression, as the implementation will call *re.escape()* on this string
as needed.

- **idpattern** - This is the regular expression describing the pattern for non-braced placeholders (the braces will be added automatically as appropriate). The default value is the regular expression "[\_a - z][\_a - z0 - 9] *".

Alternatively, you can provide the entire regular expression pattern by overriding the class attribute *pattern*. If you do this, the value must be a regular expression object with four named capturing groups. The capturing groups correspond to the rules given above, along with the invalid placeholder rule:

- **escaped** - This group matches the escape sequence, e.g. "$$", in the default pattern.
- **named** - This group matches the unbraced placeholder name; it should not include the delimiter in capturing group.
- **braced** - This group matches the brace enclosed placeholder name; it should not include either the delimiter or braces in the capturing group.
- **invalid** - This group matches any other delimiter pattern (usually a single delimiter), and it should appear last in the regular expression.
4.1.3 String functions

The following functions are available to operate on string and Unicode objects. They are not available as string methods.

**capwords(s)**

Split the argument into words using `split()`, capitalize each word using `capitalize()`, and join the capitalized words using `join()`. Note that this replaces runs of whitespace characters by a single space, and removes leading and trailing whitespace.

**maketrans(from, to)**

Return a translation table suitable for passing to `translate()` or `regex.compile()`, that will map each character in `from` into the character at the same position in `to`; `from` and `to` must have the same length.

**Warning:** Don't use strings derived from `lowercase` and `uppercase` as arguments; in some locales, these don't have the same length. For case conversions, always use `lower()` and `upper()`.
4.1.4 Deprecated string functions

The following list of functions are also defined as methods of string and Unicode objects; see "String Methods" (section 2.3.6) for more information on those. You should consider these functions as deprecated, although they will not be removed until Python 3.0. The functions defined in this module are:

\textbf{atof}(s)

\textbf{Deprecated since release 2.0.} Use the \texttt{float()}
built-in function.

Convert a string to a floating point number. The string must have
the standard syntax for a floating point literal in Python, optionally preceded by
a sign ("+" or "-"). Note that this behaves identically to the built-in function
\texttt{float()} when passed a string.

\textbf{Note:} When passing in a string, values for NaN and Infinity may be
returned, depending on the underlying C library. The specific set of strings
accepted which cause these values to be returned depends entirely on the C
library and is known to vary.

\textbf{atoi}(s, \texttt{base})

\textbf{Deprecated since release 2.0.} Use the \texttt{int()}
built-in function.

Convert string \texttt{s} to an integer in the given \texttt{base}. The string must consist of
one or more digits, optionally preceded by a sign ("+" or "-"). The \texttt{base}
defaults to 10. If it is 0, a default base is chosen depending on the leading
characters of the string (after stripping the sign): "0x" or "0X" means 16,
"0" means 8, anything else means 10. If \texttt{base} is 16, a leading "0x" or "0X"
is always accepted, though not required. This behaves identically to the
built-in function \texttt{int()} when passed a string. (Also note: for a more
flexible interpretation of numeric literals, use the built-in function
\texttt{eval()}.)

\textbf{atol}(s, \texttt{base})

\textbf{Deprecated since release 2.0.} Use the \texttt{long()}
built-in function.
Convert string $s$ to a long integer in the given $base$. The string must consist of one or more digits, optionally preceded by a sign ("+" or "-"). The $base$ argument has the same meaning as for $\texttt{atoi()}$. A trailing "L" or "L" is not allowed, except if the base is 0. Note that when invoked without $base$ or with $base$ set to 10, this behaves identical to the built-in function $\texttt{long()}$ when passed a string.

$\texttt{capitalize( word)}$

Return a copy of $word$ with only its first character capitalized.

$\texttt{expandtabs( s[, tabsize])}$

Expand tabs in a string replacing them by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. This doesn't understand other non-printing characters or escape sequences. The tab size defaults to 8.

$\texttt{find( s, sub[, start[, end]])}$

Return the lowest index in $s$ where the substring $sub$ is found such that $sub$ is wholly contained in $s[\texttt{start:} \texttt{end}]$. Return -1 on failure. Defaults for $\texttt{start}$ and $\texttt{end}$ and interpretation of negative values is the same as for slices.

$\texttt{rfind( s, sub[, start[, end]])}$

Like $\texttt{find()}$ but find the highest index.

$\texttt{index( s, sub[, start[, end]])}$

Like $\texttt{find()}$ but raise $\texttt{ValueError}$ when the substring is not found.

$\texttt{rindex( s, sub[, start[, end]])}$

Like $\texttt{rfind()}$ but raise $\texttt{ValueError}$ when the substring is not found.

$\texttt{count( s, sub[, start[, end]])}$

Return the number of (non-overlapping) occurrences of substring $sub$ in string $s[\texttt{start:} \texttt{end}]$. Defaults for $\texttt{start}$ and $\texttt{end}$ and interpretation of negative values are the same as for slices.
**lower(s)**

Return a copy of s, but with upper case letters converted to lower case.

**split(s[, sep[, maxsplit]])**

Return a list of the words of the string s. If the optional second argument sep is absent or None, the words are separated by arbitrary strings of whitespace characters (space, tab, newline, return, formfeed). If the second argument sep is present and not None, it specifies a string to be used as the word separator. The returned list will then have one more item than the number of non-overlapping occurrences of the separator in the string. The optional third argument maxsplit defaults to 0. If it is nonzero, at most maxsplit number of splits occur, and the remainder of the string is returned as the final element of the list (thus, the list will have at most maxsplit+1 elements).

The behavior of split on an empty string depends on the value of sep. If sep is not specified, or specified as None, the result will be an empty list. If sep is specified as any string, the result will be a list containing one element which is an empty string.

**rsplit(s[, sep[, maxsplit]])**

Return a list of the words of the string s, scanning s from the end. To all intents and purposes, the resulting list of words is the same as returned by split(), except when the optional third argument maxsplit is explicitly specified and nonzero. When maxsplit is nonzero, at most maxsplit number of splits - the rightmost ones - occur, and the remainder of the string is returned as the first element of the list (thus, the list will have at most maxsplit+1 elements). New in version 2.4.

**splitfields(s[, sep[, maxsplit]])**

This function behaves identically to split(). (In the past, split() was only used with one argument, while splitfields() was only used with two arguments.)

**join(words[, sep])**

Concatenate a list or tuple of words with intervening occurrences of sep. The default value for sep is a single space character. It is always true that
"string.join(string.split(s, sep), sep)" equals s.

joinfields( words[, sep])
This function behaves identically to join(). (In the past, join() was only used with one argument, while joinfields() was only used with two arguments.) Note that there is no joinfields() method on string objects; use the join() method instead.

lstrip(s[, chars])
Return a copy of the string with leading characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the beginning of the string this method is called on. Changed in version 2.2.3: The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

rstrip(s[, chars])
Return a copy of the string with trailing characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the end of the string this method is called on. Changed in version 2.2.3: The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

strip(s[, chars])
Return a copy of the string with leading and trailing characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the both ends of the string this method is called on. Changed in version 2.2.3: The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

swapcase(s)
Return a copy of s, but with lower case letters converted to upper case and vice versa.

translate(s, table[, deletechars])
Delete all characters from s that are in deletechars (if present), and then translate the characters using table, which must be a 256-character string giving the translation for each character value, indexed by its ordinal.

**upper(s)**
Return a copy of s, but with lower case letters converted to upper case.

**ljust(s, width)**
**rjust(s, width)**
**center(s, width)**
These functions respectively left-justify, right-justify and center a string in a field of given width. They return a string that is at least width characters wide, created by padding the string s with spaces until the given width on the right, left or both sides. The string is never truncated.

**zfill(s, width)**
Pad a numeric string on the left with zero digits until the given width is reached. Strings starting with a sign are handled correctly.

**replace(str, old, new[, maxreplace])**
Return a copy of string str with all occurrences of substring old replaced by new. If the optional argument maxreplace is given, the first maxreplace occurrences are replaced.
Previous: 4.1.4 Deprecated string functions  Up: 4. String Services  Next: 4.2.1 Regular Expression Syntax
4.2 re -- Regular expression operations

This module provides regular expression matching operations similar to those found in Perl. Regular expression pattern strings may not contain null bytes, but can specify the null byte using the \number notation. Both patterns and strings to be searched can be Unicode strings as well as 8-bit strings. The re module is always available.

Regular expressions use the backslash character ("\") to indicate special forms or to allow special characters to be used without invoking their special meaning. This collides with Python's usage of the same character for the same purpose in string literals; for example, to match a literal backslash, one might have to write '\\\' as the pattern string, because the regular expression must be "\\", and each backslash must be expressed as "\\" inside a regular Python string literal.

The solution is to use Python's raw string notation for regular expression patterns; backslashes are not handled in any special way in a string literal prefixed with "r". So r"\n" is a two-character string containing "\" and "n", while "\n" is a one-character string containing a newline. Usually patterns will be expressed in Python code using this raw string notation.

See Also:

Mastering Regular Expressions
Book on regular expressions by Jeffrey Friedl, published by O'Reilly. The second edition of the book no longer covers Python at all, but the first edition covered writing good regular expression patterns in great detail.

Subsections

- 4.2.1 Regular Expression Syntax
4.2.1 Regular Expression Syntax

A regular expression (or RE) specifies a set of strings that matches it; the functions in this module let you check if a particular string matches a given regular expression (or if a given regular expression matches a particular string, which comes down to the same thing).

Regular expressions can be concatenated to form new regular expressions; if \( A \) and \( B \) are both regular expressions, then \( AB \) is also a regular expression. In general, if a string \( p \) matches \( A \) and another string \( q \) matches \( B \), the string \( pq \) will match \( AB \). This holds unless \( A \) or \( B \) contain low precedence operations; boundary conditions between \( A \) and \( B \); or have numbered group references. Thus, complex expressions can easily be constructed from simpler primitive expressions like the ones described here. For details of the theory and implementation of regular expressions, consult the Friedl book referenced above, or almost any textbook about compiler construction.

A brief explanation of the format of regular expressions follows. For further information and a gentler presentation, consult the Regular Expression HOWTO, accessible from [http://www.python.org/doc/howto/](http://www.python.org/doc/howto/).

Regular expressions can contain both special and ordinary characters. Most ordinary characters, like "A", "a", or "0", are the simplest regular expressions; they simply match themselves. You can concatenate ordinary characters, so `last` matches the string 'last'. (In the rest of this section, we'll write RE's in this special style, usually without quotes, and strings to be matched 'in single quotes'.)

Some characters, like " | " or "(", are special. Special characters either stand for classes of ordinary characters, or affect how the regular expressions around them are interpreted.

The special characters are:

```
.  (Dot.) In the default mode, this matches any character except a newline. If the DOTALL flag has been specified, this matches any character including a newline.
```
"^"

(Caret.) Matches the start of the string, and in MULTILINE mode also matches immediately after each newline.

"$"

Matches the end of the string or just before the newline at the end of the string, and in MULTILINE mode also matches before a newline. `foo` matches both 'foo' and 'foobar', while the regular expression `foo$` matches only 'foo'. More interestingly, searching for `foo . $` in 'foo1
foo2
' matches 'foo2' normally, but 'foo1' in MULTILINE mode.

"*"

Causes the resulting RE to match 0 or more repetitions of the preceding RE, as many repetitions as are possible. `ab *` will match 'a', 'ab', or 'a' followed by any number of 'b's.

"+"

Causes the resulting RE to match 1 or more repetitions of the preceding RE. `ab +` will match 'a' followed by any non-zero number of 'b's; it will not match just 'a'.

"?"

Causes the resulting RE to match 0 or 1 repetitions of the preceding RE. `ab ?` will match either 'a' or 'ab'.

*?, +?, ??

The "*", "+", and "?" qualifiers are all greedy; they match as much text as possible. Sometimes this behaviour isn't desired; if the RE `<.*>` is matched against '<H1>title</H1>', it will match the entire string, and not just '<H1>'. Adding "?" after the qualifier makes it perform the match in non-greedy or minimal fashion; as few characters as possible will be matched. Using . *? in the previous expression will match only '<H1>'.

\{m\}

Specifies that exactly \(m\) copies of the previous RE should be matched; fewer matches cause the entire RE not to match. For example, \(a\{6\}\) will match exactly six "a" characters, but not five.

\{m, n\}
Causes the resulting RE to match from $m$ to $n$ repetitions of the preceding RE, attempting to match as many repetitions as possible. For example, `a{3, 5}` will match from 3 to 5 "a" characters. Omitting $m$ specifies a lower bound of zero, and omitting $n$ specifies an infinite upper bound. As an example, `a{4, }b` will match `aaaaab` or a thousand "a" characters followed by a `b`, but not `aaab`. The comma may not be omitted or the modifier would be confused with the previously described form.

`{m, n}`?
Causes the resulting RE to match from $m$ to $n$ repetitions of the preceding RE, attempting to match as few repetitions as possible. This is the non-greedy version of the previous qualifier. For example, on the 6-character string `'aaaaaa'`, `a{3, 5}` will match 5 "a" characters, while `a{3, 5}?` will only match 3 characters.

"\"
Either escapes special characters (permitting you to match characters like "*", "?", and so forth), or signals a special sequence; special sequences are discussed below.

If you're not using a raw string to express the pattern, remember that Python also uses the backslash as an escape sequence in string literals; if the escape sequence isn't recognized by Python's parser, the backslash and subsequent character are included in the resulting string. However, if Python would recognize the resulting sequence, the backslash should be repeated twice. This is complicated and hard to understand, so it's highly recommended that you use raw strings for all but the simplest expressions.

[ ]
Used to indicate a set of characters. Characters can be listed individually, or a range of characters can be indicated by giving two characters and separating them by a " - ". Special characters are not active inside sets. For example, `[akm$]` will match any of the characters "a", "k", "m", or "$"; `[a-zA-Z]` will match any lowercase letter, and `[a-zA-Z0-9]` matches any letter or digit. Character classes such as `\w` or `\S` (defined below) are also acceptable inside a range. If you want to include a "]" or a "-" inside a set, precede it with a backslash, or place it as the first character. The pattern `[ ]` will match ' ]', for example.
You can match the characters not within a range by *complementing* the set. This is indicated by including a "^\" as the first character of the set; "^\" elsewhere will simply match the "^\" character. For example, \[^5\] will match any character except "5", and \[^\^\] will match any character except "^\".

\[\]
A | B, where A and B can be arbitrary REs, creates a regular expression that will match either A or B. An arbitrary number of REs can be separated by the "|" in this way. This can be used inside groups (see below) as well. As the target string is scanned, REs separated by "|" are tried from left to right. When one pattern completely matches, that branch is accepted. This means that once A matches, B will not be tested further, even if it would produce a longer overall match. In other words, the "|" operator is never greedy. To match a literal "|", use \|, or enclose it inside a character class, as in [ | ].

(...)
Matches whatever regular expression is inside the parentheses, and indicates the start and end of a group; the contents of a group can be retrieved after a match has been performed, and can be matched later in the string with the \number special sequence, described below. To match the literals "(" or ")", use \( or \), or enclose them inside a character class: [([ ] [])].

(?!...)
This is an extension notation (a "?" following a "(" is not meaningful otherwise). The first character after the "?" determines what the meaning and further syntax of the construct is. Extensions usually do not create a new group; (?P<name>... is the only exception to this rule. Following are the currently supported extensions.

(?ilmsux)
(One or more letters from the set "i", "L", "m", "s", "u", "x".) The group matches the empty string; the letters set the corresponding flags (re.I, re.L, re.M, re.S, re.U, re.X) for the entire regular expression. This is useful if you wish to include the flags as part of the regular expression, instead of passing a *flag* argument to the *compile()* function.
Note that the (?x) flag changes how the expression is parsed. It should be used first in the expression string, or after one or more whitespace characters. If there are non-whitespace characters before the flag, the results are undefined.

(?::...)  
A non-grouping version of regular parentheses. Matches whatever regular expression is inside the parentheses, but the substring matched by the group cannot be retrieved after performing a match or referenced later in the pattern.

(?P<name>...)  
Similar to regular parentheses, but the substring matched by the group is accessible via the symbolic group name name. Group names must be valid Python identifiers, and each group name must be defined only once within a regular expression. A symbolic group is also a numbered group, just as if the group were not named. So the group named 'id' in the example above can also be referenced as the numbered group 1.

For example, if the pattern is (?P<id>\[a-zA-Z_\w*\]), the group can be referenced by its name in arguments to methods of match objects, such as m.group('id') or m.end('id'), and also by name in pattern text (for example, (?P=id)) and replacement text (such as \g<id>).

(?P=name)  
Matches whatever text was matched by the earlier group named name.

(?#...)  
A comment; the contents of the parentheses are simply ignored.

(?!...)  
Matches if ... doesn't match next. This is a negative lookahead assertion. For example, Isaac (?!Asimov) will match 'Isaac ' only if it's not followed by 'Asimov'.

(?!...)  
Matches if ... doesn't match next. This is a negative lookahead assertion. For example, Isaac (?!Asimov) will match 'Isaac ' only if it's not followed by 'Asimov'.

(?!...)
(?<=...) Matches if the current position in the string is preceded by a match for . . . that ends at the current position. This is called a positive lookbehind assertion. (?<=abc)def will find a match in "abcdef", since the lookbehind will back up 3 characters and check if the contained pattern matches. The contained pattern must only match strings of some fixed length, meaning that abc or a|b are allowed, but a* and a{3,4} are not. Note that patterns which start with positive lookbehind assertions will never match at the beginning of the string being searched; you will most likely want to use the search() function rather than the match() function:

```python
>>> import re
>>> m = re.search('(?<=abc)def', 'abcdef')
>>> m.group(0)
'def'
```

This example looks for a word following a hyphen:

```python
>>> m = re.search('(?<=-)\w+', 'spam-egg')
>>> m.group(0)
'egg'
```

(?<!...) Matches if the current position in the string is not preceded by a match for . . . This is called a negative lookbehind assertion. Similar to positive lookbehind assertions, the contained pattern must only match strings of some fixed length. Patterns which start with negative lookbehind assertions may match at the beginning of the string being searched.

(?:id/name)yes-pattern|no-pattern Will try to match with yes-pattern if the group with given id or name exists, and with no-pattern if it doesn't. |no-pattern is optional and can be omitted. For example, (<)?(\w+@\w+(:\w+.*\w+)*)?(1)></ is a poor email matching pattern, which will match with '<user@host.com>' as well as 'user@host.com', but not with '<user@host.com>'. New in version 2.4.

The special sequences consist of "\" and a character from the list below. If the ordinary character is not on the list, then the resulting RE will match the second character. For example, \$ matches the character "$".
\number

Matches the contents of the group of the same number. Groups are numbered starting from 1. For example, \( ( . + ) \1 \) matches 'the the' or '55 55', but not 'the end' (note the space after the group). This special sequence can only be used to match one of the first 99 groups. If the first digit of number is 0, or number is 3 octal digits long, it will not be interpreted as a group match, but as the character with octal value number. Inside the "[" and "]" of a character class, all numeric escapes are treated as characters.

\A

Matches only at the start of the string.

\b

Matches the empty string, but only at the beginning or end of a word. A word is defined as a sequence of alphanumeric or underscore characters, so the end of a word is indicated by whitespace or a non-alphanumeric, non-underscore character. Note that \b is defined as the boundary between \w and \W, so the precise set of characters deemed to be alphanumeric depends on the values of the UNICODE and LOCALE flags. Inside a character range, \b represents the backspace character, for compatibility with Python's string literals.

\B

Matches the empty string, but only when it is not at the beginning or end of a word. This is just the opposite of \b, so is also subject to the settings of LOCALE and UNICODE.

\d

When the UNICODE flag is not specified, matches any decimal digit; this is equivalent to the set \[0 - 9\]. With UNICODE, it will match whatever is classified as a digit in the Unicode character properties database.

\D

When the UNICODE flag is not specified, matches any non-digit character; this is equivalent to the set \[^0 - 9\]. With UNICODE, it will match anything other than character marked as digits in the Unicode character properties database.
\s
When the LOCALE and UNICODE flags are not specified, matches any whitespace character; this is equivalent to the set `\t\n\r\f\v`. With LOCALE, it will match this set plus whatever characters are defined as space for the current locale. If UNICODE is set, this will match the characters `\t\n\r\f\v` plus whatever is classified as space in the Unicode character properties database.

\S
When the LOCALE and UNICODE flags are not specified, matches any non-whitespace character; this is equivalent to the set `[^\t\n\r\f\v]`. With LOCALE, it will match any character not in this set, and not defined as space in the current locale. If UNICODE is set, this will match anything other than `\t\n\r\f\v` and characters marked as space in the Unicode character properties database.

\w
When the LOCALE and UNICODE flags are not specified, matches any alphanumeric character and the underscore; this is equivalent to the set `\w`. With LOCALE, it will match the set `\w[\w]` plus whatever characters are defined as alphanumeric for the current locale. If UNICODE is set, this will match the characters `\w[\w]` plus whatever is classified as alphanumeric in the Unicode character properties database.

\W
When the LOCALE and UNICODE flags are not specified, matches any non-alphanumeric character; this is equivalent to the set `[^a-zA-Z0-9_]`. With LOCALE, it will match any character not in the set `\w[\w]`, and not defined as alphanumeric for the current locale. If UNICODE is set, this will match anything other than `\w[\w]` and characters marked as alphanumeric in the Unicode character properties database.

\Z
Matches only at the end of the string.

Most of the standard escapes supported by Python string literals are also accepted by the regular expression parser:

\a \b \f \n
Octal escapes are included in a limited form: If the first digit is a 0, or if there are three octal digits, it is considered an octal escape. Otherwise, it is a group reference. As for string literals, octal escapes are always at most three digits in length.
4.2.2 Matching vs Searching

Python offers two different primitive operations based on regular expressions: match and search. If you are accustomed to Perl's semantics, the search operation is what you're looking for. See the `search()` function and corresponding method of compiled regular expression objects.

Note that match may differ from search using a regular expression beginning with "^": "^" matches only at the start of the string, or in `MULTILINE` mode also immediately following a newline. The `''match''` operation succeeds only if the pattern matches at the start of the string regardless of mode, or at the starting position given by the optional `pos` argument regardless of whether a newline precedes it.

```python
re.compile("a").match("ba", 1)  # succeeds
re.compile("^a").search("ba", 1)  # fails; 'a' not at start
re.compile("^a").search("\na", 1)  # fails; 'a' not at start
re.compile("^a", re.M).search("\na", 1)  # succeeds
re.compile("^a", re.M).search("ba", 1)  # fails; no preceding \n
```
4.2.3 Module Contents

The module defines several functions, constants, and an exception. Some of the functions are simplified versions of the full featured methods for compiled regular expressions. Most non-trivial applications always use the compiled form.

**compile(pattern[, flags])**

Compile a regular expression pattern into a regular expression object, which can be used for matching using its `match()` and `search()` methods, described below.

The expression's behaviour can be modified by specifying a `flags` value. Values can be any of the following variables, combined using bitwise OR (the `|` operator).

The sequence

```python
prog = re.compile(pat)
result = prog.match(str)
```

is equivalent to

```python
result = re.match(pat, str)
```

but the version using `compile()` is more efficient when the expression will be used several times in a single program.

**I**

`IGNORECASE`

Perform case-insensitive matching; expressions like `[A-Z]` will match lowercase letters, too. This is not affected by the current locale.

**L**

`LOCALE`

Make `\w`, `\W`, `\b`, `\B`, `\s` and `\S` dependent on the current locale.

**M**

`MULTILINE`

When specified, the pattern character "^" matches at the beginning of the
string and at the beginning of each line (immediately following each newline); and the pattern character "$" matches at the end of the string and at the end of each line (immediately preceding each newline). By default, "^" matches only at the beginning of the string, and "$" only at the end of the string and immediately before the newline (if any) at the end of the string.

S
DOTALL
Make the "." special character match any character at all, including a newline; without this flag, "." will match anything except a newline.

U
UNICODE
Make \w, \W, \b, \B, \d, \D, \s and \S dependent on the Unicode character properties database. New in version 2.0.

X
VERBOSE
This flag allows you to write regular expressions that look nicer. Whitespace within the pattern is ignored, except when in a character class or preceded by an unescaped backslash, and, when a line contains a "#" neither in a character class or preceded by an unescaped backslash, all characters from the leftmost such "#" through the end of the line are ignored.

search( pattern, string[, flags])
Scan through string looking for a location where the regular expression pattern produces a match, and return a corresponding MatchObject instance. Return None if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

match( pattern, string[, flags])
If zero or more characters at the beginning of string match the regular expression pattern, return a corresponding MatchObject instance. Return None if the string does not match the pattern; note that this is different from a zero-length match.
**Note:** If you want to locate a match anywhere in *string*, use `search()` instead.

`split(pattern, string[, maxsplit = 0])`

Split *string* by the occurrences of *pattern*. If capturing parentheses are used in *pattern*, then the text of all groups in the pattern are also returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits occur, and the remainder of the string is returned as the final element of the list. (Incompatibility note: in the original Python 1.5 release, *maxsplit* was ignored. This has been fixed in later releases.)

```python
>>> re.split('\\W+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('\\(\\W+)\\', 'Words, words, words.')
['Words', ',', ',', 'words', ',', ',', 'words', ',', ',', 'words', '.', '', '']
>>> re.split('\\W+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

This function combines and extends the functionality of the old `re.split()` and `re.sub.splitx()`.

`findall(pattern, string[, flags])`

Return a list of all non-overlapping matches of *pattern* in *string*. If one or more groups are present in the pattern, return a list of groups; this will be a list of tuples if the pattern has more than one group. Empty matches are included in the result unless they touch the beginning of another match. New in version 1.5.2. Changed in version 2.4: Added the optional flags argument.

`finditer(pattern, string[, flags])`

Return an iterator over all non-overlapping matches for the RE *pattern* in *string*. For each match, the iterator returns a match object. Empty matches are included in the result unless they touch the beginning of another match. New in version 2.2. Changed in version 2.4: Added the optional flags argument.

`sub(pattern, repl, string[, count])`

Return the string obtained by replacing the leftmost non-overlapping occurrences of *pattern* in *string* by the replacement *repl*. If the pattern isn't
found, string is returned unchanged. repl can be a string or a function; if it is a string, any backslash escapes in it are processed. That is, "\n" is converted to a single newline character, "\r" is converted to a linefeed, and so forth. Unknown escapes such as "\j" are left alone. Backreferences, such as "\6", are replaced with the substring matched by group 6 in the pattern. For example:

```python
>>> re.sub(r'def\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*:\s*:',
          ...       r'static PyObject*\npy_\1(void)\n{',
          ...       'def myfunc():')
'static PyObject*\npymyfunc(void)\n{'
```

If repl is a function, it is called for every non-overlapping occurrence of pattern. The function takes a single match object argument, and returns the replacement string. For example:

```python
>>> def dashrepl(matchobj):
...     if matchobj.group(0) == '-':
...         return ''
...     else:
...         return '-'

>>> re.sub('-{1,2}', dashrepl, 'pro----gram-files')
'pro--gram files'
```

The pattern may be a string or an RE object; if you need to specify regular expression flags, you must use a RE object, or use embedded modifiers in a pattern; for example, "sub("(?i)b+", "x", "bbbb BBBB")" returns 'x x'.

The optional argument count is the maximum number of pattern occurrences to be replaced; count must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous match, so "sub( 'x*', ' - ', 'abc')" returns '-a-b-c-'.

In addition to character escapes and backreferences as described above, "\g<name>" will use the substring matched by the group named "name", as defined by the (?P<name>...) syntax. "\g<number>" uses the corresponding group number; "\g<2>" is therefore equivalent to "\2", but isn't ambiguous in a replacement such as "\g<2>0". "\20" would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character "0". The backreference "\g<0>" substitutes in the entire substring matched by the RE.
subn( pattern, repl, string[, count])
    Perform the same operation as sub(), but return a tuple (new_string,
    number_of_subs_made).

escape( string)
    Return string with all non-alphanumerics backslashed; this is useful if you
    want to match an arbitrary literal string that may have regular expression
    metacharacters in it.

exception error
    Exception raised when a string passed to one of the functions here is not a
    valid regular expression (for example, it might contain unmatched
    parentheses) or when some other error occurs during compilation or
    matching. It is never an error if a string contains no match for a pattern.
4.2.4 Regular Expression Objects

Compiled regular expression objects support the following methods and attributes:

**match( string[, pos[, endpos]])**

If zero or more characters at the beginning of *string* match this regular expression, return a corresponding *MatchObject* instance. Return *None* if the string does not match the pattern; note that this is different from a zero-length match.

**Note:** If you want to locate a match anywhere in *string*, use *search()* instead.

The optional second parameter *pos* gives an index in the string where the search is to start; it defaults to 0. This is not completely equivalent to slicing the string; the '^' pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter *endpos* limits how far the string will be searched; it will be as if the string is *endpos* characters long, so only the characters from *pos* to *endpos* – 1 will be searched for a match. If *endpos* is less than *pos*, no match will be found, otherwise, if *rx* is a compiled regular expression object, *rx.match(string[, pos, 50])* is equivalent to *rx.match(string[:50], 0)*.

**search( string[, pos[, endpos]])**

Scan through *string* looking for a location where this regular expression produces a match, and return a corresponding *MatchObject* instance. Return *None* if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional *pos* and *endpos* parameters have the same meaning as for the *match()* method.

**split(**
string[, maxsplit = 0])
Identical to the split() function, using the compiled pattern.

`findall`(string[, pos[, endpos]])
Identical to the `findall()` function, using the compiled pattern.

`finditer`(string[, pos[, endpos]])
Identical to the `finditer()` function, using the compiled pattern.

sub(repl, string[, count = 0])
Identical to the `sub()` function, using the compiled pattern.

subn(repl, string[, count = 0])
Identical to the `subn()` function, using the compiled pattern.

flags
The flags argument used when the RE object was compiled, or 0 if no flags were provided.

groupindex
A dictionary mapping any symbolic group names defined by (?P<id>) to group numbers. The dictionary is empty if no symbolic groups were used in the pattern.

pattern
The pattern string from which the RE object was compiled.
4.2.5 Match Objects

MatchObject instances support the following methods and attributes:

**expand**( template)

Return the string obtained by doing backslash substitution on the template string *template*, as done by the `sub()` method. Escapes such as "\n" are converted to the appropriate characters, and numeric backreferences ("\1", "\2") and named backreferences ("\g<1>", "\g<name>") are replaced by the contents of the corresponding group.

**group**( [group1, ...])

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, *group1* defaults to zero (the whole match is returned). If a *groupN* argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range [1..99], it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an `IndexError` exception is raised. If a group is contained in a part of the pattern that did not match, the corresponding result is `None`. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

If the regular expression uses the (?P<name>...) syntax, the *groupN* arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an `IndexError` exception is raised.

A moderately complicated example:

```python
m = re.match(r"(?P<int>\d+).?\d*", '3.14')
```

After performing this match, `m.group(1)` is '3', as is `m.group('int')`, and `m.group(2)` is '14'.

**groups**( [default])
Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The default argument is used for groups that did not participate in the match; it defaults to None. (Incompatibility note: in the original Python 1.5 release, if the tuple was one element long, a string would be returned instead. In later versions (from 1.5.1 on), a singleton tuple is returned in such cases.)

**groupdict([default])**

Return a dictionary containing all the named subgroups of the match, keyed by the subgroup name. The default argument is used for groups that did not participate in the match; it defaults to None.

**start([group])**

**end([group])**

Return the indices of the start and end of the substring matched by group; group defaults to zero (meaning the whole matched substring). Return -1 if group exists but did not contribute to the match. For a match object m, and a group g that did contribute to the match, the substring matched by group g (equivalent to m.group(g)) is

\[ m.string[m.start(g):m.end(g)] \]

Note that m.start(group) will equal m.end(group) if group matched a null string. For example, after m = re.search('b(c?)', 'cba'), m.start(0) is 1, m.end(0) is 2, m.start(1) and m.end(1) are both 2, and m.start(2) raises an IndexError exception.

**span([group])**

For MatchObject m, return the 2-tuple (m.start(group), m.end(group)). Note that if group did not contribute to the match, this is (-1, -1). Again, group defaults to zero.

**pos**

The value of pos which was passed to the search() or match() method of the RegexObject. This is the index into the string at which the RE engine started looking for a match.
endpos
The value of endpos which was passed to the search() or match() method of the RegexObject. This is the index into the string beyond which the RE engine will not go.

lastindex
The integer index of the last matched capturing group, or None if no group was matched at all. For example, the expressions (a)b, ((a)(b)), and ((ab)) will have lastindex == 1 if applied to the string 'ab', while the expression (a)(b) will have lastindex == 2, if applied to the same string.

lastgroup
The name of the last matched capturing group, or None if the group didn't have a name, or if no group was matched at all.

re
The regular expression object whose match() or search() method produced this MatchObject instance.

string
The string passed to match() or search().

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
4.2.6 Examples

Simulating `scanf()`

Python does not currently have an equivalent to `scanf()`. Regular expressions are generally more powerful, though also more verbose, than `scanf()` format strings. The table below offers some more-or-less equivalent mappings between `scanf()` format tokens and regular expressions.

<table>
<thead>
<tr>
<th><code>scanf()</code> Token</th>
<th>Regular Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>%c</td>
<td>.</td>
</tr>
<tr>
<td>%5c</td>
<td>.{5}</td>
</tr>
<tr>
<td>%d</td>
<td>[-+]?\d+</td>
</tr>
<tr>
<td>%e, %E, %f, %g</td>
<td>[-+]?(\d+(.\d*)?</td>
</tr>
<tr>
<td>%i</td>
<td>[-+]?([0-9][xX][dA-Fa-f]+</td>
</tr>
<tr>
<td>%o</td>
<td>0[0-7]*</td>
</tr>
<tr>
<td>%s</td>
<td>\S+</td>
</tr>
<tr>
<td>%u</td>
<td>\d+</td>
</tr>
<tr>
<td>%x, %X</td>
<td>0[xX][dA-Fa-f]+</td>
</tr>
</tbody>
</table>

To extract the filename and numbers from a string like

```
/usr/sbin/sendmail - 0 errors, 4 warnings
```

you would use a `scanf()` format like

```
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```
(\S+) - (\d+) errors, (\d+) warnings
```

Avoiding recursion

If you create regular expressions that require the engine to perform a lot of
recursion, you may encounter a RuntimeError exception with the message `maximum recursion limit exceeded`. For example,

```python
>>> import re
>>> s = 'Begin ' + 1000*'a very long string ' + 'end'
>>> re.match('Begin (\w| )*? end', s).end()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "/usr/local/lib/python2.3/sre.py", line 132, in match
    return _compile(pattern, flags).match(string)
RuntimeError: maximum recursion limit exceeded
```

You can often restructure your regular expression to avoid recursion. Starting with Python 2.3, simple uses of the `*?` pattern are special-cased to avoid recursion. Thus, the above regular expression can avoid recursion by being recast as `Begin [a-zA-Z0-9_ ]*?end`. As a further benefit, such regular expressions will run faster than their recursive equivalents.
4.3 struct -- Interpret strings as packed binary data

This module performs conversions between Python values and C structs represented as Python strings. It uses format strings (explained below) as compact descriptions of the lay-out of the C structs and the intended conversion to/from Python values. This can be used in handling binary data stored in files or from network connections, among other sources.

The module defines the following exception and functions:

**exception error**

Exception raised on various occasions; argument is a string describing what is wrong.

**pack**( fmt, v1, v2, ...)

Return a string containing the values v1, v2, ... packed according to the given format. The arguments must match the values required by the format exactly.

**unpack**( fmt, string)

Unpack the string (presumably packed by pack(fmt, ...)) according to the given format. The result is a tuple even if it contains exactly one item. The string must contain exactly the amount of data required by the format (len(string) must equal calcsize(fmt)).

**calcsize**( fmt)

Return the size of the struct (and hence of the string) corresponding to the given format.

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types:

<table>
<thead>
<tr>
<th>Format</th>
<th>C Type</th>
<th>Python</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>pad byte</td>
<td>no value</td>
<td></td>
</tr>
<tr>
<td>c</td>
<td>char</td>
<td>string of length 1</td>
<td></td>
</tr>
<tr>
<td>----</td>
<td>--------------------</td>
<td>--------------------</td>
<td></td>
</tr>
<tr>
<td>b</td>
<td>signed char</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>B</td>
<td>unsigned char</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>h</td>
<td>short</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>H</td>
<td>unsigned short</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>i</td>
<td>int</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>I</td>
<td>unsigned int</td>
<td>long</td>
<td></td>
</tr>
<tr>
<td>l</td>
<td>long</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>L</td>
<td>unsigned long</td>
<td>long</td>
<td></td>
</tr>
<tr>
<td>q</td>
<td>long long</td>
<td>long</td>
<td></td>
</tr>
<tr>
<td>Q</td>
<td>unsigned long long</td>
<td>long</td>
<td></td>
</tr>
<tr>
<td>f</td>
<td>float</td>
<td>float</td>
<td></td>
</tr>
<tr>
<td>d</td>
<td>double</td>
<td>float</td>
<td></td>
</tr>
<tr>
<td>s</td>
<td>char[]</td>
<td>string</td>
<td></td>
</tr>
<tr>
<td>p</td>
<td>char[]</td>
<td>string</td>
<td></td>
</tr>
<tr>
<td>P</td>
<td>void *</td>
<td>integer</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) The "q" and "Q" conversion codes are available in native mode only if the platform C compiler supports C long long, or, on Windows, __int64. They are always available in standard modes. New in version 2.2.

A format character may be preceded by an integral repeat count. For example, the format string '4h' means exactly the same as 'hhhh'.

Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

For the "s" format character, the count is interpreted as the size of the string, not a repeat count like for the other format characters; for example, '10s' means a single 10-byte string, while '10c' means 10 characters. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting string always has exactly the specified number of bytes. As a special case, '0s' means a single, empty string (while '0c' means 0
characters).

The "p" format character encodes a "Pascal string", meaning a short variable-length string stored in a fixed number of bytes. The count is the total number of bytes stored. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to \texttt{pack()} is too long (longer than the count minus 1), only the leading count-1 bytes of the string are stored. If the string is shorter than count-1, it is padded with null bytes so that exactly count bytes in all are used. Note that for \texttt{unpack()}, the "p" format character consumes count bytes, but that the string returned can never contain more than 255 characters.

For the "I", "L", "q" and "Q" format characters, the return value is a Python long integer.

For the "P" format character, the return value is a Python integer or long integer, depending on the size needed to hold a pointer when it has been cast to an integer type. A NULL pointer will always be returned as the Python integer 0. When packing pointer-sized values, Python integer or long integer objects may be used. For example, the Alpha and Merced processors use 64-bit pointer values, meaning a Python long integer will be used to hold the pointer; other platforms use 32-bit pointers and will use a Python integer.

By default, C numbers are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:

<table>
<thead>
<tr>
<th>Character</th>
<th>Byte order</th>
<th>Size and alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>@</td>
<td>native</td>
<td>native</td>
</tr>
<tr>
<td>=</td>
<td>native</td>
<td>standard</td>
</tr>
<tr>
<td>&lt;</td>
<td>little-endian</td>
<td>standard</td>
</tr>
<tr>
<td>&gt;</td>
<td>big-endian</td>
<td>standard</td>
</tr>
<tr>
<td>!</td>
<td>network (= big-endian)</td>
<td>standard</td>
</tr>
</tbody>
</table>
If the first character is not one of these, "@" is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Motorola and Sun processors are big-endian; Intel and DEC processors are little-endian.

Native size and alignment are determined using the C compiler's `sizeof` expression. This is always combined with native byte order.

Standard size and alignment are as follows: no alignment is required for any type (so you have to use pad bytes); `short` is 2 bytes; `int` and `long` are 4 bytes; `long long` (`__int64` on Windows) is 8 bytes; `float` and `double` are 32-bit and 64-bit IEEE floating point numbers, respectively.

Note the difference between "@" and "=": both use native byte order, but the size and alignment of the latter is standardized.

The form "!" is available for those poor souls who claim they can't remember whether network byte order is big-endian or little-endian.

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of "<" or "><".

The "P" format character is only available for the native byte ordering (selected as the default or with the "@" byte order character). The byte order character "=" chooses to use little- or big-endian ordering based on the host system. The struct module does not interpret this as native ordering, so the "P" format is not available.

Examples (all using native byte order, size and alignment, on a big-endian machine):

```python
>>> from struct import *
>>> pack('hhl', 1, 2, 3)
'\x00\x01\x00\x02\x00\x00\x00\x03'
>>> unpack('hhl', '\x00\x01\x00\x02\x00\x00\x00\x03')
(1, 2, 3)
>>> calcsize('hhl')
8
```

Hint: to align the end of a structure to the alignment requirement of a particular
type, end the format with the code for that type with a repeat count of zero. For example, the format 'llh01' specifies two pad bytes at the end, assuming longs are aligned on 4-byte boundaries. This only works when native size and alignment are in effect; standard size and alignment does not enforce any alignment.

    Packing and unpacking of XDR data.
4.4 difflib -- Helpers for computing deltas

New in version 2.1.

class SequenceMatcher
This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are hashable. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980's by Ratcliff and Obershemp under the hyperbolic name `gestalt pattern matching." The idea is to find the longest contiguous matching subsequence that contains no `junk" elements (the Ratcliff and Obershemp algorithm doesn't address junk). The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that `look right" to people.

Timing: The basic Ratcliff-Obershemp algorithm is cubic time in the worst case and quadratic time in the expected case. SequenceMatcher is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

class Differ
This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses SequenceMatcher both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a Differ delta begins with a two-letter code:

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'-'</td>
<td>line unique to sequence 1</td>
</tr>
<tr>
<td>'+'</td>
<td>line unique to sequence 2</td>
</tr>
<tr>
<td>'*'</td>
<td>line common to both sequences</td>
</tr>
</tbody>
</table>
Lines beginning with `? ` attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

**class HtmlDiff**

This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual difference mode.

The constructor for this class is:

```python
__init__( [tabsize][, wrapcolumn][, linejunk][, charjunk])
```

Initializes instance of HtmlDiff.

*tabsize* is an optional keyword argument to specify tab stop spacing and defaults to 8.

*wrapcolumn* is an optional keyword to specify column number where lines are broken and wrapped, defaults to None where lines are not wrapped.

*linejunk* and *charjunk* are optional keyword arguments passed into *ndiff()* (used by HtmlDiff to generate the side by side HTML differences). See *ndiff()* documentation for argument default values and descriptions.

The following methods are public:

```python
make_file( fromlines, tolins [, fromdesc][, todesc][, context][, numlines])
```

Compares *fromlines* and *tolines* (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.
fromdesc and todesc are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

context and numlines are both optional keyword arguments. Set context to True when contextual differences are to be shown, else the default is False to show the full files. numlines defaults to 5. When context is True numlines controls the number of context lines which surround the difference highlights. When context is False numlines controls the number of lines which are shown before a difference highlight when using the "next" hyperlinks (setting to zero would cause the "next" hyperlinks to place the next difference highlight at the top of the browser without any leading context).

make_table(fromlines, tonlines[, fromdesc][, todesc][, context][, numlines])

Compares fromlines and tonlines (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the make_file() method.

Tools/scripts/diff.py is a command-line front-end to this class and contains a good example of its use.

New in version 2.4.

context_diff(a, b[, fromfile][, tofile][, fromfiledate][, tofiledate][, n][, lineterm])

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by n which defaults to three.

By default, the diff control lines (those with *** or - - - ) are created with a trailing newline. This is helpful so that inputs created from
file.readlines() result in diffs that are suitable for use with file.writelines() since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the lineterm argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for fromfile, tofile, fromfiledate, and tofiledate. The modification times are normally expressed in the format returned by time.ctime(). If not specified, the strings default to blanks.

Tools/scripts/diff.py is a command-line front-end for this function.

New in version 2.3.

get_close_matches( word, possibilities[, n][, cutoff])
Return a list of the best "good enough" matches. word is a sequence for which close matches are desired (typically a string), and possibilities is a list of sequences against which to match word (typically a list of strings).

Optional argument n (default 3) is the maximum number of close matches to return; n must be greater than 0.

Optional argument cutoff (default 0.6) is a float in the range [0, 1]. Possibilities that don't score at least that similar to word are ignored.

The best (no more than n) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

>>> get_close_matches('appel', ['ape', 'apple', 'peach', 'puppy', 'apple', 'ape'])
>>> import keyword
>>> get_close_matches('wheel', keyword.kwlist)
['while']
>>> get_close_matches('apple', keyword.kwlist)
[]
>>> get_close_matches('accept', keyword.kwlist)
['except']
\texttt{ndiff}(a, b[, \texttt{linejunk}][, \texttt{charjunk}])

Compare \(a\) and \(b\) (lists of strings); return a \texttt{Differ}-style delta (a generator generating the delta lines).

Optional keyword parameters \texttt{linejunk} and \texttt{charjunk} are for filter functions (or \texttt{None}):

\texttt{linejunk}: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is \texttt{(None)}, starting with Python 2.3. Before then, the default was the module-level function \texttt{IS\_LINE\_JUNK()} , which filters out lines without visible characters, except for at most one pound character ("#"). As of Python 2.3, the underlying \texttt{SequenceMatcher} class does a dynamic analysis of which lines are so frequent as to constitute noise, and this usually works better than the pre-2.3 default.

\texttt{charjunk}: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function \texttt{IS\_CHARACTER\_JUNK()} , which filters out whitespace characters (a blank or tab; note: bad idea to include newline in this!).

Tools/scripts/ndiff.py is a command-line front-end to this function.

\begin{verbatim}
>>> diff = ndiff('one
two
three
'.splitlines(1),
'ore
tree
emu
'.splitlines(1))
>>> print ''.join(diff),
 - one
 ?  ^
+ ore
 ?  ^
 - two
 - three
 ?  -
+ tree
+ emu
\end{verbatim}

\texttt{restore}(sequence, which)

Return one of the two sequences that generated a delta.

Given a \texttt{sequence} produced by \texttt{Differ.compare()} or \texttt{ndiff()}, extract lines originating from file 1 or 2 (parameter \texttt{which}), stripping off line prefixes.
Example:

```python
>>> diff = ndiff('one\ntwo
three
'.splitlines(1),
   'ore\ntree\nemu
'.splitlines(1))
>>> diff = list(diff) # materialize the generated delta into a :
>>> print ''.join(restore(diff, 1)),
one
two
three
>>> print ''.join(restore(diff, 2)),
ore
tree
emu
```

```python
unified_diff( a, b[, fromfile][, tofile][, fromfiledate][, tofiledate][, n][, linetterm])
```

Compare `a` and `b` (lists of strings); return a delta (a generator generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in an inline style (instead of separate before/after blocks). The number of context lines is set by `n` which defaults to three.

By default, the diff control lines (those with ---, +++ or @@) are created with a trailing newline. This is helpful so that inputs created from `file.readlines()` result in diffs that are suitable for use with `file.writelines()` since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the `lineterm` argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for `fromfile`, `tofile`, `fromfiledate`, and `tofiledate`. The modification times are normally expressed in the format returned by `time.ctime()`. If not specified, the strings default to blanks.

`Tools/scripts/diff.py` is a command-line front-end for this function.

New in version 2.3.
**IS_LINE_JUNK**( line)
Return true for ignorable lines. The line line is ignorable if line is blank or contains a single "#", otherwise it is not ignorable. Used as a default for parameter linejunk in ndiff() before Python 2.3.

**IS_CHARACTER_JUNK**( ch)
Return true for ignorable characters. The character ch is ignorable if ch is a space or tab, otherwise it is not ignorable. Used as a default for parameter charjunk in ndiff().

*Pattern Matching: The Gestalt Approach*
Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in *Dr. Dobb's Journal* in July, 1988.
4.4.1 SequenceMatcher Objects

The SequenceMatcher class has this constructor:

```python
class SequenceMatcher([isjunk, a[, b]])
```

Optional argument `isjunk` must be `None` (the default) or a one-argument function that takes a sequence element and returns `true` if and only if the element is ```junk``` and should be ignored. Passing `None` for `isjunk` is equivalent to passing `lambda x: 0`; in other words, no elements are ignored. For example, pass:

```python
lambda x: x in " \\t"
```

if you're comparing lines as sequences of characters, and don't want to synch up on blanks or hard tabs.

The optional arguments `a` and `b` are sequences to be compared; both default to empty strings. The elements of both sequences must be hashable.

SequenceMatcher objects have the following methods:

```python
set_seqs(a, b)
```

Set the two sequences to be compared.

SequenceMatcher computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use `set_seq2()` to set the commonly used sequence once and call `set_seq1()` repeatedly, once for each of the other sequences.

```python
set_seq1(a)
```

Set the first sequence to be compared. The second sequence to be compared is not changed.

```python
set_seq2(b)
```

Set the second sequence to be compared. The first sequence to be compared is not changed.
find_longest_match(alo, ahi, blo, bhi)

Find longest matching block in a[alo:ahi] and b[blo:bhi].

If isjunk was omitted or None, get_longest_match() returns (i, j, k) such that a[i:i+k] is equal to b[j:j+k], where alo <= i <= i+k <= ahi and blo <= j <= j+k <= bhi. For all (i', j', k') meeting those conditions, the additional conditions k >= k', i <= i', and if i == i', j <= j' are also met. In other words, of all maximal matching blocks, return one that starts earliest in a, and of all those maximal matching blocks that start earliest in a, return the one that starts earliest in b.

```python
>>> s = SequenceMatcher(None, "abcd", "abcd")
>>> s.find_longest_match(0, 5, 0, 9)
(0, 4, 5)
```

If isjunk was provided, first the longest matching block is determined as above, but with the additional restriction that no junk element appears in the block. Then that block is extended as far as possible by matching (only) junk elements on both sides. So the resulting block never matches on junk except as identical junk happens to be adjacent to an interesting match.

Here's the same example as before, but considering blanks to be junk. That prevents ' abcd' from matching the ' abcd' at the tail end of the second sequence directly. Instead only the 'abcd' can match, and matches the leftmost 'abcd' in the second sequence:

```python
>>> s = SequenceMatcher(lambda x: x==" ", "abcd", "abcd abcd")
>>> s.find_longest_match(0, 5, 0, 9)
(1, 0, 4)
```

If no blocks match, this returns (alo, blo, 0).

get_matching_blocks()

Return list of triples describing matching subsequences. Each triple is of the form (i, j, n), and means that a[i:i+n] == b[j:j+n]. The triples are monotonically increasing in i and j.

The last triple is a dummy, and has the value (len(a), len(b), 0). It is the only triple with n == 0.

```python
>>> s = SequenceMatcher(None, "abxcd", "abcd")
```
get_matching_blocks()

[(0, 0, 2), (3, 2, 2), (5, 4, 0)]

get_opcodes()

Return list of 5-tuples describing how to turn \( a \) into \( b \). Each tuple is of the form \((tag, i1, i2, j1, j2)\). The first tuple has \( i1 == j1 == 0 \), and remaining tuples have \( i1 \) equal to the \( i2 \) from the preceding tuple, and, likewise, \( j1 \) equal to the previous \( j2 \).

The \textit{tag} values are strings, with these meanings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'replace'</td>
<td>( a[i1:i2] ) should be replaced by ( b[j1:j2] ).</td>
</tr>
<tr>
<td>'delete'</td>
<td>( a[i1:i2] ) should be deleted. Note that ( j1 == j2 ) in this case.</td>
</tr>
<tr>
<td>'insert'</td>
<td>( b[j1:j2] ) should be inserted at ( a[i1:i1] ). Note that ( i1 == i2 ) in this case.</td>
</tr>
<tr>
<td>'equal'</td>
<td>( a[i1:i2] == b[j1:j2] ) (the sub-sequences are equal).</td>
</tr>
</tbody>
</table>

For example:

```python
>>> a = "qabxcd"
>>> b = "abyxcd"
>>> s = SequenceMatcher(None, a, b)
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
...     print("%7s a[%d:%d] (%s) b[%d:%d] (%s)"
...           % (tag, i1, i2, a[i1:i2], j1, j2, b[j1:j2])))
delete a[0:1] (q) b[0:0] ()
equal a[1:3] (ab) b[0:2] (ab)
replace a[3:4] (x) b[2:3] (y)
```

get_grouped_opcodes([\( n \)])

Return a generator of groups with up to \( n \) lines of context.

Starting with the groups returned by \texttt{get_opcodes()}\texttt{ }, this method splits out smaller change clusters and eliminates intervening ranges which have no changes.

The groups are returned in the same format as \texttt{get_opcodes()}\texttt{ }. New in
version 2.3.

**ratio()**
Return a measure of the sequences' similarity as a float in the range [0, 1].

Where T is the total number of elements in both sequences, and M is the number of matches, this is \(2.0 \times M / T\). Note that this is 1.0 if the sequences are identical, and 0.0 if they have nothing in common.

This is expensive to compute if `get_matching_blocks()` or `get_opcodes()` hasn't already been called, in which case you may want to try `quick_ratio()` or `real_quick_ratio()` first to get an upper bound.

**quick_ratio()**
Return an upper bound on `ratio()` relatively quickly.

This isn't defined beyond that it is an upper bound on `ratio()`, and is faster to compute.

**real_quick_ratio()**
Return an upper bound on `ratio()` very quickly.

This isn't defined beyond that it is an upper bound on `ratio()`, and is faster to compute than either `ratio()` or `quick_ratio()`.

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although `quick_ratio()` and `real_quick_ratio()` are always at least as large as `ratio()`:

```python
>>> s = SequenceMatcher(None, "abcd", "bcde")
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
1.0
```
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
4.4.2 SequenceMatcher Examples

This example compares two strings, considering blanks to be `"junk:"`

```python
>>> s = SequenceMatcher(lambda x: x == " ",
                      ...
                      "private Thread currentThread;",
                      ...
                      "private volatile Thread currentThread;"
```

`ratio()` returns a float in [0, 1], measuring the similarity of the sequences. As a rule of thumb, a `ratio()` value over 0.6 means the sequences are close matches:

```python
>>> print round(s.ratio(), 3)
0.866
```

If you're only interested in where the sequences match, `get_matching_blocks()` is handy:

```python
>>> for block in s.get_matching_blocks():
...     print "a[%d] and b[%d] match for %d elements" % block
  a[0] and b[0] match for 8 elements
  a[8] and b[17] match for 6 elements
  a[14] and b[23] match for 15 elements
  a[29] and b[38] match for 0 elements
```

Note that the last tuple returned by `get_matching_blocks()` is always a dummy, `(len(a), len(b), 0)`, and this is the only case in which the last tuple element (number of elements matched) is 0.

If you want to know how to change the first sequence into the second, use `get_opcodes()`:

```python
>>> for opcode in s.get_opcodes():
...     print "%6s a[%d:%d] b[%d:%d]" % opcode
  equal a[0:8] b[0:8]
  insert a[8:8] b[8:17]
  equal a[8:14] b[17:23]
  equal a[14:29] b[23:38]
```

See also the function `get_close_matches()` in this module, which shows how simple code building on `SequenceMatcher` can be used to do useful work.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
4.4.3 Differ Objects

Note that Differ-generated deltas make no claim to be \textbf{minimal} diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The \textbf{Differ} class has this constructor:

\begin{verbatim}
class Differ([linejunk[, charjunk]])
    Optional keyword parameters linejunk and charjunk are for filter functions (or None):

    linejunk: A function that accepts a single string argument, and returns true if the string is junk. The default is None, meaning that no line is considered junk.

    charjunk: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is None, meaning that no character is considered junk.
\end{verbatim}

Differ objects are used (deltas generated) via a single method:

\begin{verbatim}
compare(a, b)
    Compare two sequences of lines, and generate the delta (a sequence of lines).

    Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the \texttt{readlines()} method of file-like objects. The delta generated also consists of newline-terminated strings, ready to be printed as-is via the \texttt{writelines()} method of a file-like object.
\end{verbatim}
Example

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
4.4.4 Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the `readlines()` method of file-like objects):

```python
>>> text1 = ''' 1. Beautiful is better than ugly.
... 2. Explicit is better than implicit.
... 3. Simple is better than complex.
... 4. Complex is better than complicated.
... '''.splitlines(1)
>>> len(text1)
4
>>> text1[0][-1]
'\n'
>>> text2 = ''' 1. Beautiful is better than ugly.
... 3. Simple is better than complex.
... 4. Complicated is better than complex.
... 5. Flat is better than nested.
... '''.splitlines(1)

Next we instantiate a Differ object:

```python
>>> d = Differ()
```

Note that when instantiating a `Differ` object we may pass functions to filter out line and character ```junk.'' See the `Differ()` constructor for details.

Finally, we compare the two:

```python
>>> result = list(d.compare(text1, text2))
result is a list of strings, so let's pretty-print it:
```

```python
>>> from pprint import pprint
>>> pprint(result)
[' 1. Beautiful is better than ugly.\n', '- 2. Explicit is better than implicit.\n', '- 3. Simple is better than complex.\n', '+ 3. Simple is better than complex.\n', '? ++ \n', '- 4. Complex is better than complicated.\n', '? ^ ---- ^ \n', '+ 4. Complicated is better than complex.\n', '? ++++ ^ \n', '? ^ \n', '? ^ \n']
```
' 5. Flat is better than nested.

As a single multi-line string it looks like this:

```python
>>> import sys
>>> sys.stdout.writelines(result)
 1. Beautiful is better than ugly.
- 2. Explicit is better than implicit.
+ 3. Simple is better than complex.
? ++
- 4. Complex is better than complicated.
? ^ ---- ^
+ 4. Complicated is better than complex.
? +++ ^
+ 5. Flat is better than nested.
```
4.5 fpformat -- Floating point conversions

The fpformat module defines functions for dealing with floating point numbers representations in 100% pure Python. **Note:** This module is unneeded: everything here could be done via the % string interpolation operator.

The fpformat module defines the following functions and an exception:

**fix**(x, digs)

Format x as [-]ddd.ddd with digs digits after the point and at least one digit before. If digs \( \leq 0\), the decimal point is suppressed.

x can be either a number or a string that looks like one. digs is an integer.

Return value is a string.

**sci**(x, digs)

Format x as [-]d.dddE[+-]ddd with digs digits after the point and exactly one digit before. If digs \( \leq 0\), one digit is kept and the point is suppressed.

x can be either a real number, or a string that looks like one. digs is an integer.

Return value is a string.

**exception NotANumber**

Exception raised when a string passed to fix() or sci() as the x parameter does not look like a number. This is a subclass of ValueError when the standard exceptions are strings. The exception value is the improperly formatted string that caused the exception to be raised.

Example:

```python
>>> import fpformat
```
>>> fpformat.fix(1.23, 1)
'1.2'
4.6 StringIO -- Read and write strings as files

This module implements a file-like class, StringIO, that reads and writes a string buffer (also known as memory files). See the description of file objects for operations (section 2.3.9).

```python
class StringIO([buffer])
```

When a StringIO object is created, it can be initialized to an existing string by passing the string to the constructor. If no string is given, the StringIO will start empty. In both cases, the initial file position starts at zero.

The StringIO object can accept either Unicode or 8-bit strings, but mixing the two may take some care. If both are used, 8-bit strings that cannot be interpreted as 7-bit ASCII (that use the 8th bit) will cause a UnicodeError to be raised when `getvalue()` is called.

The following methods of StringIO objects require special mention:

```python
getvalue()
```

Retrieve the entire contents of the "file" at any time before the StringIO object's `close()` method is called. See the note above for information about mixing Unicode and 8-bit strings; such mixing can cause this method to raise UnicodeError.

```python
close()
```

Free the memory buffer.
4.7 cStringIO -- Faster version of StringIO

The module cStringIO provides an interface similar to that of the StringIO module. Heavy use of StringIO.StringIO objects can be made more efficient by using the function StringIO() from this module instead.

Since this module provides a factory function which returns objects of built-in types, there's no way to build your own version using subclassing. Use the original StringIO module in that case.

Unlike the memory files implemented by the StringIO module, those provided by this module are not able to accept Unicode strings that cannot be encoded as plain ASCII strings.

Another difference from the StringIO module is that calling StringIO() with a string parameter creates a read-only object. Unlike an object created without a string parameter, it does not have write methods. These objects are not generally visible. They turn up in tracebacks as StringI and StringO.

The following data objects are provided as well:

**InputType**
- The type object of the objects created by calling StringIO with a string parameter.

**OutputType**
- The type object of the objects returned by calling StringIO with no parameters.

There is a C API to the module as well; refer to the module source for more information.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
4.8 textwrap -- Text wrapping and filling

New in version 2.3.

The textwrap module provides two convenience functions, wrap() and fill(), as well as TextWrapper, the class that does all the work, and a utility function dedent(). If you're just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of TextWrapper for efficiency.

wrap( text[, width[, ...]])
   Wraps the single paragraph in text (a string) so every line is at most width characters long. Returns a list of output lines, without final newlines.

   Optional keyword arguments correspond to the instance attributes of TextWrapper, documented below. width defaults to 70.

fill( text[, width[, ...]])
   Wraps the single paragraph in text, and returns a single string containing the wrapped paragraph. fill() is shorthand for

      "\n".join(wrap(text, ...))

   In particular, fill() accepts exactly the same keyword arguments as wrap().

Both wrap() and fill() work by creating a TextWrapper instance and calling a single method on it. That instance is not reused, so for applications that wrap/fill many text strings, it will be more efficient for you to create your own TextWrapper object.

An additional utility function, dedent(), is provided to remove indentation from strings that have unwanted whitespace to the left of the text.

dedent( text)
Remove any whitespace that can be uniformly removed from the left of every line in text.

This is typically used to make triple-quoted strings line up with the left edge of screen/whatever, while still presenting it in the source code in indented form.

For example:

```python
def test():
    # end first line with \ to avoid the empty line!
    s = '''
    hello
    world
    '''
    print repr(s)  # prints '    hello
    world
    '
    print repr(dedent(s))  # prints 'hello
    world
    '
```

**class TextWrapper(...)**

The `TextWrapper` constructor accepts a number of optional keyword arguments. Each argument corresponds to one instance attribute, so for example

```python
wrapper = TextWrapper(initial_indent="* ")
```

is the same as

```python
wrapper = TextWrapper()
wrapper.initial_indent = "* 
```

You can re-use the same `TextWrapper` object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The `TextWrapper` instance attributes (and keyword arguments to the constructor) are as follows:

**width**

(default: 70) The maximum length of wrapped lines. As long as there are no individual words in the input text longer than width, `TextWrapper` guarantees that no output line will be longer than width characters.

**expand_tabs**
(default: True) If true, then all tab characters in text will be expanded to spaces using the expandtabs() method of text.

replace_whitespace
(default: True) If true, each whitespace character (as defined by string.whitespace) remaining after tab expansion will be replaced by a single space. Note: If expand_tabs is false and replace_whitespace is true, each tab character will be replaced by a single space, which is not the same as tab expansion.

initial_indent
(default: '') String that will be prepended to the first line of wrapped output. Counts towards the length of the first line.

subsequent_indent
(default: '') String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

fix_sentence_endings
(default: False) If true, TextWrapper attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of ".", "!", or "?", possibly followed by one of "" or "!", followed by a space. One problem with this is algorithm is that it is unable to detect the difference between ``Dr." in

    [...] Dr. Frankenstein's monster [...] 

and ``Spot." in

    [...] See Spot. See Spot run [...] 

fix_sentence_endings is false by default.

Since the sentence detection algorithm relies on string.lowercase for the definition of `lowercase letter," and a convention of using two spaces after a period to separate sentences on the same line, it is specific to English-language texts.
**break_long_words**

(default: `True`) If true, then words longer than `width` will be broken in order to ensure that no lines are longer than `width`. If it is false, long words will not be broken, and some lines may be longer than `width`. (Long words will be put on a line by themselves, in order to minimize the amount by which `width` is exceeded.)

**TextWrapper** also provides two public methods, analogous to the module-level convenience functions:

**wrap**( `text` )

Wraps the single paragraph in `text` (a string) so every line is at most `width` characters long. All wrapping options are taken from instance attributes of the `TextWrapper` instance. Returns a list of output lines, without final newlines.

**fill**( `text` )

Wraps the single paragraph in `text`, and returns a single string containing the wrapped paragraph.
4.9 codecs -- Codec registry and base classes

This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry which manages the codec and error handling lookup process.

It defines the following functions:

\texttt{register( search\_function)}

Register a codec search function. Search functions are expected to take one argument, the encoding name in all lower case letters, and return a tuple of functions (\texttt{encoder}, \texttt{decoder}, \texttt{stream\_reader}, \texttt{stream\_writer}) taking the following arguments:

\texttt{encoder} and \texttt{decoder}: These must be functions or methods which have the same interface as the \texttt{encode()}/\texttt{decode()} methods of Codec instances (see Codec Interface). The functions/methods are expected to work in a stateless mode.

\texttt{stream\_reader} and \texttt{stream\_writer}: These have to be factory functions providing the following interface:

\texttt{factory(stream, errors='strict')}  

The factory functions must return objects providing the interfaces defined by the base classes \texttt{StreamWriter} and \texttt{StreamReader}, respectively. Stream codecs can maintain state.

Possible values for errors are \texttt{'strict'} (raise an exception in case of an encoding error), \texttt{'replace'} (replace malformed data with a suitable replacement marker, such as "?"), \texttt{'ignore'} (ignore malformed data and continue without further notice), \texttt{'xmlcharrefreplace'} (replace with the appropriate XML character reference (for encoding only)) and \texttt{'backslashreplace'} (replace with backslashed escape sequences (for encoding only)) as well as any other error handling name defined via
register_error().

In case a search function cannot find a given encoding, it should return None.

**lookup**( *encoding*)
Looks up a codec tuple in the Python codec registry and returns the function tuple as defined above.

Encodings are first looked up in the registry's cache. If not found, the list of registered search functions is scanned. If no codecs tuple is found, a **LookupError** is raised. Otherwise, the codecs tuple is stored in the cache and returned to the caller.

To simplify access to the various codecs, the module provides these additional functions which use **lookup()** for the codec lookup:

**getencoder**( *encoding*)
Look up the codec for the given encoding and return its encoder function.

Raises a **LookupError** in case the encoding cannot be found.

**getdecoder**( *encoding*)
Look up the codec for the given encoding and return its decoder function.

Raises a **LookupError** in case the encoding cannot be found.

**getreader**( *encoding*)
Look up the codec for the given encoding and return its StreamReader class or factory function.

Raises a **LookupError** in case the encoding cannot be found.

**getwriter**( *encoding*)
Look up the codec for the given encoding and return its StreamWriter class or factory function.

Raises a **LookupError** in case the encoding cannot be found.
**register_error** (*name, error_handler*)

Register the error handling function *error_handler* under the name *name*. *error_handler* will be called during encoding and decoding in case of an error, when *name* is specified as the errors parameter.

For encoding *error_handler* will be called with a *UnicodeEncodeError* instance, which contains information about the location of the error. The error handler must either raise this or a different exception or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The encoder will encode the replacement and continue encoding the original input at the specified position. Negative position values will be treated as being relative to the end of the input string. If the resulting position is out of bound an IndexError will be raised.

Decoding and translating works similar, except *UnicodeDecodeError* or *UnicodeTranslateError* will be passed to the handler and that the replacement from the error handler will be put into the output directly.

**lookup_error** (*name*)

Return the error handler previously register under the name *name*.

Raises a *LookupError* in case the handler cannot be found.

**strict_errors** (*exception*)

Implements the strict error handling.

**replace_errors** (*exception*)

Implements the replace error handling.

**ignore_errors** (*exception*)

Implements the ignore error handling.

**xmlcharrefreplace_errors_errors** (*exception*)

Implements the xmlcharrefreplace error handling.

**backslashreplace_errors_errors** (*exception*)
Implements the `backslashreplace` error handling.

To simplify working with encoded files or stream, the module also defines these utility functions:

**open**( `filename`, `mode`[, `encoding`[, `errors`[, `buffering`]]])
Open an encoded file using the given `mode` and return a wrapped version providing transparent encoding/decoding.

**Note:** The wrapped version will only accept the object format defined by the codecs, i.e. Unicode objects for most built-in codecs. Output is also codec-dependent and will usually be Unicode as well.

`encoding` specifies the encoding which is to be used for the file.

`errors` may be given to define the error handling. It defaults to 'strict' which causes a `ValueError` to be raised in case an encoding error occurs.

`buffering` has the same meaning as for the built-in `open()` function. It defaults to line buffered.

**EncodedFile**( `file`, `input`[, `output`[, `errors`]])
Return a wrapped version of file which provides transparent encoding translation.

Strings written to the wrapped file are interpreted according to the given `input` encoding and then written to the original file as strings using the `output` encoding. The intermediate encoding will usually be Unicode but depends on the specified codecs.

If `output` is not given, it defaults to `input`.

`errors` may be given to define the error handling. It defaults to 'strict', which causes `ValueError` to be raised in case an encoding error occurs.

The module also provides the following constants which are useful for reading and writing to platform dependent files:
These constants define various encodings of the Unicode byte order mark (BOM) used in UTF-16 and UTF-32 data streams to indicate the byte order used in the stream or file and in UTF-8 as a Unicode signature. BOM.UTF16 is either BOM.UTF16_BE or BOM.UTF16_LE depending on the platform's native byte order, BOM is an alias for BOM.UTF16, BOM.LE for BOM.UTF16.LE and BOM.BE for BOM.UTF16.BE. The others represent the BOM in UTF-8 and UTF-32 encodings.
4.9.1 Codec Base Classes

The `codecs` module defines a set of base classes which define the interface and can also be used to easily write your own codecs for use in Python.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols.

The `Codec` class defines the interface for stateless encoders/decoders.

To simplify and standardize error handling, the `encode()` and `decode()` methods may implement different error handling schemes by providing the `errors` string argument. The following string values are defined and implemented by all standard Python codecs:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'strict'</td>
<td>Raise <code>UnicodeError</code> (or a subclass); this is the default.</td>
</tr>
<tr>
<td>'ignore'</td>
<td>Ignore the character and continue with the next.</td>
</tr>
<tr>
<td>'replace'</td>
<td>Replace with a suitable replacement character; Python will use the official U+FFFD REPLACEMENT CHARACTER for the built-in Unicode codecs on decoding and '?' on encoding.</td>
</tr>
<tr>
<td>'xmlcharrefreplace'</td>
<td>Replace with the appropriate XML character reference (only for encoding).</td>
</tr>
<tr>
<td>'backslashreplace'</td>
<td>Replace with backslashed escape sequences (only for encoding).</td>
</tr>
</tbody>
</table>

The set of allowed values can be extended via `register_error`.

See About this document... for information on suggesting changes.
4.9.2 Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

- an ISO 8859 codeset
- a Microsoft Windows code page, which is typically derived from a 8859 codeset, but replaces control characters with additional graphic characters
- an IBM EBCDIC code page
- an IBM PC code page, which is ASCII compatible

</table>
A number of codecs are specific to Python, so their codec names have no meaning outside Python. Some of them don't convert from Unicode strings to byte strings, but instead use the property of the Python codecs machinery that any bijective function with one argument can be considered as an encoding.
For the codecs listed below, the result in the "encoding" direction is always a byte string. The result of the "decoding" direction is listed as operand type in the table.

4.9.3 encodings.idna -- Internationalized Domain Names in Applications

New in version 2.3.

This module implements RFC 3490 (Internationalized Domain Names in Applications) and RFC 3492 (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the punycode encoding and stringprep.

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as ``www.Alliancefrançaise.nu'') is converted into an ASCII-compatible encoding (ACE, such as ``www.xn-alliancefranaise-npb.nu''). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP Host: fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: The idna codec allows to convert between Unicode and the ACE. Furthermore, the socket module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket module. On top of that, modules that have host names as function parameters, such as httplib and ftplib, accept Unicode host names (httplib then also transparently sends an IDNA hostname in the Host: field if it sends that field at all).

When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed: Applications wishing to present such host names to the user should decode them to Unicode.

The module encodings.idna also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The
nameprep functions can be used directly if desired.

**nameprep**( *label*)

Return the nameprepped version of *label*. The implementation currently assumes query strings, so *AllowUnassigned* is true.

**ToASCII**( *label*)

Convert a label to ASCII, as specified in [RFC 3490](https://www.rfc-editor.org/rfc/rfc3490). *UseSTD3ASCIIIRules* is assumed to be false.

**ToUnicode**( *label*)

Convert a label to Unicode, as specified in [RFC 3490](https://www.rfc-editor.org/rfc/rfc3490).
4.10 unicodedata -- Unicode Database

This module provides access to the Unicode Character Database which defines character properties for all Unicode characters. The data in this database is based on the UnicodeData.txt file version 3.2.0 which is publically available from ftp://ftp.unicode.org/.

The module uses the same names and symbols as defined by the UnicodeData File Format 3.2.0 (see http://www.unicode.org/Public/3.2-Update/UnicodeData-3.2.0.html). It defines the following functions:

- **lookup**(name)
  Look up character by name. If a character with the given name is found, return the corresponding Unicode character. If not found, **KeyError** is raised.

- **name**(unichr[, default])
  Returns the name assigned to the Unicode character unichr as a string. If no name is defined, default is returned, or, if not given, **ValueError** is raised.

- **decimal**(unichr[, default])
  Returns the decimal value assigned to the Unicode character unichr as integer. If no such value is defined, default is returned, or, if not given, **ValueError** is raised.

- **digit**(unichr[, default])
  Returns the digit value assigned to the Unicode character unichr as integer. If no such value is defined, default is returned, or, if not given, **ValueError** is raised.

- **numeric**(unichr[, default])
  Returns the numeric value assigned to the Unicode character unichr as
float. If no such value is defined, default is returned, or, if not given, ValueError is raised.

category( unichr )
Returns the general category assigned to the Unicode character unichr as string.

bidirectional( unichr )
Returns the bidirectional category assigned to the Unicode character unichr as string. If no such value is defined, an empty string is returned.

combining( unichr )
Returns the canonical combining class assigned to the Unicode character unichr as integer. Returns 0 if no combining class is defined.

east_asian_width( unichr )
Returns the east asian width assigned to the Unicode character unichr as string. New in version 2.4.
mirrored( unichr )
Returns the mirrored property assigned to the Unicode character unichr as integer. Returns 1 if the character has been identified as a "mirrored" character in bidirectional text, 0 otherwise.

decomposition( unichr )
Returns the character decomposition mapping assigned to the Unicode character unichr as string. An empty string is returned in case no such mapping is defined.

normalize( form, unistr )
Return the normal form form for the Unicode string unistr. Valid values for form are 'NFC', 'NFKC', 'NFD', and 'NFKD'.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various way. For example, the character U+00C7 (LATIN CAPITAL LETTER C
WITH CEDILLA) can also be expressed as the sequence U+0043 (LATIN CAPITAL LETTER C) U+0327 (COMBINING CEDILLA).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the compatibility decomposition, followed by the canonical composition.

New in version 2.3.

In addition, the module exposes the following constant:

**unidata_version**

The version of the Unicode database used in this module.

New in version 2.3.
4.11 stringprep -- Internet String Preparation

When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for ``equality''. Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of ``printable'' characters.

RFC 3454 defines a procedure for ``preparing'' Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the stringprep procedure are part of the profile. One example of a stringprep profile is nameprep, which is used for internationalized domain names.

The module stringprep only exposes the tables from RFC 3454. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the mkstringprep.py utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, stringprep provides the ``characteristic function'', i.e. a function that returns true if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it returns the associated value. Below is a list of all functions available in the module.

**in_table_a1(code)**

Determine whether *code* is in tableA.1 (Unassigned code points in Unicode 3.2).

**in_table_b1(code)**
Determine whether code is in tableB.1 (Commonly mapped to nothing).

map_table_b2(code)
Return the mapped value for code according to tableB.2 (Mapping for case-folding used with NFKC).

map_table_b3(code)
Return the mapped value for code according to tableB.3 (Mapping for case-folding used with no normalization).

in_table_c11(code)
Determine whether code is in tableC.1.1 (ASCII space characters).

in_table_c12(code)
Determine whether code is in tableC.1.2 (Non-ASCII space characters).

in_table_c11_c12(code)
Determine whether code is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

in_table_c21(code)
Determine whether code is in tableC.2.1 (ASCII control characters).

in_table_c22(code)
Determine whether code is in tableC.2.2 (Non-ASCII control characters).

in_table_c21_c22(code)
Determine whether code is in tableC.2 (Control characters, union of C.2.1 and C.2.2).

in_table_c3(code)
Determine whether code is in tableC.3 (Private use).

in_table_c4(code)
Determine whether code is in tableC.4 (Non-character code points).

in_table_c5(code)
Determine whether code is in tableC.5 (Surrogate codes).

\texttt{in\_table\_c6}(code)
Determine whether code is in tableC.6 (Inappropriate for plain text).

\texttt{in\_table\_c7}(code)
Determine whether code is in tableC.7 (Inappropriate for canonical representation).

\texttt{in\_table\_c8}(code)
Determine whether code is in tableC.8 (Change display properties or are deprecated).

\texttt{in\_table\_c9}(code)
Determine whether code is in tableC.9 (Tagging characters).

\texttt{in\_table\_d1}(code)
Determine whether code is in tableD.1 (Characters with bidirectional property `\`R`` or `\`AL``).

\texttt{in\_table\_d2}(code)
Determine whether code is in tableD.2 (Characters with bidirectional property `\`L``).
5. Miscellaneous Services

The modules described in this chapter provide miscellaneous services that are available in all Python versions. Here's an overview:

- **pydoc**: Documentation generator and online help system.
- **doctest**: A framework for verifying interactive Python examples.
- **unittest**: Unit testing framework for Python.
- **test**: Regression tests package containing the testing suite for Python.
- **test.test_support**: Support for Python regression tests.
- **math**: Mathematical functions (\(\sin()\) etc.).
- **cmath**: Mathematical functions for complex numbers.
- **random**: Generate pseudo-random numbers with various common distributions.
- **whrandom**: Floating point pseudo-random number generator.
- **bisect**: Array bisection algorithms for binary searching.
- **collections**: High-performance datatypes.
- **heapq**: Heap queue algorithm (a.k.a. priority queue).
- **array**: Efficient arrays of uniformly typed numeric values.
- **sets**: Implementation of sets of unique elements.
- **itertools**: Functions creating iterators for efficient looping.
- **ConfigParser**: Configuration file parser.
- **fileinput**: Perl-like iteration over lines from multiple input streams, with ``save in place'' capability.
- **calendar**: Functions for working with calendars, including some emulation of the UNIX cal program.
- **cmd**: Build line-oriented command interpreters.
- **shlex**: Simple lexical analysis for UNIX shell-like languages.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.1 pydoc -- Documentation generator and online help system

New in version 2.1.

The pydoc module automatically generates documentation from Python modules. The documentation can be presented as pages of text on the console, served to a Web browser, or saved to HTML files.

The built-in function help() invokes the online help system in the interactive interpreter, which uses pydoc to generate its documentation as text on the console. The same text documentation can also be viewed from outside the Python interpreter by running pydoc as a script at the operating system's command prompt. For example, running

        pydoc sys

at a shell prompt will display documentation on the sys module, in a style similar to the manual pages shown by the Unix man command. The argument to pydoc can be the name of a function, module, or package, or a dotted reference to a class, method, or function within a module or module in a package. If the argument to pydoc looks like a path (that is, it contains the path separator for your operating system, such as a slash in Unix), and refers to an existing Python source file, then documentation is produced for that file.

Specifying a -w flag before the argument will cause HTML documentation to be written out to a file in the current directory, instead of displaying text on the console.

Specifying a -k flag before the argument will search the synopsis lines of all available modules for the keyword given as the argument, again in a manner similar to the Unix man command. The synopsis line of a module is the first line of its documentation string.

You can also use pydoc to start an HTTP server on the local machine that will serve documentation to visiting Web browsers. pydoc -p 1234 will start a HTTP server on port 1234, allowing you to browse the documentation at
http://localhost:1234/ in your preferred Web browser. `pydoc -g` will start the server and additionally bring up a small Tkinter-based graphical interface to help you search for documentation pages.

When `pydoc` generates documentation, it uses the current environment and path to locate modules. Thus, invoking `pydoc spam` documents precisely the version of the module you would get if you started the Python interpreter and typed "import spam".

Module docs for core modules are assumed to reside in http://www.python.org/doc/current/lib/. This can be overridden by setting the PYTHONDOCS environment variable to a different URL or to a local directory containing the Library Reference Manual pages.
5.2.1 Simple Usage: Checking
5.2 doctest -- Test interactive Python examples

The doctest module searches for pieces of text that look like interactive Python sessions, and then executes those sessions to verify that they work exactly as shown. There are several common ways to use doctest:

- To check that a module's docstrings are up-to-date by verifying that all interactive examples still work as documented.
- To perform regression testing by verifying that interactive examples from a test file or a test object work as expected.
- To write tutorial documentation for a package, liberally illustrated with input-output examples. Depending on whether the examples or the expository text are emphasized, this has the flavor of "literate testing" or "executable documentation".

Here's a complete but small example module:

"""
This is the "example" module.

The example module supplies one function, factorial(). For example,

>>> factorial(5)
120
"""

def factorial(n):
    """Return the factorial of n, an exact integer >= 0.

    If the result is small enough to fit in an int, return an int.
    Else return a long.
    """

    [factorial(n) for n in range(6)]
    [1, 1, 2, 6, 24, 120]
    >>> [factorial(long(n)) for n in range(6)]
    [1, 1, 2, 6, 24, 120]
    >>> factorial(30)
    265252859812191058636308480000000L
    >>> factorial(30L)
    265252859812191058636308480000000L
    >>> factorial(-1)
Traceback (most recent call last):
...
ValueError: n must be >= 0

Factorials of floats are OK, but the float must be an exact inte
>>> factorial(30.1)
Traceback (most recent call last):
...
ValueError: n must be exact integer
>>> factorial(30.0)
265252859812191058636308480000000L

It must also not be ridiculously large:
>>> factorial(1e100)
Traceback (most recent call last):
...
OverflowError: n too large

""

import math
if not n >= 0:
    raise ValueError("n must be >= 0")
if math.floor(n) != n:
    raise ValueError("n must be exact integer")
if n+1 == n:  # catch a value like 1e300
    raise OverflowError("n too large")
result = 1
factor = 2
while factor < n:
    result *= factor
    factor += 1
return result

def _test():
    import doctest
doctest.testmod()

if __name__ == "__main__":
    _test()

If you run example.py directly from the command line, doctest works its magic:

$ python example.py
$

There's no output! That's normal, and it means all the examples worked. Pass -v to the script, and doctest prints a detailed log of what it's trying, and prints a summary at the end:
$ python example.py -v
Trying:
  factorial(5)
Expecting:
    120
  ok
Trying:
  [factorial(n) for n in range(6)]
Expecting:
    [1, 1, 2, 6, 24, 120]
  ok
Trying:
  [factorial(long(n)) for n in range(6)]
Expecting:
    [1, 1, 2, 6, 24, 120]
  ok

And so on, eventually ending with:

Trying:
  factorial(1e100)
Expecting:
    Traceback (most recent call last):
      ...
    OverflowError: n too large
  ok
1 items had no tests:
  __main__.test
2 items passed all tests:
  1 tests in __main__
    8 tests in __main__.factorial
9 tests in 3 items.
9 passed and 0 failed.
Test passed.
$ 

That's all you need to know to start making productive use of doctest! Jump in. The following sections provide full details. Note that there are many examples of doctests in the standard Python test suite and libraries. Especially useful examples can be found in the standard test file Lib/test/test_doctest.py.

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
5.2.1 Simple Usage: Checking Examples in Docstrings

The simplest way to start using doctest (but not necessarily the way you'll continue to do it) is to end each module \( M \) with:

```python
def _test():
    import doctest
    doctest.testmod()

if __name__ == '__main__':
    _test()
```

\texttt{doctest} then examines docstrings in module \( M \).

Running the module as a script causes the examples in the docstrings to get executed and verified:

```bash
python M.py
```

This won't display anything unless an example fails, in which case the failing example(s) and the cause(s) of the failure(s) are printed to stdout, and the final line of output is "***Test Failed*** \( N \) failures.", where \( N \) is the number of examples that failed.

Run it with the \(-v\) switch instead:

```bash
python M.py -v
```

and a detailed report of all examples tried is printed to standard output, along with assorted summaries at the end.

You can force verbose mode by passing \texttt{verbose=True} to \texttt{testmod()}, or prohibit it by passing \texttt{verbose=False}. In either of those cases, \texttt{sys.argv} is not examined by \texttt{testmod()} (so passing \texttt{-v} or not has no effect).

For more information on \texttt{testmod()}, see section 5.2.4.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
5.2.2 Simple Usage: Checking Examples in a Text File

Another simple application of doctest is testing interactive examples in a text file. This can be done with the testfile() function:

```
import doctest
doctest.testfile("example.txt")
```

That short script executes and verifies any interactive Python examples contained in the file example.txt. The file content is treated as if it were a single giant docstring; the file doesn't need to contain a Python program! For example, perhaps example.txt contains this:

```
The ``example`` module

Using ``factorial``

This is an example text file in reStructuredText format. First impo
``factorial`` from the ``example`` module:

```python
>>> from example import factorial
```

Now use it:

```
>>> factorial(6)
120
```

Running doctest.testfile("example.txt") then finds the error in this documentation:

```
File "./example.txt", line 14, in example.txt
Failed example:
    factorial(6)
Expected:
    120
Got:
    720
```

As with testmod(), testfile() won't display anything unless an example fails. If an example does fail, then the failing example(s) and the cause(s) of the failure(s) are printed to stdout, using the same format as testmod().
By default, `testfile()` looks for files in the calling module's directory. See section 5.2.4 for a description of the optional arguments that can be used to tell it to look for files in other locations.

Like `testmod()`, `testfile()`'s verbosity can be set with the `-v` command-line switch or with the optional keyword argument `verbose`.

For more information on `testfile()`, see section 5.2.4.
5.2.3 How It Works

This section examines in detail how doctest works: which docstrings it looks at, how it finds interactive examples, what execution context it uses, how it handles exceptions, and how option flags can be used to control its behavior. This is the information that you need to know to write doctest examples; for information about actually running doctest on these examples, see the following sections.

Subsections

- 5.2.3.1 Which Docstrings Are Examined?
- 5.2.3.2 How are Docstring Examples Recognized?
- 5.2.3.3 What's the Execution Context?
- 5.2.3.4 What About Exceptions?
- 5.2.3.5 Option Flags and Directives
- 5.2.3.6 Warnings
5.2.4 Basic API

The functions testmod() and testfile() provide a simple interface to doctest that should be sufficient for most basic uses. For a less formal introduction to these two functions, see sections 5.2.1 and 5.2.2.

\[
\text{testfile( } \text{filename, module_relative, name, package, globs,}
\]

All arguments except filename are optional, and should be specified in keyword form.

Test examples in the file named filename. Return "(failure_count, test_count)".

Optional argument module_relative specifies how the filename should be interpreted:

- If module_relative is True (the default), then filename specifies an OS-independent module-relative path. By default, this path is relative to the calling module's directory; but if the package argument is specified, then it is relative to that package. To ensure OS-independence, filename should use / characters to separate path segments, and may not be an absolute path (i.e., it may not begin with /).
- If module_relative is False, then filename specifies an OS-specific path. The path may be absolute or relative; relative paths are resolved with respect to the current working directory.

Optional argument name gives the name of the test; by default, or if None, os.path.basename(filename) is used.

Optional argument package is a Python package or the name of a Python package whose directory should be used as the base directory for a module-relative filename. If no package is specified, then the calling module's directory is used as the base directory for module-relative filenames. It is an
error to specify package if module_relative is False.

Optional argument globs gives a dict to be used as the globals when executing examples. A new shallow copy of this dict is created for the doctest, so its examples start with a clean slate. By default, or if None, a new empty dict is used.

Optional argument extraglobs gives a dict merged into the globals used to execute examples. This works like dict.update(): if globs and extraglobs have a common key, the associated value in extraglobs appears in the combined dict. By default, or if None, no extra globals are used. This is an advanced feature that allows parameterization of doctests. For example, a doctest can be written for a base class, using a generic name for the class, then reused to test any number of subclasses by passing an extraglobs dict mapping the generic name to the subclass to be tested.

Optional argument verbose prints lots of stuff if true, and prints only failures if false; by default, or if None, it's true if and only if ' -v ' is in sys.argv.

Optional argument report prints a summary at the end when true, else prints nothing at the end. In verbose mode, the summary is detailed, else the summary is very brief (in fact, empty if all tests passed).

Optional argument optionflags or's together option flags. See section 5.2.3.

Optional argument raise_on_error defaults to false. If true, an exception is raised upon the first failure or unexpected exception in an example. This allows failures to be post-mortem debugged. Default behavior is to continue running examples.

Optional argument parser specifies a DocTestParser (or subclass) that should be used to extract tests from the files. It defaults to a normal parser (i.e., DocTestParser()).

New in version 2.4.
All arguments are optional, and all except for \textit{m} should be specified in keyword form.

Test examples in docstrings in functions and classes reachable from module \textit{m} (or module \textit{__main__} if \textit{m} is not supplied or is \texttt{None}), starting with \textit{m.\_\_doc\_\_}.

Also test examples reachable from dict \textit{m.\_\_test\_\_}, if it exists and is not \texttt{None}. \textit{m.\_\_test\_\_} maps names (strings) to functions, classes and strings; function and class docstrings are searched for examples; strings are searched directly, as if they were docstrings.

Only docstrings attached to objects belonging to module \textit{m} are searched.

Return "\texttt{(failure\_count, test\_count)}".

Optional argument \textit{name} gives the name of the module; by default, or if \texttt{None}, \textit{m.\_\_name\_\_} is used.

Optional argument \textit{exclude\_empty} defaults to false. If true, objects for which no doctests are found are excluded from consideration. The default is a backward compatibility hack, so that code still using \texttt{doctest.master.summarize()} in conjunction with \texttt{testmod()} continues to get output for objects with no tests. The \textit{exclude\_empty} argument to the newer \texttt{DocTestFinder} constructor defaults to true.

Optional arguments \textit{extraglobs}, \textit{verbose}, \textit{report}, \textit{optionflags}, \textit{raise\_on\_error}, and \textit{globs} are the same as for function \texttt{testfile()} above, except that \textit{globs} defaults to \textit{m.\_\_dict\_\_}.

Optional argument \textit{isprivate} specifies a function used to determine whether a name is private. The default function treats all names as public. \textit{isprivate} can be set to \texttt{doctest.is\_private} to skip over names that are private according to Python's underscore naming convention.

\textbf{Deprecated since release 2.4.} \textit{isprivate} was a stupid idea - don't use it. If you need to skip tests based on name, filter the list returned by \texttt{DocTestFinder.find()} instead.
Changed in version 2.3: The parameter `optionflags` was added.

Changed in version 2.4: The parameters `extraglobs`, `raise_on_error` and `exclude_empty` were added.

There's also a function to run the doctests associated with a single object. This function is provided for backward compatibility. There are no plans to deprecate it, but it's rarely useful:

```python
run_docstring_examples(f, globs[, verbose][, name][, compileflags][, optionflags])
```

Test examples associated with object `f`; for example, `f` may be a module, function, or class object.

A shallow copy of dictionary argument `globs` is used for the execution context.

Optional argument `name` is used in failure messages, and defaults to "NoName".

If optional argument `verbose` is true, output is generated even if there are no failures. By default, output is generated only in case of an example failure.

Optional argument `compileflags` gives the set of flags that should be used by the Python compiler when running the examples. By default, or if `None`, flags are deduced corresponding to the set of future features found in `globs`.

Optional argument `optionflags` works as for function `testfile()` above.
5.2.5 Unittest API

As your collection of doctest'ed modules grows, you'll want a way to run all their doctests systematically. Prior to Python 2.4, `doctest` had a barely documented `Tester` class that supplied a rudimentary way to combine doctests from multiple modules. `Tester` was feeble, and in practice most serious Python testing frameworks build on the `unittest` module, which supplies many flexible ways to combine tests from multiple sources. So, in Python 2.4, `doctest`'s `Tester` class is deprecated, and `doctest` provides two functions that can be used to create `unittest` test suites from modules and text files containing doctests. These test suites can then be run using `unittest` test runners:

```python
import unittest
import doctest
import my_module_with_doctests, and_another

suite = unittest.TestSuite()
for mod in my_module_with_doctests, and_another:
    suite.addTest(doctest.DocTestSuite(mod))
runner = unittest.TextTestRunner()
runner.run(suite)
```

There are two main functions for creating `unittest` .TestSuite instances from text files and modules with doctests:

`DocFileSuite`([`module_relative`][, `package`][, `setUp`][, `tearDown`][, `globs`][, `optionflags`][, `parser`])

Convert doctest tests from one or more text files to a `unittest` .TestSuite.

The returned `unittest` .TestSuite is to be run by the unittest framework and runs the interactive examples in each file. If an example in any file fails, then the synthesized unit test fails, and a `failureException` exception is raised showing the name of the file containing the test and a (sometimes approximate) line number.

Pass one or more paths (as strings) to text files to be examined.

Options may be provided as keyword arguments:
Optional argument `module_relative` specifies how the filenames in paths should be interpreted:

- If `module_relative` is `True` (the default), then each filename specifies an OS-independent module-relative path. By default, this path is relative to the calling module's directory; but if the `package` argument is specified, then it is relative to that package. To ensure OS-independence, each filename should use `/` characters to separate path segments, and may not be an absolute path (i.e., it may not begin with `/`).
- If `module_relative` is `False`, then each filename specifies an OS-specific path. The path may be absolute or relative; relative paths are resolved with respect to the current working directory.

Optional argument `package` is a Python package or the name of a Python package whose directory should be used as the base directory for module-relative filenames. If no package is specified, then the calling module's directory is used as the base directory for module-relative filenames. It is an error to specify `package` if `module_relative` is `False`.

Optional argument `setUp` specifies a set-up function for the test suite. This is called before running the tests in each file. The `setUp` function will be passed a `DocTest` object. The `setUp` function can access the test globals as the `globs` attribute of the test passed.

Optional argument `tearDown` specifies a tear-down function for the test suite. This is called after running the tests in each file. The `tearDown` function will be passed a `DocTest` object. The `tearDown` function can access the test globals as the `globs` attribute of the test passed.

Optional argument `globs` is a dictionary containing the initial global variables for the tests. A new copy of this dictionary is created for each test. By default, `globs` is a new empty dictionary.

Optional argument `optionflags` specifies the default doctest options for the tests, created by or-ing together individual option flags. See section 5.2.3. See function `set_unittest_reportflags()` below for a better way to set reporting options.
Optional argument `parser` specifies a `DocTestParser` (or subclass) that should be used to extract tests from the files. It defaults to a normal parser (i.e., `DocTestParser()`).

New in version 2.4.

```
DocTestSuite([module], globs, extraglobs, test_finder, setUp, tearDown, checker)
```

Convert doctest tests for a module to a `unittest` TestSuite.

The returned `unittest` TestSuite is to be run by the unittest framework and runs each doctest in the module. If any of the doctests fail, then the synthesized unit test fails, and a `failureException` exception is raised showing the name of the file containing the test and a (sometimes approximate) line number.

Optional argument `module` provides the module to be tested. It can be a module object or a (possibly dotted) module name. If not specified, the module calling this function is used.

Optional argument `globs` is a dictionary containing the initial global variables for the tests. A new copy of this dictionary is created for each test. By default, `globs` is a new empty dictionary.

Optional argument `extraglobs` specifies an extra set of global variables, which is merged into `globs`. By default, no extra globals are used.

Optional argument `test_finder` is the `DocTestFinder` object (or a drop-in replacement) that is used to extract doctests from the module.

Optional arguments `setUp`, `tearDown`, and `optionflags` are the same as for function `DocFileSuite()` above.

New in version 2.3.

Changed in version 2.4: The parameters `globs`, `extraglobs`, `test_finder`, `setUp`, `tearDown`, and `optionflags` were added; this function now uses the same search technique as `testmod()`.
Under the covers, `DocTestSuite()` creates a `unittest.TestSuite` out of `doctest.DocTestCase` instances, and `DocTestCase` is a subclass of `unittest.TestCase`. `DocTestCase` isn't documented here (it's an internal detail), but studying its code can answer questions about the exact details of `unittest` integration.

Similarly, `DocFileSuite()` creates a `unittest.TestSuite` out of `doctest.DocFileCase` instances, and `DocFileCase` is a subclass of `DocTestCase`.

So both ways of creating a `unittest.TestSuite` run instances of `DocTestCase`. This is important for a subtle reason: when you run `doctest` functions yourself, you can control the `doctest` options in use directly, by passing option flags to `doctest` functions. However, if you're writing a `unittest` framework, `unittest` ultimately controls when and how tests get run. The framework author typically wants to control `doctest` reporting options (perhaps, e.g., specified by command line options), but there's no way to pass options through `unittest` to `doctest` test runners.

For this reason, `doctest` also supports a notion of `doctest` reporting flags specific to `unittest` support, via this function:

```
set_unittest_reportflags(flags)
```

Set the `doctest` reporting flags to use.

Argument `flags` or's together option flags. See section 5.2.3. Only "reporting flags" can be used.

This is a module-global setting, and affects all future doctests run by module `unittest`: the `runTest()` method of `DocTestCase` looks at the option flags specified for the test case when the `DocTestCase` instance was constructed. If no reporting flags were specified (which is the typical and expected case), `doctest`'s `unittest` reporting flags are or'ed into the option flags, and the option flags so augmented are passed to the `DocTestRunner` instance created to run the doctest. If any reporting flags were specified when the `DocTestCase` instance was constructed, `doctest`'s `unittest` reporting flags are ignored.
The value of the `unittest` reporting flags in effect before the function was called is returned by the function.

New in version 2.4.
5.2.6 Advanced API

The basic API is a simple wrapper that's intended to make doctest easy to use. It is fairly flexible, and should meet most users' needs; however, if you require more fine-grained control over testing, or wish to extend doctest's capabilities, then you should use the advanced API.

The advanced API revolves around two container classes, which are used to store the interactive examples extracted from doctest cases:

- **Example**: A single python statement, paired with its expected output.
- **DocTest**: A collection of Examples, typically extracted from a single docstring or text file.

Additional processing classes are defined to find, parse, and run, and check doctest examples:

- **DocTestFinder**: Finds all docstrings in a given module, and uses a DocTestParser to create a DocTest from every docstring that contains interactive examples.
- **DocTestParser**: Creates a DocTest object from a string (such as an object's docstring).
- **DocTestRunner**: Executes the examples in a DocTest, and uses an OutputChecker to verify their output.
- **OutputChecker**: Compares the actual output from a doctest example with the expected output, and decides whether they match.

The relationships among these processing classes are summarized in the following diagram:
Subsections

- 5.2.6.1 DocTest Objects
- 5.2.6.2 Example Objects
- 5.2.6.3 DocTestFinder objects
- 5.2.6.4 DocTestParser objects
- 5.2.6.5 DocTestRunner objects
- 5.2.6.6 OutputChecker objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.2.7 Debugging

Doctest provides several mechanisms for debugging doctest examples:

- Several functions convert doctests to executable Python programs, which can be run under the Python debugger, pdb.
- The DebugRunner class is a subclass of DocTestRunner that raises an exception for the first failing example, containing information about that example. This information can be used to perform post-mortem debugging on the example.
- The unittest cases generated by DocTestSuite() support the debug() method defined by unittest.TestCase.
- You can add a call to pdb.set_trace() in a doctest example, and you'll drop into the Python debugger when that line is executed. Then you can inspect current values of variables, and so on. For example, suppose a.py contains just this module docstring:

```
""
>>> def f(x):
...     g(x*2)
>>> def g(x):
...     print x+3
...     import pdb; pdb.set_trace()
>>> f(3)
9
""
```

Then an interactive Python session may look like this:

```
>>> import a, doctest
>>> doctest.testmod(a)
--Return--
> <doctest a[1]>(3)g()--None
-> import pdb; pdb.set_trace()
(Pdb) list
  1    def g(x):
  2       print x+3
  3    -> import pdb; pdb.set_trace()
[EOF]
(Pdb) print x
6
(Pdb) step
--Return--
> <doctest a[0]>(2)f()--None
```
-> g(x*2)
(Pdb) list
  1    def f(x):
  2      -> g(x*2)
[EOF]
(Pdb) print x
3
(Pdb) step
--Return--
> <doctest a[2]>(1)?()->None
-> f(3)
(Pdb) cont
(0, 3)
>>>

Changed in version 2.4: The ability to use `pdb.set_trace()` usefully inside doctests was added.

Functions that convert doctests to Python code, and possibly run the synthesized code under the debugger:

**script_from_examples**(s)

Convert text with examples to a script.

Argument s is a string containing doctest examples. The string is converted to a Python script, where doctest examples in s are converted to regular code, and everything else is converted to Python comments. The generated script is returned as a string. For example,

```python
import doctest
print doctest.script_from_examples(r""
    Set x and y to 1 and 2.
    >>> x, y = 1, 2

    Print their sum:
    >>> print x+y
    3
""
)
```

displays:

```python
# Set x and y to 1 and 2.
x, y = 1, 2
#
# Print their sum:
print x+y
# Expected:
```

```python
# Set x and y to 1 and 2.
x, y = 1, 2
#
# Print their sum:
print x+y
# Expected:
```
This function is used internally by other functions (see below), but can also be useful when you want to transform an interactive Python session into a Python script.

New in version 2.4.

**testsource** *(module, name)*

Convert the doctest for an object to a script.

Argument *module* is a module object, or dotted name of a module, containing the object whose doctests are of interest. Argument *name* is the name (within the module) of the object with the doctests of interest. The result is a string, containing the object's docstring converted to a Python script, as described for **script_from_examples**() above. For example, if module a.py contains a top-level function f(), then

```python
import a, doctest
print doctest.testsource(a, "a.f")
```

prints a script version of function f()’s docstring, with doctests converted to code, and the rest placed in comments.

New in version 2.3.

**debug** *(module, name[, pm]*)

Debug the doctests for an object.

The *module* and *name* arguments are the same as for function **testsource**() above. The synthesized Python script for the named object's docstring is written to a temporary file, and then that file is run under the control of the Python debugger, **pdb**.

A shallow copy of *module*.__dict__ is used for both local and global execution context.

Optional argument *pm* controls whether post-mortem debugging is used. If *pm* has a true value, the script file is run directly, and the debugger gets involved only if the script terminates via raising an unhandled exception. If
it does, then post-mortem debugging is invoked, via
\texttt{pdb.post\_mortem()}, passing the traceback object from the unhandled
exception. If \texttt{pm} is not specified, or is false, the script is run under the
debugger from the start, via passing an appropriate \texttt{execfile()} call to
\texttt{pdb.run()}.

New in version 2.3.

Changed in version 2.4: The \texttt{pm} argument was added.

\texttt{debug\_src( src[, pm][, globs])}

Debug the doctests in a string.

This is like function \texttt{debug()} above, except that a string containing
doctest examples is specified directly, via the \texttt{src} argument.

Optional argument \texttt{pm} has the same meaning as in function \texttt{debug()} above.

Optional argument \texttt{globs} gives a dictionary to use as both local and global
execution context. If not specified, or \texttt{None}, an empty dictionary is used. If
specified, a shallow copy of the dictionary is used.

New in version 2.4.

The \texttt{DebugRunner} class, and the special exceptions it may raise, are of most
interest to testing framework authors, and will only be sketched here. See the
source code, and especially \texttt{DebugRunner}'s docstring (which is a doctest!) for
more details:

\texttt{class DebugRunner([checker][, verbose][, optionflags])}

A subclass of \texttt{DocTestRunner} that raises an exception as soon as a
failure is encountered. If an unexpected exception occurs, an
\texttt{UnexpectedException} exception is raised, containing the test, the
example, and the original exception. If the output doesn't match, then a
\texttt{DocTestFailure} exception is raised, containing the test, the example,
and the actual output.
For information about the constructor parameters and methods, see the documentation for `DocTestRunner` in section 5.2.6.

There are two exceptions that may be raised by `DebugRunner` instances:

**exception DocTestFailure**(`test, example, got`)
An exception thrown by `DocTestRunner` to signal that a doctest example's actual output did not match its expected output. The constructor arguments are used to initialize the member variables of the same names.

`DocTestFailure` defines the following member variables:

```
**test**
The `DocTest` object that was being run when the example failed.

**example**
The `Example` that failed.

**got**
The example's actual output.
```

**exception UnexpectedException**(`test, example, exc_info`)
An exception thrown by `DocTestRunner` to signal that a doctest example raised an unexpected exception. The constructor arguments are used to initialize the member variables of the same names.

`UnexpectedException` defines the following member variables:

```
**test**
The `DocTest` object that was being run when the example failed.

**example**
The `Example` that failed.

**exc_info**
A tuple containing information about the unexpected exception, as returned by `sys.exc_info()`.
```
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
5.2.8 Soapbox

As mentioned in the introduction, doctest has grown to have three primary uses:

1. Checking examples in docstrings.
2. Regression testing.
3. Executable documentation / literate testing.

These uses have different requirements, and it is important to distinguish them. In particular, filling your docstrings with obscure test cases makes for bad documentation.

When writing a docstring, choose docstring examples with care. There's an art to this that needs to be learned--it may not be natural at first. Examples should add genuine value to the documentation. A good example can often be worth many words. If done with care, the examples will be invaluable for your users, and will pay back the time it takes to collect them many times over as the years go by and things change. I'm still amazed at how often one of my doctest examples stops working after a "harmless" change.

Doctest also makes an excellent tool for regression testing, especially if you don't skimp on explanatory text. By interleaving prose and examples, it becomes much easier to keep track of what's actually being tested, and why. When a test fails, good prose can make it much easier to figure out what the problem is, and how it should be fixed. It's true that you could write extensive comments in code-based testing, but few programmers do. Many have found that using doctest approaches instead leads to much clearer tests. Perhaps this is simply because doctest makes writing prose a little easier than writing code, while writing comments in code is a little harder. I think it goes deeper than just that: the natural attitude when writing a doctest-based test is that you want to explain the fine points of your software, and illustrate them with examples. This in turn naturally leads to test files that start with the simplest features, and logically progress to complications and edge cases. A coherent narrative is the result, instead of a collection of isolated functions that test isolated bits of functionality seemingly at random. It's a different attitude, and produces different results, blurring the distinction between testing and explaining.
Regression testing is best confined to dedicated objects or files. There are several options for organizing tests:

- Write text files containing test cases as interactive examples, and test the files using `testfile()` or `DocFileSuite()`. This is recommended, although is easiest to do for new projects, designed from the start to use doctest.
- Define functions named `_regrtest_topic` that consist of single docstrings, containing test cases for the named topics. These functions can be included in the same file as the module, or separated out into a separate test file.
- Define a `__test__` dictionary mapping from regression test topics to docstrings containing test cases.
5.3 unittest -- Unit testing framework

New in version 2.1.

The Python unit testing framework, often referred to as ``PyUnit,'' is a Python language version of JUnit, by Kent Beck and Erich Gamma. JUnit is, in turn, a Java version of Kent's Smalltalk testing framework. Each is the de facto standard unit testing framework for its respective language.

PyUnit supports test automation, sharing of setup and shutdown code for tests, aggregation of tests into collections, and independence of the tests from the reporting framework. The unittest module provides classes that make it easy to support these qualities for a set of tests.

To achieve this, PyUnit supports some important concepts:

**test fixture**
A test fixture represents the preparation needed to perform one or more tests, and any associate cleanup actions. This may involve, for example, creating temporary or proxy databases, directories, or starting a server process.

**test case**
A test case is the smallest unit of testing. It checks for a specific response to a particular set of inputs. PyUnit provides a base class, TestCase, which may be used to create new test cases. You may provide your own implementation that does not subclass from TestCase, of course.

**test suite**
A test suite is a collection of test cases, test suites, or both. It is used to aggregate tests that should be executed together.

**test runner**
A test runner is a component which orchestrates the execution of tests and provides the outcome to the user. The runner may use a graphical interface,
a textual interface, or return a special value to indicate the results of executing the tests.

The test case and test fixture concepts are supported through the `TestCase` and `FunctionTestCase` classes; the former should be used when creating new tests, and the latter can be used when integrating existing test code with a PyUnit-driven framework. When building test fixtures using `TestCase`, the `setUp()` and `tearDown()` methods can be overridden to provide initialization and cleanup for the fixture. With `FunctionTestCase`, existing functions can be passed to the constructor for these purposes. When the test is run, the fixture initialization is run first; if it succeeds, the cleanup method is run after the test has been executed, regardless of the outcome of the test. Each instance of the `TestCase` will only be used to run a single test method, so a new fixture is created for each test.

Test suites are implemented by the `TestSuite` class. This class allows individual tests and test suites to be aggregated; when the suite is executed, all tests added directly to the suite and in "child" test suites are run.

A test runner is an object that provides a single method, `run()`, which accepts a `TestCase` or `TestSuite` object as a parameter, and returns a result object. The class `TestResult` is provided for use as the result object. PyUnit provide the `TextTestRunner` as an example test runner which reports test results on the standard error stream by default. Alternate runners can be implemented for other environments (such as graphical environments) without any need to derive from a specific class.

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.3.1 Basic example

The unittest module provides a rich set of tools for constructing and running tests. This section demonstrates that a small subset of the tools suffice to meet the needs of most users.

Here is a short script to test three functions from the random module:

```python
import random
import unittest

class TestSequenceFunctions(unittest.TestCase):
    def setUp(self):
        self.seq = range(10)

    def testshuffle(self):
        # make sure the shuffled sequence does not lose any elements
        random.shuffle(self.seq)
        self.seq.sort()
        self.assertEqual(self.seq, range(10))

    def testchoice(self):
        element = random.choice(self.seq)
        self.assert_(element in self.seq)

    def testsample(self):
        self.assertRaises(ValueError, random.sample, self.seq, 20)
        for element in random.sample(self.seq, 5):
            self.assert_(element in self.seq)

if __name__ == '__main__':
    unittest.main()
```

A testcase is created by subclassing unittest.TestCase. The three individual tests are defined with methods whose names start with the letters "test". This naming convention informs the test runner about which methods represent tests.

The crux of each test is a call to assertEquals() to check for an expected result; assert_() to verify a condition; or assertRaises() to verify that an expected exception gets raised. These methods are used instead of the assert statement so the test runner can accumulate all test results and produce a report.
When a `setUp()` method is defined, the test runner will run that method prior to each test. Likewise, if a `tearDown()` method is defined, the test runner will invoke that method after each test. In the example, `setUp()` was used to create a fresh sequence for each test.

The final block shows a simple way to run the tests. `unittest.main()` provides a command line interface to the test script. When run from the command line, the above script produces an output that looks like this:

```
... 
Ran 3 tests in 0.000s
OK
```

Instead of `unittest.main()`, there are other ways to run the tests with a finer level of control, less terse output, and no requirement to be run from the command line. For example, the last two lines may be replaced with:

```python
suite = unittest.makeSuite(TestSequenceFunctions)
unittest.TextTestRunner(verbosity=2).run(suite)
```

Running the revised script from the interpreter or another script produces the following output:

```
testchoice (__main__.TestSequenceFunctions) ... ok
testsample (__main__.TestSequenceFunctions) ... ok
testshuffle (__main__.TestSequenceFunctions) ... ok

Ran 3 tests in 0.110s
OK
```

The above examples show the most commonly used `unittest` features which are sufficient to meet many everyday testing needs. The remainder of the documentation explores the full feature set from first principles.
5.3.2 Organizing test code

The basic building blocks of unit testing are test cases -- single scenarios that must be set up and checked for correctness. In PyUnit, test cases are represented by instances of the `TestCase` class in the `unittest` module. To make your own test cases you must write subclasses of `TestCase`, or use `FunctionTestCase`.

An instance of a `TestCase`-derived class is an object that can completely run a single test method, together with optional set-up and tidy-up code.

The testing code of a `TestCase` instance should be entirely self contained, such that it can be run either in isolation or in arbitrary combination with any number of other test cases.

The simplest test case subclass will simply override the `runTest()` method in order to perform specific testing code:

```python
import unittest

class DefaultWidgetSizeTestCase(unittest.TestCase):
    def runTest(self):
        widget = Widget("The widget")
        self.failUnless(widget.size() == (50,50), 'incorrect default size')
```

Note that in order to test something, we use the one of the `assert*()` or `fail*()` methods provided by the `TestCase` base class. If the test fails when the test case runs, an exception will be raised, and the testing framework will identify the test case as a failure. Other exceptions that do not arise from checks made through the `assert*()` and `fail*()` methods are identified by the testing framework as errors.

The way to run a test case will be described later. For now, note that to construct an instance of such a test case, we call its constructor without arguments:

```python
testCase = DefaultWidgetSizeTestCase()
```

Now, such test cases can be numerous, and their set-up can be repetitive. In the above case, constructing a "Widget" in each of 100 Widget test case subclasses would mean unsightly duplication.
Luckily, we can factor out such set-up code by implementing a method called `setUp()`, which the testing framework will automatically call for us when we run the test:

```python
import unittest

class SimpleWidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget("The widget")

class DefaultWidgetSizeTestCase(SimpleWidgetTestCase):
    def runTest(self):
        self.failUnless(self.widget.size() == (50, 50),
                        'incorrect default size')

class WidgetResizeTestCase(SimpleWidgetTestCase):
    def runTest(self):
        self.widget.resize(100, 150)
        self.failUnless(self.widget.size() == (100, 150),
                        'wrong size after resize')
```

If the `setUp()` method raises an exception while the test is running, the framework will consider the test to have suffered an error, and the `runTest()` method will not be executed.

Similarly, we can provide a `tearDown()` method that tidies up after the `runTest()` method has been run:

```python
import unittest

class SimpleWidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget("The widget")

    def tearDown(self):
        self.widget.dispose()
        self.widget = None
```

If `setUp()` succeeded, the `tearDown()` method will be run regardless of whether or not `runTest()` succeeded.

Such a working environment for the testing code is called a *fixture*.

Often, many small test cases will use the same fixture. In this case, we would end up subclassing `SimpleWidgetTestCase` into many small one-method classes such as `DefaultWidgetSizeTestCase`. This is time-consuming
and discouraging, so in the same vein as JUnit, PyUnit provides a simpler mechanism:

```python
import unittest

class WidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget("The widget")

    def tearDown(self):
        self.widget.dispose()
        self.widget = None

    def testDefaultSize(self):
        self.failUnless(self.widget.size() == (50, 50),
                        'incorrect default size')

    def testResize(self):
        self.widget.resize(100, 150)
        self.failUnless(self.widget.size() == (100, 150),
                        'wrong size after resize')
```

Here we have not provided a runTest() method, but have instead provided two different test methods. Class instances will now each run one of the test*() methods, with self.widget created and destroyed separately for each instance. When creating an instance we must specify the test method it is to run. We do this by passing the method name in the constructor:

```python
def_suiteCase = WidgetTestCase("testDefaultSize")
resizeCase = WidgetTestCase("testResize")
```

Test case instances are grouped together according to the features they test. PyUnit provides a mechanism for this: the test suite, represented by the class TestSuite in the unittest module:

```python
widgetSuite = unittest.TestSuite()
widgetSuite.addTest(WidgetTestCase("testDefaultSize"))
widgetSuite.addTest(WidgetTestCase("testResize"))
```

For the ease of running tests, as we will see later, it is a good idea to provide in each test module a callable object that returns a pre-built test suite:

```python
def suite():
    suite = unittest.TestSuite()
    suite.addTest(WidgetTestCase("testDefaultSize"))
    suite.addTest(WidgetTestCase("testResize"))
    return suite
```
or even:

```python
class WidgetTestSuite(unittest.TestSuite):
    def __init__(self):
        unittest.TestSuite.__init__(self, map(WidgetTestCase, "testDefaultSize", "testResize"))
```

(The latter is admittedly not for the faint-hearted!)

Since it is a common pattern to create a `TestCase` subclass with many similarly named test functions, there is a convenience function called `makeSuite()` that constructs a test suite that comprises all of the test cases in a test case class:

```python
suite = unittest.makeSuite(WidgetTestCase)
```

Note that when using the `makeSuite()` function, the order in which the various test cases will be run by the test suite is the order determined by sorting the test function names using the `cmp()` built-in function.

Often it is desirable to group suites of test cases together, so as to run tests for the whole system at once. This is easy, since `TestSuite` instances can be added to a `TestSuite` just as `TestCase` instances can be added to a `TestSuite`:

```python
suite1 = module1.TestSuite()
suite2 = module2.TestSuite()
alltests = unittest.TestSuite((suite1, suite2))
```

You can place the definitions of test cases and test suites in the same modules as the code they are to test (such as `widget.py`), but there are several advantages to placing the test code in a separate module, such as `widgettests.py`:

- The test module can be run standalone from the command line.
- The test code can more easily be separated from shipped code.
- There is less temptation to change test code to fit the code it tests without a good reason.
- Test code should be modified much less frequently than the code it tests.
- Tested code can be refactored more easily.
- Tests for modules written in C must be in separate modules anyway, so why not be consistent?
If the testing strategy changes, there is no need to change the source code.
5.3.3 Re-using old test code

Some users will find that they have existing test code that they would like to run from PyUnit, without converting every old test function to a `TestCase` subclass.

For this reason, PyUnit provides a `FunctionTestCase` class. This subclass of `TestCase` can be used to wrap an existing test function. Set-up and tear-down functions can also optionally be wrapped.

Given the following test function:

```python
def testSomething():
    something = makeSomething()
    assert something.name is not None
    # ...
```

one can create an equivalent test case instance as follows:

```python
testcase = unittest.FunctionTestCase(testSomething)
```

If there are additional set-up and tear-down methods that should be called as part of the test case's operation, they can also be provided:

```python
testcase = unittest.FunctionTestCase(testSomething,
    setUp=makeSomethingDB,
    tearDown=deleteSomethingDB)
```

**Note:** PyUnit supports the use of `AssertionError` as an indicator of test failure, but does not recommend it. Future versions may treat `AssertionError` differently.
5.3.4 Classes and functions

class **TestCase**()

Instances of the **TestCase** class represent the smallest testable units in a set of tests. This class is intended to be used as a base class, with specific tests being implemented by concrete subclasses. This class implements the interface needed by the test runner to allow it to drive the test, and methods that the test code can use to check for and report various kinds of failures.

class **FunctionTestCase**( testFunc[, setUp[, tearDown[, description]]])

This class implements the portion of the **TestCase** interface which allows the test runner to drive the test, but does not provide the methods which test code can use to check and report errors. This is used to create test cases using legacy test code, allowing it to be integrated into a **unittest**-based test framework.

class **TestSuite**([tests])

This class represents an aggregation of individual tests cases and test suites. The class presents the interface needed by the test runner to allow it to be run as any other test case, but all the contained tests and test suites are executed. Additional methods are provided to add test cases and suites to the aggregation. If `tests` is given, it must be a sequence of individual tests that will be added to the suite.

class **TestLoader**()

This class is responsible for loading tests according to various criteria and returning them wrapped in a **TestSuite**. It can load all tests within a given module or **TestCase** class. When loading from a module, it considers all **TestCase**-derived classes. For each such class, it creates an instance for each method with a name beginning with the string "test".

default**TestLoader**

Instance of the **TestLoader** class which can be shared. If no customization of the **TestLoader** is needed, this instance can always be used instead of creating new instances.
class TextTestRunner([stream[, descriptions[, verbosity]]])
A basic test runner implementation which prints results on standard output. It has a few configurable parameters, but is essentially very simple. Graphical applications which run test suites should provide alternate implementations.

main([module[, defaultTest[, argv[, testRunner[, testRunner]]]]])
A command-line program that runs a set of tests; this is primarily for making test modules conveniently executable. The simplest use for this function is:

    if __name__ == '__main__':
        unittest.main()

In some cases, the existing tests may have be written using the doctest module. If so, that module provides a DocTestSuite class that can automatically build unittest.TestSuite instances from the existing test code. New in version 2.3.
5.3.5 TestCase Objects

Each TestCase instance represents a single test, but each concrete subclass may be used to define multiple tests -- the concrete class represents a single test fixture. The fixture is created and cleaned up for each test case.

TestCase instances provide three groups of methods: one group used to run the test, another used by the test implementation to check conditions and report failures, and some inquiry methods allowing information about the test itself to be gathered.

Methods in the first group are:

**setUp()**
Method called to prepare the test fixture. This is called immediately before calling the test method; any exception raised by this method will be considered an error rather than a test failure. The default implementation does nothing.

**tearDown()**
Method called immediately after the test method has been called and the result recorded. This is called even if the test method raised an exception, so the implementation in subclasses may need to be particularly careful about checking internal state. Any exception raised by this method will be considered an error rather than a test failure. This method will only be called if the setUp() succeeds, regardless of the outcome of the test method. The default implementation does nothing.

**run([result])**
Run the test, collecting the result into the test result object passed as result. If result is omitted or None, a temporary result object is created and used, but is not made available to the caller. This is equivalent to simply calling the TestCase instance.

**debug()**
Run the test without collecting the result. This allows exceptions raised by
the test to be propagated to the caller, and can be used to support running tests under a debugger.

The test code can use any of the following methods to check for and report failures.

**assert_(expr[, msg])**

**failUnless(expr[, msg])**

  Signal a test failure if expr is false; the explanation for the error will be msg if given, otherwise it will be None.

**assertEqual(first, second[, msg])**

**failUnlessEqual(first, second[, msg])**

  Test that first and second are equal. If the values do not compare equal, the test will fail with the explanation given by msg, or None. Note that using failUnlessEqual() improves upon doing the comparison as the first parameter to failUnless(): the default value for msg can be computed to include representations of both first and second.

**assertNotEqual(first, second[, msg])**

**failIfEqual(first, second[, msg])**

  Test that first and second are not equal. If the values do compare equal, the test will fail with the explanation given by msg, or None. Note that using failIfEqual() improves upon doing the comparison as the first parameter to failUnless() is that the default value for msg can be computed to include representations of both first and second.

**assertAlmostEqual(first, second[, places[, msg]]**

**failUnlessAlmostEqual(first, second[, places[, msg]]**

  Test that first and second are approximately equal by computing the difference, rounding to the given number of places, and comparing to zero. Note that comparing a given number of decimal places is not the same as comparing a given number of significant digits. If the values do not compare equal, the test will fail with the explanation given by msg, or None.
assertNotAlmostEqual(first, second[, places[, msg]])

failIfAlmostEqual(first, second[, places[, msg]])

Test that first and second are not approximately equal by computing the difference, rounding to the given number of places, and comparing to zero. Note that comparing a given number of decimal places is not the same as comparing a given number of significant digits. If the values do not compare equal, the test will fail with the explanation given by msg, or None.

assertRaises(exception, callable, ...)

failUnlessRaises(exception, callable, ...)

Test that an exception is raised when callable is called with any positional or keyword arguments that are also passed to assertRaises(). The test passes if exception is raised, is an error if another exception is raised, or fails if no exception is raised. To catch any of a group of exceptions, a tuple containing the exception classes may be passed as exception.

failIf(expr[, msg])

The inverse of the failUnless() method is the failIf() method. This signals a test failure if expr is true, with msg or None for the error message.

fail([msg])

Signals a test failure unconditionally, with msg or None for the error message.

failureException

This class attribute gives the exception raised by the test() method. If a test framework needs to use a specialized exception, possibly to carry additional information, it must subclass this exception in order to "play fair" with the framework. The initial value of this attribute is AssertionError.

Testing frameworks can use the following methods to collect information on the test:

countTestCases()
Return the number of tests represented by the this test object. For
TestCase instances, this will always be 1, but this method is also
implemented by the TestSuite class, which can return larger values.

defaultTestResult()

Return the default type of test result object to be used to run this test.

id()

Return a string identifying the specific test case. This is usually the full
name of the test method, including the module and class names.

shortDescription()

Returns a one-line description of the test, or None if no description has
been provided. The default implementation of this method returns the first
line of the test method's docstring, if available, or None.
5.3.6 TestSuite Objects

TestSuite objects behave much like TestCase objects, except they do not actually implement a test. Instead, they are used to aggregate tests into groups that should be run together. Some additional methods are available to add tests to TestSuite instances:

**addTest**( *test*)

Add a TestCase or TestSuite to the set of tests that make up the suite.

**addTests**( *tests*)

Add all the tests from a sequence of TestCase and TestSuite instances to this test suite.

The `run()` method is also slightly different:

**run**( *result*)

Run the tests associated with this suite, collecting the result into the test result object passed as `result`. Note that unlike `TestCase.run()`, `TestSuite.run()` requires the result object to be passed in.

In the typical usage of a TestSuite object, the `run()` method is invoked by a TestRunner rather than by the end-user test harness.
5.3.7 TestResult Objects

A TestResult object stores the results of a set of tests. The TestCase and TestSuite classes ensure that results are properly stored; test authors do not need to worry about recording the outcome of tests.

Testing frameworks built on top of unittest may want access to the TestResult object generated by running a set of tests for reporting purposes; a TestResult instance is returned by the TestRunner.run() method for this purpose.

Each instance holds the total number of tests run, and collections of failures and errors that occurred among those test runs. The collections contain tuples of (testcase, traceback), where traceback is a string containing a formatted version of the traceback for the exception.

TestResult instances have the following attributes that will be of interest when inspecting the results of running a set of tests:

**errors**
A list containing pairs of TestCase instances and the formatted tracebacks for tests which raised an exception but did not signal a test failure. Changed in version 2.2: Contains formatted tracebacks instead of sys.exc_info() results.

**failures**
A list containing pairs of TestCase instances and the formatted tracebacks for tests which signalled a failure in the code under test. Changed in version 2.2: Contains formatted tracebacks instead of sys.exc_info() results.

**testsRun**
The number of tests which have been started.

**wasSuccessful()**
Returns true if all tests run so far have passed, otherwise returns false.
The following methods of the `TestResult` class are used to maintain the internal data structures, and may be extended in subclasses to support additional reporting requirements. This is particularly useful in building tools which support interactive reporting while tests are being run.

`startTest(test)`
Called when the test case `test` is about to be run.

`stopTest(test)`
Called when the test case `test` has been executed, regardless of the outcome.

`addError(test, err)`
Called when the test case `test` raises an exception without signalling a test failure. `err` is a tuple of the form returned by `sys.exc_info()`: `(type, value, traceback)`.

`addFailure(test, err)`
Called when the test case `test` signals a failure. `err` is a tuple of the form returned by `sys.exc_info()`: `(type, value, traceback)`.

`addSuccess(test)`
This method is called for a test that does not fail; `test` is the test case object.

One additional method is available for `TestResult` objects:

`stop()`
This method can be called to signal that the set of tests being run should be aborted. Once this has been called, the `TestRunner` object return to its caller without running any additional tests. This is used by the `TextTestRunner` class to stop the test framework when the user signals an interrupt from the keyboard. Interactive tools which provide runners can use this in a similar manner.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
5.3.8 TestLoader Objects

The TestLoader class is used to create test suites from classes and modules. Normally, there is no need to create an instance of this class; the unittest module provides an instance that can be shared as the defaultTestLoader module attribute. Using a subclass or instance would allow customization of some configurable properties.

TestLoader objects have the following methods:

**loadTestsFromTestCase(testCaseClass)**

Return a suite of all tests cases contained in the TestCase-derived class testCaseClass.

**loadTestsFromModule(module)**

Return a suite of all tests cases contained in the given module. This method searches module for classes derived from TestCase and creates an instance of the class for each test method defined for the class.

**Warning:** While using a hierarchy of Testcase-derived classes can be convenient in sharing fixtures and helper functions, defining test methods on base classes that are not intended to be instantiated directly does not play well with this method. Doing so, however, can be useful when the fixtures are different and defined in subclasses.

**loadTestsFromName(name[, module])**

Return a suite of all tests cases given a string specifier.

The specifier name is a ``dotted name`` that may resolve either to a module, a test case class, a test method within a test case class, or a callable object which returns a TestCase or TestSuite instance. For example, if you have a module SampleTests containing a TestCase-derived class SampleTestCase with three test methods (test_one(), test_two(), and test_three()), the specifier 'SampleTests.SampleTestCase' would cause this method to return a suite which will run all three test methods. Using the specifier
'SampleTests.SampleTestCase.test_two' would cause it to return a test suite which will run only the test_two() test method. The specifier can refer to modules and packages which have not been imported; they will be imported as a side-effect.

The method optionally resolves name relative to a given module.

loadTestsFromNames( names[, module])

Similar to loadTestsFromName(), but takes a sequence of names rather than a single name. The return value is a test suite which supports all the tests defined for each name.

getTestCaseNames( testCaseClass)

Return a sorted sequence of method names found within testCaseClass.

The following attributes of a TestLoader can be configured either by subclassing or assignment on an instance:

testMethodPrefix

String giving the prefix of method names which will be interpreted as test methods. The default value is 'test'.

sortTestMethodsUsing

Function to be used to compare method names when sorting them in getTestCaseNames(). The default value is the built-in cmp() function; it can be set to None to disable the sort.

suiteClass

Callable object that constructs a test suite from a list of tests. No methods on the resulting object are needed. The default value is the TestSuite class.
5.4 test -- Regression tests package for Python

The test package contains all regression tests for Python as well as the modules test.test_support and test.regrtest. test.test_support is used to enhance your tests while test.regrtest drives the testing suite.

Each module in the test package whose name starts with "test_" is a testing suite for a specific module or feature. All new tests should be written using the unittest module; using unittest is not required but makes the tests more flexible and maintenance of the tests easier. Some older tests are written to use doctest and a "traditional" testing style; these styles of tests will not be covered.

Tests embedded in documentation strings.

Subsections

- 5.4.1 Writing Unit Tests for the test package
- 5.4.2 Running tests using test.regrtest

Previous: 5.3.8 TestLoader Objects  Up: 5. Miscellaneous Services  Next: 5.4.1 Writing Unit Tests
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.4.1 Writing Unit Tests for the test package

It is preferred that tests for the test package use the unittest module and follow a few guidelines. One is to have the name of all the test methods start with "test_" as well as the module's name. This is needed so that the methods are recognized by the test driver as test methods. Also, no documentation string for the method should be included. A comment (such as "# Tests function returns only True or False") should be used to provide documentation for test methods. This is done because documentation strings get printed out if they exist and thus what test is being run is not stated.

A basic boilerplate is often used:

```python
import unittest
from test import test_support

class MyTestCase1(unittest.TestCase):
    # Only use setUp() and tearDown() if necessary
    def setUp(self):
        ... code to execute in preparation for tests ...
    
    def tearDown(self):
        ... code to execute to clean up after tests ...
    
    def test_feature_one(self):
        # Test feature one.
        ... testing code ...
    
    def test_feature_two(self):
        # Test feature two.
        ... testing code ...
    
    ... more test methods ...

class MyTestCase2(unittest.TestCase):
    ... same structure as MyTestCase1 ...

    ... more test classes ...

def test_main():
    test_support.run_unittest(MyTestCase1,
                               MyTestCase2,
                               ... list other tests ...
    )
```
This boilerplate code allows the testing suite to be run by `test.regrtest` as well as on its own as a script.

The goal for regression testing is to try to break code. This leads to a few guidelines to be followed:

- The testing suite should exercise all classes, functions, and constants. This includes not just the external API that is to be presented to the outside world but also "private" code.
- Whitebox testing (examining the code being tested when the tests are being written) is preferred. Blackbox testing (testing only the published user interface) is not complete enough to make sure all boundary and edge cases are tested.
- Make sure all possible values are tested including invalid ones. This makes sure that not only all valid values are acceptable but also that improper values are handled correctly.
- Exhaust as many code paths as possible. Test where branching occurs and thus tailor input to make sure as many different paths through the code are taken.
- Add an explicit test for any bugs discovered for the tested code. This will make sure that the error does not crop up again if the code is changed in the future.
- Make sure to clean up after your tests (such as close and remove all temporary files).
- Import as few modules as possible and do it as soon as possible. This minimizes external dependencies of tests and also minimizes possible anomalous behavior from side-effects of importing a module.
- Try to maximize code reuse. On occasion, tests will vary by something as small as what type of input is used. Minimize code duplication by subclassing a basic test class with a class that specifies the input:

```python
class TestFuncAcceptsSequences(unittest.TestCase):
    func = mySuperWhammyFunction

    def test_func(self):
        self.func(self.arg)
```
class AcceptLists(TestFuncAcceptsSequences):
    arg = [1,2,3]

class AcceptStrings(TestFuncAcceptsSequences):
    arg = 'abc'

class AcceptTuples(TestFuncAcceptsSequences):
    arg = (1,2,3)

See Also:

Test Driven Development
A book by Kent Beck on writing tests before code.
5.4.2 Running tests using test.regrtest

test.regrtest can be used as a script to drive Python's regression test suite. Running the script by itself automatically starts running all regression tests in the test package. It does this by finding all modules in the package whose name starts with "test_", importing them, and executing the function test_main() if present. The names of tests to execute may also be passed to the script. Specifying a single regression test (python regrtest.py test_spam.py) will minimize output and only print whether the test passed or failed and thus minimize output.

Running test.regrtest directly allows what resources are available for tests to use to be set. You do this by using the -u command-line option. Run python regrtest.py -uall to turn on all resources; specifying all as an option for -u enables all possible resources. If all but one resource is desired (a more common case), a comma-separated list of resources that are not desired may be listed after all. The command python regrtest.py -uall,-audio,-largefile will run test.regrtest with all resources except the audio and largefile resources. For a list of all resources and more command-line options, run python regrtest.py -h.

Some other ways to execute the regression tests depend on what platform the tests are being executed on. On UNIX, you can run make test at the top-level directory where Python was built. On Windows, executing rt.bat from your PCBuild directory will run all regression tests.
5.5 test.test_support -- Utility functions for tests

The test.test_support module provides support for Python's regression tests.

This module defines the following exceptions:

exception TestFailed
    Exception to be raised when a test fails.

exception TestSkipped
    Subclass of TestFailed. Raised when a test is skipped. This occurs when a needed resource (such as a network connection) is not available at the time of testing.

exception ResourceDenied
    Subclass of TestSkipped. Raised when a resource (such as a network connection) is not available. Raised by the requires() function.

The test.test_support module defines the following constants:

verbose
    True when verbose output is enabled. Should be checked when more detailed information is desired about a running test. verbose is set by test.regrtest.

have_unicode
    True when Unicode support is available.

is_jython
    True if the running interpreter is Jython.

TESTFN
    Set to the path that a temporary file may be created at. Any temporary that is created should be closed and unlinked (removed).
The `test.test_support` module defines the following functions:

**forget(module_name)**
Removes the module named `module_name` from `sys.modules` and deletes any byte-compiled files of the module.

**is_resource_enabled(resource)**
Returns `True` if `resource` is enabled and available. The list of available resources is only set when `test.regrtest` is executing the tests.

**requires(resource[, msg])**
Raises `ResourceDenied` if `resource` is not available. `msg` is the argument to `ResourceDenied` if it is raised. Always returns true if called by a function whose `__name__` is '__main__'. Used when tests are executed by `test.regrtest`.

**findfile(filename)**
Return the path to the file named `filename`. If no match is found `filename` is returned. This does not equal a failure since it could be the path to the file.

**run_unittest(*classes)**
Execute `unittest.TestCase` subclasses passed to the function. The function scans the classes for methods starting with the prefix "test_" and executes the tests individually. This is the preferred way to execute tests.

**run_suite(suite[, testclass])**
Execute the `unittest.TestSuite` instance `suite`. The optional argument `testclass` accepts one of the test classes in the suite so as to print out more detailed information on where the testing suite originated from.
5.6 decimal -- Decimal floating point arithmetic

New in version 2.4.

The decimal module provides support for decimal floating point arithmetic. It offers several advantages over the float() datatype:

- Decimal numbers can be represented exactly. In contrast, numbers like 1.1 do not have an exact representation in binary floating point. End users typically would not expect 1.1 to display as 1.1000000000000001 as it does with binary floating point.

- The exactness carries over into arithmetic. In decimal floating point, "0.1 + 0.1 + 0.1 - 0.3" is exactly equal to zero. In binary floating point, result is 5.5511151231257827e-017. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal would be preferred in accounting applications which have strict equality invariants.

- The decimal module incorporates a notion of significant places so that "1.30 + 1.20" is 2.50. The trailing zero is kept to indicate significance. This is the customary presentation for monetary applications. For multiplication, the "schoolbook" approach uses all the figures in the multiplicands. For instance, "1.3 * 1.2" gives 1.56 while "1.30 * 1.20" gives 1.5600.

- Unlike hardware based binary floating point, the decimal module has a user settable precision (defaulting to 28 places) which can be as large as needed for a given problem:

```python
>>> getcontext().prec = 6
>>> Decimal(1) / Decimal(7)
Decimal("0.142857")
>>> getcontext().prec = 28
>>> Decimal(1) / Decimal(7)
Decimal("0.1428571428571428571428571429")
```
• Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not truncate trailing zeroes. Decimals also include special values such as Infinity, -Infinity, and NaN. The standard also differentiates -0 from +0.

The context for arithmetic is an environment specifying precision, rounding rules, limits on exponents, flags indicating the results of operations, and trap enablers which determine whether signals are treated as exceptions. Rounding options include ROUND_CEILING, ROUND_DOWN, ROUND_FLOOR, ROUND_HALF_DOWN, ROUND_HALF_EVEN, ROUND_HALF_UP, and ROUND_UP.

Signals are groups of exceptional conditions arising during the course of computation. Depending on the needs of the application, signals may be ignored, considered as informational, or treated as exceptions. The signals in the decimal module are: Clamped, InvalidOperation, DivisionByZero, Inexact, Rounded, Subnormal, Overflow, and Underflow.

For each signal there is a flag and a trap enabler. When a signal is encountered, its flag incremented from zero and, then, if the trap enabler is set to one, an exception is raised. Flags are sticky, so the user needs to reset them before monitoring a calculation.

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.6.1 Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with `getcontext()` and, if necessary, setting new values for precision, rounding, or enabled traps:

```python
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999,
capitals=1, flags=[], traps=[Overflow, InvalidOperation, DivisionByZero])

>>> getcontext().prec = 7 # Set a new precision
```

Decimal instances can be constructed from integers, strings or tuples. To create a Decimal from a `float`, first convert it to a string. This serves as an explicit reminder of the details of the conversion (including representation error). Decimal numbers include special values such as `NaN` which stands for "Not a number", positive and negative `Infinity`, and `-0`.

```python
>>> Decimal(10)
Decimal("10")
>>> Decimal("3.14")
Decimal("3.14")
>>> Decimal((0, (3, 1, 4), -2))
Decimal("3.14")
>>> Decimal(str(2.0 ** 0.5))
Decimal("1.41421356237")
>>> Decimal("NaN")
Decimal("NaN")
>>> Decimal("-Infinity")
Decimal("-Infinity")
```

The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come into play during arithmetic operations.

```python
>>> getcontext().prec = 6
>>> Decimal('3.0')
Decimal("3.0")
>>> Decimal('3.1415926535')
Decimal("3.1415926535")
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal("5.85987")
>>> getcontext().rounding = ROUND_UP
```
Decimals interact well with much of the rest of python. Here is a small decimal floating point flying circus:

```python
>>> data = map(Decimal, '1.34 1.87 3.45 2.35 1.00 0.03 9.25'.split())
>>> max(data)
Decimal("9.25")
>>> min(data)
Decimal("0.03")
>>> sorted(data)
[Decimal("0.03"), Decimal("1.00"), Decimal("1.34"), Decimal("1.87"),
 Decimal("2.35"), Decimal("3.45"), Decimal("9.25")]
>>> sum(data)
Decimal("19.29")
>>> a, b, c = data[:3]
>>> str(a)
'1.34'
>>> float(a)
1.3400000000000001
>>> round(a, 1)  # round() first converts to binary floating point
1.3
>>> int(a)
1
>>> a * 5
Decimal("6.70")
>>> a * b
Decimal("2.5058")
>>> c % a
Decimal("0.77")
```

The `quantize()` method rounds a number to a fixed exponent. This method is useful for monetary applications that often round results to a fixed number of places:

```python
>>> Decimal('7.325').quantize(Decimal('.01'), rounding=ROUND_DOWN)
Decimal("7.32")
>>> Decimal('7.325').quantize(Decimal('1.'), rounding=ROUND_UP)
Decimal("8")
```

As shown above, the `getcontext()` function accesses the current context and allows the settings to be changed. This approach meets the needs of most applications.

For more advanced work, it may be useful to create alternate contexts using the
Context() constructor. To make an alternate active, use the setcontext() function.

In accordance with the standard, the Decimal module provides two ready to use standard contexts, BasicContext and ExtendedContext. The former is especially useful for debugging because many of the traps are enabled:

```python
>>> myothercontext = Context(prec=60, rounding=ROUND_HALF_DOWN)
>>> setcontext(myothercontext)
Decimal('0.142857142857142857142857142857142857142857142857142857142857')

>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999, capitals=1, flags=[], traps=[])
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857143')
>>> Decimal(42) / Decimal(0)
Decimal('Infinity')

>>> setcontext(BasicContext)
>>> Decimal(42) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#143>", line 1, in -toplevel-
    Decimal(42) / Decimal(0)
DivisionByZero: x / 0
```

Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the clear_flags() method.

```python
>>> setcontext(ExtendedContext)
>>> getcontext().clear_flags()
>>> Decimal(355) / Decimal(113)
Decimal('3.14159292')
>>> getcontext()
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999, capitals=1, flags=[Inexact, Rounded], traps=[])
```

The flags entry shows that the rational approximation to Pi was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the traps field of a context:
>>> Decimal(1) / Decimal(0)
Decimal("Infinity")
>>> getcontext().traps[DivisionByZero] = 1
>>> Decimal(1) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#112>", line 1, in -toplevel-
    Decimal(1) / Decimal(0)
DivisionByZero: x / 0

Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to `Decimal` with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.
5.6.2 Decimal objects

class Decimal([value [, context]])

Constructs a new Decimal object based from value.

value can be an integer, string, tuple, or another Decimal object. If no value is given, returns Decimal("0"). If value is a string, it should conform to the decimal numeric string syntax:

- **sign**: ::= '+' | '-'
- **digit**: ::= '0' | '1' | '2' | '3' | '4' | '5' | '6'
- **indicator**: ::= 'e' | 'E'
- **digits**: ::= digit [digit]...
- **decimal-part**: ::= digits '.' [digits] | ['.'] digits
- **exponent-part**: ::= indicator [sign] digits
- **infinity**: ::= 'Infinity' | 'Inf'
- **nan**: ::= 'NaN' [digits] | 'sNaN' [digits]
- **numeric-value**: ::= decimal-part [exponent-part] | infinity
- **numeric-string**: ::= [sign] numeric-value | [sign] nan

If value is a tuple, it should have three components, a sign (0 for positive or 1 for negative), a tuple of digits, and an integer exponent. For example, "Decimal((0, (1, 4, 1, 4), -3))" returns Decimal("1.414").

The context precision does not affect how many digits are stored. That is determined exclusively by the number of digits in value. For example, "Decimal("3.00000")" records all five zeroes even if the context precision is only three.

The purpose of the context argument is determining what to do if value is a malformed string. If the context traps InvalidOperation, an exception is raised; otherwise, the constructor returns a new Decimal with the value of NaN.

Once constructed, Decimal objects are immutable.

Decimal floating point objects share many properties with the other builtin numeric types such as float and int. All of the usual math operations and special methods apply. Likewise, decimal objects can be copied, pickled, printed,
used as dictionary keys, used as set elements, compared, sorted, and coerced to another type (such as float or long).

In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

adjusted()
Return the adjusted exponent after shifting out the coefficient's rightmost digits until only the lead digit remains:
Decimal("321e+5").adjusted() returns seven. Used for determining the position of the most significant digit with respect to the decimal point.

as_tuple()
Returns a tuple representation of the number: "(sign, digittuple, exponent)".

compare(other[, context])
Compares like __cmp__() but returns a decimal instance:

- a or b is a NaN ==> Decimal("NaN")
- a < b ==> Decimal("-1")
- a == b ==> Decimal("0")
- a > b ==> Decimal("1")

max(other[, context])
Like "max(self, other)" except that the context rounding rule is applied before returning and that NaN values are either signalled or ignored (depending on the context and whether they are signaling or quiet).

min(other[, context])
Like "min(self, other)" except that the context rounding rule is applied before returning and that NaN values are either signalled or ignored (depending on the context and whether they are signaling or quiet).

normalize([context])
Normalize the number by stripping the rightmost trailing zeroes and converting any result equal to Decimal("0") to Decimal("0e0").
Used for producing canonical values for members of an equivalence class. For example, `Decimal("32.100")` and `Decimal("0.321000e+2")` both normalize to the equivalent value `Decimal("32.1")`.

```python
quantize(exp[, rounding[, context[, watchexp]]])
```
Quantize makes the exponent the same as `exp`. Searches for a rounding method in `rounding`, then in `context`, and then in the current context.

If `watchexp` is set (default), then an error is returned whenever the resulting exponent is greater than `Emax` or less than `Etiny`.

```python
remainder_near(other[, context])
```
Computes the modulo as either a positive or negative value depending on which is closest to zero. For instance, "`Decimal(10).remainder_near(6)`" returns `Decimal("-2")` which is closer to zero than `Decimal("4")`.

If both are equally close, the one chosen will have the same sign as `self`.

```python
same_quantum(other[, context])
```
Test whether `self` and `other` have the same exponent or whether both are NaN.

```python
sqrt([context])
```
Return the square root to full precision.

```python
to_eng_string([context])
```
Convert to an engineering-type string.

Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts `Decimal('123E+1')` to `Decimal("1.23E+3")`.

```python
to_integral([rounding[, context]])
```
Rounds to the nearest integer without signaling Inexact or Rounded. If given, applies `rounding`; otherwise, uses the rounding method in either the
supplied context or the current context.
5.6.3 Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the getcontext() and setcontext() functions:

**getcontext()**
Return the current context for the active thread.

**setcontext(c)**
Set the current context for the active thread to c.

New contexts can formed using the Context constructor described below. In addition, the module provides three pre-made contexts:

**class BasicContext**
This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to ROUND_HALF_UP. All flags are cleared. All traps are enabled (treated as exceptions) except Inexact, Rounded, and Subnormal.

Because many of the traps are enabled, this context is useful for debugging.

**class ExtendedContext**
This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to ROUND_HALF_EVEN. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the trapped are disabled, this context is useful for applications that prefer to have result value of NaN or Infinity instead of raising exceptions. This allows an application to complete a run in the presence of conditions that would otherwise halt the program.
**class DefaultContext**
This context is used by the `Context` constructor as a prototype for new contexts. Changing a field (such as a precision) has the effect of changing the default for new contexts created by the `Context` constructor.

This context is most useful in multi-threaded environments. Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are precision=28, rounding=ROUND_HALF_EVEN, and enabled traps for Overflow, InvalidOperation, and DivisionByZero.

In addition to the three supplied contexts, new contexts can be created with the `Context` constructor.

**class Context**(prec=None, rounding=None, traps=None, flags=None, Emin=None, Emax=None, capitals=1)

 Creates a new context. If a field is not specified or is None, the default values are copied from the DefaultContext. If the flags field is not specified or is None, all flags are cleared.

The `prec` field is a positive integer that sets the precision for arithmetic operations in the context.

The `rounding` option is one of:

- ROUND_CEILING (towards Infinity),
- ROUND_DOWN (towards zero),
- ROUND_FLOOR (towards -Infinity),
- ROUND_HALF_DOWN (to nearest with ties going towards zero),
- ROUND_HALF_EVEN (to nearest with ties going to nearest even integer),
- ROUND_HALF_UP (to nearest with ties going away from zero), or
- ROUND_UP (away from zero).
The traps and flags fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.

The Emin and Emax fields are integers specifying the outer limits allowable for exponents.

The capitals field is either 0 or 1 (the default). If set to 1, exponents are printed with a capital E; otherwise, a lowercase e is used:

```
Decimal('6.02e+23')
```

The Context class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context.

**clear_flags()**

Resets all of the flags to 0.

**copy()**

Return a duplicate of the context.

**create_decimal(num)**

Creates a new Decimal instance from num but using self as context. Unlike the Decimal constructor, the context precision, rounding method, flags, and traps are applied to the conversion.

This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:

```
>>> getcontext().prec = 3
>>> Decimal("3.4445") + Decimal("1.0023")
Decimal("4.45")
>>> Decimal("3.4445") + Decimal(0) + Decimal("1.0023")
Decimal("4.44")
```

**Etiny()**

Returns a value equal to "Emin - prec + 1" which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to Etiny.
Etop()  
Returns a value equal to "Emax - prec + 1".

The usual approach to working with decimals is to create Decimal instances and then apply arithmetic operations which take place within the current context for the active thread. An alternate approach is to use context methods for calculating within a specific context. The methods are similar to those for the Decimal class and are only briefly recounted here.

abs(x)  
Returns the absolute value of x.

add(x, y)  
Return the sum of x and y.

compare(x, y)  
Compares values numerically.

    Like __cmp__() but returns a decimal instance:

    a or b is a NaN ==> Decimal("NaN")
    a < b         ==> Decimal("-1")
    a == b        ==> Decimal("0")
    a > b         ==> Decimal("1")

divide(x, y)  
Return x divided by y.

divmod(x, y)  
Divides two numbers and returns the integer part of the result.

max(x, y)  
Compare two values numerically and return the maximum.

    If they are numerically equal then the left-hand operand is chosen as the result.

min(x, y)  
Compare two values numerically and return the minimum.
If they are numerically equal then the left-hand operand is chosen as the result.

**minus**(*x*)

Minus corresponds to the unary prefix minus operator in Python.

**multiply**(*x, y*)

Return the product of *x* and *y*.

**normalize**(*x*)

Normalize reduces an operand to its simplest form.

Essentially a plus operation with all trailing zeros removed from the result.

**plus**(*x*)

Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is not an identity operation.

**power**(*x, y[, modulo]*)

Return "x  **  y" to the modulo if given.

The right-hand operand must be a whole number whose integer part (after any exponent has been applied) has no more than 9 digits and whose fractional part (if any) is all zeros before any rounding. The operand may be positive, negative, or zero; if negative, the absolute value of the power is used, and the left-hand operand is inverted (divided into 1) before use.

If the increased precision needed for the intermediate calculations exceeds the capabilities of the implementation then an **InvalidOperation** condition is signaled.

If, when raising to a negative power, an underflow occurs during the division into 1, the operation is not halted at that point but continues.

**quantize**(*x, y*)

Returns a value equal to *x* after rounding and having the exponent of *y*. 
Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an **InvalidOperation** is signaled. This guarantees that, unless there is an error condition, the quantized exponent is always equal to that of the right-hand operand.

Also unlike other operations, quantize never signals Underflow, even if the result is subnormal and inexact.

**remainder**(x, y)

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the original dividend.

**remainder_near**(x, y)

Computed the modulo as either a positive or negative value depending on which is closest to zero. For instance, 
"Decimal(10).remainder_near(6)" returns Decimal("-2") which is closer to zero than Decimal("4").

If both are equally close, the one chosen will have the same sign as *self*.

**same_quantum**(x, y)

Test whether x and y have the same exponent or whether both are NaN.

**sqrt**(x)

Return the square root of x to full precision.

**subtract**(x, y)

Return the difference between x and y.

**to_eng_string()**

Convert to engineering-type string.

Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts Decimal('123E+1') to Decimal("1.23E+3")
to_integral\(x\)
Rounds to the nearest integer without signaling Inexact or Rounded.

to_sci_string\(x\)
Converts a number to a string using scientific notation.
5.6.4 Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is incremented whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context's trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the DivisionByZero trap is set, then a DivisionByZero exception is raised upon encountering the condition.

**class Clamped**
Altered an exponent to fit representation constraints.

Typically, clamping occurs when an exponent falls outside the context's Emin and Emax limits. If possible, the exponent is reduced to fit by adding zeroes to the coefficient.

**class DecimalException**
Base class for other signals and is a subclass of ArithmeticError.

**class DivisionByZero**
Signals the division of a non-infinite number by zero.

Can occur with division, modulo division, or when raising a number to a negative power. If this signal is not trapped, returns Infinity or -Infinity with the sign determined by the inputs to the calculation.

**class Inexact**
Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.
class InvalidOperation
An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns NaN. Possible causes include:

- \(\text{Infinity} - \text{Infinity}\)
- \(0 \times \text{Infinity}\)
- \(\text{Infinity} / \text{Infinity}\)
- \(x \% 0\)
- \(\text{Infinity} \% x\)
- \(x \_\text{rescale}(\text{non-integer})\)
- \(\text{sqrt}(-x)\) and \(x > 0\)
- \(0 \times 0\)
- \(x \times (\text{non-integer})\)
- \(x \times \text{Infinity}\)

class Overflow
Numerical overflow.

Indicates the exponent is larger than \(E_{\text{max}}\) after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to Infinity. In either case, Inexact and Rounded are also signaled.

class Rounded
Rounding occurred though possibly no information was lost.

Signaled whenever rounding discards digits; even if those digits are zero (such as rounding 5.00 to 5.0). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

class Subnormal
Exponent was lower than \(E_{\text{min}}\) prior to rounding.

Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.

class Underflow
Numerical underflow with result rounded to zero.

Occurs when a subnormal result is pushed to zero by rounding. Inexact
and Subnormal are also signaled.

The following table summarizes the hierarchy of signals:

exceptions.ArithmeticError(exceptions.StandardError)
    DecimalException
        Clamped
        DivisionByZero(DecimalException, exceptions.ZeroDivisionError)
    Inexact
        Overflow(Inexact, Rounded)
        Underflow(Inexact, Rounded, Subnormal)
    InvalidOperation
    Rounded
    Subnormal
5.6.6 Working with threads

The `getcontext()` function accesses a different `Context` object for each thread. Having separate thread contexts means that threads may make changes (such as `getcontext.prec=10`) without interfering with other threads.

Likewise, the `setcontext()` function automatically assigns its target to the current thread.

If `setcontext()` has not been called before `getcontext()`, then `getcontext()` will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called `DefaultContext`. To control the defaults so that each thread will use the same values throughout the application, directly modify the `DefaultContext` object. This should be done before any threads are started so that there won't be a race condition between threads calling `getcontext()`. For example:

```python
# Set applicationwide defaults for all threads about to be launched
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
t1.start()
t2.start()
t3.start()
...```

Previous: 5.6.5.2 Special values  Up: 5.6 decimal  Next: 5.6.7 Recipes

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
Here are a few recipes that serve as utility functions and that demonstrate ways to work with the Decimal class:

```python
def moneyfmt(value, places=2, curr='\', sep='\', dp='.', pos='\', neg='-', trailneg=' '):
    """Convert Decimal to a money formatted string.

    places: required number of places after the decimal point
    curr: optional currency symbol before the sign (may be blank)
    sep: optional grouping separator (comma, period, space, or blank)
    dp: decimal point indicator (comma or period)
        only specify as blank when places is zero
    pos: optional sign for positive numbers: '+', space or blank
    neg: optional sign for negative numbers: '-', '(', space or blank
    trailneg: optional trailing minus indicator: '-', ')', space or blank

    >>> d = Decimal('-1234567.8901')
    >>> moneyfmt(d, curr='$')
    '-$1,234,567.89'
    >>> moneyfmt(d, places=0, sep='.', dp='', pos='', neg='', trailneg='-')
    '1.234.568-'
    >>> moneyfmt(d, curr='$', neg='(', trailneg=')')
    '($1,234,567.89)'
    >>> moneyfmt(Decimal('123456789'), sep='	')
    '123 456 789.00'
    >>> moneyfmt(Decimal('-0.02'), neg='<', trailneg='>')
    '<.02>'
    ""
    q = Decimal((0, (1,), -places))  # 2 places --> '.01'
    sign, digits, exp = value.quantize(q).as_tuple()
    assert exp == -places
    result = []
    digits = map(str, digits)
    build, next = result.append, digits.pop
    if sign:
        build(trailneg)
    for i in range(places):
        if digits:
            build(next())
        else:
            build('0')
    build(dp)
    i = 0
    while digits:
        build(next())
        i += 1
```

5.6.7 Recipes
if i == 3 and digits:
    i = 0
    build(sep)
build(curr)
if sign:

FAQ

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.6.8 Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5').` Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```python
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal("4.68")
```

Q. In a fixed-point application with two decimal places, some inputs have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The `quantize()` method rounds to a fixed number of decimal places. If the `Inexact` trap is set, it is also useful for validation:

```python
>>> TWOPLACES = Decimal(10) ** -2  # same as Decimal('0.01')

>>> # Round to two places
>>> Decimal("3.214").quantize(TWOPLACES)
Decimal("3.21")

>>> # Validate that a number does not exceed two places
>>> Decimal("3.21").quantize(TWOPLACES, context=Context(traps=[Inexact]))
Decimal("3.21")

>>> Decimal("3.214").quantize(TWOPLACES, context=Context(traps=[Inexact]))
Traceback (most recent call last):
...
Inexact: Changed in rounding
```

Q. Once I have valid two place inputs, how do I maintain that invariant throughout an application?

A. Some operations like addition and subtraction automatically preserve fixed point. Others, like multiplication and division, change the number of decimal places and need to be followed-up with a `quantize()` step.

Q. There are many ways to express the same value. The numbers `200`, `200.000`, `2E2`, and `.02E+4` all have the same value at various precisions. Is
there a way to transform them to a single recognizable canonical value?

A. The `normalize()` method maps all equivalent values to a single representative:

```python
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split())
>>> [v.normalize() for v in values]
[Decimal("2E+2"), Decimal("2E+2"), Decimal("2E+2"), Decimal("2E+2"),]
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing `5.0E+3` as `5000` keeps the value constant but cannot show the original's two-place significance.

Q. Is there a way to convert a regular float to a `Decimal`?

A. Yes, all binary floating point numbers can be exactly expressed as a Decimal. An exact conversion may take more precision than intuition would suggest, so trapping `Inexact` will signal a need for more precision:

```python
def floatToDecimal(f):
    """Convert a floating point number to a Decimal with no loss of info"
    mantissa, exp = math.frexp(f)
    while mantissa != int(mantissa):
        mantissa *= 2.0
        exp -= 1
    mantissa = int(mantissa)

    oldcontext = getcontext()
    setcontext(Context(traps=[Inexact]))
    try:
        while True:
            try:
                return mantissa * Decimal(2) ** exp
            except Inexact:
                getcontext().prec += 1
    finally:
        setcontext(oldcontext)
```

Q. Why isn't the floatToDecimal() routine included in the module?

A. There is some question about whether it is advisable to mix binary and decimal floating point. Also, its use requires some care to avoid the representation issues associated with binary floating point:

```python
>>> floatToDecimal(1.1)
Decimal("1.100000000000000088817841970012523233890533447265625")
```

Q. Within a complex calculation, how can I make sure that I haven't gotten a spurious result because of insufficient precision or rounding anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that `what you type is what you get`. A disadvantage is that the results can look odd if you forget that the inputs haven't been rounded:

```python
>>> getcontext().prec = 3
>>> Decimal('3.104') + D('2.104')
Decimal("5.21")
>>> Decimal('3.104') + D('0.000') + D('2.104')
Decimal("5.20")
```

The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```python
>>> getcontext().prec = 3
>>> +Decimal('1.23456789')  # unary plus triggers rounding
Decimal("1.23")
```

Alternatively, inputs can be rounded upon creation using the `Context.create_decimal()` method:

```python
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal('1.2345678')
```
Decimal("1.2345")

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.7 math -- Mathematical functions

This module is always available. It provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the cmath module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don't is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.

Number-theoretic and representation functions:

**ceil**(x)
Return the ceiling of x as a float, the smallest integer value greater than or equal to x.

**fabs**(x)
Return the absolute value of x.

**floor**(x)
Return the floor of x as a float, the largest integer value less than or equal to x.

**fmod**(x, y)
Return fmod(x, y), as defined by the platform C library. Note that the Python expression x % y may not return the same result. The intent of the C standard is that fmod(x, y) be exactly (mathematically; to infinite precision) equal to x - n*y for some integer n such that the result has the same sign as x and magnitude less than abs(y). Python's x % y returns a
result with the sign of \( y \) instead, and may not be exactly computable for float arguments. For example, \( \text{fmod}(-1e-100, 1e100) \) is \(-1e-100\), but the result of Python's \(-1e-100 \% 1e100\) is \(1e100 - 1e-100\), which cannot be represented exactly as a float, and rounds to the surprising \( 1e100 \). For this reason, function \( \text{fmod()} \) is generally preferred when working with floats, while Python's \( x \% y \) is preferred when working with integers.

\[ \text{frexp}(x) \]
Return the mantissa and exponent of \( x \) as the pair \((m, e)\). \( m \) is a float and \( e \) is an integer such that \( x \equiv m \times 2^e \) exactly. If \( x \) is zero, returns \((0.0, 0)\), otherwise \( 0.5 \leq \text{abs}(m) < 1 \). This is used to "pick apart" the internal representation of a float in a portable way.

\[ \text{ldexp}(x, i) \]
Return \( x \times (2^i) \). This is essentially the inverse of function \( \text{frexp}() \).

\[ \text{modf}(x) \]
Return the fractional and integer parts of \( x \). Both results carry the sign of \( x \), and both are floats.

Note that \( \text{frexp()} \) and \( \text{modf()} \) have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an `output parameter' (there is no such thing in Python).

For the \( \text{ceil()}, \text{floor()}, \) and \( \text{modf()} \) functions, note that all floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the same as the platform C double type), in which case any float \( x \) with \( \text{abs}(x) \geq 2^{52} \) necessarily has no fractional bits.

Power and logarithmic functions:

\[ \text{exp}(x) \]
Return \( e^{**}x \).

\[ \text{log}(x[, \text{base}]) \]
Return the logarithm of \( x \) to the given \( base \). If the \( base \) is not specified, return the natural logarithm of \( x \) (that is, the logarithm to base \( e \)). Changed in version 2.3: \( base \) argument added.

\( \log_{10}(x) \)
Return the base-10 logarithm of \( x \).

\( \text{pow}(x, y) \)
Return \( x^{**}y \).

\( \sqrt{x} \)
Return the square root of \( x \).

Trigonometric functions:

\( \text{acos}(x) \)
Return the arc cosine of \( x \), in radians.

\( \text{asin}(x) \)
Return the arc sine of \( x \), in radians.

\( \text{atan}(x) \)
Return the arc tangent of \( x \), in radians.

\( \text{atan2}(y, x) \)
Return \( \text{atan}(y / x) \), in radians. The result is between -\( \pi \) and \( \pi \). The vector in the plane from the origin to point \( (x, y) \) makes this angle with the positive X axis. The point of \( \text{atan2}(\cdot) \) is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, \( \text{atan}(1) \) and \( \text{atan2}(1, 1) \) are both \( \pi/4 \), but \( \text{atan2}(-1, -1) \) is \( -3*\pi/4 \).

\( \text{cos}(x) \)
Return the cosine of \( x \) radians.

\( \text{hypot}(x, y) \)
Return the Euclidean norm, \( \sqrt{x^2 + y^2} \). This is the length of the
vector from the origin to point \((x, y)\).

\textbf{\textit{sin}}(x)
Return the sine of \(x\) radians.

\textbf{\textit{tan}}(x)
Return the tangent of \(x\) radians.

Angular conversion:

\textbf{\textit{degrees}}(x)
Converts angle \(x\) from radians to degrees.

\textbf{\textit{radians}}(x)
Converts angle \(x\) from degrees to radians.

Hyperbolic functions:

\textbf{\textit{cosh}}(x)
Return the hyperbolic cosine of \(x\).

\textbf{\textit{sinh}}(x)
Return the hyperbolic sine of \(x\).

\textbf{\textit{tanh}}(x)
Return the hyperbolic tangent of \(x\).

The module also defines two mathematical constants:

\textbf{\textit{pi}}
The mathematical constant \(\pi\).

\textbf{\textit{e}}
The mathematical constant \(e\).

\textbf{Note:} The \texttt{math} module consists mostly of thin wrappers around the platform C math library functions. Behavior in
exceptional cases is loosely specified by the C standards, and Python inherits much of its math-function error-reporting behavior from the platform C implementation. As a result, the specific exceptions raised in error cases (and even whether some arguments are considered to be exceptional at all) are not defined in any useful cross-platform or cross-release way. For example, whether `math.log(0)` returns `-Inf` or raises `ValueError` or `OverflowError` isn't defined, and in cases where `math.log(0)` raises `OverflowError`, `math.log(0L)` may raise `ValueError` instead.

See About this document... for information on suggesting changes.
5.8 cmath -- Mathematical functions for complex numbers

This module is always available. It provides access to mathematical functions for complex numbers. The functions are:

\textbf{acos}(x)
\begin{quote}
Return the arc cosine of \( x \). There are two branch cuts: One extends right from 1 along the real axis to \( \infty \), continuous from below. The other extends left from -1 along the real axis to \(-\infty\), continuous from above.
\end{quote}

\textbf{acosh}(x)
\begin{quote}
Return the hyperbolic arc cosine of \( x \). There is one branch cut, extending left from 1 along the real axis to \(-\infty\), continuous from above.
\end{quote}

\textbf{asin}(x)
\begin{quote}
Return the arc sine of \( x \). This has the same branch cuts as \textbf{acos}( ).
\end{quote}

\textbf{asinh}(x)
\begin{quote}
Return the hyperbolic arc sine of \( x \). There are two branch cuts, extending left from \( \pm 1j \) to \( \pm -\infty j \), both continuous from above. These branch cuts should be considered a bug to be corrected in a future release. The correct branch cuts should extend along the imaginary axis, one from \( 1j \) up to \( \infty j \) and continuous from the right, and one from \(-1j \) down to \(-\infty j \) and continuous from the left.
\end{quote}

\textbf{atan}(x)
\begin{quote}
Return the arc tangent of \( x \). There are two branch cuts: One extends from \( 1j \) along the imaginary axis to \( \infty j \), continuous from the left. The other extends from \(-1j \) along the imaginary axis to \(-\infty j \), continuous from the left. (This should probably be changed so the upper cut becomes continuous from the other side.)
\end{quote}

\textbf{atanh}(x)
Return the hyperbolic arc tangent of $x$. There are two branch cuts: One extends from 1 along the real axis to $\infty$, continuous from above. The other extends from -1 along the real axis to $-\infty$, continuous from above. (This should probably be changed so the right cut becomes continuous from the other side.)

\texttt{\textbf{cos}( x )}  
Return the cosine of $x$.

\texttt{\textbf{cosh}( x )}  
Return the hyperbolic cosine of $x$.

\texttt{\textbf{exp}( x )}  
Return the exponential value $e^{**}x$.

\texttt{\textbf{log}( x[, base] )}  
Returns the logarithm of $x$ to the given \texttt{base}. If the \texttt{base} is not specified, returns the natural logarithm of $x$. There is one branch cut, from 0 along the negative real axis to $-\infty$, continuous from above. Changed in version 2.4: \texttt{base} argument added.

\texttt{\textbf{log10}( x )}  
Return the base-10 logarithm of $x$. This has the same branch cut as \texttt{log( )}.

\texttt{\textbf{sin}( x )}  
Return the sine of $x$.

\texttt{\textbf{sinh}( x )}  
Return the hyperbolic sine of $x$.

\texttt{\textbf{sqrt}( x )}  
Return the square root of $x$. This has the same branch cut as \texttt{log( )}.

\texttt{\textbf{tan}( x )}  
Return the tangent of $x$.

\texttt{\textbf{tanh}( x )}
Return the hyperbolic tangent of \( x \).

The module also defines two mathematical constants:

\[ \textbf{pi} \]

The mathematical constant \( \pi \), as a real.

\[ \textbf{e} \]

The mathematical constant \( e \), as a real.

Note that the selection of functions is similar, but not identical, to that in module \texttt{math}. The reason for having two modules is that some users aren't interested in complex numbers, and perhaps don't even know what they are. They would rather have \texttt{math.sqrt(-1)} raise an exception than return a complex number. Also note that the functions defined in \texttt{cmath} always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

See Also:

5.9 random -- Generate pseudo-random numbers

This module implements pseudo-random number generators for various distributions.

For integers, uniform selection from a range. For sequences, uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function `random()`, which generates a random float uniformly in the semi-open range [0.0, 1.0). Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of $2^{**}19937-1$. The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the `random.Random` class. You can instantiate your own instances of Random to get generators that don't share state. This is especially useful for multi-threaded programs, creating a different instance of Random for each thread, and using the `jumpahead()` method to ensure that the generated sequences seen by each thread don't overlap.

Class Random can also be subclassed if you want to use a different basic generator of your own devising: in that case, override the `random()`, `seed()`, `getstate()`, `setstate()` and `jumpahead()` methods. Optionally, a new generator can supply a `getrandombits()` method -- this allows `randrange()` to produce selections over an arbitrarily large range. New in version 2.4: the `getrandombits()` method.
As an example of subclassing, the `random` module provides the `WichmannHill` class which implements an alternative generator in pure Python. The class provides a backward compatible way to reproduce results from earlier versions of Python which used the Wichmann-Hill algorithm as the core generator. Changed in version 2.3: Substituted MersenneTwister for Wichmann-Hill.

Bookkeeping functions:

```
seed([x])
```

Initialize the basic random number generator. Optional argument `x` can be any hashable object. If `x` is omitted or `None`, current system time is used; current system time is also used to initialize the generator when the module is first imported. If randomness sources are provided by the operating system, they are used instead of the system time (see the `os.urandom()` function for details on availability). Changed in version 2.4: formerly, operating system resources were not used. If `x` is not `None` or an int or long, `hash(x)` is used instead. If `x` is an int or long, `x` is used directly.

```
getstate()
```

Return an object capturing the current internal state of the generator. This object can be passed to `setstate()` to restore the state. New in version 2.1.

```
setstate(state)
```

`state` should have been obtained from a previous call to `getstate()`, and `setstate()` restores the internal state of the generator to what it was at the time `setstate()` was called. New in version 2.1.

```
jumpahead(n)
```

Change the internal state to one different from and likely far away from the current state. `n` is a non-negative integer which is used to scramble the current state vector. This is most useful in multi-threaded programs, in conjunction with multiple instances of the `Random` class: `setstate()` or `seed()` can be used to force all instances into the same internal state, and then `jumpahead()` can be used to force the instances' states far apart. New in version 2.1. Changed in version 2.3: Instead of jumping to a
specific state, \( n \) steps ahead, \( \text{jumpahead}(n) \) jumps to another state likely to be separated by many steps.

**getrandbits\( (k) \)**

Returns a python `long` int with \( k \) random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, \( \text{getrandbits()} \) enables \( \text{randrange()} \) to handle arbitrarily large ranges. New in version 2.4.

Functions for integers:

**randrange\( ([start,] \, \text{stop[,} \, \text{step}]) \)**

Return a randomly selected element from \( \text{range}(\text{start,} \, \text{stop,} \, \text{step}) \). This is equivalent to \( \text{choice(range(\text{start,} \, \text{stop,} \, \text{step}))} \), but doesn't actually build a range object. New in version 1.5.2.

**randint\( (a, \, b) \)**

Return a random integer \( N \) such that \( a \leq N \leq b \).

Functions for sequences:

**choice\( (seq) \)**

Return a random element from the non-empty sequence \( seq \). If \( seq \) is empty, raises `IndexError`.

**shuffle\( (x[, \, random]) \)**

Shuffle the sequence \( x \) in place. The optional argument `random` is a 0-argument function returning a random float in \([0.0, 1.0)\); by default, this is the function `random()`.

Note that for even rather small \( \text{len}(x) \), the total number of permutations of \( x \) is larger than the period of most random number generators; this implies that most permutations of a long sequence can never be generated.

**sample\( (population, \, k) \)**

Return a \( k \) length list of unique elements chosen from the population
sequence. Used for random sampling without replacement. New in version 2.3.

Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the sub-slices).

Members of the population need not be hashable or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

To choose a sample from a range of integers, use `xrange` as an argument. This is especially fast and space efficient for sampling from a large population: `sample(xrange(1000000), 60).

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution's equation, as used in common mathematical practice; most of these equations can be found in any statistics text.

**random()**
Return the next random floating point number in the range [0.0, 1.0).

**uniform( a, b)**
Return a random real number \( N \) such that \( a \leq N < b \).

**betavariate( alpha, beta)**
Beta distribution. Conditions on the parameters are \( \alpha > -1 \) and \( \beta > -1 \). Returned values range between 0 and 1.

**expovariate( lambd)**
Exponential distribution. \( \lambda \) is 1.0 divided by the desired mean. (The parameter would be called `\`lambda", but that is a reserved word in Python.) Returned values range from 0 to positive infinity.

**gammavariate( alpha, beta)**
Gamma distribution. *(Not the gamma function!)* Conditions on the parameters are $alpha > 0$ and $beta > 0$.

**gauss**( $mu$, $sigma$)
Gaussian distribution. $mu$ is the mean, and $sigma$ is the standard deviation. This is slightly faster than the `normalvariate()` function defined below.

**lognormvariate**( $mu$, $sigma$)
Log normal distribution. If you take the natural logarithm of this distribution, you'll get a normal distribution with mean $mu$ and standard deviation $sigma$. $mu$ can have any value, and $sigma$ must be greater than zero.

**normalvariate**( $mu$, $sigma$)
Normal distribution. $mu$ is the mean, and $sigma$ is the standard deviation.

**vonmisesvariate**( $mu$, $kappa$)
$mu$ is the mean angle, expressed in radians between 0 and $2*\pi$, and $kappa$ is the concentration parameter, which must be greater than or equal to zero. If $kappa$ is equal to zero, this distribution reduces to a uniform random angle over the range 0 to $2*\pi$.

**paretovariate**( $alpha$)
Pareto distribution. $alpha$ is the shape parameter.

**weibullvariate**( $alpha$, $beta$)
Weibull distribution. $alpha$ is the scale parameter and $beta$ is the shape parameter.

Alternative Generators

**class WichmannHill**([seed])
Class that implements the Wichmann-Hill algorithm as the core generator. Has all of the same methods as `Random` plus the `whseed` method described below. Because this class is implemented in pure Python, it is not threadsafe and may require locks between calls. The period of the generator
is 6,953,607,871,644 which is small enough to require care that two independent random sequences do not overlap.

**whseed([x])**

This is obsolete, supplied for bit-level compatibility with versions of Python prior to 2.1. See `seed` for details. `whseed` does not guarantee that distinct integer arguments yield distinct internal states, and can yield no more than about $2^{*24}$ distinct internal states in all.

**class SystemRandom([seed])**

Class that uses the `os.urandom()` function for generating random numbers from sources provided by the operating system. Not available on all systems. Does not rely on software state and sequences are not reproducible. Accordingly, the `seed()` and `jumpahead()` methods have no effect and are ignored. The `getstate()` and `setstate()` methods raise `NotImplementedError` if called. New in version 2.4.

**See Also:**

5.10 whrandom -- Pseudo-random number generator

Deprecated since release 2.1. Use random instead.

Note: This module was an implementation detail of the random module in releases of Python prior to 2.1. It is no longer used. Please do not use this module directly; use random instead.

This module implements a Wichmann-Hill pseudo-random number generator class that is also named whrandom. Instances of the whrandom class conform to the Random Number Generator interface described in the docs for the random module. They also offer the following method, specific to the Wichmann-Hill algorithm:

```
seed( [x, y, z])
```

Initializes the random number generator from the integers x, y and z. When the module is first imported, the random number is initialized using values derived from the current time. If x, y, and z are either omitted or 0, the seed will be computed from the current system time. If one or two of the parameters are 0, but not all three, the zero values are replaced by ones. This causes some apparently different seeds to be equal, with the corresponding result on the pseudo-random series produced by the generator.

Other supported methods include:

```
choice( seq)
```

Chooses a random element from the non-empty sequence seq and returns it.

```
randint( a, b)
```

Returns a random integer N such that $a \leq N \leq b$.

```
random()
```

Returns the next random floating point number in the range [0.0 ... 1.0).
**seed** \((x, y, z)\)

Initializes the random number generator from the integers \(x, y\) and \(z\). When the module is first imported, the random number is initialized using values derived from the current time.

**uniform** \((a, b)\)

Returns a random real number \(N\) such that \(a \leq N < b\).

When imported, the `whrandom` module also creates an instance of the `whrandom` class, and makes the methods of that instance available at the module level. Therefore one can write either \(N = \text{whrandom.random}()\) or:

```python
    generator = whrandom.whrandom()
    N = generator.random()
```

Note that using separate instances of the generator leads to independent sequences of pseudo-random numbers.

### See Also:

Module `random`:

Generators for various random distributions and documentation for the Random Number Generator interface.

5.11 bisect -- Array bisection algorithm

This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called bisect because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

-bisect_left( *list*, *item*, *lo*, *hi* )

  Locate the proper insertion point for *item* in *list* to maintain sorted order. The parameters *lo* and *hi* may be used to specify a subset of the list which should be considered; by default the entire list is used. If *item* is already present in *list*, the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to *list*.insert(). This assumes that *list* is already sorted. New in version 2.1.

-bisect_right( *list*, *item*, *lo*, *hi* )

  Similar to bisect_left(), but returns an insertion point which comes after (to the right of) any existing entries of *item* in *list*. New in version 2.1.

-bisect(...)

  Alias for bisect_right().

-insort_left( *list*, *item*, *lo*, *hi* )

  Insert *item* in *list* in sorted order. This is equivalent to *list*.insert(bisect.bisect_left(*list*, *item*, *lo*, *hi*), *item*). This assumes that *list* is already sorted. New in version 2.1.

-insort_right( *list*, *item*, *lo*, *hi* )
Similar to \texttt{insort\_left()}, but inserting \texttt{item} in \texttt{list} after any existing entries of \texttt{item}. New in version 2.1.

\texttt{insort(...)}

Alias for \texttt{insort\_right()}.

Subsections

- \texttt{5.11.1 Examples}

---

Previous: \texttt{5.10 \texttt{whrandom}}  Up: \texttt{5. Miscellaneous Services}  Next: \texttt{5.11.1 Examples}

Release 2.4.4c1, documentation updated on 11 October 2006.
See \texttt{About this document...} for information on suggesting changes.
5.11.1 Examples

The bisect() function is generally useful for categorizing numeric data. This example uses bisect() to look up a letter grade for an exam total (say) based on a set of ordered numeric breakpoints: 85 and up is an `A', 75..84 is a `B', etc.

```python
>>> grades = "FEDCBA"
>>> breakpoints = [30, 44, 66, 75, 85]
>>> from bisect import bisect
>>> def grade(total):
...     return grades[bisect(breakpoints, total)]
...     ...
>>> grade(66)
'C'
>>> map(grade, [33, 99, 77, 44, 12, 88])
['E', 'A', 'B', 'D', 'F', 'A']
```
5.12 collections -- High-performance container datatypes

New in version 2.4.

This module implements high-performance container datatypes. Currently, the only datatype is a deque. Future additions may include B-trees and Fibonacci heaps.

**deque([[iterable]])**

Returns a new deque object initialized left-to-right (using `append()`) with data from `iterable`. If `iterable` is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced "deck" and is short for "double-ended queue"). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same $O(1)$ performance in either direction.

Though `list` objects support similar operations, they are optimized for fast fixed-length operations and incur $O(n)$ memory movement costs for "pop(0)" and "insert(0, v)" operations which change both the size and position of the underlying data representation. New in version 2.4.

Deque objects support the following methods:

**append(x)**

Add `x` to the right side of the deque.

**appendleft(x)**

Add `x` to the left side of the deque.

**clear()**

Remove all elements from the deque leaving it with length 0.

**extend(iterable)**
Extend the right side of the deque by appending elements from the iterable argument.

**extendleft**( iterable)
Extend the left side of the deque by appending elements from iterable. Note, the series of left appends results in reversing the order of elements in the iterable argument.

**pop()**
Remove and return an element from the right side of the deque. If no elements are present, raises an IndexError.

**popleft()**
Remove and return an element from the left side of the deque. If no elements are present, raises an IndexError.

**rotate**( n)
Rotate the deque n steps to the right. If n is negative, rotate to the left. Rotating one step to the right is equivalent to: "d.appendleft(d.pop())".

In addition to the above, deques support iteration, pickling, "len(d)", "reversed(d)" , "copy.copy(d)" , "copy.deepcopy(d)" , membership testing with the in operator, and subscript references such as "d[-1]".

Example:

```python
>>> from collections import deque
>>> d = deque('ghi')  # make a new deque with three i
... for elem in d:    # iterate over the deque's elements
  print elem.upper()
G
H
I

>>> d.append('j')    # add a new entry to the right
>>> d.appendleft('f') # add a new entry to the left side
>>> d               # show the representation of the deque
deque(['f', 'g', 'h', 'i', 'j'])

>>> d.pop()          # return and remove the rightmost entry
'j'
```
>>> d.popleft()  # return and remove the leftmost item
'f'

>>> list(d)  # list the contents of the deque
['g', 'h', 'i']

>>> d[0]  # peek at leftmost item
'g'

>>> d[-1]  # peek at rightmost item
'i'

>>> list(reversed(d))  # list the contents of a deque
['i', 'h', 'g']

>>> 'h' in d  # search the deque
True

>>> d.extend('jkl')  # add multiple elements at once

>>> d  # current state of the deque
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> d.rotate(1)  # right rotation

>>> d  # current state of the deque
deque(['l', 'g', 'h', 'i', 'j', 'k'])

>>> d.rotate(-1)  # left rotation

>>> d  # current state of the deque
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> deque(reversed(d))  # make a new deque in reverse order
deque(['l', 'k', 'j', 'i', 'h', 'g'])

>>> d.clear()  # empty the deque

>>> d.pop()  # cannot pop from an empty deque

Traceback (most recent call last):
  File "<pyshell#6>", line 1, in -toplevel-
    d.pop()
IndexError: pop from an empty deque

>>> d.extendleft('abc')  # extendleft() reverses the input order

>>> d  # current state of the deque
deque(['c', 'b', 'a'])

>>> d.extendleft('abc')

>>> d  # current state of the deque
deque(['a', 'b', 'c'])

Subsections

- 5.12.1 Recipes
5.12.1 Recipes

This section shows various approaches to working with deques.

The rotate() method provides a way to implement deque slicing and deletion. For example, a pure python implementation of del d[n] relies on the rotate() method to position elements to be popped:

```python
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement deque slicing, use a similar approach applying rotate() to bring a target element to the left side of the deque. Remove old entries with popleft(), add new entries with extend(), and then reverse the rotation.

With minor variations on that approach, it is easy to implement Forth style stack manipulations such as dup, drop, swap, over, pick, rot, and roll.

A roundrobin task server can be built from a deque using popleft() to select the current task and append() to add it back to the tasklist if the input stream is not exhausted:

```python
def roundrobin(*iterables):
    pending = deque(iter(i) for i in iterables)
    while pending:
        task = pending.popleft()
        try:
            yield task.next()
        except StopIteration:
            continue
        pending.append(task)

>>> for value in roundrobin('abc', 'd', 'efgh'):
...     print value
```

```
a
d
e
b
f
c
g```
Multi-pass data reduction algorithms can be succinctly expressed and efficiently coded by extracting elements with multiple calls to `popleft()`, applying the reduction function, and calling `append()` to add the result back to the queue.

For example, building a balanced binary tree of nested lists entails reducing two adjacent nodes into one by grouping them in a list:

```python
def maketree(iterable):
    d = deque(iterable)
    while len(d) > 1:
        pair = [d.popleft(), d.popleft()]
        d.append(pair)
    return list(d)

>>> print maketree('abcdefgh')
[[[['a', 'b'], ['c', 'd']], [['e', 'f'], ['g', 'h']]]]
```
5.13 heapq -- Heap queue algorithm

New in version 2.3.

This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are arrays for which \(heap[k] \leq heap[2*k+1]\) and \(heap[k] \leq heap[2*k+2]\) for all \(k\), counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that \(heap[0]\) is always its smallest element.

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our pop method returns the smallest item, not the largest (called a "min heap" in textbooks; a "max heap" is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: \(heap[0]\) is the smallest item, and \(heap.sort()\) maintains the heap invariant!

To create a heap, use a list initialized to [], or you can transform a populated list into a heap via function heapify().

The following functions are provided:

**heappush** *(heap, item)*

Push the value item onto the heap, maintaining the heap invariant.

**heappop** *(heap)*

Pop and return the smallest item from the heap, maintaining the heap invariant. If the heap is empty, IndexError is raised.

**heapify** *(x)*
Transform list \( x \) into a heap, in-place, in linear time.

**heapprereplace** \((heap, item)\)

Pop and return the smallest item from the heap, and also push the new item. The heap size doesn't change. If the heap is empty, IndexError is raised. This is more efficient than heappop() followed by heappush(), and can be more appropriate when using a fixed-size heap. Note that the value returned may be larger than item! That constrains reasonable uses of this routine unless written as part of a conditional replacement:

\[
\text{if item > heap[0]:} \\
\text{item = heapprereplace(heap, item)}
\]

Example of use:

```python
>>> from heapq import heappush, heappop
>>> heap = []
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> for item in data:
...    heappush(heap, item)
... ...
>>> sorted = []
>>> while heap:
...    sorted.append(heappop(heap))
... ...
>>> print sorted
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> data.sort()
>>> print data == sorted
True
>>>```

The module also offers two general purpose functions based on heaps.

**nlargest** \((n, iterable)\)

Return a list with the \( n \) largest elements from the dataset defined by iterable. Equivalent to: sorted(iterable, reverse=True)[:n]
New in version 2.4.

**nsmallest** \((n, iterable)\)

Return a list with the \( n \) smallest elements from the dataset defined by iterable. Equivalent to: sorted(iterable)[:n] New in version 2.4.

Both functions perform best for smaller values of \( n \). For larger values, it is more
efficient to use the `sorted()` function. Also, when `n==1`, it is more efficient to use the builtin `min()` and `max()` functions.

Subsections

- 5.13.1 Theory
5.13.1 Theory

(This explanation is due to François Pinard. The Python code for this module was contributed by Kevin O'Connor.)

Heaps are arrays for which \( a[k] \leq a[2*k+1] \) and \( a[k] \leq a[2*k+2] \) for all \( k \), counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that \( a[0] \) is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are \( k \), not \( a[k] \):

\[
\begin{array}{cccccccccccc}
0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14 \\
\end{array}
\]

In the tree above, each cell \( k \) is topping \( 2*k+1 \) and \( 2*k+2 \). In an usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell "wins" over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the overall winner. The simplest algorithmic way to remove it and find the "next" winner is to move some loser (let's say cell 30 in the diagram above) into the 0 position, and then percolate this new 0 down the tree, exchanging values, until the invariant is re-established. This is clearly logarithmic on the total number of items in the tree. By iterating over all items, you get an \( O(n \log n) \) sort.

A nice feature of this sort is that you can efficiently insert new items while the
sort is going on, provided that the inserted items are not "better" than the last 0'th element you extracted. This is especially useful in simulation contexts, where the tree holds all incoming events, and the "win" condition means the smallest scheduled time. When an event schedule other events for execution, they are scheduled into the future, so they can easily go into the heap. So, a heap is a good structure for implementing schedulers (this is what I used for my MIDI sequencer :-).

Various structures for implementing schedulers have been extensively studied, and heaps are good for this, as they are reasonably speedy, the speed is almost constant, and the worst case is not much different than the average case. However, there are other representations which are more efficient overall, yet the worst cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all know that a big sort implies producing "runs" (which are pre-sorted sequences, which size is usually related to the amount of CPU memory), followed by a merging passes for these runs, which merging is often very cleverly organised. It is very important that the initial sort produces the longest runs possible. Tournaments are a good way to that. If, using all the memory available to hold a tournament, you replace and percolate items that happen to fit the current run, you'll produce runs which are twice the size of the memory for random input, and much better for input fuzzily ordered.

Moreover, if you output the 0'th item on disk and get an input which may not fit in the current tournament (because the value "wins" over the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a `heap' module around. :-)

---

**Footnotes**
... organised

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had to be very clever to ensure (far in advance) that each tape movement will be the most effective possible (that is, will best participate at "progressing" the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)

Previous: 5.13 heapq  Up: 5.13 heapq  Next: 5.14 array

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.14 array -- Efficient arrays of numeric values

This module defines an object type which can efficiently represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a type code, which is a single character. The following type codes are defined:

<table>
<thead>
<tr>
<th>Type code</th>
<th>C Type</th>
<th>Python Type</th>
<th>Minimum size in bytes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'c'</td>
<td>char</td>
<td>character</td>
<td>1</td>
</tr>
<tr>
<td>'b'</td>
<td>signed char</td>
<td>int</td>
<td>1</td>
</tr>
<tr>
<td>'B'</td>
<td>unsigned char</td>
<td>int</td>
<td>1</td>
</tr>
<tr>
<td>'u'</td>
<td>Py_UNICODE</td>
<td>Unicode character</td>
<td>2</td>
</tr>
<tr>
<td>'h'</td>
<td>signed short</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'H'</td>
<td>unsigned short</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'i'</td>
<td>signed int</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'I'</td>
<td>unsigned int</td>
<td>long</td>
<td>2</td>
</tr>
<tr>
<td>'l'</td>
<td>signed long</td>
<td>int</td>
<td>4</td>
</tr>
<tr>
<td>'L'</td>
<td>unsigned long</td>
<td>long</td>
<td>4</td>
</tr>
<tr>
<td>'f'</td>
<td>float</td>
<td>float</td>
<td>4</td>
</tr>
<tr>
<td>'d'</td>
<td>double</td>
<td>float</td>
<td>8</td>
</tr>
</tbody>
</table>

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual size can be accessed through the `itemsize` attribute. The values stored for 'L' and 'I' items will be represented as Python long integers when retrieved, because Python's plain integer type cannot represent the full range of C's unsigned (long) integers.

The module defines the following type:

```python
array( typecode[, initializer])
```

Return a new array whose items are restricted by `typecode`, and initialized
from the optional *initializer* value, which must be a list, string, or iterable over elements of the appropriate type. Changed in version 2.4: Formerly, only lists or strings were accepted. If given a list or string, the initializer is passed to the new array's *fromlist(), fromstring(), or fromunicode() method* (see below) to add initial items to the array. Otherwise, the iterable initializer is passed to the *extend() method*.

**ArrayType**

Obsolete alias for *array*.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, *TypeError* is raised. Array objects also implement the buffer interface, and may be used wherever buffer objects are supported.

The following data items and methods are also supported:

**typecode**

The typecode character used to create the array.

**itemsize**

The length in bytes of one array item in the internal representation.

**append(x)**

Append a new item with value *x* to the end of the array.

**buffer_info()**

Return a tuple (*address, length*) giving the current memory address and the length in elements of the buffer used to hold array's contents. The size of the memory buffer in bytes can be computed as

*array.buffer_info()[1] * *array.itemsize*. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain *ioctl() operations*. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.

**Note:** When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use
the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code. The buffer interface is documented in the *Python/C API Reference Manual*.

**byteswap()**

``Byteswap`` all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, `RuntimeError` is raised. It is useful when reading data from a file written on a machine with a different byte order.

**count(x)**

Return the number of occurrences of `x` in the array.

**extend(iterable)**

Append items from `iterable` to the end of the array. If `iterable` is another array, it must have exactly the same type code; if not, `TypeError` will be raised. If `iterable` is not an array, it must be iterable and its elements must be the right type to be appended to the array. Changed in version 2.4: Formerly, the argument could only be another array.

**fromfile(f, n)**

Read `n` items (as machine values) from the file object `f` and append them to the end of the array. If less than `n` items are available, `EOFError` is raised, but the items that were available are still inserted into the array. `f` must be a real built-in file object; something else with a `read()` method won't do.

**fromlist(list)**

Append items from the list. This is equivalent to "for `x` in `list`:
`a.append(x)`"except that if there is a type error, the array is unchanged.

**fromstring(s)**

Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the `fromfile()` method).

**fromunicode(s)**

Extends this array with data from the given unicode string. The array must
be a type 'u' array; otherwise a ValueError is raised. Use "array.fromstring(ustr.decode(enc))" to append Unicode data to an array of some other type.

**index**(*x*)

Return the smallest *i* such that *i* is the index of the first occurrence of *x* in the array.

**insert**(*i*, *x*)

Insert a new item with value *x* in the array before position *i*. Negative values are treated as being relative to the end of the array.

**pop**(*i*)

Removes the item with the index *i* from the array and returns it. The optional argument defaults to -1, so that by default the last item is removed and returned.

**read**(*f*, *n*)

*Deprecated since release 1.5.1.* Use the fromfile() method.

Read *n* items (as machine values) from the file object *f* and append them to the end of the array. If less than *n* items are available, EOFError is raised, but the items that were available are still inserted into the array. *f* must be a real built-in file object; something else with a read() method won't do.

**remove**(*x*)

Remove the first occurrence of *x* from the array.

**reverse**()

Reverse the order of the items in the array.

**tofile**(*f*)

Write all items (as machine values) to the file object *f*.

**tolist**()

Convert the array to an ordinary list with the same items.
**tostring()**

Convert the array to an array of machine values and return the string representation (the same sequence of bytes that would be written to a file by the tofile() method.)

**tounicode()**

Convert the array to a unicode string. The array must be a type 'u' array; otherwise a ValueError is raised. Use array.tostring().decode(enc) to obtain a unicode string from an array of some other type.

**write(f)**

*Deprecated since release 1.5.1.* Use the tofile() method.

Write all items (as machine values) to the file object f.

When an array object is printed or converted to a string, it is represented as array(typecode, initializer). The initializer is omitted if the array is empty, otherwise it is a string if the typecode is 'c', otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using reverse quotes (``), so long as the array() function has been imported using from array import array. Examples:

```python
array('l')
array('c', 'hello world')
array('u', u'hello \textbackslash u2641')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
```

5.15 sets -- Unordered collections of unique elements

New in version 2.3.

The sets module provides classes for constructing and manipulating unordered collections of unique elements. Common uses include membership testing, removing duplicates from a sequence, and computing standard math operations on sets such as intersection, union, difference, and symmetric difference.

Like other collections, sets support $x \text{ in } \textit{set}$, $\text{len}(\textit{set})$, and $\text{for } x \text{ in } \textit{set}$. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

Most set applications use the \texttt{Set} class which provides every set method except for \texttt{__hash__}(). For advanced applications requiring a hash method, the \texttt{ImmutableSet} class adds a \texttt{__hash__}() method but omits methods which alter the contents of the set. Both \texttt{Set} and \texttt{ImmutableSet} derive from \texttt{BaseSet}, an abstract class useful for determining whether something is a set: $\text{isinstance}(\textit{obj}, \texttt{BaseSet})$.

The set classes are implemented using dictionaries. Accordingly, the requirements for set elements are the same as those for dictionary keys; namely, that the element defines both \texttt{__eq__} and \texttt{__hash__}. As a result, sets cannot contain mutable elements such as lists or dictionaries. However, they can contain immutable collections such as tuples or instances of \texttt{ImmutableSet}. For convenience in implementing sets of sets, inner sets are automatically converted to immutable form, for example, $\text{Set}([[\text{Set}(['\text{dog}'])]])$ is transformed to $\text{Set}([[\text{ImmutableSet}(['\text{dog}'])]])$.

\texttt{class Set([iterable])}

Constructs a new empty \texttt{Set} object. If the optional \texttt{iterable} parameter is supplied, updates the set with elements obtained from iteration. All of the elements in \texttt{iterable} should be immutable or be transformable to an
immutable using the protocol described in section 5.15.3.

class ImmutableSet([iterable])

Constructs a new empty ImmutableSet object. If the optional iterable parameter is supplied, updates the set with elements obtained from iteration. All of the elements in iterable should be immutable or be transformable to an immutable using the protocol described in section 5.15.3.

Because ImmutableSet objects provide a __hash__() method, they can be used as set elements or as dictionary keys. ImmutableSet objects do not have methods for adding or removing elements, so all of the elements must be known when the constructor is called.

---

Subsections

- 5.15.1 Set Objects
- 5.15.2 Example
- 5.15.3 Protocol for automatic conversion to immutable
- 5.15.4 Comparison to the built-in set types
### 5.15.1 Set Objects

Instances of Set and ImmutableSet both provide the following operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>len(s)</code></td>
<td></td>
<td>cardinality of set s</td>
</tr>
<tr>
<td><code>x in s</code></td>
<td></td>
<td>test x for membership in s</td>
</tr>
<tr>
<td><code>x not in s</code></td>
<td></td>
<td>test x for non-membership in s</td>
</tr>
<tr>
<td><code>s.issubset(t)</code></td>
<td><code>s &lt;= t</code></td>
<td>test whether every element in s is in t</td>
</tr>
<tr>
<td><code>s.issuperset(t)</code></td>
<td><code>s &gt;= t</code></td>
<td>test whether every element in t is in s</td>
</tr>
<tr>
<td><code>s.union(t)</code></td>
<td>`s</td>
<td>t`</td>
</tr>
<tr>
<td><code>s.intersection(t)</code></td>
<td><code>s &amp; t</code></td>
<td>new set with elements common to s and t</td>
</tr>
<tr>
<td><code>s.difference(t)</code></td>
<td><code>s - t</code></td>
<td>new set with elements in s but not in t</td>
</tr>
<tr>
<td><code>s.symmetric_difference(t)</code></td>
<td><code>s ^ t</code></td>
<td>new set with elements in either s or t but not both</td>
</tr>
<tr>
<td><code>s.copy()</code></td>
<td></td>
<td>new set with a shallow copy of s</td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `union()`, `intersection()`, `difference()`, and `symmetric_difference()` will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `Set('abc') & 'cbs'` in favor of the more readable `Set('abc').intersection('cbs')`. Changed in version 2.3.1: Formerly all arguments were required to be sets.

In addition, both Set and ImmutableSet support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is
greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so all of the following return False: $a < b$, $a = b$, or $a > b$. Accordingly, sets do not implement the `__cmp__` method.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

The following table lists operations available in `ImmutableSet` but not found in `Set`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>hash(s)</code></td>
<td>returns a hash value for $s$</td>
</tr>
</tbody>
</table>

The following table lists operations available in `Set` but not found in `ImmutableSet`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>s.update(t)</code></td>
<td>$s</td>
<td>= t$</td>
</tr>
<tr>
<td><code>s.intersection_update(t)</code></td>
<td>$s &amp;</td>
<td>= t$</td>
</tr>
<tr>
<td><code>s.difference_update(t)</code></td>
<td>$s -= t$</td>
<td>return set $s$ after removing elements found in $t$</td>
</tr>
<tr>
<td><code>s.symmetric_difference_update(t)</code></td>
<td>$s ^= t$</td>
<td>return set $s$ with elements from $s$ or $t$ but not both</td>
</tr>
<tr>
<td><code>s.add(x)</code></td>
<td></td>
<td>add element $x$ to set $s$</td>
</tr>
<tr>
<td>Method</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>----------</td>
<td>-----------------------------------------------------------------------------</td>
<td></td>
</tr>
<tr>
<td><code>s.remove(x)</code></td>
<td>remove <code>x</code> from set <code>s</code>; raises KeyError if not present</td>
<td></td>
</tr>
<tr>
<td><code>s.discard(x)</code></td>
<td>removes <code>x</code> from set <code>s</code> if present</td>
<td></td>
</tr>
<tr>
<td><code>s.pop()</code></td>
<td>remove and return an arbitrary element from <code>s</code>; raises KeyError if empty</td>
<td></td>
</tr>
<tr>
<td><code>s.clear()</code></td>
<td>remove all elements from set <code>s</code></td>
<td></td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `update()`, `intersection_update()`, `difference_update()`, and `symmetric_difference_update()` will accept any iterable as an argument. Changed in version 2.3.1: Formerly all arguments were required to be sets.

Also note, the module also includes a `union_update()` method which is an alias for `update()`. The method is included for backwards compatibility. Programmers should prefer the `update()` method because it is supported by the builtin `set()` and `frozenset()` types.
5.15.2 Example

```python
>>> from sets import Set
>>> engineers = Set(['John', 'Jane', 'Jack', 'Janice'])
>>> programmers = Set(['Jack', 'Sam', 'Susan', 'Janice'])
>>> managers = Set(['Jane', 'Jack', 'Susan', 'Zack'])
>>> employees = engineers | programmers | managers # union
>>> engineering_management = engineers & managers # inter
>>> fulltime_management = managers - engineers - programmers # diffe
>>> engineers.add('Marvin') # add e
>>> print engineers
Set(['Jane', 'Marvin', 'Janice', 'John', 'Jack'])
>>> employees.issuperset(engineers) # superset test
False
>>> employees.union_update(engineers) # update from another
>>> employees.issuperset(engineers)
True
>>> for group in [engineers, programmers, managers, employees]:
...     group.discard('Susan') # unconditionally remo
...     print group
...                      group
true
Set(['Jane', 'Marvin', 'Janice', 'John', 'Jack'])
Set(['Janice', 'Jack', 'Sam'])
Set(['Jane', 'Zack', 'Jack'])
Set(['Jack', 'Sam', 'Jane', 'Marvin', 'Janice', 'John', 'Zack'])
```

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.15.3 Protocol for automatic conversion to immutable

Sets can only contain immutable elements. For convenience, mutable Set objects are automatically copied to an ImmutableSet before being added as a set element.

The mechanism is to always add a hashable element, or if it is not hashable, the element is checked to see if it has an __as_immutable__() method which returns an immutable equivalent.

Since Set objects have a __as_immutable__() method returning an instance of ImmutableSet, it is possible to construct sets of sets.

A similar mechanism is needed by the __contains__() and remove() methods which need to hash an element to check for membership in a set. Those methods check an element for hashability and, if not, check for a __as_temporarily_immutable__() method which returns the element wrapped by a class that provides temporary methods for __hash__(), __eq__(), and __ne__().

The alternate mechanism spares the need to build a separate copy of the original mutable object.

Set objects implement the __as_temporarily_immutable__() method which returns the Set object wrapped by a new class _TemporarilyImmutableSet.

The two mechanisms for adding hashability are normally invisible to the user; however, a conflict can arise in a multi-threaded environment where one thread is updating a set while another has temporarily wrapped it in _TemporarilyImmutableSet. In other words, sets of mutable sets are not thread-safe.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
5.15.4 Comparison to the built-in set types

The built-in set and frozenset types were designed based on lessons learned from the sets module. The key differences are:

- Set and ImmutableSet were renamed to set and frozenset.
- There is no equivalent to BaseSet. Instead, use `isinstance(x, (set, frozenset))`.
- The hash algorithm for the built-ins performs significantly better (fewer collisions) for most datasets.
- The built-in versions have more space efficient pickles.
- The built-in versions do not have a `union_update()` method. Instead, use the `update()` method which is equivalent.
- The built-in versions do not have a `_repr(sorted=True)` method. Instead, use the built-in `repr()` and `sorted()` functions: `repr(sorted(s))`.
- The built-in version does not have a protocol for automatic conversion to immutable. Many found this feature to be confusing and no one in the community reported having found real uses for it.
5.16 itertools -- Functions creating iterators for efficient looping

New in version 2.3.

This module implements a number of iterator building blocks inspired by constructs from the Haskell and SML programming languages. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Standardization helps avoid the readability and reliability problems which arise when many different individuals create their own slightly varying implementations, each with their own quirks and naming conventions.

The tools are designed to combine readily with one another. This makes it easy to construct more specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence $f(0), f(1), \ldots$ . This toolbox provides `imap()` and `count()` which can be combined to form `imap(f, count())` and produce an equivalent result.

Likewise, the functional tools are designed to work well with the high-speed functions provided by the `operator` module.

The module author welcomes suggestions for other basic building blocks to be added to future versions of the module.

Whether cast in pure python form or compiled code, tools that use iterators are more memory efficient (and faster) than their list based counterparts. Adopting the principles of just-in-time manufacturing, they create data when and where needed instead of consuming memory with the computer equivalent of "inventory".
The performance advantage of iterators becomes more acute as the number of elements increases - at some point, lists grow large enough to severely impact memory cache performance and start running slowly.

Release 2.4.4c1, documentation updated on 11 October 2006.
See *About this document* for information on suggesting changes.
5.16.1 Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

**chain( *iterables)**

Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Equivalent to:

```python
def chain(*iterables):
    for it in iterables:
        for element in it:
            yield element
```

**count([n])**

Make an iterator that returns consecutive integers starting with n. If not specified n defaults to zero. Does not currently support python long integers. Often used as an argument to `imap()` to generate consecutive data points. Also, used with `izip()` to add sequence numbers. Equivalent to:

```python
def count(n=0):
    while True:
        yield n
    n += 1
```

Note, `count()` does not check for overflow and will return negative numbers after exceeding `sys.maxint`. This behavior may change in the future.

**cycle( iterable)**

Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Equivalent to:

```python
def cycle(iterable):
```
```python
saved = []
for element in iterable:
    yield element
    saved.append(element)
while saved:
    for element in saved:
        yield element
```

Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

**dropwhile**(*predicate*, *iterable*)

Make an iterator that drops elements from the iterable as long as the predicate is true; afterwards, returns every element. Note, the iterator does not produce *any* output until the predicate is true, so it may have a lengthy start-up time. Equivalent to:

```python
def dropwhile(predicate, iterable):
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
            break
    for x in iterable:
        yield x
```

**groupby**(*iterable*, *key*)

Make an iterator that returns consecutive keys and groups from the `iterable`. The `key` is a function computing a key value for each element. If not specified or is *None*, `key` defaults to an identity function and returns the element unchanged. Generally, the iterable needs to already be sorted on the same key function.

The returned group is itself an iterator that shares the underlying iterable with `groupby()`. Because the source is shared, when the `groupby` object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```python
groups = []
uniquekeys = []
for k, g in groupby(data, keyfunc):
    groups.append(list(g))  # Store group iterator as a list
    uniquekeys.append(k)
```
groupby() is equivalent to:

```python
class groupby(object):
    def __init__(self, iterable, key=None):
        if key is None:
            key = lambda x: x
        self.keyfunc = key
        self.it = iter(iterable)
        self.tgtkey = self.currkey = self.currvalue = xrange(0)
    def __iter__(self):
        return self
    def next(self):
        while self.currkey == self.tgtkey:
            self.currvalue = self.it.next() # Exit on StopIter
            self.currkey = self.keyfunc(self.currvalue)
            self.tgtkey = self.currkey
        return (self.currkey, self._grouper(self.tgtkey))
    def _grouper(self, tgtkey):
        while self.currkey == tgtkey:
            yield self.currvalue
            self.currvalue = self.it.next() # Exit on StopIter
            self.currkey = self.keyfunc(self.currvalue)
```

New in version 2.4.

**ifilter** *(predicate, iterable)*

Make an iterator that filters elements from iterable returning only those for which the predicate is True. If *predicate* is None, return the items that are true. Equivalent to:

```python
def ifilter(predicate, iterable):
    if predicate is None:
        predicate = bool
    for x in iterable:
        if predicate(x):
            yield x
```

**ifilterfalse** *(predicate, iterable)*

Make an iterator that filters elements from iterable returning only those for which the predicate is False. If *predicate* is None, return the items that are false. Equivalent to:

```python
def ifilterfalse(predicate, iterable):
    if predicate is None:
        predicate = bool
    for x in iterable:
        if not predicate:
```
yield x

imap( function, *iterables)
Make an iterator that computes the function using arguments from each of
the iterables. If function is set to None, then imap() returns the arguments
as a tuple. Like map() but stops when the shortest iterable is exhausted
instead of filling in None for shorter iterables. The reason for the difference
is that infinite iterator arguments are typically an error for map() (because
the output is fully evaluated) but represent a common and useful way of
supplying arguments to imap(). Equivalent to:

def imap(function, *iterables):
    iterables = map(iter, iterables)
    while True:
        args = [i.next() for i in iterables]
        if function is None:
            yield tuple(args)
        else:
            yield function(*args)

islice( iterable, [start,] stop [,, step])
Make an iterator that returns selected elements from the iterable. If start is
non-zero, then elements from the iterable are skipped until start is reached.
Afterward, elements are returned consecutively unless step is set higher
than one which results in items being skipped. If stop is None, then
iteration continues until the iterator is exhausted, if at all; otherwise, it stops
at the specified position. Unlike regular slicing, islice() does not
support negative values for start, stop, or step. Can be used to extract
related fields from data where the internal structure has been flattened (for
example, a multi-line report may list a name field on every third line).
Equivalent to:

def islice(iterable, *args):
    s = slice(*args)
    it = iter(xrange(s.start or 0, s.stop or sys.maxint, s.
    nexti = it.next()
    for i, element in enumerate(iterable):
        if i == nexti:
            yield element
    nexti = it.next()

izip( *iterables)
Make an iterator that aggregates elements from each of the iterables. Like zip() except that it returns an iterator instead of a list. Used for lock-step iteration over several iterables at a time. Equivalent to:

```python
def izip(*iterables):
    iterables = map(iter, iterables)
    while iterables:
        result = [it.next() for it in iterables]
        yield tuple(result)
```

Changed in version 2.4: When no iterables are specified, returns a zero length iterator instead of raising a TypeError exception.

Note, the left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into n-length groups using "izip(*[iter(s)]*n)". For data that doesn't fit n-length groups exactly, the last tuple can be pre-padded with fill values using "izip(*[chain(s, [None]*(n-1))]>*n)".

Note, when izip() is used with unequal length inputs, subsequent iteration over the longer iterables cannot reliably be continued after izip() terminates. Potentially, up to one entry will be missing from each of the left-over iterables. This occurs because a value is fetched from each iterator in-turn, but the process ends when one of the iterators terminates. This leaves the last fetched values in limbo (they cannot be returned in a final, incomplete tuple and they are cannot be pushed back into the iterator for retrieval with it.next()). In general, izip() should only be used with unequal length inputs when you don't care about trailing, unmatched values from the longer iterables.

**repeat** *(object[, times])*

Make an iterator that returns object over and over again. Runs indefinitely unless the times argument is specified. Used as argument to imap() for invariant parameters to the called function. Also used with izip() to create an invariant part of a tuple record. Equivalent to:

```python
def repeat(object, times=None):
    if times is None:
        while True:
            yield object
    else:
```
for i in xrange(times):
    yield object

**starmap** *(function, iterable)*

Make an iterator that computes the function using arguments tuples obtained from the iterable. Used instead of `imap()` when argument parameters are already grouped in tuples from a single iterable (the data has been "pre-zipped"). The difference between `imap()` and `starmap()` parallels the distinction between `function(a, b)` and `function(*c)`. Equivalent to:

```python
def starmap(function, iterable):
    iterable = iter(iterable)
    while True:
        yield function(*iterable.next())
```

**takewhile** *(predicate, iterable)*

Make an iterator that returns elements from the iterable as long as the predicate is true. Equivalent to:

```python
def takewhile(predicate, iterable):
    for x in iterable:
        if predicate(x):
            yield x
        else:
            break
```

**tee** *(iterable[, n=2])*

Return n independent iterators from a single iterable. The case where n==2 is equivalent to:

```python
def tee(iterable):
    def gen(next, data={}, cnt=[0]):
        for i in count():
            if i == cnt[0]:
                item = data[i] = next()
                cnt[0] += 1
            else:
                item = data.pop(i)
                yield item
    it = iter(iterable)
    return (gen(it.next), gen(it.next))
```

Note, once `tee()` has made a split, the original *iterable* should not be used
anywhere else; otherwise, the iterable could get advanced without the tee objects being informed.

Note, this member of the toolkit may require significant auxiliary storage (depending on how much temporary data needs to be stored). In general, if one iterator is going to use most or all of the data before the other iterator, it is faster to use list() instead of tee(). New in version 2.4.
5.16.2 Examples

The following examples show common uses for each tool and demonstrate ways they can be combined.

```python
>>> amounts = [120.15, 764.05, 823.14]
>>> for checknum, amount in izip(count(1200), amounts):
...     print 'Check %d is for $%.2f' % (checknum, amount)
...
Check 1200 is for $120.15
Check 1201 is for $764.05
Check 1202 is for $823.14

>>> import operator
>>> for cube in imap(operator.pow, xrange(1,5), repeat(3)):
...     print cube
...
1
8
27
64

>>> reportlines = ['EuroPython', 'Roster', '', 'alex', '', 'laura', '', 'martin', '', 'walter', '', 'mark']
>>> for name in islice(reportlines, 3, None, 2):
...     print name.title()
...
Alex
Laura
Martin
Walter
Mark

# Show a dictionary sorted and grouped by value
>>> from operator import itemgetter
>>> d = dict(a=1, b=2, c=1, d=2, e=1, f=2, g=3)
>>> di = sorted(d.iteritems(), key=itemgetter(1))
>>> for k, g in groupby(di, key=itemgetter(1)):
...     print k, map(itemgetter(0), g)
...
1 ['a', 'c', 'e']
2 ['b', 'd', 'f']
3 ['g']

# Find runs of consecutive numbers using groupby. The key to the so
# is differencing with a range so that consecutive numbers all appea
# same group.
>>> data = [ 1, 4,5,6, 10, 15,16,17,18, 22, 25,26,27,28]
>>> for k, g in groupby(enumerate(data), lambda (i,x):i-x):
...     print k, map(itemgetter(1), g)
...
... print map(operator.itemgetter(1), g)
...
[1]
[4, 5, 6]
[10]
[15, 16, 17, 18]
[22]
[25, 26, 27, 28]
5.16.3 Recipes

This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The extended tools offer the same high performance as the underlying toolset. The superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring ``vectorized'' building blocks over the use of for-loops and generators which incur interpreter overhead.

```python
def take(n, seq):
    return list(islice(seq, n))

def enumerate(iterable):
    return izip(count(), iterable)

def tabulate(function):
    "Return function(0), function(1), ..."
    return imap(function, count())

def iteritems(mapping):
    return izip(mapping.iterkeys(), mapping.itervalues())

def nth(iterable, n):
    "Returns the nth item"
    return list(islice(iterable, n, n+1))

def all(seq, pred=bool):
    "Returns True if pred(x) is True for every element in the iterab
    for elem in ifilterfalse(pred, seq):
        return False
    return True

def any(seq, pred=bool):
    "Returns True if pred(x) is True for at least one element in the
    for elem in ifilter(pred, seq):
        return True
    return False

def no(seq, pred=bool):
    "Returns True if pred(x) is False for every element in the itera
    for elem in ifilter(pred, seq):
        return False
```
return True

def quantify(seq, pred=bool):
    "Count how many times the predicate is True in the sequence"
return sum(imap(pred, seq))

def padnone(seq):
    """Returns the sequence elements and then returns None indefinitely.
    Useful for emulating the behavior of the built-in map() function"""
return chain(seq, repeat(None))

def ncycles(seq, n):
    "Returns the sequence elements n times"
return chain(*repeat(seq, n))

def dotproduct(vec1, vec2):
return sum(imap(operator.mul, vec1, vec2))

def flatten(listOfLists):
return list(chain(*listOfLists))

def repeatfunc(func, times=None, *args):
    """Repeat calls to func with specified arguments.
    Example: repeatfunc(random.random)
    """
if times is None:
    return starmap(func, repeat(args))
else:
    return starmap(func, repeat(args, times))

def pairwise(iterable):
    "s -> (s0,s1), (s1,s2), (s2, s3), ..."
a, b = tee(iterable)
try:
    b.next()
except StopIteration:
    pass
return izip(a, b)

def grouper(n, iterable, padvalue=None):
    "grouper(3, 'abcdefg', 'x') --> ('a','b','c'), ('d','e','f'), ('x',"
return izip(*[chain(iterable, repeat(padvalue, n-1))]*)
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
5.17 ConfigParser -- Configuration file parser

This module defines the class ConfigParser. The ConfigParser class implements a basic configuration file parser language which provides a structure similar to what you would find on Microsoft Windows INI files. You can use this to write Python programs which can be customized by end users easily.

**Warning:** This library does *not* interpret or write the value-type prefixes used in the Windows Registry extended version of INI syntax.

The configuration file consists of sections, led by a "[section]" header and followed by "name: value" entries, with continuations in the style of RFC 822; "name=value" is also accepted. Note that leading whitespace is removed from values. The optional values can contain format strings which refer to other values in the same section, or values in a special DEFAULT section. Additional defaults can be provided on initialization and retrieval. Lines beginning with "#" or "%;" are ignored and may be used to provide comments.

For example:

```
[My Section]
foodir: %(dir)s/whatever
dir=frob
```

would resolve the "%(dir)s" to the value of "dir" ("frob" in this case). All reference expansions are done on demand.

Default values can be specified by passing them into the ConfigParser constructor as a dictionary. Additional defaults may be passed into the get() method which will override all others.

```
class RawConfigParser([defaults])
```
The basic configuration object. When \textit{defaults} is given, it is initialized into the dictionary of intrinsic defaults. This class does not support the magical interpolation behavior. New in version 2.3.

\textbf{class \texttt{ConfigParser}([\texttt{defaults}]})

Derived class of \texttt{RawConfigParser} that implements the magical interpolation feature and adds optional arguments to the \texttt{get()} and \texttt{items()} methods. The values in \textit{defaults} must be appropriate for the "\% ()s" string interpolation. Note that \texttt{__name__} is an intrinsic default; its value is the section name, and will override any value provided in \textit{defaults}.

All option names used in interpolation will be passed through the \texttt{optionxform()} method just like any other option name reference. For example, using the default implementation of \texttt{optionxform()} (which converts option names to lower case), the values "ou \%(bar)s" and "\fou \%(BAR)s" are equivalent.

\textbf{class \texttt{SafeConfigParser}([\texttt{defaults}]})

Derived class of \texttt{ConfigParser} that implements a more-sane variant of the magical interpolation feature. This implementation is more predictable as well. New applications should prefer this version if they don't need to be compatible with older versions of Python. New in version 2.3.

\textbf{exception \texttt{NoSectionError}}

Exception raised when a specified section is not found.

\textbf{exception \texttt{DuplicateSectionError}}

Exception raised if \texttt{add_section()} is called with the name of a section that is already present.

\textbf{exception \texttt{NoOptionError}}

Exception raised when a specified option is not found in the specified section.

\textbf{exception \texttt{InterpolationError}}

Base class for exceptions raised when problems occur performing string interpolation.
exception InterpolationDepthError
Exception raised when string interpolation cannot be completed because the number of iterations exceeds MAX_INTERPOLATION_DEPTH. Subclass of InterpolationError.

exception InterpolationMissingOptionError
Exception raised when an option referenced from a value does not exist. Subclass of InterpolationError. New in version 2.3.

exception InterpolationSyntaxError
Exception raised when the source text into which substitutions are made does not conform to the required syntax. Subclass of InterpolationError. New in version 2.3.

exception MissingSectionHeaderError
Exception raised when attempting to parse a file which has no section headers.

exception ParsingError
Exception raised when errors occur attempting to parse a file.

MAX_INTERPOLATION_DEPTH
The maximum depth for recursive interpolation for get() when the raw parameter is false. This is relevant only for the ConfigParser class.

See Also:
Module shlex:
Support for creating UNIX shell-like mini-languages which can be used as an alternate format for application configuration files.

Subsections
- 5.17.1 RawConfigParser Objects
- 5.17.2 ConfigParser Objects
- 5.17.3 SafeConfigParser Objects
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
5.17.1 RawConfigParser Objects

RawConfigParser instances have the following methods:

**defaults()**
Return a dictionary containing the instance-wide defaults.

**sections()**
Return a list of the sections available; DEFAULT is not included in the list.

**add_section(section)**
Add a section named *section* to the instance. If a section by the given name already exists, DuplicateSectionError is raised.

**has_section(section)**
Indicates whether the named section is present in the configuration. The DEFAULT section is not acknowledged.

**options(section)**
Returns a list of options available in the specified *section*.

**has_option(section, option)**
If the given section exists, and contains the given option, return True; otherwise return False. New in version 1.6.

**read(filenames)**
Attempt to read and parse a list of filenames, returning a list of filenames which were successfully parsed. If *filenames* is a string or Unicode string, it is treated as a single filename. If a file named in *filenames* cannot be opened, that file will be ignored. This is designed so that you can specify a list of potential configuration file locations (for example, the current directory, the user's home directory, and some system-wide directory), and all existing configuration files in the list will be read. If none of the named files exist, the ConfigParser instance will contain an empty dataset. An application which requires initial values to be loaded from a file should load the required file or files using readfp() before calling read() for any
optional files:

```python
import ConfigParser, os
config = ConfigParser.ConfigParser()
config.readfp(open('defaults.cfg'))
config.read(["site.cfg", os.path.expanduser('~/.myapp.cfg')])
```

Changed in version 2.4: Returns list of successfully parsed filenames.

**readfp** *(fp[, filename]*)

Read and parse configuration data from the file or file-like object in *fp* (only the **readline()** method is used). If *filename* is omitted and *fp* has a *name* attribute, that is used for *filename*; the default is "<???>".

**get** *(section, option)*

Get an *option* value for the named *section*.

**getint** *(section, option)*

A convenience method which coerces the *option* in the specified *section* to an integer.

**getfloat** *(section, option)*

A convenience method which coerces the *option* in the specified *section* to a floating point number.

**getboolean** *(section, option)*

A convenience method which coerces the *option* in the specified *section* to a Boolean value. Note that the accepted values for the option are "1", "yes", "true", and "on", which cause this method to return True, and "0", "no", "false", and "off", which cause it to return False. These string values are checked in a case-insensitive manner. Any other value will cause it to raise ValueError.

**items** *(section)*

Return a list of *(name, value)* pairs for each option in the given *section*.

**set** *(section, option, value)*

If the given section exists, set the given option to the specified value;
otherwise raise NoSectionError. While it is possible to use RawConfigParser (or ConfigParser with raw parameters set to true) for internal storage of non-string values, full functionality (including interpolation and output to files) can only be achieved using string values. New in version 1.6.

```
write(fileobject)
```
Write a representation of the configuration to the specified file object. This representation can be parsed by a future read() call. New in version 1.6.

```
remove_option(section, option)
```
Remove the specified option from the specified section. If the section does not exist, raise NoSectionError. If the option existed to be removed, return True; otherwise return False. New in version 1.6.

```
remove_section(section)
```
Remove the specified section from the configuration. If the section in fact existed, return True. Otherwise return False.

```
optionxform(option)
```
Transforms the option name option as found in an input file or as passed in by client code to the form that should be used in the internal structures. The default implementation returns a lower-case version of option; subclasses may override this or client code can set an attribute of this name on instances to affect this behavior. Setting this to str(), for example, would make option names case sensitive.
5.17.2 ConfigParser Objects

The ConfigParser class extends some methods of the RawConfigParser interface, adding some optional arguments.

**get**( *section*, *option*[, *raw*, *vars]*)

Get an *option* value for the named *section*. All the "%" interpolations are expanded in the return values, based on the defaults passed into the constructor, as well as the options *vars* provided, unless the *raw* argument is true.

**items**( *section*, *raw*, *vars*)

Return a list of (*name*, *value*) pairs for each option in the given *section*. Optional arguments have the same meaning as for the get() method. New in version 2.3.
5.17.3 SafeConfigParser Objects

The SafeConfigParser class implements the same extended interface as ConfigParser, with the following addition:

```python
set(section, option, value)
```

If the given section exists, set the given option to the specified value; otherwise raise NoSectionError. value must be a string (str or unicode); if not, TypeError is raised. New in version 2.4.
5.18 fileinput -- Iterate over lines from multiple input streams

This module implements a helper class and functions to quickly write a loop over standard input or a list of files.

The typical use is:

```python
import fileinput
for line in fileinput.input():
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is `'-'`, it is also replaced by `sys.stdin`. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode. If an I/O error occurs during opening or reading a file, `IOError` is raised.

If `sys.stdin` is used more than once, the second and further use will return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using `sys.stdin.seek(0)`).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last file opened is empty.

It is possible that the last line of a file does not end in a newline character; lines are returned including the trailing newline when it is present.

The following function is the primary interface of this module:

```python
input([files[, inplace[, backup]]])
```

Create an instance of the FileInput class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the FileInput class.
The following functions use the global state created by `input()`; if there is no active state, `RuntimeError` is raised.

**filename()**
Return the name of the file currently being read. Before the first line has been read, returns None.

**lineno()**
Return the cumulative line number of the line that has just been read. Before the first line has been read, returns 0. After the last line of the last file has been read, returns the line number of that line.

**filelineno()**
Return the line number in the current file. Before the first line has been read, returns 0. After the last line of the last file has been read, returns the line number of that line within the file.

**isfirstline()**
Returns true if the line just read is the first line of its file, otherwise returns false.

**isstdin()**
Returns true if the last line was read from `sys.stdin`, otherwise returns false.

**nextfile()**
Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

**close()**
Close the sequence.

The class which implements the sequence behavior provided by the module is
available for subclassing as well:

```python
class FileInput([files[, inplace[, backup]]])
```

Class `FileInput` is the implementation; its methods `filename()`, `lineno()`, `fileline()`, `isfirstline()`, `isstdin()` and `close()` correspond to the functions of the same name in the module. In addition it has a `readline()` method which returns the next input line, and a `__getitem__()` method which implements the sequence behavior. The sequence must be accessed in strictly sequential order; random access and `readline()` cannot be mixed.

**Optional in-place filtering:** if the keyword argument `inplace=1` is passed to `input()` or to the `FileInput` constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the keyword argument `backup='.<some extension>'` is also given, it specifies the extension for the backup file, and the backup file remains around; by default, the extension is `'.bak'` and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

**Caveat:** The current implementation does not work for MS-DOS 8+3 filesystems.
5.19 calendar -- General calendar-related functions

This module allows you to output calendars like the UNIX cal program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use setfirstweekday() to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers.

Most of these functions rely on the datetime module which uses an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. This matches the definition of the "proleptic Gregorian" calendar in Dershowitz and Reingold's book "Calendrical Calculations", where it's the base calendar for all computations.

**setfirstweekday**( **weekday** )
Sets the weekday (0 is Monday, 6 is Sunday) to start each week. The values MONDAY, TUESDAY, WEDNESDAY, THURSDAY, FRIDAY, SATURDAY, and SUNDAY are provided for convenience. For example, to set the first weekday to Sunday:

```python
import calendar
calendar.setfirstweekday(calendar.SUNDAY)
```

New in version 2.0.

**firstweekday()**
Returns the current setting for the weekday to start each week. New in version 2.0.

**isleap**( **year** )
Returns True if year is a leap year, otherwise False.

**leapdays**( **y1**, **y2** )
Returns the number of leap years in the range [y1...y2), where y1 and y2 are
years. Changed in version 2.0: This function didn't work for ranges spanning a century change in Python 1.5.2.

**weekday**(year, month, day)
Returns the day of the week (0 is Monday) for year (1970-...), month (1-12), day (1-31).

**weekheader**(n)
Return a header containing abbreviated weekday names. n specifies the width in characters for one weekday.

**monthrange**(year, month)
Returns weekday of first day of the month and number of days in month, for the specified year and month.

**monthcalendar**(year, month)
Returns a matrix representing a month's calendar. Each row represents a week; days outside of the month a represented by zeros. Each week begins with Monday unless set by `setfirstweekday()`.

**prmonth**(theyear, themonth[, w[, l]])
Prints a month's calendar as returned by `month()`.

**month**(theyear, themonth[, w[, l]])
Returns a month's calendar in a multi-line string. If w is provided, it specifies the width of the date columns, which are centered. If l is given, it specifies the number of lines that each week will use. Depends on the first weekday as set by `setfirstweekday()`.

**prcal**(year[, w[, l[c]]])
Prints the calendar for an entire year as returned by `calendar()`.

**calendar**(year[, w[, l[c]]])
Returns a 3-column calendar for an entire year as a multi-line string. Optional parameters w, l, and c are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on
the first weekday as set by \texttt{setfirstweekday()}. The earliest year for which a calendar can be generated is platform-dependent. New in version 2.0.

\texttt{timegm( tuple)}

An unrelated but handy function that takes a time tuple such as returned by the \texttt{gmtime()} function in the \texttt{time} module, and returns the corresponding UNIX timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, \texttt{time.gmtime()} and \texttt{timegm()} are each others' inverse. New in version 2.0.

\textbf{See Also:}

Module \texttt{datetime}:

Object-oriented interface to dates and times with similar functionality to the \texttt{time} module.

Module \texttt{time}:

Low-level time related functions.
5.20 cmd -- Support for line-oriented command interpreters

The Cmd class provides a simple framework for writing line-oriented command interpreters. These are often useful for test harnesses, administrative tools, and prototypes that will later be wrapped in a more sophisticated interface.

```python
class Cmd([completekey, stdin[, stdout]])
```

A Cmd instance or subclass instance is a line-oriented interpreter framework. There is no good reason to instantiate Cmd itself; rather, it's useful as a superclass of an interpreter class you define yourself in order to inherit Cmd's methods and encapsulate action methods.

The optional argument `completekey` is the `readline` name of a completion key; it defaults to Tab. If `completekey` is not `None` and `readline` is available, command completion is done automatically.

The optional arguments `stdin` and `stdout` specify the input and output file objects that the Cmd instance or subclass instance will use for input and output. If not specified, they will default to `sys.stdin` and `sys.stdout`.

Changed in version 2.3: The `stdin` and `stdout` parameters were added.
5.20.1 Cmd Objects

A Cmd instance has the following methods:

**cmdloop([intro])**

Repeatedly issue a prompt, accept input, parse an initial prefix off the received input, and dispatch to action methods, passing them the remainder of the line as argument.

The optional argument is a banner or intro string to be issued before the first prompt (this overrides the `intro` class member).

If the `readline` module is loaded, input will automatically inherit bash-like history-list editing (e.g. `Control-P` scrolls back to the last command, `Control-N` forward to the next one, `Control-F` moves the cursor to the right non-destructively, `Control-B` moves the cursor to the left non-destructively, etc.).

An end-of-file on input is passed back as the string `'EOF'`.

An interpreter instance will recognize a command name "foo" if and only if it has a method `do_foo()`. As a special case, a line beginning with the character "?" is dispatched to the method `do_help()`. As another special case, a line beginning with the character "!" is dispatched to the method `do_shell()` (if such a method is defined).

This method will return when the `postcmd()` method returns a true value. The `stop` argument to `postcmd()` is the return value from the command's corresponding `do_*()` method.

If completion is enabled, completing commands will be done automatically, and completing of commands args is done by calling `complete_foo()` with arguments `text`, `line`, `begidx`, and `endidx`. `text` is the string prefix we are attempting to match: all returned matches must begin with it. `line` is the current input line with leading whitespace removed, `begidx` and `endidx` are the beginning and ending indexes of the prefix text, which could be used to provide different completion depending upon which position the argument
All subclasses of `Cmd` inherit a predefined `do_help()`. This method, called with an argument 'bar', invokes the corresponding method `help_bar()`. With no argument, `do_help()` lists all available help topics (that is, all commands with corresponding `help_*()` methods), and also lists any undocumented commands.

`onecmd(str)`
Interpret the argument as though it had been typed in response to the prompt. This may be overridden, but should not normally need to be; see the `precmd()` and `postcmd()` methods for useful execution hooks. The return value is a flag indicating whether interpretation of commands by the interpreter should stop. If there is a `do_*()` method for the command `str`, the return value of that method is returned, otherwise the return value from the `default()` method is returned.

`emptyline()`
Method called when an empty line is entered in response to the prompt. If this method is not overridden, it repeats the last nonempty command entered.

`default(line)`
Method called on an input line when the command prefix is not recognized. If this method is not overridden, it prints an error message and returns.

`completedefault(text, line, begidx, endidx)`
Method called to complete an input line when no command-specific `complete_*()` method is available. By default, it returns an empty list.

`precmd(line)`
Hook method executed just before the command line `line` is interpreted, but after the input prompt is generated and issued. This method is a stub in `Cmd`; it exists to be overridden by subclasses. The return value is used as the command which will be executed by the `onecmd()` method; the `precmd()` implementation may re-write the command or simply return `line` unchanged.
**postcmd**(*stop, line*)

Hook method executed just after a command dispatch is finished. This method is a stub in **Cmd**; it exists to be overridden by subclasses. *line* is the command line which was executed, and *stop* is a flag which indicates whether execution will be terminated after the call to **postcmd()**; this will be the return value of the **onecmd()** method. The return value of this method will be used as the new value for the internal flag which corresponds to *stop*; returning false will cause interpretation to continue.

**preloop()**

Hook method executed once when **cmdloop()** is called. This method is a stub in **Cmd**; it exists to be overridden by subclasses.

**postloop()**

Hook method executed once when **cmdloop()** is about to return. This method is a stub in **Cmd**; it exists to be overridden by subclasses.

Instances of **Cmd** subclasses have some public instance variables:

**prompt**

The prompt issued to solicit input.

**identchars**

The string of characters accepted for the command prefix.

**lastcmd**

The last nonempty command prefix seen.

**intro**

A string to issue as an intro or banner. May be overridden by giving the **cmdloop()** method an argument.

**doc_header**

The header to issue if the help output has a section for documented commands.

**misc_header**

The header to issue if the help output has a section for miscellaneous help topics (that is, there are **help_*()** methods without corresponding **do_***
() methods).

**undoc_header**

The header to issue if the help output has a section for undocumented commands (that is, there are do_*( ) methods without corresponding help_*( ) methods).

**ruler**

The character used to draw separator lines under the help-message headers. If empty, no ruler line is drawn. It defaults to "=".

**use_rawinput**

A flag, defaulting to true. If true, cmdloop() uses raw_input() to display a prompt and read the next command; if false, sys.stdout.write() and sys.stdin.readline() are used. (This means that by importing readline, on systems that support it, the interpreter will automatically support Emacs-like line editing and command-history keystrokes.)
5.21 shlex -- Simple lexical analysis

New in version 1.5.2.

The shlex class makes it easy to write lexical analyzers for simple syntaxes resembling that of the UNIX shell. This will often be useful for writing minilanguages, (for example, in run control files for Python applications) or for parsing quoted strings.

**Note:** The shlex module currently does not support Unicode input.

The shlex module defines the following functions:

**split**(*s[, comments]*)

Split the string *s* using shell-like syntax. If *comments* is `False` (the default), the parsing of comments in the given string will be disabled (setting the *commenters* member of the shlex instance to the empty string). This function operates in POSIX mode. New in version 2.3.

The shlex module defines the following class:

**class shlex([instream[, infile[, posix]]])**

A shlex instance or subclass instance is a lexical analyzer object. The initialization argument, if present, specifies where to read characters from. It must be a file-/stream-like object with `read()` and `readline()` methods, or a string (strings are accepted since Python 2.3). If no argument is given, input will be taken from `sys.stdin`. The second optional argument is a filename string, which sets the initial value of the infile member. If the *instream* argument is omitted or equal to `sys.stdin`, this second argument defaults to ``stdin``. The *posix* argument was introduced in Python 2.3, and defines the operational mode. When *posix* is not true (default), the shlex instance will operate in compatibility mode. When operating in POSIX mode, shlex will try to be as close as possible to the POSIX shell parsing rules. See section [5.21.1](#).

Module **ConfigParser**: Parser for configuration files similar to the Windows .ini files.

Subsections

- 5.21.1 shlex Objects
- 5.21.2 Parsing Rules

Release 2.4.4c1, documentation updated on 11 October 2006. See [About this document...] for information on suggesting changes.
5.21.1 shlex Objects

A shlex instance has the following methods:

**get_token()**
Return a token. If tokens have been stacked using push_token(), pop a token off the stack. Otherwise, read one from the input stream. If reading encounters an immediate end-of-file, self.eof is returned (the empty string ('') in non-POSIX mode, and None in POSIX mode).

**push_token( str)**
Push the argument onto the token stack.

**read_token()**
Read a raw token. Ignore the pushback stack, and do not interpret source requests. (This is not ordinarily a useful entry point, and is documented here only for the sake of completeness.)

**sourcehook( filename)**
When shlex detects a source request (see source below) this method is given the following token as argument, and expected to return a tuple consisting of a filename and an open file-like object.

Normally, this method first strips any quotes off the argument. If the result is an absolute pathname, or there was no previous source request in effect, or the previous source was a stream (such as sys.stdin), the result is left alone. Otherwise, if the result is a relative pathname, the directory part of the name of the file immediately before it on the source inclusion stack is prepended (this behavior is like the way the C preprocessor handles #include "file.h").

The result of the manipulations is treated as a filename, and returned as the first component of the tuple, with open() called on it to yield the second component. (Note: this is the reverse of the order of arguments in instance initialization!)
This hook is exposed so that you can use it to implement directory search paths, addition of file extensions, and other namespace hacks. There is no corresponding `close' hook, but a shlex instance will call the close() method of the sourced input stream when it returns EOF.

For more explicit control of source stacking, use the push_source() and pop_source() methods.

**push_source**(stream[, filename])

Push an input source stream onto the input stack. If the filename argument is specified it will later be available for use in error messages. This is the same method used internally by the sourcehook method. New in version 2.1.

**pop_source()**

Pop the last-pushed input source from the input stack. This is the same method used internally when the lexer reaches EOF on a stacked input stream. New in version 2.1.

**error_leader**( [file[, line]])

This method generates an error message leader in the format of a UNIX C compiler error label; the format is ""%s", line %d: ", where the "%s" is replaced with the name of the current source file and the "%d" with the current input line number (the optional arguments can be used to override these).

This convenience is provided to encourage shlex users to generate error messages in the standard, parseable format understood by Emacs and other UNIX tools.

Instances of shlex subclasses have some public instance variables which either control lexical analysis or can be used for debugging:

**commenters**

The string of characters that are recognized as comment beginners. All characters from the comment beginner to end of line are ignored. Includes just "#" by default.
**wordchars**  
The string of characters that will accumulate into multi-character tokens. By default, includes all ASCII alphanumerics and underscore.

**whitespace**  
Characters that will be considered whitespace and skipped. Whitespace bounds tokens. By default, includes space, tab, linefeed and carriage-return.

**escape**  
Characters that will be considered as escape. This will be only used in POSIX mode, and includes just "\" by default. New in version 2.3.

**quotes**  
Characters that will be considered string quotes. The token accumulates until the same quote is encountered again (thus, different quote types protect each other as in the shell.) By default, includes ASCII single and double quotes.

**escapedquotes**  
Characters in quotes that will interpret escape characters defined in escape. This is only used in POSIX mode, and includes just "\" by default. New in version 2.3.

**whitespace_split**  
If True, tokens will only be split in whitespaces. This is useful, for example, for parsing command lines with shlex, getting tokens in a similar way to shell arguments. New in version 2.3.

**infile**  
The name of the current input file, as initially set at class instantiation time or stacked by later source requests. It may be useful to examine this when constructing error messages.

**instream**  
The input stream from which this shlex instance is reading characters.

**source**  
This member is None by default. If you assign a string to it, that string will be recognized as a lexical-level inclusion request similar to the "source"
The keyword in various shells. That is, the immediately following token will opened as a filename and input taken from that stream until EOF, at which point the `close()` method of that stream will be called and the input source will again become the original input stream. Source requests may be stacked any number of levels deep.

**debug**

If this member is numeric and 1 or more, a `shlex` instance will print verbose progress output on its behavior. If you need to use this, you can read the module source code to learn the details.

**lineno**

Source line number (count of newlines seen so far plus one).

**token**

The token buffer. It may be useful to examine this when catching exceptions.

**eof**

Token used to determine end of file. This will be set to the empty string ("'"), in non-POSIX mode, and to `None` in POSIX mode. New in version 2.3.
5.21.2 Parsing Rules

When operating in non-POSIX mode, shlex will try to obey to the following rules.

- Quote characters are not recognized within words (\texttt{Do"Not"Separate} is parsed as the single word \texttt{Do"Not"Separate});
- Escape characters are not recognized;
- Enclosing characters in quotes preserve the literal value of all characters within the quotes;
- Closing quotes separate words (\texttt{"Do"Separate} is parsed as \texttt{"Do"} and \texttt{Separate});
- If \texttt{whitespace\_split} is \texttt{False}, any character not declared to be a word character, whitespace, or a quote will be returned as a single-character token. If it is \texttt{True}, shlex will only split words in whitespaces;
- EOF is signaled with an empty string (\texttt{""});
- It's not possible to parse empty strings, even if quoted.

When operating in POSIX mode, shlex will try to obey to the following parsing rules.

- Quotes are stripped out, and do not separate words (\texttt{"Do"Not"Separate} is parsed as the single word \texttt{DoNotSeparate});
- Non-quoted escape characters (e.g. \texttt{"\"}) preserve the literal value of the next character that follows;
- Enclosing characters in quotes which are not part of escapedquotes (e.g. \texttt{"'\"}) preserve the literal value of all characters within the quotes;
- Enclosing characters in quotes which are part of escapedquotes (e.g. \texttt{""\"}) preserves the literal value of all characters within the quotes, with the exception of the characters mentioned in escape. The escape characters retain its special meaning only when followed by the quote in use, or the escape character itself. Otherwise the escape character will be considered a normal character.
- EOF is signaled with a \texttt{None} value;
- Quoted empty strings (\texttt{"'\"}) are allowed;
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6. Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modeled after the Unix or C interfaces, but they are available on most other systems as well. Here's an overview:

- **os**
  
  Miscellaneous operating system interfaces.

- **os.path**
  
  Common pathname manipulations.

- **dircache**
  
  Return directory listing, with cache mechanism.

- **stat**
  
  Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().

- **statcache**
  
  Stat files, and remember results.

- **statvfs**
  
  Constants for interpreting the result of os.statvfs().

- **filecmp**
  
  Compare files efficiently.

- **subprocess**
  
  Subprocess management.

- **popen2**
  
  Subprocesses with accessible standard I/O streams.

- **datetime**
  
  Basic date and time types.

- **time**
  
  Time access and conversions.

- **sched**
  
  General purpose event scheduler.

- **mutex**
  
  Lock and queue for mutual exclusion.

- **getpass**
  
  Portable reading of passwords and retrieval of the userid.

- **curses**
  
  An interface to the curses library, providing portable terminal handling.

- **curses.textpad**
  
  Emacs-like input editing in a curses window.

- **curses.wrapper**
  
  Terminal configuration wrapper for curses programs.

- **curses.ascii**
  
  Constants and set-membership functions for ASCII characters.

- **curses.panel**
  
  A panel stack extension that adds depth to curses windows.
getopt
Portable parser for command line options; support both short and long option names.

optparse
More convenient, flexible, and powerful command-line parsing library.

tempfile
Generate temporary files and directories.

errno
Standard errno system symbols.

glob
UNIX shell style pathname pattern expansion.

fnmatch
UNIX shell style filename pattern matching.

shutil
High-level file operations, including copying.

locale
Internationalization services.

gettext
Multilingual internationalization services.

logging
Logging module for Python based on PEP 282.

platform
Retrieves as much platform identifying data as possible.
6.1 os -- Miscellaneous operating system interfaces

This module provides a more portable way of using operating system dependent functionality than importing a operating system dependent built-in module like `posix` or `nt`.

This module searches for an operating system dependent built-in module like `mac` or `posix` and exports the same functions and data as found there. The design of all Python's built-in operating system dependent modules is such that as long as the same functionality is available, it uses the same interface; for example, the function `os.stat(path)` returns stat information about `path` in the same format (which happens to have originated with the POSIX interface).

Extensions peculiar to a particular operating system are also available through the `os` module, but using them is of course a threat to portability!

Note that after the first time `os` is imported, there is no performance penalty in using functions from `os` instead of directly from the operating system dependent built-in module, so there should be no reason not to use `os`!

The `os` module contains many functions and data values. The items below and in the following sub-sections are all available directly from the `os` module.

**exception error**

This exception is raised when a function returns a system-related error (not for illegal argument types or other incidental errors). This is also known as the built-in exception `OSError`. The accompanying value is a pair containing the numeric error code from `errno` and the corresponding string, as would be printed by the C function `perror()`. See the module `errno`, which contains names for the error codes defined by the underlying operating system.

When exceptions are classes, this exception carries two attributes, `errno` and `strerror`. The first holds the value of the C `errno` variable, and the latter holds the corresponding error message from `strerror()`. For
exceptions that involve a file system path (such as `chdir()` or `unlink()`), the exception instance will contain a third attribute, `filename`, which is the file name passed to the function.

**name**

The name of the operating system dependent module imported. The following names have currently been registered: 'posix', 'nt', 'mac', 'os2', 'ce', 'java', 'riscos'.

**path**

The corresponding operating system dependent standard module for pathname operations, such as `posixpath` or `macpath`. Thus, given the proper imports, `os.path.split(file)` is equivalent to but more portable than `posixpath.split(file)`. Note that this is also an importable module: it may be imported directly as `os.path`.

- [6.1.7 Miscellaneous Functions](#)

---

**Python Library Reference**

6.1.1 Process Parameters

These functions and data items provide information and operate on the current process and user.

**environ**

A mapping object representing the string environment. For example, `environ['HOME']` is the pathname of your home directory (on some platforms), and is equivalent to `getenv("HOME")` in C.

This mapping is captured the first time the `os` module is imported, typically during Python startup as part of processing `site.py`. Changes to the environment made after this time are not reflected in `os.environ`, except for changes made by modifying `os.environ` directly.

If the platform supports the `putenv()` function, this mapping may be used to modify the environment as well as query the environment. `putenv()` will be called automatically when the mapping is modified. **Note:** Calling `putenv()` directly does not change `os.environ`, so it's better to modify `os.environ`. **Note:** On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv()`.

If `putenv()` is not provided, a modified copy of this mapping may be passed to the appropriate process-creation functions to cause child processes to use a modified environment.

If the platform supports the `unsetenv()` function, you can delete items in this mapping to unset environment variables. `unsetenv()` will be called automatically when an item is deleted from `os.environ`.

**chdir**(path)

**fchdir**(fd)

**getcwd**()

These functions are described in ``Files and Directories`` (section 6.1.4).
ctermid()  
Return the filename corresponding to the controlling terminal of the process. Availability: UNIX.

getegid()  
Return the effective group id of the current process. This corresponds to the `set id' bit on the file being executed in the current process. Availability: UNIX.

geteuid()  
Return the current process' effective user id. Availability: UNIX.

getgid()  
Return the real group id of the current process. Availability: UNIX.

groups()  
Return list of supplemental group ids associated with the current process. Availability: UNIX.

glogin()  
Return the name of the user logged in on the controlling terminal of the process. For most purposes, it is more useful to use the environment variable LOGNAME to find out who the user is, or pwd.getpwuid(os.getuid())[0] to get the login name of the currently effective user ID. Availability: UNIX.

gpgid(pid)  
Return the process group id of the process with process id pid. If pid is 0, the process group id of the current process is returned. Availability: UNIX. New in version 2.3.

gpgrp()  
Return the id of the current process group. Availability: UNIX.

 getpid()  
Return the current process id. Availability: UNIX, Windows.
getppid()
Return the parent's process id. Availability: UNIX.

getuid()
Return the current process' user id. Availability: UNIX.

getenv( varname[, value])
Return the value of the environment variable varname if it exists, or value if it doesn't. value defaults to None. Availability: most flavors of UNIX, Windows.

putenv( varname, value)
Set the environment variable named varname to the string value. Such changes to the environment affect subprocesses started with os.system(), popen() or fork() and execv(). Availability: most flavors of UNIX, Windows.

Note: On some platforms, including FreeBSD and Mac OS X, setting environ may cause memory leaks. Refer to the system documentation for putenv.

When putenv() is supported, assignments to items in os.environ are automatically translated into corresponding calls to putenv(); however, calls to putenv() don't update os.environ, so it is actually preferable to assign to items of os.environ.

setegid( egid)
Set the current process's effective group id. Availability: UNIX.

seteuid( euid)
Set the current process's effective user id. Availability: UNIX.

setgid( gid)
Set the current process' group id. Availability: UNIX.

setgroups( groups)
Set the list of supplemental group ids associated with the current process to
groups. groups must be a sequence, and each element must be an integer identifying a group. This operation is typical available only to the superuser. Availability: UNIX. New in version 2.2.

\textbf{setpgrp()}
Calls the system call \texttt{setpgrp()} or \texttt{setpgrp(0, 0)} depending on which version is implemented (if any). See the UNIX manual for the semantics. Availability: UNIX.

\textbf{setpgid}(\textit{pid}, \textit{pgrp})
Calls the system call \texttt{setpgid()} to set the process group id of the process with id \textit{pid} to the process group with id \textit{pgrp}. See the UNIX manual for the semantics. Availability: UNIX.

\textbf{setreuid}(\textit{ruid}, \textit{euid})
Set the current process's real and effective user ids. Availability: UNIX.

\textbf{setregid}(\textit{rgid}, \textit{egid})
Set the current process's real and effective group ids. Availability: UNIX.

\textbf{getsid}(\textit{pid})
Calls the system call \texttt{getsid()}. See the UNIX manual for the semantics. Availability: UNIX. New in version 2.4.

\textbf{setsid()}
Calls the system call \texttt{setsid()}. See the UNIX manual for the semantics. Availability: UNIX.

\textbf{setuid}(\textit{uid})
Set the current process' user id. Availability: UNIX.

\textbf{strerror}(\textit{code})
Return the error message corresponding to the error code in \textit{code}. Availability: UNIX, Windows.

\textbf{umask}(\textit{mask})
Set the current numeric umask and returns the previous umask. Availability:
Unix, Windows.

uname()

Return a 5-tuple containing information identifying the current operating system. The tuple contains 5 strings: (sysname, nodename, release, version, machine). Some systems truncate the nodename to 8 characters or to the leading component; a better way to get the hostname is socket.gethostname() or even socket.gethostbyaddr(socket.gethostname()). Availability: recent flavors of Unix.

unsetenv( varname)

Unset (delete) the environment variable named varname. Such changes to the environment affect subprocesses started with os.system(), popen() or fork() and execv(). Availability: most flavors of Unix, Windows.

When unsetenv() is supported, deletion of items in os.environ is automatically translated into a corresponding call to unsetenv(); however, calls to unsetenv() don't update os.environ, so it is actually preferable to delete items of os.environ.
6.1.2 File Object Creation

These functions create new file objects.

**fdopen**(*fd*, *mode*, *bufsize*)

Return an open file object connected to the file descriptor *fd*. The *mode* and *bufsize* arguments have the same meaning as the corresponding arguments to the built-in `open()` function. Availability: Macintosh, UNIX, Windows.

Changed in version 2.3: When specified, the *mode* argument must now start with one of the letters "r", "w", or "a", otherwise a `ValueError` is raised.

**popen**(*command*, *mode*, *bufsize*)

Open a pipe to or from *command*. The return value is an open file object connected to the pipe, which can be read or written depending on whether *mode* is 'r' (default) or 'w'. The *bufsize* argument has the same meaning as the corresponding argument to the built-in `open()` function. The exit status of the command (encoded in the format specified for `wait()` is available as the return value of the `close()` method of the file object, except that when the exit status is zero (termination without errors), `None` is returned. Availability: Macintosh, UNIX, Windows.

Changed in version 2.0: This function worked unreliably under Windows in earlier versions of Python. This was due to the use of the `_popen()` function from the libraries provided with Windows. Newer versions of Python do not use the broken implementation from the Windows libraries.

**tmpfile**()

Return a new file object opened in update mode ("w+b"). The file has no directory entries associated with it and will be automatically deleted once there are no file descriptors for the file. Availability: Macintosh, UNIX, Windows.

For each of the following `popen()` variants, if *bufsize* is specified, it specifies the buffer size for the I/O pipes. *mode*, if provided, should be the string 'b' or 't'; on Windows this is needed to determine whether the file objects should be
opened in binary or text mode. The default value for mode is 't'.

Also, for each of these variants, on UNIX, cmd may be a sequence, in which case arguments will be passed directly to the program without shell intervention (as with os.spawnv()). If cmd is a string it will be passed to the shell (as with os.system()).

These methods do not make it possible to retrieve the exit status from the child processes. The only way to control the input and output streams and also retrieve the return codes is to use the Popen3 and Popen4 classes from the popen2 module; these are only available on UNIX.

For a discussion of possible deadlock conditions related to the use of these functions, see ``Flow Control Issues'' (section 6.9.2).

**popen2**(cmd[, mode[, bufsize]])

**popen3**(cmd[, mode[, bufsize]])

**popen4**(cmd[, mode[, bufsize]])

(Note that child_stdin, child_stdout, and child_stderr are named from the point of view of the child process, so child_stdin is the child's standard input.)

This functionality is also available in the popen2 module using functions of the same names, but the return values of those functions have a different order.

---

Python Library Reference
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
6.1.3 File Descriptor Operations

These functions operate on I/O streams referred to using file descriptors.

**close** (*fd*)

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `open()` or `pipe()`. To close a ``file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, use its `close()` method.

**dup** (*fd*)

Return a duplicate of file descriptor *fd*. Availability: Macintosh, UNIX, Windows.

**dup2** (*fd, fd2*)

Duplicate file descriptor *fd* to *fd2*, closing the latter first if necessary. Availability: Macintosh, UNIX, Windows.

**fdatasync** (*fd*)

Force write of file with filedescriptor *fd* to disk. Does not force update of metadata. Availability: UNIX.

**fpathconf** (*fd, name*)

Return system configuration information relevant to an open file. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, UNIX 95, UNIX 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted. Availability: Macintosh, UNIX.
If name is a string and is not known, ValueError is raised. If a specific value for name is not supported by the host system, even if it is included in pathconf_names, an OSError is raised with errno.EINVAL for the error number.

**fstat(fd)**  
Return status for file descriptor fd, like stat(). Availability: Macintosh, UNIX, Windows.

**fstatvfs(fd)**  
Return information about the filesystem containing the file associated with file descriptor fd, like statvfs(). Availability: UNIX.

**fsync(fd)**  
Force write of file with file descriptor fd to disk. On UNIX, this calls the native fsync() function; on Windows, the MS _commit() function.

If you're starting with a Python file object f, first do f.flush(), and then do os.fsync(f.fileno()), to ensure that all internal buffers associated with f are written to disk. Availability: Macintosh, UNIX, and Windows starting in 2.2.3.

**ftruncate(fd, length)**  
Truncate the file corresponding to file descriptor fd, so that it is at most length bytes in size. Availability: Macintosh, UNIX.

**isatty(fd)**  
Return True if the file descriptor fd is open and connected to a tty(-like) device, else False. Availability: Macintosh, UNIX.

**lseek(fd, pos, how)**  
Set the current position of file descriptor fd to position pos, modified by how: 0 to set the position relative to the beginning of the file; 1 to set it relative to the current position; 2 to set it relative to the end of the file. Availability: Macintosh, UNIX, Windows.

**open(file, flags[, mode])**
Open the file *file* and set various flags according to *flags* and possibly its mode according to *mode*. The default *mode* is 0777 (octal), and the current umask value is first masked out. Return the file descriptor for the newly opened file. Availability: Macintosh, UNIX, Windows.

For a description of the flag and mode values, see the C run-time documentation; flag constants (like O_RDONLY and O_WRONLY) are defined in this module too (see below).

**Note:** This function is intended for low-level I/O. For normal usage, use the built-in function `open()`, which returns a ``file object'' with `read()` and `write()` methods (and many more). To wrap a file descriptor in a ``file object'', use `fdopen()`.

**openpty()**
Open a new pseudo-terminal pair. Return a pair of file descriptors (master, slave) for the pty and the tty, respectively. For a (slightly) more portable approach, use the pty module. Availability: Macintosh, Some flavors of UNIX.

**pipe()**
Create a pipe. Return a pair of file descriptors (r, w) usable for reading and writing, respectively. Availability: Macintosh, UNIX, Windows.

**read(fd, n)**
Read at most *n* bytes from file descriptor *fd*. Return a string containing the bytes read. If the end of the file referred to by *fd* has been reached, an empty string is returned. Availability: Macintosh, UNIX, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `open()` or `pipe()`. To read a ``file object'' returned by the built-in function `open()` or by `popen()` or `fdopen()`, or `sys.stdin`, use its `read()` or `readline()` methods.
**tcgetpgrp**(fd)
Return the process group associated with the terminal given by *fd* (an open file descriptor as returned by `open()`). Availability: Macintosh, UNIX.

**tcsetpgrp**(fd, pg)
Set the process group associated with the terminal given by *fd* (an open file descriptor as returned by `open()`) to *pg*. Availability: Macintosh, UNIX.

**ttyname**(fd)
Return a string which specifies the terminal device associated with file-descriptor *fd*. If *fd* is not associated with a terminal device, an exception is raised. Availability: Macintosh, UNIX.

**write**(fd, str)
Write the string *str* to file descriptor *fd*. Return the number of bytes actually written. Availability: Macintosh, UNIX, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `open()` or `pipe()`. To write a "file object" returned by the built-in function `open()` or by `popen()` or `fdopen()`, or `sys.stdout` or `sys.stderr`, use its `write()` method.

The following data items are available for use in constructing the *flags* parameter to the `open()` function.

0_RDONLY
0_WRONLY
0_RDWR
0_APPEND
0_CREAT
0_EXCL
0_TRUNC

Options for the *flag* argument to the `open()` function. These can be bitwise OR’d together. Availability: Macintosh, UNIX, Windows.
More options for the flag argument to the open() function. Availability: Macintosh, UNIX.

O_BINARY
Option for the flag argument to the open() function. This can be bit-wise OR'd together with those listed above. Availability: Windows.

O_NOINHERIT
O_SHORT_LIVED
O_TEMPORARY
O_RANDOM
O_SEQUENTIAL
O_TEXT
Options for the flag argument to the open() function. These can be bit-wise OR'd together. Availability: Windows.
6.1.4 Files and Directories

`access(path, mode)`

Use the real uid/gid to test for access to `path`. Note that most operations will use the effective uid/gid, therefore this routine can be used in a suid/sgid environment to test if the invoking user has the specified access to `path`. `mode` should be `F_OK` to test the existence of `path`, or it can be the inclusive OR of one or more of `R_OK`, `W_OK`, and `X_OK` to test permissions. Return `True` if access is allowed, `False` if not. See the UNIX man page `access(2)` for more information. Availability: Macintosh, UNIX, Windows.

**Note:** Using `access()` to check if a user is authorized to e.g. open a file before actually doing so using `open()` creates a security hole, because the user might exploit the short time interval between checking and opening the file to manipulate it.

**Note:** I/O operations may fail even when `access()` indicates that they would succeed, particularly for operations on network filesystems which may have permissions semantics beyond the usual POSIX permission-bit model.

**F_OK**

Value to pass as the `mode` parameter of `access()` to test the existence of `path`.

**R_OK**

Value to include in the `mode` parameter of `access()` to test the readability of `path`.

**W_OK**

Value to include in the `mode` parameter of `access()` to test the writability of `path`.

**X_OK**

Value to include in the `mode` parameter of `access()` to determine if `path` can be executed.
**chdir**(*path*)
Change the current working directory to *path*. Availability: Macintosh, UNIX, Windows.

**fchdir**(*fd*)
Change the current working directory to the directory represented by the file descriptor *fd*. The descriptor must refer to an opened directory, not an open file. Availability: UNIX. New in version 2.3.

**getcwd**()
Return a string representing the current working directory. Availability: Macintosh, UNIX, Windows.

**getcwdu**()
Return a Unicode object representing the current working directory. Availability: Macintosh, UNIX, Windows. New in version 2.3.

**chroot**(*path*)
Change the root directory of the current process to *path*. Availability: Macintosh, UNIX. New in version 2.2.

**chmod**(*path*, *mode*)
Change the mode of *path* to the numeric *mode*. *mode* may take one of the following values (as defined in the stat module) or bitwise or-ed combinations of them:

- S_ISUID
- S_ISGID
- S_ENFMT
- S_ISVTX
- S_IREAD
- S_IWRITE
- S_IEXEC
- S_IRWXU
- S_IRUSR
- S_IWUSR
- S_IXUSR
- S_IRWXG
- S_IROTH
- S_IWOTH
- S_IXOTH
- S_IRGRP
- S_IWGRP
- S_IXGRP
- S_IRWXO
- S_IROTH
- S_IWOTH
- S_IXOTH

Availability: Macintosh, UNIX, Windows.

**Note:** Although Windows supports `chmod()`, you can only set the file's read-only flag with it (via the `S_IWRITE` and `S_IREAD` constants or a corresponding integer value). All other bits are ignored.

**chown( path, uid, gid)**

Change the owner and group id of path to the numeric uid and gid. To leave one of the ids unchanged, set it to -1. Availability: Macintosh, UNIX.

**lchown( path, uid, gid)**

Change the owner and group id of path to the numeric uid and gid. This function will not follow symbolic links. Availability: Macintosh, UNIX. New in version 2.3.

**link( src, dst)**

Create a hard link pointing to src named dst. Availability: Macintosh, UNIX.

**listdir( path)**

Return a list containing the names of the entries in the directory. The list is in arbitrary order. It does not include the special entries '. ' and ' .. ' even if they are present in the directory. Availability: Macintosh, UNIX, Windows.

Changed in version 2.3: On Windows NT/2k/XP and Unix, if path is a Unicode object, the result will be a list of Unicode objects.

**lstat( path)**

Like `stat()`, but do not follow symbolic links. Availability: Macintosh, UNIX.
**mkfifo**(*path[, mode]*)
Create a FIFO (a named pipe) named *path* with numeric mode *mode*. The default *mode* is 0666 (octal). The current umask value is first masked out from the mode. Availability: Macintosh, UNIX.

FIFOs are pipes that can be accessed like regular files. FIFOs exist until they are deleted (for example with os.unlink()). Generally, FIFOs are used as rendezvous between "client" and "server" type processes: the server opens the FIFO for reading, and the client opens it for writing. Note that mkfifo() doesn't open the FIFO -- it just creates the rendezvous point.

**mknod**(*filename[, mode=0600, device]*)
Create a filesystem node (file, device special file or named pipe) named *filename*. *mode* specifies both the permissions to use and the type of node to be created, being combined (bitwise OR) with one of S_IFREG, S_IFCHR, S_IFBLK, and S_IFIFO (those constants are available in stat). For S_IFCHR and S_IFBLK, *device* defines the newly created device special file (probably using os.makedev()), otherwise it is ignored. New in version 2.3.

**major**(*device*)
Extracts the device major number from a raw device number (usually the st_dev or st_rdev field from stat). New in version 2.3.

**minor**(*device*)
Extracts the device minor number from a raw device number (usually the st_dev or st_rdev field from stat). New in version 2.3.

**makedev**(*major, minor*)
Composes a raw device number from the major and minor device numbers. New in version 2.3.

**mkdir**(*path[, mode]*)
Create a directory named *path* with numeric mode *mode*. The default *mode* is 0777 (octal). On some systems, *mode* is ignored. Where it is used, the current umask value is first masked out. Availability: Macintosh, UNIX,
Windows.

**makedirs**(*path[, mode]*)

Recursive directory creation function. Like `mkdir()`, but makes all intermediate-level directories needed to contain the leaf directory. Throws an error exception if the leaf directory already exists or cannot be created. The default `mode` is 0777 (octal). On some systems, `mode` is ignored. Where it is used, the current umask value is first masked out. **Note:** `makedirs()` will become confused if the path elements to create include `os.pardir`. New in version 1.5.2. Changed in version 2.3: This function now handles UNC paths correctly.

**pathconf**(*path, name*)

Return system configuration information relevant to a named file. `name` specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, UNIX 95, UNIX 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for `name` is also accepted. Availability: Macintosh, UNIX.

If `name` is a string and is not known, `ValueError` is raised. If a specific value for `name` is not supported by the host system, even if it is included in `pathconf_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

**pathconf_names**

Dictionary mapping names accepted by `pathconf()` and `fpathconf()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. Availability: Macintosh, UNIX.

**readlink**(*path*)

Return a string representing the path to which the symbolic link points. The result may be either an absolute or relative pathname; if it is relative, it may be converted to an absolute pathname using `os.path.join(os.path.dirname(path), result)`. Availability:
Macintosh, UNIX.

remove(path)
Remove the file path. If path is a directory, OSError is raised; see rmdir() below to remove a directory. This is identical to the unlink() function documented below. On Windows, attempting to remove a file that is in use causes an exception to be raised; on UNIX, the directory entry is removed but the storage allocated to the file is not made available until the original file is no longer in use. Availability: Macintosh, UNIX, Windows.

removedirs(path)
Removes directories recursively. Works like rmdir() except that, if the leaf directory is successfully removed, removedirs() tries to successively remove every parent directory mentioned in path until an error is raised (which is ignored, because it generally means that a parent directory is not empty). For example, "os.removedirs('foo/bar/baz')" will first remove the directory "'foo/bar/baz'", and then remove "'foo/bar'"and "'foo'" if they are empty. Raises OSError if the leaf directory could not be successfully removed. New in version 1.5.2.

rename(src, dst)
Rename the file or directory src to dst. If dst is a directory, OSError will be raised. On UNIX, if dst exists and is a file, it will be removed silently if the user has permission. The operation may fail on some UNIX flavors if src and dst are on different filesystems. If successful, the renaming will be an atomic operation (this is a POSIX requirement). On Windows, if dst already exists, OSError will be raised even if it is a file; there may be no way to implement an atomic rename when dst names an existing file. Availability: Macintosh, UNIX, Windows.

renames(old, new)
Recursive directory or file renaming function. Works like rename(), except creation of any intermediate directories needed to make the new pathname good is attempted first. After the rename, directories corresponding to rightmost path segments of the old name will be pruned away using removedirs(). New in version 1.5.2.
**Note:** This function can fail with the new directory structure made if you lack permissions needed to remove the leaf directory or file.

`rmdir(path)`
Remove the directory `path`. Availability: Macintosh, UNIX, Windows.

`stat(path)`
Perform a `stat()` system call on the given path. The return value is an object whose attributes correspond to the members of the `stat` structure, namely: `st_mode` (protection bits), `st_ino` (inode number), `st_dev` (device), `st_nlink` (number of hard links), `st_uid` (user ID of owner), `st_gid` (group ID of owner), `st_size` (size of file, in bytes), `st_atime` (time of most recent access), `st_mtime` (time of most recent content modification), `st_ctime` (platform dependent; time of most recent metadata change on UNIX, or the time of creation on Windows).

Changed in version 2.3: If `stat_float_times` returns true, the time values are floats, measuring seconds. Fractions of a second may be reported if the system supports that. On Mac OS, the times are always floats. See `stat_float_times` for further discussion.

On some Unix systems (such as Linux), the following attributes may also be available: `st_blocks` (number of blocks allocated for file), `st_blksize` (filesystem blocksize), `st_rdev` (type of device if an inode device).

On Mac OS systems, the following attributes may also be available: `st_rsize, st_creator, st_type`.

On RISCOS systems, the following attributes are also available: `st_ftype` (file type), `st_attrs` (attributes), `st_obtype` (object type).

For backward compatibility, the return value of `stat()` is also accessible as a tuple of at least 10 integers giving the most important (and portable) members of the `stat` structure, in the order `st_mode, st_ino, st_dev, st_nlink, st_uid, st_gid, st_size, st_atime, st_mtime, st_ctime`. 
More items may be added at the end by some implementations. The standard module `stat` defines functions and constants that are useful for extracting information from a stat structure. (On Windows, some items are filled with dummy values.)

**Note:** The exact meaning and resolution of the `st_atime`, `st_mtime`, and `st_ctime` members depends on the operating system and the file system. For example, on Windows systems using the FAT or FAT32 file systems, `st_mtime` has 2-second resolution, and `st_atime` has only 1-day resolution. See your operating system documentation for details.

Availability: Macintosh, UNIX, Windows.

Changed in version 2.2: Added access to values as attributes of the returned object.

```python
stat_float_times([newvalue])
```

Determine whether `stat_result` represents time stamps as float objects. If `newvalue` is `True`, future calls to `stat()` return floats, if it is `False`, future calls return ints. If `newvalue` is omitted, return the current setting.

For compatibility with older Python versions, accessing `stat_result` as a tuple always returns integers. For compatibility with Python 2.2, accessing the time stamps by field name also returns integers. Applications that want to determine the fractions of a second in a time stamp can use this function to have time stamps represented as floats. Whether they will actually observe non-zero fractions depends on the system.

Future Python releases will change the default of this setting; applications that cannot deal with floating point time stamps can then use this function to turn the feature off.

It is recommended that this setting is only changed at program startup time in the `__main__` module; libraries should never change this setting. If an application uses a library that works incorrectly if floating point time stamps are processed, this application should turn the feature off until the library has been corrected.

```python
statvfs(path)
```
Perform a `statvfs()` system call on the given path. The return value is an object whose attributes describe the filesystem on the given path, and correspond to the members of the `statvfs` structure, namely: `f_bsize`, `f_frsize`, `f_blocks`, `f_bfree`, `f_bavail`, `f_files`, `f_ffree`, `f_favail`, `f_flag`, `f_namemax`. Availability: UNIX.

For backward compatibility, the return value is also accessible as a tuple whose values correspond to the attributes, in the order given above. The standard module `statvfs` defines constants that are useful for extracting information from a `statvfs` structure when accessing it as a sequence; this remains useful when writing code that needs to work with versions of Python that don't support accessing the fields as attributes.

Changed in version 2.2: Added access to values as attributes of the returned object.

`symlink(src, dst)`
Create a symbolic link pointing to `src` named `dst`. Availability: UNIX.

`tempnam([dir[, prefix]])`
Return a unique path name that is reasonable for creating a temporary file. This will be an absolute path that names a potential directory entry in the directory `dir` or a common location for temporary files if `dir` is omitted or `None`. If given and not `None`, `prefix` is used to provide a short prefix to the filename. Applications are responsible for properly creating and managing files created using paths returned by `tempnam()`; no automatic cleanup is provided. On UNIX, the environment variable TMPDIR overrides `dir`, while on Windows the TMP is used. The specific behavior of this function depends on the C library implementation; some aspects are underspecified in system documentation. **Warning:** Use of `tempnam()` is vulnerable to symlink attacks; consider using `tmpfile()` (section 6.1.2) instead. Availability: Macintosh, UNIX, Windows.

`tmpnam()`
Return a unique path name that is reasonable for creating a temporary file. This will be an absolute path that names a potential directory entry in a common location for temporary files. Applications are responsible for properly creating and managing files created using paths returned by
tmpnam(); no automatic cleanup is provided. **Warning:** Use of tmpnam() is vulnerable to symlink attacks; consider using tmpfile() (section 6.1.2) instead. Availability: UNIX, Windows. This function probably shouldn't be used on Windows, though: Microsoft's implementation of tmpnam() always creates a name in the root directory of the current drive, and that's generally a poor location for a temp file (depending on privileges, you may not even be able to open a file using this name).

**TMP_MAX**
The maximum number of unique names that tmpnam() will generate before reusing names.

**unlink**(path)
Remove the file path. This is the same function as remove(); the unlink() name is its traditional UNIX name. Availability: Macintosh, UNIX, Windows.

**utime**(path, times)
Set the access and modified times of the file specified by path. If times is None, then the file's access and modified times are set to the current time. Otherwise, times must be a 2-tuple of numbers, of the form (atime, mtime) which is used to set the access and modified times, respectively. Whether a directory can be given for path depends on whether the operating system implements directories as files (for example, Windows does not). Note that the exact times you set here may not be returned by a subsequent stat() call, depending on the resolution with which your operating system records access and modification times; see stat(). Changed in version 2.0: Added support for None for times. Availability: Macintosh, UNIX, Windows.

**walk**(top[, topdown=True [, onerror=None]])
walk() generates the file names in a directory tree, by walking the tree either top down or bottom up. For each directory in the tree rooted at directory top (including top itself), it yields a 3-tuple (dirpath, dirnames, filenames).

dirpath is a string, the path to the directory. dirnames is a list of the names of the subdirectories in dirpath (excluding '.' and '..'). filenames is a
list of the names of the non-directory files in `dirpath`. Note that the names in the lists contain no path components. To get a full path (which begins with `top`) to a file or directory in `dirpath`, do `os.path.join(dirpath, name)`.

If optional argument `topdown` is true or not specified, the triple for a directory is generated before the triples for any of its subdirectories (directories are generated top-down). If `topdown` is false, the triple for a directory is generated after the triples for all of its subdirectories (directories are generated bottom-up).

When `topdown` is true, the caller can modify the `dirnames` list in-place (perhaps using `del` or slice assignment), and `walk()` will only recurse into the subdirectories whose names remain in `dirnames`; this can be used to prune the search, impose a specific order of visiting, or even to inform `walk()` about directories the caller creates or renames before it resumes `walk()` again. Modifying `dirnames` when `topdown` is false is ineffective, because in bottom-up mode the directories in `dirnames` are generated before `dirpath` itself is generated.

By default errors from the `os.listdir()` call are ignored. If optional argument `onerror` is specified, it should be a function; it will be called with one argument, an `OSError` instance. It can report the error to continue with the walk, or raise the exception to abort the walk. Note that the `filename` is available as the `filename` attribute of the exception object.

---

**Note:** If you pass a relative pathname, don't change the current working directory between resumptions of `walk()`. `walk()` never changes the current directory, and assumes that its caller doesn't either.

---

**Note:** On systems that support symbolic links, links to subdirectories appear in `dirnames` lists, but `walk()` will not visit them (infinite loops are hard to avoid when following symbolic links). To visit linked directories, you can identify them with `os.path.islink(path)`, and invoke
walk(path) on each directly.

This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn't look under any CVS subdirectory:

```python
import os
from os.path import join, getsize
for root, dirs, files in os.walk('python/Lib/email'):
    print root, "consumes",
    print sum(getsize(join(root, name)) for name in files),
    print "bytes in", len(files), "non-directory files"
    if 'CVS' in dirs:
        dirs.remove('CVS')  # don't visit CVS directories
```

In the next example, walking the tree bottom up is essential: rmdir() doesn't allow deleting a directory before the directory is empty:

```python
# Delete everything reachable from the directory named in 'top',
# assuming there are no symbolic links.
# CAUTION: This is dangerous! For example, if top == '/', it
# could delete all your disk files.
import os
for root, dirs, files in os.walk(top, topdown=False):
    for name in files:
        os.remove(os.path.join(root, name))
    for name in dirs:
        os.rmdir(os.path.join(root, name))
```

New in version 2.3.
6.1.5 Process Management

These functions may be used to create and manage processes.

The various `exec*()` functions take a list of arguments for the new program loaded into the process. In each case, the first of these arguments is passed to the new program as its own name rather than as an argument a user may have typed on a command line. For the C programmer, this is the `argv[0]` passed to a program's `main()`. For example, `os.execv('/bin/echo', ['foo', 'bar'])` will only print "bar" on standard output; "foo" will seem to be ignored.

**abort()**

Generate a SIGABRT signal to the current process. On UNIX, the default behavior is to produce a core dump; on Windows, the process immediately returns an exit code of 3. Be aware that programs which use `signal.signal()` to register a handler for SIGABRT will behave differently. Availability: Macintosh, UNIX, Windows.

`exec1(path, arg0, arg1, ...)`
`execle(path, arg0, arg1, ..., env)`
`execlp(file, arg0, arg1, ...)`
`execlepe(file, arg0, arg1, ..., env)`
`execv(path, args)`
`execve(path, args, env)`
`execvp(file, args)`
`execvpe(file, args, env)`

These functions all execute a new program, replacing the current process; they do not return. On UNIX, the new executable is loaded into the current process, and will have the same process ID as the caller. Errors will be reported as `OSError` exceptions.

The "l" and "v" variants of the `exec*()` functions differ in how command-line arguments are passed. The "l" variants are perhaps the
easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `execl*()` functions. The "v" variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process should start with the name of the command being run, but this is not enforced.

The variants which include a "p" near the end (`execlp()`, `execlpe()`, `execvp()`, and `execvpe()`) will use the PATH environment variable to locate the program file. When the environment is being replaced (using one of the `exec*e()` variants, discussed in the next paragraph), the new environment is used as the source of the PATH variable. The other variants, `execl()`, `execle()`, `execv()`, and `execve()`, will not use the PATH variable to locate the executable; `path` must contain an appropriate absolute or relative path.

For `execle()`, `execlpe()`, `execve()`, and `execvpe()` (note that these all end in "e"), the `env` parameter must be a mapping which is used to define the environment variables for the new process; the `execl()`, `execlp()`, `execv()`, and `execvp()` all cause the new process to inherit the environment of the current process. Availability: Macintosh, UNIX, Windows.

```python
_exit(n)
```

Exit to the system with status `n`, without calling cleanup handlers, flushing stdio buffers, etc. Availability: Macintosh, UNIX, Windows.

**Note:** The standard way to exit is `sys.exit(n)`. `_exit()` should normally only be used in the child process after a `fork()`.

The following exit codes are a defined, and can be used with `_exit()`, although they are not required. These are typically used for system programs written in Python, such as a mail server's external command delivery program. **Note:** Some of these may not be available on all UNIX platforms, since there is some variation. These constants are defined where they are defined by the underlying platform.
**EX_OK**
Exit code that means no error occurred. Availability: Macintosh, UNIX. New in version 2.3.

**EX_USAGE**
Exit code that means the command was used incorrectly, such as when the wrong number of arguments are given. Availability: Macintosh, UNIX. New in version 2.3.

**EX_DATAERR**
Exit code that means the input data was incorrect. Availability: Macintosh, UNIX. New in version 2.3.

**EX_NOINPUT**
Exit code that means an input file did not exist or was not readable. Availability: Macintosh, UNIX. New in version 2.3.

**EX_NOUSER**
Exit code that means a specified user did not exist. Availability: Macintosh, UNIX. New in version 2.3.

**EX_NOHOST**
Exit code that means a specified host did not exist. Availability: Macintosh, UNIX. New in version 2.3.

**EX_UNAVAILABLE**
Exit code that means that a required service is unavailable. Availability: Macintosh, UNIX. New in version 2.3.

**EX_SOFTWARE**
Exit code that means an internal software error was detected. Availability: Macintosh, UNIX. New in version 2.3.

**EX_OSERR**
Exit code that means an operating system error was detected, such as the inability to fork or create a pipe. Availability: Macintosh, UNIX. New in version 2.3.

**EX_OSFIL**
Exit code that means some system file did not exist, could not be opened, or
had some other kind of error. Availability: Macintosh, UNIX. New in version 2.3.

`EX_CANTCREAT`
Exit code that means a user specified output file could not be created. Availability: Macintosh, UNIX. New in version 2.3.

`EX_IOERR`
Exit code that means that an error occurred while doing I/O on some file. Availability: Macintosh, UNIX. New in version 2.3.

`EX_TEMPFAIL`
Exit code that means a temporary failure occurred. This indicates something that may not really be an error, such as a network connection that couldn't be made during a retryable operation. Availability: Macintosh, UNIX. New in version 2.3.

`EX_PROTOCOL`
Exit code that means that a protocol exchange was illegal, invalid, or not understood. Availability: Macintosh, UNIX. New in version 2.3.

`EX_NOPERM`
Exit code that means that there were insufficient permissions to perform the operation (but not intended for file system problems). Availability: Macintosh, UNIX. New in version 2.3.

`EX_CONFIG`
Exit code that means that some kind of configuration error occurred. Availability: Macintosh, UNIX. New in version 2.3.

`EX_NOTFOUND`
Exit code that means something like ``an entry was not found''. Availability: Macintosh, UNIX. New in version 2.3.

`fork()`
Fork a child process. Return 0 in the child, the child's process id in the parent. Availability: Macintosh, UNIX.

`forkpty()`
Fork a child process, using a new pseudo-terminal as the child's controlling terminal. Return a pair of \((pid, \, fd)\), where \(pid\) is 0 in the child, the new child's process id in the parent, and \(fd\) is the file descriptor of the master end of the pseudo-terminal. For a more portable approach, use the \texttt{pty} module. Availability: Macintosh, Some flavors of \texttt{UNIX}.

\texttt{kill}(pid, \, sig)
Send signal \(sig\) to the process \(pid\). Constants for the specific signals available on the host platform are defined in the \texttt{signal} module. Availability: Macintosh, \texttt{UNIX}.

\texttt{killpg}(pgid, \, sig)
Send the signal \(sig\) to the process group \(pgid\). Availability: Macintosh, \texttt{UNIX}. New in version 2.3.

\texttt{nice}(increment)
Add \(increment\) to the process's ```niceness```. Return the new niceness. Availability: Macintosh, \texttt{UNIX}.

\texttt{plock}(op)
Lock program segments into memory. The value of \(op\) (defined in \texttt{<sys/lock.h>}) determines which segments are locked. Availability: Macintosh, \texttt{UNIX}.

\texttt{popen}(...)
\texttt{popen2}(...)
\texttt{popen3}(...)
\texttt{popen4}(...)
Run child processes, returning opened pipes for communications. These functions are described in section 6.1.2.

\texttt{spawnl}(mode, path, ...)
\texttt{spawnle}(mode, path, ..., env)
\texttt{spawnlp}(mode, file, ...)
\texttt{spawnlpe}(mode, file, ..., env)
spawnv(mode, path, args)
spawnve(mode, path, args, env)
spawnvp(mode, file, args)
spawnvpe(mode, file, args, env)

Execute the program path in a new process. If mode is P_NOWAIT, this function returns the process ID of the new process; if mode is P_WAIT, returns the process's exit code if it exits normally, or -signal, where signal is the signal that killed the process. On Windows, the process ID will actually be the process handle, so can be used with the waitpid() function.

The "l" and "v" variants of the spawn*() functions differ in how command-line arguments are passed. The "l" variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the spawnl*() functions. The "v" variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the args parameter. In either case, the arguments to the child process must start with the name of the command being run.

The variants which include a second "p" near the end (spawnlp(), spawnlpe(), spawnvp(), and spawnvpe()) will use the PATH environment variable to locate the program file. When the environment is being replaced (using one of the spawn*e() variants, discussed in the next paragraph), the new environment is used as the source of the PATH variable. The other variants, spawnl(), spawnle(), spawnv(), and spawnve(), will not use the PATH variable to locate the executable; path must contain an appropriate absolute or relative path.

For spawnle(), spawnlpe(), spawnve(), and spawnvpe() (note that these all end in "e"), the env parameter must be a mapping which is used to define the environment variables for the new process; the spawnl(), spawnlp(), spawnv(), and spawnvp() all cause the new process to inherit the environment of the current process.

As an example, the following calls to spawnlp() and spawnvpe() are equivalent:
import os
os.spawnlp(os.P_WAIT, 'cp', 'cp', 'index.html', '/dev/null')

L = ['cp', 'index.html', '/dev/null']
os.spawnvpe(os.P_WAIT, 'cp', L, os.environ)

Availability: **UNIX**, **Windows**. spawnlp(), spawnlpe(), spawnvp() and spawnvpe() are not available on **Windows**. New in version 1.6.

**P_NOWAIT**

**P_NOWAITO**

Possible values for the *mode* parameter to the spawn*()* family of functions. If either of these values is given, the spawn*() functions will return as soon as the new process has been created, with the process ID as the return value. Availability: **Macintosh**, **UNIX**, **Windows**. New in version 1.6.

**P_WAIT**

Possible value for the *mode* parameter to the spawn*()* family of functions. If this is given as *mode*, the spawn*() functions will not return until the new process has run to completion and will return the exit code of the process the run is successful, or `-signal` if a signal kills the process. Availability: **Macintosh**, **UNIX**, **Windows**. New in version 1.6.

**P_DETACH**

**P_OVERLAY**

Possible values for the *mode* parameter to the spawn*()* family of functions. These are less portable than those listed above. P_DETACH is similar to P_NOWAIT, but the new process is detached from the console of the calling process. If P_OVERLAY is used, the current process will be replaced; the spawn*() function will not return. Availability: **Windows**. New in version 1.6.

**startfile(path)**

Start a file with its associated application. This acts like double-clicking the file in Windows Explorer, or giving the file name as an argument to the start command from the interactive command shell: the file is opened with whatever application (if any) its extension is associated.

**startfile()** returns as soon as the associated application is launched.
There is no option to wait for the application to close, and no way to retrieve the application's exit status. The path parameter is relative to the current directory. If you want to use an absolute path, make sure the first character is not a slash ("/"); the underlying Win32 `ShellExecute()` function doesn't work if it is. Use the `os.path.normpath()` function to ensure that the path is properly encoded for Win32. Availability: Windows. New in version 2.0.

`system(command)`

Execute the command (a string) in a subshell. This is implemented by calling the Standard C function `system()`, and has the same limitations. Changes to `posix.environ`, `sys.stdin`, etc. are not reflected in the environment of the executed command.

On UNIX, the return value is the exit status of the process encoded in the format specified for `wait()`. Note that POSIX does not specify the meaning of the return value of the C `system()` function, so the return value of the Python function is system-dependent.

On Windows, the return value is that returned by the system shell after running `command`, given by the Windows environment variable `COMSPEC`: on `command.com` systems (Windows 95, 98 and ME) this is always 0; on `cmd.exe` systems (Windows NT, 2000 and XP) this is the exit status of the command run; on systems using a non-native shell, consult your shell documentation.

Availability: Macintosh, UNIX, Windows.

`times()`

Return a 5-tuple of floating point numbers indicating accumulated (processor or other) times, in seconds. The items are: user time, system time, children's user time, children's system time, and elapsed real time since a fixed point in the past, in that order. See the UNIX manual page `times(2)` or the corresponding Windows Platform API documentation. Availability: Macintosh, UNIX, Windows.

`wait()`

Wait for completion of a child process, and return a tuple containing its pid
and exit status indication: a 16-bit number, whose low byte is the signal number that killed the process, and whose high byte is the exit status (if the signal number is zero); the high bit of the low byte is set if a core file was produced. Availability: Macintosh, UNIX.

\textbf{waitpid}( pid, options) \\
The details of this function differ on UNIX and Windows.

On UNIX: Wait for completion of a child process given by process id \textit{pid}, and return a tuple containing its process id and exit status indication (encoded as for \texttt{wait()}). The semantics of the call are affected by the value of the integer options, which should be 0 for normal operation.

If pid is greater than 0, \texttt{waitpid()} requests status information for that specific process. If \textit{pid} is 0, the request is for the status of any child in the process group of the current process. If \textit{pid} is -1, the request pertains to any child of the current process. If \textit{pid} is less than -1, status is requested for any process in the process group -\textit{pid} (the absolute value of \textit{pid}).

On Windows: Wait for completion of a process given by process handle \textit{pid}, and return a tuple containing \textit{pid}, and its exit status shifted left by 8 bits (shifting makes cross-platform use of the function easier). A \textit{pid} less than or equal to 0 has no special meaning on Windows, and raises an exception. The value of integer options has no effect. \textit{pid} can refer to any process whose id is known, not necessarily a child process. The \texttt{spawn()} functions called with \texttt{P_NOWAIT} return suitable process handles.

\textbf{WNOHANG} \\
The option for \texttt{waitpid()} to return immediately if no child process status is available immediately. The function returns (0, 0) in this case. Availability: Macintosh, UNIX.

\textbf{WCONTINUED} \\
This option causes child processes to be reported if they have been continued from a job control stop since their status was last reported. Availability: Some UNIX systems. New in version 2.3.

\textbf{WUNTRACED} \\
This option causes child processes to be reported if they have been stopped
but their current state has not been reported since they were stopped. Availability: Macintosh, UNIX. New in version 2.3.

The following functions take a process status code as returned by `system()`, `wait()`, or `waitpid()` as a parameter. They may be used to determine the disposition of a process.

`WCOREDUMP(status)`

Returns `True` if a core dump was generated for the process, otherwise it returns `False`. Availability: Macintosh, UNIX. New in version 2.3.

`WIFCONTINUED(status)`

Returns `True` if the process has been continued from a job control stop, otherwise it returns `False`. Availability: UNIX. New in version 2.3.

`WIFSTOPPED(status)`

Returns `True` if the process has been stopped, otherwise it returns `False`. Availability: UNIX.

`WIFSIGNALED(status)`

Returns `True` if the process exited due to a signal, otherwise it returns `False`. Availability: Macintosh, UNIX.

`WIFEXITED(status)`

Returns `True` if the process exited using the `exit(2)` system call, otherwise it returns `False`. Availability: Macintosh, UNIX.

`WEXITSTATUS(status)`

If `WIFEXITED(status)` is true, return the integer parameter to the `exit(2)` system call. Otherwise, the return value is meaningless. Availability: Macintosh, UNIX.

`WSTOPSIG(status)`

Return the signal which caused the process to stop. Availability: Macintosh, UNIX.

`WTERMSIG(status)`
Return the signal which caused the process to exit. Availability: Macintosh, UNIX.
6.1.6 Miscellaneous System Information

**confstr**( *name*)
Return string-valued system configuration values. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX, UNIX 95, UNIX 98, and others). Some platforms define additional names as well. The names known to the host operating system are given as the keys of the *confstr_names* dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted. Availability: Macintosh, UNIX.

If the configuration value specified by *name* isn't defined, the empty string is returned.

If *name* is a string and is not known, ValueError is raised. If a specific value for *name* is not supported by the host system, even if it is included in *confstr_names*, an OSError is raised with *errno.EINVAL* for the error number.

**confstr_names**
Dictionary mapping names accepted by *confstr()* to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. Availability: Macintosh, UNIX.

**getloadavg()**
Return the number of processes in the system run queue averaged over the last 1, 5, and 15 minutes or raises OSError if the load average was unobtainable.

New in version 2.3.

**sysconf**( *name*)
Return integer-valued system configuration values. If the configuration value specified by *name* isn't defined, -1 is returned. The comments regarding the *name* parameter for *confstr()* apply here as well; the
dictionary that provides information on the known names is given by sysconf_names. Availability: Macintosh, UNIX.

sysconf_names
Dictionary mapping names accepted by sysconf() to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. Availability: Macintosh, UNIX.

The following data values are used to support path manipulation operations. These are defined for all platforms.

Higher-level operations on pathnames are defined in the os.path module.

curdir
The constant string used by the operating system to refer to the current directory. For example: '.' for POSIX or ':' for Mac OS 9. Also available via os.path.

pardir
The constant string used by the operating system to refer to the parent directory. For example: '..' for POSIX or '::' for Mac OS 9. Also available via os.path.

sep
The character used by the operating system to separate pathname components, for example, '/' for POSIX or ':' for Mac OS 9. Note that knowing this is not sufficient to be able to parse or concatenate pathnames - use os.path.split() and os.path.join() -- but it is occasionally useful. Also available via os.path.

altsep
An alternative character used by the operating system to separate pathname components, or None if only one separator character exists. This is set to '/' on Windows systems where sep is a backslash. Also available via os.path.

extsep
The character which separates the base filename from the extension; for
example, the "." in os.py. Also available via os.path. New in version 2.2.

pathsep
The character conventionally used by the operating system to separate search path components (as in PATH), such as ":" for POSIX or ";" for Windows. Also available via os.path.

defpath
The default search path used by exec*p*() and spawn*p*() if the environment doesn't have a 'PATH' key. Also available via os.path.

linesep
The string used to separate (or, rather, terminate) lines on the current platform. This may be a single character, such as '
' for POSIX or '' for Mac OS, or multiple characters, for example, '
' for Windows.

devnull
The file path of the null device. For example: '/dev/null' for POSIX or 'Dev:Nul' for Mac OS 9. Also available via os.path. New in version 2.4.
6.1.7 Miscellaneous Functions

**urandom**( \( n \))

Return a string of \( n \) random bytes suitable for cryptographic use.

This function returns random bytes from an OS-specific randomness source. The returned data should be unpredictable enough for cryptographic applications, though its exact quality depends on the OS implementation. On a UNIX-like system this will query /dev/urandom, and on Windows it will use CryptGenRandom. If a randomness source is not found, `NotImplementedError` will be raised. New in version 2.4.
6.2 os.path -- Common pathname manipulations

This module implements some useful functions on pathnames.

**Warning:** On Windows, many of these functions do not properly support UNC pathnames. `splitunc()` and `ismount()` do handle them correctly.

**`abspath(path)`**
Return a normalized absolutized version of the pathname `path`. On most platforms, this is equivalent to `normpath(join(os.getcwd(), path))`. New in version 1.5.2.

**`basename(path)`**
Return the base name of pathname `path`. This is the second half of the pair returned by `split(path)`. Note that the result of this function is different from the UNIX `basename` program; where `basename` for `'/foo/bar/'` returns `'bar'`, the `basename()` function returns an empty string (`''`).

**`commonprefix(list)`**
Return the longest path prefix (taken character-by-character) that is a prefix of all paths in `list`. If `list` is empty, return the empty string (`''`). Note that this may return invalid paths because it works a character at a time.

**`dirname(path)`**
Return the directory name of pathname `path`. This is the first half of the pair returned by `split(path)`.

**`exists(path)`**
Return `True` if `path` refers to an existing path. Returns `False` for broken symbolic links. On some platforms, this function may return `False` if permission is not granted to execute `os.stat()` on the requested file, even if the `path` physically exists.
lexists(path)
Return True if path refers to an existing path. Returns True for broken symbolic links. Equivalent to exists() on platforms lacking os.lstat(). New in version 2.4.

expanduser(path)
On UNIX, return the argument with an initial component of "~" or "~user" replaced by that user's home directory. An initial "~" is replaced by the environment variable HOME if it is set; otherwise the current user's home directory is looked up in the password directory through the built-in module pwd. An initial "~user" is looked up directly in the password directory.

On Windows, only "~" is supported; it is replaced by the environment variable HOME or by a combination of HOMEDRIVE and HOMEPATH.

If the expansion fails or if the path does not begin with a tilde, the path is returned unchanged.

expandvars(path)
Return the argument with environment variables expanded. Substrings of the form "$name" or "${name}" are replaced by the value of environment variable name. Malformed variable names and references to non-existing variables are left unchanged.

getatime(path)
Return the time of last access of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise os.error if the file does not exist or is inaccessible. New in version 1.5.2. Changed in version 2.3: If os.stat_float_times() returns True, the result is a floating point number.

getmtime(path)
Return the time of last modification of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise os.error if the file does not exist or is inaccessible. New in version 1.5.2. Changed in version 2.3: If os.stat_float_times() returns True, the result is a floating point number.
getctime(*path*)

Return the system's ctime which, on some systems (like UNIX) is the time of the last change, and, on others (like Windows), is the creation time for *path*. The return value is a number giving the number of seconds since the epoch (see the `time` module). Raise `os.error` if the file does not exist or is inaccessible. New in version 2.3.

getsize(*path*)

Return the size, in bytes, of *path*. Raise `os.error` if the file does not exist or is inaccessible. New in version 1.5.2.

isabs(*path*)

Return `True` if *path* is an absolute pathname (begins with a slash).

isfile(*path*)

Return `True` if *path* is an existing regular file. This follows symbolic links, so both `islink()` and `isfile()` can be true for the same path.

isdir(*path*)

Return `True` if *path* is an existing directory. This follows symbolic links, so both `islink()` and `isdir()` can be true for the same path.

islink(*path*)

Return `True` if *path* refers to a directory entry that is a symbolic link. Always `False` if symbolic links are not supported.

ismount(*path*)

Return `True` if pathname *path* is a mount point: a point in a file system where a different file system has been mounted. The function checks whether *path*'s parent, *path*/.., is on a different device than *path*, or whether *path*/.. and *path* point to the same i-node on the same device -- this should detect mount points for all UNIX and POSIX variants.

join(*path1[, path2[, ...]]*)

Join one or more path components intelligently. If any component is an absolute path, all previous components (on Windows, including the previous drive letter, if there was one) are thrown away, and joining
continues. The return value is the concatenation of \textit{path1}, and optionally \textit{path2}, etc., with exactly one directory separator (\texttt{os.sep}) inserted between components, unless \textit{path2} is empty. Note that on Windows, since there is a current directory for each drive, \texttt{os.path.join("c:","foo")} represents a path relative to the current directory on drive C: (\texttt{c:foo}), not \texttt{c:\\foo}.

\texttt{normcase(path)}

Normalize the case of a pathname. On \texttt{UNIX}, this returns the path unchanged; on case-insensitive filesystems, it converts the path to lowercase. On Windows, it also converts forward slashes to backward slashes.

\texttt{normpath(path)}

Normalize a pathname. This collapses redundant separators and up-level references so that \texttt{A//B}, \texttt{A/.B} and \texttt{A/foo/../B} all become \texttt{A/B}. It does not normalize the case (use \texttt{normcase()} for that). On Windows, it converts forward slashes to backward slashes. It should be understood that this may change the meaning of the path if it contains symbolic links!

\texttt{realpath(path)}

Return the canonical path of the specified filename, eliminating any symbolic links encountered in the path (if they are supported by the operating system). New in version 2.2.

\texttt{samefile(path1, path2)}

Return \texttt{True} if both pathname arguments refer to the same file or directory (as indicated by device number and i-node number). Raise an exception if a \texttt{os.stat()} call on either pathname fails. Availability: Macintosh, \texttt{UNIX}.

\texttt{sameopenfile(fp1, fp2)}

Return \texttt{True} if the file descriptors \texttt{fp1} and \texttt{fp2} refer to the same file. Availability: Macintosh, \texttt{UNIX}.

\texttt{samestat(stat1, stat2)}

Return \texttt{True} if the stat tuples \texttt{stat1} and \texttt{stat2} refer to the same file. These structures may have been returned by \texttt{fstat()}, \texttt{lstat()}, or \texttt{stat()}. 
This function implements the underlying comparison used by `samefile()` and `sameopenfile()`. Availability: Macintosh, UNIX.

**split** *(path)*

Split the pathname *path* into a pair, \((head, \ tail)\) where \(\ tail\) is the last pathname component and *head* is everything leading up to that. The \(\ tail\) part will never contain a slash; if *path* ends in a slash, \(\ tail\) will be empty. If there is no slash in *path*, *head* will be empty. If *path* is empty, both *head* and \(\ tail\) are empty. Trailing slashes are stripped from *head* unless it is the root (one or more slashes only). In nearly all cases, \(\text{join}(head, tail)\) equals *path* (the only exception being when there were multiple slashes separating *head* from \(\ tail\)).

**splitdrive** *(path)*

Split the pathname *path* into a pair \((drive, \ tail)\) where *drive* is either a drive specification or the empty string. On systems which do not use drive specifications, \(\ drive\) will always be the empty string. In all cases, \(\ drive + \ tail\) will be the same as *path*. New in version 1.3.

**splitext** *(path)*

Split the pathname *path* into a pair \((root, \ ext)\) such that \(\ root + \ ext == path\), and *ext* is empty or begins with a period and contains at most one period.

**splitunc** *(path)*

Split the pathname *path* into a pair \((unc, \ rest)\) so that *unc* is the UNC mount point (such as \(r'\backslash\host\backslash\mount'\), if present, and \(\ rest\) the rest of the path (such as \(r'\backslash\path\file.ext'\)). For paths containing drive letters, \(unc\) will always be the empty string. Availability: Windows.

**walk** *(path, visit, arg)*

Calls the function *visit* with arguments \((arg, \ dirname, \ names)\) for each directory in the directory tree rooted at *path* (including *path* itself, if it is a directory). The argument *dirname* specifies the visited directory, the argument *names* lists the files in the directory (gotten from \(\text{os.listdir}(dirname)\)). The *visit* function may modify *names* to influence the set of directories visited below *dirname*, e.g. to avoid visiting
certain parts of the tree. (The object referred to by names must be modified in place, using del or slice assignment.)

Note: Symbolic links to directories are not treated as subdirectories, and that walk() therefore will not visit them. To visit linked directories you must identify them with os.path.islink(file) and os.path.isdir(file), and invoke walk() as necessary.

Note: The newer os.walk() generator supplies similar functionality and can be easier to use.

supports_unicode_filenames
True if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system), and if os.listdir() returns Unicode strings for a Unicode argument. New in version 2.3.
6.3 dircache -- Cached directory listings

The dircache module defines a function for reading directory listing using a cache, and cache invalidation using the *mtime* of the directory. Additionally, it defines a function to annotate directories by appending a slash.

The dircache module defines the following functions:

**listdir**( *path*)

Return a directory listing of *path*, as gotten from `os.listdir()`.

Note that unless *path* changes, further call to `listdir()` will not re-read the directory structure.

Note that the list returned should be regarded as read-only. (Perhaps a future version should change it to return a tuple?)

**opendir**( *path*)

Same as `listdir()`.

Defined for backwards compatibility.

**annotate**( *head*, *list*)

Assume *list* is a list of paths relative to *head*, and append, in place, a "/" to each path which points to a directory.

```python
>>> import dircache
>>> a = dircache.listdir('/')
>>> a = a[:] # Copy the return value so we can change 'a'
>>> a
['bin', 'boot', 'cdrom', 'dev', 'etc', 'floppy', 'home', 'initrd', 'found', 'mnt', 'proc', 'root', 'sbin', 'tmp', 'usr', 'var', 'vmlinuz
>>> dircache.annotate('/', a)
>>> a
['bin/', 'boot/', 'cdrom/', 'dev/', 'etc/', 'floppy/', 'home/', 'initrd/', 'found/', 'mnt/', 'proc/', 'root/', 'sbin/', 'tmp/', 'usr/', 'vmlinuz']
```
6.4 stat -- Interpreting stat() results

The stat module defines constants and functions for interpreting the results of os.stat(), os.fstat() and os.lstat() (if they exist). For complete details about the stat(), fstat() and lstat() calls, consult the documentation for your system.

The stat module defines the following functions to test for specific file types:

**S_ISDIR**(mode)
Return non-zero if the mode is from a directory.

**S_ISCHR**(mode)
Return non-zero if the mode is from a character special device file.

**S_ISBLK**(mode)
Return non-zero if the mode is from a block special device file.

**S_ISREG**(mode)
Return non-zero if the mode is from a regular file.

**S_ISFIFO**(mode)
Return non-zero if the mode is from a FIFO (named pipe).

**S_ISLNK**(mode)
Return non-zero if the mode is from a symbolic link.

**S_ISSOCK**(mode)
Return non-zero if the mode is from a socket.

Two additional functions are defined for more general manipulation of the file's mode:
**S_IMODE**(mode)
Return the portion of the file's mode that can be set by `os.chmod()`—that is, the file's permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

**S_IFMT**(mode)
Return the portion of the file's mode that describes the file type (used by the `S_IS*()` functions above).

Normally, you would use the `os.path.is*()` functions for testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the `stat()` system call for each test. These are also useful when checking for information about a file that isn't handled by `os.path`, like the tests for block and character devices.

All the variables below are simply symbolic indexes into the 10-tuple returned by `os.stat()`, `os.fstat()` or `os.lstat()`.

**ST_MODE**
Inode protection mode.

**ST_INO**
Inode number.

**ST_DEV**
Device inode resides on.

**ST_NLINK**
Number of links to the inode.

**ST_UID**
User id of the owner.

**ST_GID**
Group id of the owner.

**ST_SIZE**
Size in bytes of a plain file; amount of data waiting on some special files.
**ST_ATIME**
Time of last access.

**ST_MTIME**
Time of last modification.

**ST_CTIME**
The ``ctime'' as reported by the operating system. On some systems (like UNIX) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of ``file size'' changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of UNIX (including Linux in particular), the ``size'' is the number of bytes waiting to be read at the time of the call to os.stat(), os.fstat(), or os.lstat(); this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the underlying system call.

Example:

```python
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted at top,
calling the callback function for each regular file'''

    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.stat(pathname)[ST_MODE]
        if S_ISDIR(mode):
            # It's a directory, recurse into it
            walktree(pathname, callback)
        elif S_ISREG(mode):
            # It's a file, call the callback function
            callback(pathname)
        else:
            # Unknown file type, print a message
            print 'Skipping %s' % pathname

    def visitfile(file):
        print 'visiting', file
```
if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)
6.5 statcache -- An optimization of os.stat()

**Deprecated since release 2.2.** Use `os.stat()` directly instead of using the cache; the cache introduces a very high level of fragility in applications using it and complicates application code with the addition of cache management support.

The `statcache` module provides a simple optimization to `os.stat()`: remembering the values of previous invocations.

The `statcache` module defines the following functions:

**stat(path)**
This is the main module entry-point. Identical for `os.stat()`, except for remembering the result for future invocations of the function.

The rest of the functions are used to clear the cache, or parts of it.

**reset()**
Clear the cache: forget all results of previous `stat()` calls.

**forget(path)**
Forget the result of `stat(path)`, if any.

**forget_prefix(prefix)**
Forget all results of `stat(path)` for `path` starting with `prefix`.

**forget_dir(prefix)**
Forget all results of `stat(path)` for `path` a file in the directory `prefix`, including `stat(prefix)`.

**forget_except_prefix(prefix)**
Similar to `forget_prefix()`, but for all `path` values *not* starting with `prefix`. 
Example:

```python
>>> import os, statcache
>>> statcache.stat('.
(16893, 2049, 772, 18, 1000, 1000, 2048, 929609777, 929609777, 92960
>>> os.stat('.
(16893, 2049, 772, 18, 1000, 1000, 2048, 929609777, 929609777, 92960
```
6.6 statvfs -- Constants used with os.statvfs()

The `statvfs` module defines constants so interpreting the result if `os.statvfs()`, which returns a tuple, can be made without remembering ``magic numbers." Each of the constants defined in this module is the index of the entry in the tuple returned by `os.statvfs()` that contains the specified information.

**F_BSIZE**
Preferred file system block size.

**F_FRSIZE**
Fundamental file system block size.

**F_BLOCKS**
Total number of blocks in the filesystem.

**F_BFREE**
Total number of free blocks.

**F_BAVAIL**
Free blocks available to non-super user.

**F_FILES**
Total number of file nodes.

**F_FFREE**
Total number of free file nodes.

**F_FAVAIL**
Free nodes available to non-super user.

**F_FLAG**
Flags. System dependent: see `statvfs()` man page.

**F_NAMemax**
Maximum file name length.
6.7 filecmp -- File and Directory Comparisons

The filecmp module defines functions to compare files and directories, with various optional time/correctness trade-offs.

The filecmp module defines the following functions:

\[ \text{cmp}(f1, f2[, shallow[, use_statcache]]) \]

Compare the files named \( f1 \) and \( f2 \), returning \texttt{True} if they seem equal, \texttt{False} otherwise.

Unless \texttt{shallow} is given and is false, files with identical \texttt{os.stat()} signatures are taken to be equal. Changed in version 2.3: \texttt{use_statcache} is obsolete and ignored.

Files that were compared using this function will not be compared again unless their \texttt{os.stat()} signature changes.

Note that no external programs are called from this function, giving it portability and efficiency.

\[ \text{cmpfiles}(dir1, dir2, common[, shallow[, use_statcache]]) \]

Returns three lists of file names: \texttt{match}, \texttt{mismatch}, \texttt{errors}. \texttt{match} contains the list of files match in both directories, \texttt{mismatch} includes the names of those that don't, and \texttt{errors} lists the names of files which could not be compared. Files may be listed in \texttt{errors} because the user may lack permission to read them or many other reasons, but always that the comparison could not be done for some reason.

The \texttt{common} parameter is a list of file names found in both directories. The \texttt{shallow} and \texttt{use_statcache} parameters have the same meanings and default values as for filecmp.cmp().

Example:
>>> import filecmp
>>> filecmp.cmp('libundoc.tex', 'libundoc.tex')
True
>>> filecmp.cmp('libundoc.tex', 'lib.tex')
False

Subsections

- 6.7.1 The dircmp class

Python Library Reference

Previous: 6.6 statvfs  Up: 6. Generic Operating System  Next: 6.7.1 The dircmp class

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.7.1 The `dircmp` class

dircmp instances are built using this constructor:

```python
class dircmp(a, b[, ignore[, hide]])
```

Construct a new directory comparison object, to compare the directories `a` and `b`. `ignore` is a list of names to ignore, and defaults to `['RCS', 'CVS', 'tags']`. `hide` is a list of names to hide, and defaults to `[os.curdir, os.pardir]`.

The `dircmp` class provides the following methods:

- `report()`
  - Print (to `sys.stdout`) a comparison between `a` and `b`.

- `report_partial_closure()`
  - Print a comparison between `a` and `b` and common immediate subdirectories.

- `report_full_closure()`
  - Print a comparison between `a` and `b` and common subdirectories (recursively).

The `dircmp` offers a number of interesting attributes that may be used to get various bits of information about the directory trees being compared.

Note that via `__getattr__()` hooks, all attributes are computed lazily, so there is no speed penalty if only those attributes which are lightweight to compute are used.

- `left_list`
  - Files and subdirectories in `a`, filtered by `hide` and `ignore`.

- `right_list`
  - Files and subdirectories in `b`, filtered by `hide` and `ignore`.

- `common`
  - Files and subdirectories in both `a` and `b`. 
**left_only**
Files and subdirectories only in \(a\).

**right_only**
Files and subdirectories only in \(b\).

**common_dirs**
Subdirectories in both \(a\) and \(b\).

**common_files**
Files in both \(a\) and \(b\)

**common_funny**
Names in both \(a\) and \(b\), such that the type differs between the directories, or names for which os.stat() reports an error.

**same_files**
Files which are identical in both \(a\) and \(b\).

**diff_files**
Files which are in both \(a\) and \(b\), whose contents differ.

**funny_files**
Files which are in both \(a\) and \(b\), but could not be compared.

**subdirs**
A dictionary mapping names in common_dirs to dircmp objects.
6.8 subprocess -- Subprocess management

New in version 2.4.

The subprocess module allows you to spawn new processes, connect to their input/output/error pipes, and obtain their return codes. This module intends to replace several other, older modules and functions, such as:

```python
os.system
os.spawn*
os.popen*
popen2.*
commands.*
```

Information about how the subprocess module can be used to replace these modules and functions can be found in the following sections.

  - 6.8.3.5 Replacing os.popen*
  - 6.8.3.6 Replacing popen2.*

---

Python Library Reference

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.8.1 Using the subprocess Module

This module defines one class called Popen:

```python
class Popen(
    args, bufsize=0, executable=None, stdin=None, stdout=None,
    stderr=None, preexec_fn=None, close_fds=False, shell=False,
    cwd=None, env=None, universal_newlines=False,
    startupinfo=None, creationflags=0
)
```

Arguments are:

- `args` should be a string, or a sequence of program arguments. The program to execute is normally the first item in the `args` sequence or string, but can be explicitly set by using the `executable` argument.

On UNIX, with `shell=False` (default): In this case, the Popen class uses `os.execvp()` to execute the child program. `args` should normally be a sequence. A string will be treated as a sequence with the string as the only item (the program to execute).

On UNIX, with `shell=True`: If `args` is a string, it specifies the command string to execute through the shell. If `args` is a sequence, the first item specifies the command string, and any additional items will be treated as additional shell arguments.

On Windows: the Popen class uses `CreateProcess()` to execute the child program, which operates on strings. If `args` is a sequence, it will be converted to a string using the `list2cmdline` method. Please note that not all MS Windows applications interpret the command line the same way: `list2cmdline` is designed for applications using the same rules as the MS C runtime.

- `bufsize`, if given, has the same meaning as the corresponding argument to the built-in `open()` function: 0 means unbuffered, 1 means line buffered, any other positive value means use a buffer of (approximately) that size. A negative `bufsize` means to use the system default, which usually means fully buffered. The default value for `bufsize` is 0 (unbuffered).
The *executable* argument specifies the program to execute. It is very seldom needed: Usually, the program to execute is defined by the *args* argument. If `shell=True`, the *executable* argument specifies which shell to use. On U*NIX*, the default shell is `/bin/sh`. On Windows, the default shell is specified by the COMSPEC environment variable.

`stdin`, `stdout` and `stderr` specify the executed programs' standard input, standard output and standard error file handles, respectively. Valid values are PIPE, an existing file descriptor (a positive integer), an existing file object, and None. PIPE indicates that a new pipe to the child should be created. With None, no redirection will occur; the child's file handles will be inherited from the parent. Additionally, `stderr` can be STDOUT, which indicates that the stderr data from the applications should be captured into the same file handle as for stdout.

If `preexec_fn` is set to a callable object, this object will be called in the child process just before the child is executed. (U*NIX* only)

If `close_fds` is true, all file descriptors except 0, 1 and 2 will be closed before the child process is executed. (U*NIX* only)

If `shell` is True, the specified command will be executed through the shell.

If `cwd` is not None, the child's current directory will be changed to `cwd` before it is executed. Note that this directory is not considered when searching the executable, so you can't specify the program's path relative to `cwd`.

If `env` is not None, it defines the environment variables for the new process.

If `universal_newlines` is True, the file objects `stdout` and `stderr` are opened as text files, but lines may be terminated by any of '\n', the Unix end-of-line convention, '\r', the Macintosh convention or '\r\n', the Windows convention. All of these external representations are seen as '\n' by the Python program. **Note:** This feature is only available if Python is built with universal newline support (the default). Also, the newlines attribute of the file objects `stdout`, `stdin` and `stderr` are not updated by the communicate() method.
The `startupinfo` and `creationflags`, if given, will be passed to the underlying `CreateProcess()` function. They can specify things such as appearance of the main window and priority for the new process. (Windows only)

---

*Release 2.4.4c1, documentation updated on 11 October 2006.*

See [About this document...](#) for information on suggesting changes.
6.8.2 Popen Objects

Instances of the Popen class have the following methods:

**poll()**
Check if child process has terminated. Returns returncode attribute.

**wait()**
Wait for child process to terminate. Returns returncode attribute.

**communicate( input=None)**
Interact with process: Send data to stdin. Read data from stdout and stderr, until end-of-file is reached. Wait for process to terminate. The optional input argument should be a string to be sent to the child process, or None, if no data should be sent to the child.

communicate() returns a tuple (stdout, stderr).

*Note:* The data read is buffered in memory, so do not use this method if the data size is large or unlimited.

The following attributes are also available:

**stdin**
If the stdin argument is PIPE, this attribute is a file object that provides input to the child process. Otherwise, it is None.

**stdout**
If the stdout argument is PIPE, this attribute is a file object that provides output from the child process. Otherwise, it is None.

**stderr**
If the stderr argument is PIPE, this attribute is file object that provides error output from the child process. Otherwise, it is None.

**pid**
The process ID of the child process.
**returncode**

The child return code. A `None` value indicates that the process hasn't terminated yet. A negative value `-N` indicates that the child was terminated by signal N (UNIX only).
6.8.3 Replacing Older Functions with the subprocess Module

In this section, "a ==> b" means that b can be used as a replacement for a.

**Note:** All functions in this section fail (more or less) silently if the executed program cannot be found; this module raises an **OSError** exception.

In the following examples, we assume that the subprocess module is imported with "from subprocess import *".

---

Subsections

- 6.8.3.1 Replacing /bin/sh shell backquote
- 6.8.3.2 Replacing shell pipe line
- 6.8.3.3 Replacing os.system()
- 6.8.3.4 Replacing os.spawn*
- 6.8.3.5 Replacing os.popen*
- 6.8.3.6 Replacing popen2.*
6.9 popen2 -- Subprocesses with accessible I/O streams

Availability: Unix, Windows.

This module allows you to spawn processes and connect to their input/output/error pipes and obtain their return codes under UNIX and Windows.

Note that starting with Python 2.0, this functionality is available using functions from the os module which have the same names as the factory functions here, but the order of the return values is more intuitive in the os module variants.

The primary interface offered by this module is a trio of factory functions. For each of these, if bufsize is specified, it specifies the buffer size for the I/O pipes. mode, if provided, should be the string 'b' or 't'; on Windows this is needed to determine whether the file objects should be opened in binary or text mode. The default value for mode is 't'.

On UNIX, cmd may be a sequence, in which case arguments will be passed directly to the program without shell intervention (as with os.spawnv()). If cmd is a string it will be passed to the shell (as with os.system()).

The only way to retrieve the return codes for the child processes is by using the poll() or wait() methods on the Popen3 and Popen4 classes; these are only available on UNIX. This information is not available when using the popen2(), popen3(), and popen4() functions, or the equivalent functions in the os module. (Note that the tuples returned by the os module's functions are in a different order from the ones returned by the popen2 module.)

popen2( cmd[, bufsize[, mode]])
  Executes cmd as a sub-process. Returns the file objects (child_stdout, child_stdin).

popen3( cmd[, bufsize[, mode]])
  Executes cmd as a sub-process. Returns the file objects (child_stdout,
popen4( cmd[, bufsize[, mode]])

Executes cmd as a sub-process. Returns the file objects

On UNIX, a class defining the objects returned by the factory functions is also available. These are not used for the Windows implementation, and are not available on that platform.

class Popen3( cmd[, capturestderr[, bufsize]])

This class represents a child process. Normally, Popen3 instances are created using the popen2() and popen3() factory functions described above.

If not using one of the helper functions to create Popen3 objects, the parameter cmd is the shell command to execute in a sub-process. The capturestderr flag, if true, specifies that the object should capture standard error output of the child process. The default is false. If the bufsize parameter is specified, it specifies the size of the I/O buffers to/from the child process.

class Popen4( cmd[, bufsize])

Similar to Popen3, but always captures standard error into the same file object as standard output. These are typically created using popen4(). New in version 2.0.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
6.9.1 Popen3 and Popen4 Objects

Instances of the Popen3 and Popen4 classes have the following methods:

**poll()**
- Returns -1 if child process hasn't completed yet, or its return code otherwise.

**wait()**
- Waits for and returns the status code of the child process. The status code encodes both the return code of the process and information about whether it exited using the `exit()` system call or died due to a signal. Functions to help interpret the status code are defined in the `os` module; see section 6.1.5 for the `W*()` family of functions.

The following attributes are also available:

**fromchild**
- A file object that provides output from the child process. For Popen4 instances, this will provide both the standard output and standard error streams.

**tochild**
- A file object that provides input to the child process.

**childerr**
- A file object that provides error output from the child process, if `capturestderr` was true for the constructor, otherwise None. This will always be None for Popen4 instances.

**pid**
- The process ID of the child process.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
6.9.2 Flow Control Issues

Any time you are working with any form of inter-process communication, control flow needs to be carefully thought out. This remains the case with the file objects provided by this module (or the `os` module equivalents).

When reading output from a child process that writes a lot of data to standard error while the parent is reading from the child's standard output, a deadlock can occur. A similar situation can occur with other combinations of reads and writes. The essential factors are that more than `_PC_PIPE_BUF` bytes are being written by one process in a blocking fashion, while the other process is reading from the other process, also in a blocking fashion.

There are several ways to deal with this situation.

The simplest application change, in many cases, will be to follow this model in the parent process:

```python
import popen2

r, w, e = popen2.popen3('python slave.py')
e.readlines()
r.readlines()
r.close()
e.close()
w.close()
```

with code like this in the child:

```python
import os
import sys

# note that each of these print statements
# writes a single long string

print >>sys.stderr, 400 * 'this is a test\n'
os.close(sys.stderr.fileno())
print >>sys.stdout, 400 * 'this is another test\n'
```

In particular, note that `sys.stderr` must be closed after writing all data, or `readlines()` won't return. Also note that `os.close()` must be used, as `sys.stderr.close()` won't close `stderr` (otherwise assigning to
sys.stderr will silently close it, so no further errors can be printed).

Applications which need to support a more general approach should integrate I/O over pipes with their `select()` loops, or use separate threads to read each of the individual files provided by whichever `popen*()` function or `Popen*` class was used.
6.10 datetime -- Basic date and time types

New in version 2.3.

The datetime module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation.

There are two kinds of date and time objects: ``naive'' and ``aware''. This distinction refers to whether the object has any notion of time zone, daylight saving time, or other kind of algorithmic or political time adjustment. Whether a naive datetime object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it's up to the program whether a particular number represents metres, miles, or mass. Naive datetime objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring more, datetime and time objects have an optional time zone information member, tzinfo, that can contain an instance of a subclass of the abstract tzinfo class. These tzinfo objects capture information about the offset from UTC time, the time zone name, and whether Daylight Saving Time is in effect. Note that no concrete tzinfo classes are supplied by the datetime module. Supporting timezones at whatever level of detail is required is up to the application. The rules for time adjustment across the world are more political than rational, and there is no standard suitable for every application.

The datetime module exports the following constants:

MINYEAR
  The smallest year number allowed in a date or datetime object. MINYEAR is 1.

MAXYEAR
The largest year number allowed in a `date` or `datetime` object. MAXYEAR is 9999.

See Also:

Module `calendar`:
General calendar related functions.

Module `time`:
Time access and conversions.

Subsections

- 6.10.1 Available Types
- 6.10.2 `timedelta` Objects
- 6.10.3 `date` Objects
- 6.10.4 `datetime` Objects
- 6.10.5 `time` Objects
- 6.10.6 `tzinfo` Objects
- 6.10.7 `strftime()` Behavior

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.10.1 Available Types

class date
    An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: year, month, and day.

class time
    An idealized time, independent of any particular day, assuming that every day has exactly 24*60*60 seconds (there is no notion of "leap seconds" here). Attributes: hour, minute, second, microsecond, and tzinfo.

class datetime
    A combination of a date and a time. Attributes: year, month, day, hour, minute, second, microsecond, and tzinfo.

class timedelta
    A duration expressing the difference between two date, time, or datetime instances to microsecond resolution.

class tzinfo
    An abstract base class for time zone information objects. These are used by the datetime and time classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

Objects of these types are immutable.

Objects of the date type are always naive.

An object d of type time or datetime may be naive or aware. d is aware if d.tzinfo is not None and d.tzinfo.utcoffset(d) does not return None. If d.tzinfo is None, or if d.tzinfo is not None but d.tzinfo.utcoffset(d) returns None, d is naive.

The distinction between naive and aware doesn't apply to timedelta objects.
Subclass relationships:

```
object
timedelta
tzinfo
time
date
datetime
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.10.2 timedelta Objects

A timedelta object represents a duration, the difference between two dates or times.

class timedelta([days[, seconds[, microseconds[, milliseconds[, minutes[, hours[, weeks]]]]]]])

All arguments are optional and default to 0. Arguments may be ints, longs, or floats, and may be positive or negative.

Only days, seconds and microseconds are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and days, seconds and microseconds are then normalized so that the representation is unique, with

- $0 \leq micro\text{seconds} < 1000000$
- $0 \leq seconds < 3600*24$ (the number of seconds in one day)
- $-999999999 \leq days \leq 999999999$

If any argument is a float and there are fractional microseconds, the fractional microseconds left over from all arguments are combined and their sum is rounded to the nearest microsecond. If no argument is a float, the conversion and normalization processes are exact (no information is lost).

If the normalized value of days lies outside the indicated range, OverflowError is raised.

Note that normalization of negative values may be surprising at first. For example,

```python
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
```
Class attributes are:

**min**

The most negative `timedelta` object, `timedelta(-999999999)`.  

**max**

The most positive `timedelta` object,  
`timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.  

**resolution**

The smallest possible difference between non-equal `timedelta` objects,  
`timedelta(microseconds=1)`.  

Note that, because of normalization, `timedelta.max > -timedelta.min`. `-timedelta.max` is not representable as a `timedelta` object.

Instance attributes (read-only):

<table>

<tbody>
<tr>
<td>-t1</td>
<td>equivalent to timedelta(-t1.days, -t1.seconds, -t1.microseconds), and to t1* -1. (1)(4)</td>
</tr>
<tr>
<td>abs(t)</td>
<td>equivalent to +t when t.days &gt;= 0, and to -t when t.days &lt; 0. (2)</td>
</tr>
</tbody>
</table>

Notes:

(1)
This is exact, but may overflow.

(2)
This is exact, and cannot overflow.

(3)
Division by 0 raises ZeroDivisionError.

(4)
-timedelta.max is not representable as a timedelta object.

In addition to the operations listed above timedelta objects support certain additions and subtractions with date and datetime objects (see below).

Comparisons of timedelta objects are supported with the timedelta object representing the smaller duration considered to be the smaller timedelta. In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a timedelta object is compared to an object of a different type, TypeError is raised unless the comparison is == or !=. The latter cases return False or True, respectively.

timedelta objects are hashable (usable as dictionary keys), support efficient pickling, and in Boolean contexts, a timedelta object is considered to be true if and only if it isn't equal to timedelta(0).
6.10.3 date Objects

A date object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. This matches the definition of the "proleptic Gregorian" calendar in Dershowitz and Reingold's book *Calendrical Calculations*, where it's the base calendar for all computations. See the book for algorithms for converting between proleptic Gregorian ordinals and many other calendar systems.

**class date**(year, month, day)

All arguments are required. Arguments may be ints or longs, in the following ranges:

- MINYEAR <= year <= MAXYEAR
- 1 <= month <= 12
- 1 <= day <= number of days in the given month and year

If an argument outside those ranges is given, ValueError is raised.

Other constructors, all class methods:

**today()**

Return the current local date. This is equivalent to
date.fromtimestamp(time.time()).

**fromtimestamp**(timestamp)

Return the local date corresponding to the POSIX timestamp, such as is returned by time.time(). This may raise ValueError, if the timestamp is out of the range of values supported by the platform C localtime() function. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by fromtimestamp().
fromordinal(ordinal)

Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. ValueError is raised unless 1 <= ordinal <= date.max.toordinal(). For any date d,
date.fromordinal(d.toordinal()) == d.

Class attributes:

min

The earliest representable date, date(MINYEAR, 1, 1).

max

The latest representable date, date(MAXYEAR, 12, 31).

resolution

The smallest possible difference between non-equal date objects,
timedelta(days=1).

Instance attributes (read-only):

year

Between MINYEAR and MAXYEAR inclusive.

month

Between 1 and 12 inclusive.

day

Between 1 and the number of days in the given month of the given year.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>date2 = date1 + timedelta</td>
<td>date2 is timedelta.days days removed from date1. (1)</td>
</tr>
<tr>
<td>date2 = date1 - timedelta</td>
<td>Computes date2 such that date2 + timedelta == date1. (2)</td>
</tr>
<tr>
<td>timedelta = date1 - date2</td>
<td>(3)</td>
</tr>
<tr>
<td>date1 &lt; date2</td>
<td>date1 is considered less than date2 when date1</td>
</tr>
</tbody>
</table>
Notes:

(1)  
\textit{date2} is moved forward in time if \textit{timedelta}.\texttt{days} > 0, or backward if \textit{timedelta}.\texttt{days} < 0. Afterward \textit{date2} - \textit{date1} == \textit{timedelta}.\texttt{days}. \textit{timedelta}.\texttt{seconds} and \textit{timedelta}.\texttt{microseconds} are ignored. \texttt{OverflowError} is raised if \textit{date2}.\texttt{year} would be smaller than \texttt{MINYEAR} or larger than \texttt{MAXYEAR}.

(2)  
This isn't quite equivalent to \textit{date1} + (-\textit{timedelta}), because -\textit{timedelta} in isolation can overflow in cases where \textit{date1} - \textit{timedelta} does not. \textit{timedelta}.\texttt{seconds} and \textit{timedelta}.\texttt{microseconds} are ignored.

(3)  
This is exact, and cannot overflow. \textit{timedelta}.\texttt{seconds} and \textit{timedelta}.\texttt{microseconds} are 0, and \textit{date2} + \textit{timedelta} == \textit{date1} after.

(4)  
In other words, \textit{date1} < \textit{date2} if and only if \textit{date1}.\texttt{toordinal}() < \textit{date2}.\texttt{toordinal}(). In order to stop comparison from falling back to the default scheme of comparing object addresses, date comparison normally raises \texttt{TypeError} if the other comparand isn't also a \texttt{date} object. However, \texttt{NotImplemented} is returned instead if the other comparand has a \texttt{timetuple} attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a \texttt{date} object is compared to an object of a different type, \texttt{TypeError} is raised unless the comparison is == or !=. The latter cases return \texttt{False} or \texttt{True}, respectively.

Dates can be used as dictionary keys. In Boolean contexts, all \texttt{date} objects are considered to be true.

Instance methods:

\texttt{replace(year, month, day)}

Return a date with the same value, except for those members given new
values by whichever keyword arguments are specified. For example, if \( d = date(2002, 12, 31) \), then \( d.replace(day=26) == date(2002, 12, 26) \).

**timetuple()**

Return a `time.struct_time` such as returned by `time.localtime()`. The hours, minutes and seconds are 0, and the DST flag is -1. \( d.timetuple() \) is equivalent to

\[
(\text{d.year, d.month, d.day, 0, 0, 0, d.weekday(), d.toordinal() - date(d.year, 1, 1).toordinal() + 1, -1})
\]

**toordinal()**

Return the proleptic Gregorian ordinal of the date, where January 1 of year 1 has ordinal 1. For any `date` object \( d \),

\[
date.fromordinal(d.toordinal()) == d.
\]

**weekday()**

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. For example, \( date(2002, 12, 4).weekday() == 2 \), a Wednesday. See also `isoweekday()`.

**isoweekday()**

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. For example, \( date(2002, 12, 4).isoweekday() == 3 \), a Wednesday. See also `weekday()`, `isocalendar()`.

**isocalendar()**

Return a 3-tuple, (ISO year, ISO week number, ISO weekday).

The ISO calendar is a widely used variant of the Gregorian calendar. See [http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm](http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm) for a good explanation.

The ISO year consists of 52 or 53 full weeks, and where a week starts on a Monday and ends on a Sunday. The first week of an ISO year is the first (Gregorian) calendar week of a year containing a Thursday. This is called
week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004, so that `date(2003, 12, 29).isocalendar() == (2004, 1, 1)` and `date(2004, 1, 4).isocalendar() == (2004, 1, 7)`.

**isoformat()**
Return a string representing the date in ISO 8601 format, 'YYYY-MM-DD'. For example, `date(2002, 12, 4).isoformat() == '2002-12-04'`.

**__str__()**
For a date `d`, `str(d)` is equivalent to `d.isoformat()`.

**ctime()**
Return a string representing the date, for example `date(2002, 12, 4).ctime() == 'Wed Dec 4 00:00:00 2002'`. `d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `date.ctime()` does not invoke) conforms to the C standard.

**strftime(format)**
Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. See the section on `strftime()` behavior.
6.10.4 datetime Objects

A `datetime` object is a single object containing all the information from a `date` object and a `time` object. Like a `date` object, `datetime` assumes the current Gregorian calendar extended in both directions; like a time object, `datetime` assumes there are exactly $3600 \times 24$ seconds in every day.

Constructor:

```python
class datetime(year, month, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]])
```

The year, month and day arguments are required. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be ints or longs, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <=` number of days in the given month and year
- `0 <= hour < 24`
- `0 <= minute < 60`
- `0 <= second < 60`
- `0 <= microsecond < 1000000`

If an argument outside those ranges is given, `ValueError` is raised.

Other constructors, all class methods:

```python
today()  
```

Return the current local datetime, with `tzinfo None`. This is equivalent to `datetime.fromtimestamp(time.time())`. See also `now()`, `fromtimestamp()`.

```python
now([tz])
```

Return the current local date and time. If optional argument `tz` is `None` or not specified, this is like `today()`, but, if possible, supplies more
precision than can be gotten from going through a \texttt{time.time()} timestamp (for example, this may be possible on platforms supplying the C \texttt{gettimeofday()} function).

Else \texttt{tz} must be an instance of a class \texttt{tzinfo} subclass, and the current date and time are converted to \texttt{tz}'s time zone. In this case the result is equivalent to \texttt{tz.fromutc(datetime.utcnow().replace(tzinfo=tz))}. See also \texttt{today()}, \texttt{utcnow()}.

\texttt{utcnow()}

Return the current UTC date and time, with \texttt{tzinfo None}. This is like \texttt{now()}, but returns the current UTC date and time, as a naive \texttt{datetime} object. See also \texttt{now()}.

\texttt{fromtimestamp(timestamp[, tz])}

Return the local date and time corresponding to the POSIX timestamp, such as is returned by \texttt{time.time()}. If optional argument \texttt{tz} is \texttt{None} or not specified, the timestamp is converted to the platform's local date and time, and the returned \texttt{datetime} object is naive.

Else \texttt{tz} must be an instance of a class \texttt{tzinfo} subclass, and the timestamp is converted to \texttt{tz}'s time zone. In this case the result is equivalent to \texttt{tz.fromutc(datetime.fromtimestamp(timestamp).replace(tzinfo=tz))}. \texttt{fromtimestamp()} may raise \texttt{ValueError}, if the timestamp is out of the range of values supported by the platform C \texttt{localtime()} or \texttt{gmtime()} functions. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by \texttt{fromtimestamp()}, and then it's possible to have two timestamps differing by a second that yield identical \texttt{datetime} objects. See also \texttt{utcfromtimestamp()}.

\texttt{utcfromtimestamp(timestamp)}

Return the UTC \texttt{datetime} corresponding to the POSIX timestamp, with \texttt{tzinfo None}. This may raise \texttt{ValueError}, if the timestamp is out of
the range of values supported by the platform C *gmtime()* function. It's common for this to be restricted to years in 1970 through 2038. See also *fromtimestamp()*.

**fromordinal** (*ordinal*)
Return the datetime corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. *ValueError* is raised unless 1 \leq ordinal \leq datetime.max.toordinal() . The hour, minute, second and microsecond of the result are all 0, and tzinfo is None.

**combine** (*date, time*)
Return a new datetime object whose date members are equal to the given date object's, and whose time and tzinfo members are equal to the given time object's. For any datetime object *d*, *d* == *datetime.combine(d.date(), d.timetz())*. If date is a datetime object, its time and tzinfo members are ignored.

Class attributes:

**min**
The earliest representable datetime, datetime(MINYEAR, 1, 1, tzinfo=None).

**max**
The latest representable datetime, datetime(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None).

**resolution**
The smallest possible difference between non-equal datetime objects, timedelta(microseconds=1).

Instance attributes (read-only):

**year**
Between MINYEAR and MAXYEAR inclusive.

**month**
Between 1 and 12 inclusive.
day
   Between 1 and the number of days in the given month of the given year.

hour
   In range(24).

minute
   In range(60).

second
   In range(60).

microsecond
   In range(1000000).

tzinfo
   The object passed as the tzinfo argument to the datetime constructor, or
   None if none was passed.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>datetime2 = datetime1 + timedelta</code></td>
<td>(1)</td>
</tr>
<tr>
<td><code>datetime2 = datetime1 - timedelta</code></td>
<td>(2)</td>
</tr>
<tr>
<td><code>timedelta = datetime1 - datetime2</code></td>
<td>(3)</td>
</tr>
<tr>
<td><code>datetime1 &lt; datetime2</code></td>
<td>Compares datetime to datetime.</td>
</tr>
</tbody>
</table>

(1)
datetime2 is a duration of timedelta removed from datetime1, moving
forward in time if `timedelta.days` > 0, or backward if `timedelta.days` <
0. The result has the same tzinfo member as the input datetime, and
datetime2 - datetime1 == timedelta after. OverflowError is raised if
datetime2.year would be smaller than MINYEAR or larger than MAXYEAR.
Note that no time zone adjustments are done even if the input is an aware object.

(2)
Computes the datetime2 such that datetime2 + timedelta == datetime1. As for addition, the result has the same tzinfo member as the input datetime, and no time zone adjustments are done even if the input is aware. This isn't quite equivalent to datetime1 + (-timedelta), because -timedelta in isolation can overflow in cases where datetime1 - timedelta does not.

(3)
Subtraction of a datetime from a datetime is defined only if both operands are naive, or if both are aware. If one is aware and the other is naive, TypeError is raised.

If both are naive, or both are aware and have the same tzinfo member, the tzinfo members are ignored, and the result is a timedelta object t such that datetime2 + t == datetime1. No time zone adjustments are done in this case.

If both are aware and have different tzinfo members, a-b acts as if a and b were first converted to naive UTC datetimes first. The result is (a.replace(tzinfo=None) - a.utcoffset()) - (b.replace(tzinfo=None) - b.utcoffset()) except that the implementation never overflows.

(4)

datetime1 is considered less than datetime2 when datetime1 precedes datetime2 in time.

If one comparand is naive and the other is aware, TypeError is raised. If both comparands are aware, and have the same tzinfo member, the common tzinfo member is ignored and the base datetimes are compared. If both comparands are aware and have different tzinfo members, the comparands are first adjusted by subtracting their UTC offsets (obtained from self.utcoffset()). Note: In order to stop comparison from falling back to the default scheme of comparing object addresses, datetime comparison normally raises TypeError if the other comparand isn't also a
datetime object. However, NotImplemented is returned instead if the other comparand has a timetuple attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a datetime object is compared to an object of a different type, TypeError is raised unless the comparison is == or !=. The latter cases return False or True, respectively.

datetime objects can be used as dictionary keys. In Boolean contexts, all datetime objects are considered to be true.

Instance methods:

date()
Return date object with same year, month and day.

time()
Return time object with same hour, minute, second and microsecond. tzinfo is None. See also method timetz().

timetz()
Return time object with same hour, minute, second, microsecond, and tzinfo members. See also method time().

replace(*year[ , month[ , day[ , hour[ , minute[ , second[ , microsecond[ , tzinfo]]]]]]]]
Return a datetime with the same members, except for those members given new values by whichever keyword arguments are specified. Note that tzinfo=None can be specified to create a naive datetime from an aware datetime with no conversion of date and time members.

astimezone(tz)
Return a datetime object with new tzinfo member tz, adjusting the date and time members so the result is the same UTC time as self, but in tz's local time.

tz must be an instance of a tzinfo subclass, and its utcoffset() and dst() methods must not return None. self must be aware (self.tzinfo
must not be None, and self.utcoffset() must not return None).

If self.tzinfo is tz, self.astimezone(tz) is equal to self: no
adjustment of date or time members is performed. Else the result is local
time in time zone tz, representing the same UTC time as self: after
astz = dt.astimezone(tz), astz - astz.utcoffset() will usually have
the same date and time members as dt - dt.utcoffset(). The discussion
of class tzinfo explains the cases at Daylight Saving Time transition
boundaries where this cannot be achieved (an issue only if tz models both
standard and daylight time).

If you merely want to attach a time zone object tz to a datetime dt
without adjustment of date and time members, use dt.replace(tzinfo=tz).
If you merely want to remove the time zone object from an aware datetime dt
without conversion of date and time members, use

    dt.replace(tzinfo=None).

Note that the default tzinfo.fromutc() method can be overridden in a
tzinfo subclass to affect the result returned by astimezone().
Ignoring error cases, astimezone() acts like:

def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    # Convert self to UTC, and attach the new time zone object
    utc = (self - self.utcoffset()).replace(tzinfo=tz)
    # Convert from UTC to tz's local time.
    return tz.fromutc(utc)

utcoffset()
If tzinfo is None, returns None, else returns
self.tzinfo.utcoffset(self), and raises an exception if the latter
doesn't return None, or a timedelta object representing a whole number
of minutes with magnitude less than one day.

dst()
If tzinfo is None, returns None, else returns self.tzinfo.dst(self),
and raises an exception if the latter doesn't return None, or a timedelta
object representing a whole number of minutes with magnitude less than
one day.
tzname()
If tzinfo is None, returns None, else returns
self.tzinfo.tzname(self), raises an exception if the latter doesn't
return None or a string object,

timetuple()
Return a time.struct_time such as returned by
time.localtime(d).timetuple() is equivalent to
time.struct_time((d.year, d.month, d.day, d.hour,
d.minute, d.second, d.weekday(), d.toordinal() -
date(d.year, 1, 1).toordinal() + 1, dst)) The
tm_isdst flag of the result is set according to the dst() method:
tzinfo is None or dst() returns None, tm_isdst is set to -1; else if
dst() returns a non-zero value, tm_isdst is set to 1; else tm_isdst is
set to 0.

utctimetuple()
If datetime instance d is naive, this is the same as d.timetuple()
except that tm_isdst is forced to 0 regardless of what d.dst() returns.
DST is never in effect for a UTC time.

If d is aware, d is normalized to UTC time, by subtracting
d.utcoffset(), and a time.struct_time for the normalized time
is returned. tm_isdst is forced to 0. Note that the result's tm_year
member may be MINYEAR-1 or MAXYEAR+1, if d.year was MINYEAR or
MAXYEAR and UTC adjustment spills over a year boundary.

toordinal()
Return the proleptic Gregorian ordinal of the date. The same as
self.date().toordinal().

weekday()
Return the day of the week as an integer, where Monday is 0 and Sunday is
6. The same as self.date().weekday(). See also isoweekday().

isoweekday()
Return the day of the week as an integer, where Monday is 1 and Sunday is
7. The same as `self.date().isoweekday()`. See also `weekday()`, `isocalendar()`.

**isocalendar()**

Return a 3-tuple, (ISO year, ISO week number, ISO weekday). The same as `self.date().isocalendar()`.

**isoformat([sep])**

Return a string representing the date and time in ISO 8601 format, `YYYY-MM-DDTHH:MM:SS.mmmmmm` or, if `microsecond` is 0, `YYYY-MM-DDTHH:MM:SS`

If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: `YYYY-MM-DDTHH:MM:SS.mmmmmm+HH:MM` or, if `microsecond` is 0 `YYYY-MM-DDTHH:MM:SS+HH:MM`

The optional argument `sep` (default 'T') is a one-character separator, placed between the date and time portions of the result. For example,

```python
>>> from datetime import tzinfo, timedelta, datetime
>>> class TZ(tzinfo):
...     def utcoffset(self, dt): return timedelta(minutes=-399)
...     ...
>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat(' ')
'2002-12-25 00:00:00-06:39'
```

**__str__()**

For a `datetime` instance `d`, `str(d)` is equivalent to `d.isoformat(' ')`.

**ctime()**

Return a string representing the date and time, for example

```python
datetime(2002, 12, 4, 20, 30, 40).ctime() == 'Wed Dec 4 20:30:40 2002'.d.ctime() is equivalent to
time.ctime(time.mktime(d.timetuple())) on platforms
where the native C `ctime()` function (which `time.ctime()` invokes, but which `datetime.ctime()` does not invoke) conforms to the C standard.
**strftime(format)**

Return a string representing the date and time, controlled by an explicit format string. See the section on `strftime()` behavior.
6.10.5 time Objects

A time object represents a (local) time of day, independent of any particular day, and subject to adjustment via a tzinfo object.

```python
class time(hour[, minute[, second[, microsecond[, tzinfo]]]])
```

All arguments are optional. tzinfo may be None, or an instance of a tzinfo subclass. The remaining arguments may be ints or longs, in the following ranges:

- \(0 \leq \text{hour} < 24\)
- \(0 \leq \text{minute} < 60\)
- \(0 \leq \text{second} < 60\)
- \(0 \leq \text{microsecond} < 1000000\).

If an argument outside those ranges is given, ValueError is raised. All default to 0 except tzinfo, which defaults to None.

Class attributes:

- **min**
  
  The earliest representable time, time(0, 0, 0, 0).

- **max**
  
  The latest representable time, time(23, 59, 59, 999999).

- **resolution**
  
  The smallest possible difference between non-equal time objects, timedelta(microseconds=1), although note that arithmetic on time objects is not supported.

Instance attributes (read-only):

- **hour**
  
  In range(24).

- **minute**
In range(60).

**second**
In range(60).

**microsecond**
In range(1000000).

**tzinfo**
The object passed as the tzinfo argument to the time constructor, or None if none was passed.

Supported operations:

- comparison of time to time, where a is considered less than b when a precedes b in time. If one comparand is naive and the other is aware, TypeError is raised. If both comparands are aware, and have the same tzinfo member, the common tzinfo member is ignored and the base times are compared. If both comparands are aware and have different tzinfo members, the comparands are first adjusted by subtracting their UTC offsets (obtained from self.utcoffset()). In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a time object is compared to an object of a different type, TypeError is raised unless the comparison is == or !=. The latter cases return False or True, respectively.

- hash, use as dict key

- efficient pickling

- in Boolean contexts, a time object is considered to be true if and only if, after converting it to minutes and subtracting utcoffset() (or 0 if that's None), the result is non-zero.

Instance methods:

**replace([hour[, minute[, second[, microsecond[, tzinfo]]]]]))**
Return a time with the same value, except for those members given new values by whichever keyword arguments are specified. Note that
tzinfo=None can be specified to create a naive time from an aware time, without conversion of the time members.

**isoformat()**
Return a string representing the time in ISO 8601 format, HH:MM:SS.mmmmmm or, if self.microsecond is 0, HH:MM:SS If utcoffset() does not return None, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: HH:MM:SS.mmmmmm+HH:MM or, if self.microsecond is 0, HH:MM:SS+HH:MM

**__str__()**
For a time t, str(t) is equivalent to t.isoformat().

**strftime(format)**
Return a string representing the time, controlled by an explicit format string. See the section on strftime() behavior.

**utcoffset()**
If tzinfo is None, returns None, else returns self.tzinfo.utcoffset(None), and raises an exception if the latter doesn't return None or a timedelta object representing a whole number of minutes with magnitude less than one day.

**dst()**
If tzinfo is None, returns None, else returns self.tzinfo.dst(None), and raises an exception if the latter doesn't return None, or a timedelta object representing a whole number of minutes with magnitude less than one day.

**tzname()**
If tzinfo is None, returns None, else returns self.tzinfo.tzname(None), or raises an exception if the latter doesn't return None or a string object.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
Behavior
6.10.6 tzinfo Objects

tzinfo is an abstract base class, meaning that this class should not be instantiated directly. You need to derive a concrete subclass, and (at least) supply implementations of the standard tzinfo methods needed by the datetime methods you use. The datetime module does not supply any concrete subclasses of tzinfo.

An instance of (a concrete subclass of) tzinfo can be passed to the constructors for datetime and time objects. The latter objects view their members as being in local time, and the tzinfo object supports methods revealing offset of local time from UTC, the name of the time zone, and DST offset, all relative to a date or time object passed to them.

Special requirement for pickling: A tzinfo subclass must have an __init__ method that can be called with no arguments, else it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of tzinfo may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware datetime objects. If in doubt, simply implement all of them.

utcoffset( self, dt)

Return offset of local time from UTC, in minutes east of UTC. If local time is west of UTC, this should be negative. Note that this is intended to be the total offset from UTC; for example, if a tzinfo object represents both time zone and DST adjustments, utcoffset() should return their sum. If the UTC offset isn't known, return None. Else the value returned must be a timedelta object specifying a whole number of minutes in the range -1439 to 1439 inclusive (1440 = 24*60; the magnitude of the offset must be less than one day). Most implementations of utcoffset() will probably look like one of these two:

```
return CONSTANT                  # fixed-offset class
return CONSTANT + self.dst(dt)  # daylight-aware class
```
If `utcoffset()` does not return `None`, `dst()` should not return `None` either.

The default implementation of `utcoffset()` raises `NotImplementedError`.

`dst(self, dt)`
Return the daylight saving time (DST) adjustment, in minutes east of UTC, or `None` if DST information isn't known. Return `timedelta(0)` if DST is not in effect. If DST is in effect, return the offset as a `timedelta` object (see `utcoffset()` for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by `utcoffset()`, so there's no need to consult `dst()` unless you're interested in obtaining DST info separately. For example, `datetime.timetuple()` calls its `tzinfo` member's `dst()` method to determine how the `tm_isdst` flag should be set, and `tzinfo.fromutc()` calls `dst()` to account for DST changes when crossing time zones.

An instance `tz` of a `tzinfo` subclass that models both standard and daylight times must be consistent in this sense:

```
tz.utcoffset(dt) - tz.dst(dt)
```

must return the same result for every `datetime dt` with `dt.tzinfo == tz` For sane `tzinfo` subclasses, this expression yields the time zone's "standard offset", which should not depend on the date or the time, but only on geographic location. The implementation of `datetime.astimezone()` relies on this, but cannot detect violations; it's the programmer's responsibility to ensure it. If a `tzinfo` subclass cannot guarantee this, it may be able to override the default implementation of `tzinfo.fromutc()` to work correctly with `astimezone()` regardless.

Most implementations of `dst()` will probably look like one of these two:

```python
def dst(self):
    # a fixed-offset class: doesn't account for DST
    return timedelta(0)
```
or

```python
def dst(self):
    # Code to set dston and dstoff to the time zone's DST
    # transition times based on the input dt.year, and express
    # in standard local time. Then
    if dston <= dt.replace(tzinfo=None) < dstoff:
        return timedelta(hours=1)
    else:
        return timedelta(0)
```

The default implementation of `dst()` raises `NotImplementedError`.

**tzname**( `self`, `dt` )

Return the time zone name corresponding to the `datetime` object `dt`, as a string. Nothing about string names is defined by the `datetime` module, and there's no requirement that it mean anything in particular. For example, "GMT", "UTC", ",-500", "-5:00", "EDT", "US/Eastern", "America/New York" are all valid replies. Return `None` if a string name isn't known. Note that this is a method rather than a fixed string primarily because some `tzinfo` subclasses will wish to return different names depending on the specific value of `dt` passed, especially if the `tzinfo` class is accounting for daylight time.

The default implementation of `tzname()` raises `NotImplementedError`.

These methods are called by a `datetime` or `time` object, in response to their methods of the same names. A `datetime` object passes itself as the argument, and a `time` object passes `None` as the argument. A `tzinfo` subclass's methods should therefore be prepared to accept a `dt` argument of `None`, or of class `datetime`.

When `None` is passed, it's up to the class designer to decide the best response. For example, returning `None` is appropriate if the class wishes to say that time objects don't participate in the `tzinfo` protocols. It may be more useful for `utcoffset(None)` to return the standard UTC offset, as there is no other convention for discovering the standard offset.

When a `datetime` object is passed in response to a `datetime` method,
dt.tzinfo is the same object as self.tzinfo methods can rely on this, unless user code calls tzinfo methods directly. The intent is that the tzinfo methods interpret dt as being in local time, and not need worry about objects in other timezones.

There is one more tzinfo method that a subclass may wish to override:

**fromutc**(self, dt)

This is called from the default datetime.astimezone() implementation. When called from that, dt.tzinfo is self, and dt's date and time members are to be viewed as expressing a UTC time. The purpose of fromutc() is to adjust the date and time members, returning an equivalent datetime in self's local time.

Most tzinfo subclasses should be able to inherit the default fromutc() implementation without problems. It's strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default fromutc() implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of astimezone() and fromutc() may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default fromutc() implementation acts like:

```python
def fromutc(self, dt):
    # raise ValueError error if dt.tzinfo is not self
dtoff = dt.utcoffset()
dtdst = dt.dst()
    # raise ValueError if dtoff is None or dtdst is None
delta = dtoff - dtdst  # this is self's standard offset
    if delta:
        dt += delta  # convert to standard local time
dtdst = dt.dst()
        # raise ValueError if dtdst is None
    if dtdst:
        return dt + dtdst
    else:
        return dt
```
Example `tzinfo` classes:

```python
from datetime import tzinfo, timedelta, datetime

ZERO = timedelta(0)
HOUR = timedelta(hours=1)

# A UTC class.
class UTC(tzinfo):
    """UTC""
    def utcoffset(self, dt):
        return ZERO
    def tzname(self, dt):
        return "UTC"
    def dst(self, dt):
        return ZERO

utc = UTC()

# A class building tzinfo objects for fixed-offset time zones.
# Note that FixedOffset(0, "UTC") is a different way to build a
# UTC tzinfo object.
class FixedOffset(tzinfo):
    """Fixed offset in minutes east from UTC.""
    def __init__(self, offset, name):
        self.__offset = timedelta(minutes = offset)
        self.__name = name
    def utcoffset(self, dt):
        return self.__offset
    def tzname(self, dt):
        return self.__name
    def dst(self, dt):
        return ZERO

# A class capturing the platform's idea of local time.
import time as _time

STDOFFSET = timedelta(seconds = -_time.timezone)
if _time.daylight:
    DSTOFFSET = timedelta(seconds = -_time.altzone)
else:
    DSTOFFSET = STDOFFSET
```
DSTDIFF = DSTOFFSET - STDOFFSET

class LocalTimezone(tzinfo):
    def utcoffset(self, dt):
        if self._isdst(dt):
            return DSTOFFSET

Pacific = USTimeZone(-8, "Pacific", "PST", "PDT")

Download as text (original file name: tzinfo-examples.py).

Note that there are unavoidable subtleties twice per year in a tzinfo subclass accounting for both standard and daylight time, at the DST transition points. For concreteness, consider US Eastern (UTC -0500), where EDT begins the minute after 1:59 (EST) on the first Sunday in April, and ends the minute after 1:59 (EDT) on the last Sunday in October:

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>UTC</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
When DST starts (the "start" line), the local wall clock leaps from 1:59 to 3:00. A wall time of the form 2:MM doesn't really make sense on that day, so `astimezone(Eastern)` won't deliver a result with `hour == 2` on the day DST begins. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the "missing hour" (2:MM for Eastern) to be in daylight time.

When DST ends (the "end" line), there's a potentially worse problem: there's an hour that can't be spelled unambiguously in local wall time: the last hour of daylight time. In Eastern, that's times of the form 5:MM UTC on the day daylight time ends. The local wall clock leaps from 1:59 (daylight time) back to 1:00 (standard time) again. Local times of the form 1:MM are ambiguous. `astimezone()` mimics the local clock's behavior by mapping two adjacent UTC hours into the same local hour then. In the Eastern example, UTC times of the form 5:MM and 6:MM both map to 1:MM when converted to Eastern. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the "repeated hour" to be in standard time. This is easily arranged, as in the example, by expressing DST switch times in the time zone's standard local time.

Applications that can't bear such ambiguities should avoid using hybrid `tzinfo` subclasses; there are no ambiguities when using UTC, or any other fixed-offset `tzinfo` subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).
6.10.7 strftime() Behavior

date, datetime, and time objects all support a strftime(format) method, to create a string representing the time under the control of an explicit format string. Broadly speaking, d.strftime(fmt) acts like the time module's time.strftime(fmt, d.timetuple()) although not all objects support a timetuple() method.

For time objects, the format codes for year, month, and day should not be used, as time objects have no such values. If they're used anyway, 1900 is substituted for the year, and 0 for the month and day.

For date objects, the format codes for hours, minutes, and seconds should not be used, as date objects have no such values. If they're used anyway, 0 is substituted for them.

For a naive object, the %z and %Z format codes are replaced by empty strings.

For an aware object:

%z
utcoffset() is transformed into a 5-character string of the form +HHMM or -HHMM, where HH is a 2-digit string giving the number of UTC offset hours, and MM is a 2-digit string giving the number of UTC offset minutes. For example, if utcoffset() returns timedelta(hours=-3, minutes=-30), %z is replaced with the string '-0330'.

%Z
If tzname() returns None, %Z is replaced by an empty string. Otherwise %Z is replaced by the returned value, which must be a string.

The full set of format codes supported varies across platforms, because Python calls the platform C library's strftime() function, and platform variations are common. The documentation for Python's time module lists the format codes that the C standard (1989 version) requires, and those work on all platforms with a standard C implementation. Note that the 1999 version of the C
standard added additional format codes.

The exact range of years for which `strftime()` works also varies across platforms. Regardless of platform, years before 1900 cannot be used.
6.11 time -- Time access and conversions

This module provides various time-related functions. It is always available, but not all functions are available on all platforms. Most of the functions defined in this module call platform C library functions with the same name. It may sometimes be helpful to consult the platform documentation, because the semantics of these functions varies among platforms.

An explanation of some terminology and conventions is in order.

- The *epoch* is the point where the time starts. On January 1st of that year, at 0 hours, the "time since the epoch" is zero. For UNIX, the epoch is 1970. To find out what the epoch is, look at `gmtime(0)`.

- The functions in this module do not handle dates and times before the epoch or far in the future. The cut-off point in the future is determined by the C library; for UNIX, it is typically in 2038.

- **Year 2000 (Y2K) issues**: Python depends on the platform's C library, which generally doesn't have year 2000 issues, since all dates and times are represented internally as seconds since the epoch. Functions accepting a `struct_time` (see below) generally require a 4-digit year. For backward compatibility, 2-digit years are supported if the module variable `accept2dyear` is a non-zero integer; this variable is initialized to 1 unless the environment variable PYTHON2K is set to a non-empty string, in which case it is initialized to 0. Thus, you can set PYTHON2K to a non-empty string in the environment to require 4-digit years for all year input. When 2-digit years are accepted, they are converted according to the POSIX or X/Open standard: values 69-99 are mapped to 1969-1999, and values 0-68 are mapped to 2000-2068. Values 100-1899 are always illegal. Note that this is new as of Python 1.5.2(a2); earlier versions, up to Python 1.5.1 and 1.5.2a1, would add 1900 to year values below 1900.

- UTC is Coordinated Universal Time (formerly known as Greenwich Mean Time, or GMT). The acronym UTC is not a mistake but a compromise.
between English and French.

- DST is Daylight Saving Time, an adjustment of the timezone by (usually) one hour during part of the year. DST rules are magic (determined by local law) and can change from year to year. The C library has a table containing the local rules (often it is read from a system file for flexibility) and is the only source of True Wisdom in this respect.

- The precision of the various real-time functions may be less than suggested by the units in which their value or argument is expressed. E.g. on most UNIX systems, the clock ``ticks'' only 50 or 100 times a second, and on the Mac, times are only accurate to whole seconds.

- On the other hand, the precision of time() and sleep() is better than their UNIX equivalents: times are expressed as floating point numbers, time() returns the most accurate time available (using UNIX gettimeofday() where available), and sleep() will accept a time with a nonzero fraction (UNIX select() is used to implement this, where available).

- The time value as returned by gmtime(), localtime(), and strftime(), and accepted by asctime(), mktime() and strftime(), is a sequence of 9 integers. The return values of gmtime(), localtime(), and strftime() also offer attribute names for individual fields.

<table>

<td>tm_yday</td>
<td>range [1,366]</td>
</tr>
<tr>
<td>8</td>
<td>tm_isdst</td>
<td>0, 1 or -1; see below</td>
</tr>
</tbody>
</table>
Note that unlike the C structure, the month value is a range of 1-12, not 0-11. A year value will be handled as described under "Year 2000 (Y2K) issues" above. A -1 argument as the daylight savings flag, passed to mktime() will usually result in the correct daylight savings state to be filled in.

When a tuple with an incorrect length is passed to a function expecting a struct_time, or having elements of the wrong type, a TypeError is raised.

Changed in version 2.2: The time value sequence was changed from a tuple to a struct_time, with the addition of attribute names for the fields.

The module defines the following functions and data items:

**accept2dyear**
Boolean value indicating whether two-digit year values will be accepted. This is true by default, but will be set to false if the environment variable PYTHONY2K has been set to a non-empty string. It may also be modified at run time.

**altzone**
The offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local DST timezone is east of UTC (as in Western Europe, including the UK). Only use this if daylight is nonzero.

**asctime([t])**
Convert a tuple or struct_time representing a time as returned by gmtime() or localtime() to a 24-character string of the following form: 'Sun Jun 20 23:21:05 1993'. If t is not provided, the current time as returned by localtime() is used. Locale information is not used by asctime(). Note: Unlike the C function of the same name, there is no trailing newline. Changed in version 2.1: Allowed t to be omitted.

**clock()**
On UNIX, return the current processor time as a floating point number expressed in seconds. The precision, and in fact the very definition of the
meaning of ``processor time'', depends on that of the C function of the same
name, but in any case, this is the function to use for benchmarking Python
or timing algorithms.

On Windows, this function returns wall-clock seconds elapsed since the
first call to this function, as a floating point number, based on the Win32
function `QueryPerformanceCounter()`. The resolution is typically
better than one microsecond.

cftime([secs])
Convert a time expressed in seconds since the epoch to a string representing
local time. If secs is not provided or None, the current time as returned by
time() is used. cftime(secs) is equivalent to
asctime(localtime(secs)). Locale information is not used by
cftime(). Changed in version 2.1: Allowed secs to be omitted. Changed in
version 2.4: If secs is None, the current time is used.

daylight
Nonzero if a DST timezone is defined.

gmtime([secs])
Convert a time expressed in seconds since the epoch to a struct_time
in UTC in which the dst flag is always zero. If secs is not provided or
None, the current time as returned by time() is used. Fractions of a
second are ignored. See above for a description of the struct_time
object. See calendar.timegm() for the inverse of this function.
Changed in version 2.1: Allowed secs to be omitted. Changed in version
2.4: If secs is None, the current time is used.

localtime([secs])
Like gmtime() but converts to local time. If secs is not provided or
None, the current time as returned by time() is used. The dst flag is set
to 1 when DST applies to the given time. Changed in version 2.1: Allowed
secs to be omitted. Changed in version 2.4: If secs is None, the current time
is used.

mktime(t)
This is the inverse function of `localtime()`. Its argument is the `struct_time` or full 9-tuple (since the dst flag is needed; use -1 as the dst flag if it is unknown) which expresses the time in local time, not UTC. It returns a floating point number, for compatibility with `time()`. If the input value cannot be represented as a valid time, either `OverflowError` or `ValueError` will be raised (which depends on whether the invalid value is caught by Python or the underlying C libraries). The earliest date for which it can generate a time is platform-dependent.

**sleep(secs)**
Suspend execution for the given number of seconds. The argument may be a floating point number to indicate a more precise sleep time. The actual suspension time may be less than that requested because any caught signal will terminate the `sleep()` following execution of that signal's catching routine. Also, the suspension time may be longer than requested by an arbitrary amount because of the scheduling of other activity in the system.

**strftime(format[, t])**
Convert a tuple or `struct_time` representing a time as returned by `gmtime()` or `localtime()` to a string as specified by the `format` argument. If `t` is not provided, the current time as returned by `localtime()` is used. `format` must be a string. `ValueError` is raised if any field in `t` is outside of the allowed range. Changed in version 2.1: Allowed `t` to be omitted. Changed in version 2.4: `ValueError` raised if a field in `t` is out of range.

The following directives can be embedded in the `format` string. They are shown without the optional field width and precision specification, and are replaced by the indicated characters in the `strftime()` result:

<table>

<tr>
<td>%X</td>
<td>Locale's appropriate time representation.</td>
<td></td>
</tr>
<tr>
<td>%y</td>
<td>Year without century as a decimal number [00,99].</td>
<td></td>
</tr>
<tr>
<td>%Y</td>
<td>Year with century as a decimal number.</td>
<td></td>
</tr>
<tr>
<td>%Z</td>
<td>Time zone name (no characters if no time zone exists).</td>
<td></td>
</tr>
<tr>
<td>%%</td>
<td>A literal &quot;%&quot; character.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) When used with the `strptime()` function, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.

(2) The range really is θ to 61; this accounts for leap seconds and the (very rare) double leap seconds.

(3) When used with the `strptime()` function, `%U` and `%W` are only used in calculations when the day of the week and the year are specified.
Here is an example, a format for dates compatible with that specified in the [RFC 2822](https://tools.ietf.org/html/rfc2822) Internet email standard. 6.1

```python
>>> from time import gmtime, strftime
>>> strftime("%a, %d %b %Y %H:%M:%S +0000", gmtime())
'Thu, 28 Jun 2001 14:17:15 +0000'
```

Additional directives may be supported on certain platforms, but only the ones listed here have a meaning standardized by ANSI C.

On some platforms, an optional field width and precision specification can immediately follow the initial "%" of a directive in the following order; this is also not portable. The field width is normally 2 except for %j where it is 3.

```python
strptime(string[, format])
```

Parse a string representing a time according to a format. The return value is a `struct_time` as returned by `gmtime()` or `localtime()`. The `format` parameter uses the same directives as those used by `strftime()`; it defaults to "%a %b %d %H:%M:%S %Y" which matches the formatting returned by `ctime()`. If `string` cannot be parsed according to `format`, `ValueError` is raised. If the string to be parsed has excess data after parsing, `ValueError` is raised. The default values used to fill in any missing data when more accurate values cannot be inferred are `(1900, 1, 1, 0, 0, 0, 0, 1, -1)`.

Support for the %Z directive is based on the values contained in `tzname` and whether `daylight` is true. Because of this, it is platform-specific except for recognizing UTC and GMT which are always known (and are considered to be non-daylight savings timezones).

```python
struct_time
```

The type of the time value sequence returned by `gmtime()`, `localtime()`, and `strptime()`. New in version 2.2.

```python
time()
```

Return the time as a floating point number expressed in seconds since the epoch, in UTC. Note that even though the time is always returned as a floating point number, not all systems provide time with a better precision.
than 1 second. While this function normally returns non-decreasing values, it can return a lower value than a previous call if the system clock has been set back between the two calls.

**timezone**
The offset of the local (non-DST) timezone, in seconds west of UTC (negative in most of Western Europe, positive in the US, zero in the UK).

**tzname**
A tuple of two strings: the first is the name of the local non-DST timezone, the second is the name of the local DST timezone. If no DST timezone is defined, the second string should not be used.

**tzset()**
Resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done. New in version 2.3.

Availability: UNIX.

**Note:** Although in many cases, changing the TZ environment variable may affect the output of functions like `localtime` without calling `tzset`, this behavior should not be relied on.

The TZ environment variable should contain no whitespace.

The standard format of the TZ environment variable is: (whitespace added for clarity)

```
std offset [dst [offset] [,start[/time], end[/time]]]
```

Where:

std and dst
Three or more alphanumerics giving the timezone abbreviations.
These will be propagated into time.tzname
The offset has the form: ± hh[:mm[:ss]]. This indicates the value added the local time to arrive at UTC. If preceded by a '-', the timezone is east of the Prime Meridian; otherwise, it is west. If no offset follows dst, summer time is assumed to be one hour ahead of standard time.

Indicates when to change to and back from DST. The format of the start and end dates are one of the following:

\[Jn\]
The Julian day \(n\) (1 \(\leq n \leq 365\)). Leap days are not counted, so in all years February 28 is day 59 and March 1 is day 60.

\[n\]
The zero-based Julian day (0 \(\leq n \leq 365\)). Leap days are counted, and it is possible to refer to February 29.

\[Mm.n.d\]
The \(d\)'th day (0 \(\leq d \leq 6\)) or week \(n\) of month \(m\) of the year (1 \(\leq n \leq 5\), 1 \(\leq m \leq 12\), where week 5 means "the last \(d\) day in month \(m\)" which may occur in either the fourth or the fifth week). Week 1 is the first week in which the \(d\)'th day occurs. Day zero is Sunday.

time has the same format as offset except that no leading sign ('-' or '+') is allowed. The default, if time is not given, is 02:00:00.

```python
>>> os.environ['TZ'] = 'EST+05EDT,M4.1.0,M10.5.0'
>>> time.tzset()
>>> time.strftime('%X %x %Z')
'02:07:36 05/08/03 EDT'
>>> os.environ['TZ'] = 'AEST-10AEDT-11,M10.5.0,M3.5.0'
>>> time.tzset()
>>> time.strftime('%X %x %Z')
'16:08:12 05/08/03 AEST'
```

On many Unix systems (including *BSD, Linux, Solaris, and Darwin), it is more convenient to use the system's zoneinfo (tzfile(5)) database to specify the timezone rules. To do this, set the TZ environment variable to the path of the required timezone datafile, relative to the root of the systems 'zoneinfo' timezone database, usually located at /usr/share/zoneinfo. For
example, 'US/Eastern', 'Australia/Melbourne', 'Egypt' or 'Europe/Amsterdam'.

```python
>>> os.environ['TZ'] = 'US/Eastern'
>>> time.tzset()
>>> time.tzname
('EST', 'EDT')
>>> os.environ['TZ'] = 'Egypt'
>>> time.tzset()
>>> time.tzname
('EET', 'EEST')
```

See Also:

Module **datetime**: More object-oriented interface to dates and times.

Module **locale**: Internationalization services. The locale settings can affect the return values for some of the functions in the time module.

Module **calendar**: General calendar-related functions. timegm() is the inverse of gmtime() from this module.

Footnotes

... standard §6.1

The use of %Z is now deprecated, but the %z escape that expands to the preferred hour/minute offset is not supported by all ANSI C libraries. Also, a strict reading of the original 1982 RFC 822 standard calls for a two-digit year (%y rather than %Y), but practice moved to 4-digit years long before the year 2000. The 4-digit year has been mandated by RFC 2822, which obsoletes RFC 822.
The `sched` module defines a class which implements a general purpose event scheduler:

**class scheduler**(*timefunc*, *delayfunc*)

The `scheduler` class defines a generic interface to scheduling events. It needs two functions to actually deal with the ``outside world'' -- `timefunc` should be callable without arguments, and return a number (the ``time'', in any units whatsoever). The `delayfunc` function should be callable with one argument, compatible with the output of `timefunc`, and should delay that many time units. `delayfunc` will also be called with the argument `0` after each event is run to allow other threads an opportunity to run in multi-threaded applications.

Example:

```python
>>> import sched, time
>>> s=sched.scheduler(time.time, time.sleep)
>>> def print_time(): print "From print_time", time.time()
... DEF print_some_times():
... print time.time()
... s.enter(5, 1, print_time, ())
... s.enter(10, 1, print_time, ())
... s.run()
... print time.time()
... DEF print_some_times():
... print_some_times()
930343690.257
From print_time 930343695.274
From print_time 930343700.273
From print_time 930343700.276
```

**Subsections**

- [6.12.1 Scheduler Objects](#)
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
6.12.1 Scheduler Objects

scheduler instances have the following methods:

**enterabs**( time, priority, action, argument)
Schedule a new event. The time argument should be a numeric type compatible with the return value of the timefunc function passed to the constructor. Events scheduled for the same time will be executed in the order of their priority.

Executing the event means executing action(*argument). argument must be a sequence holding the parameters for action.

Return value is an event which may be used for later cancellation of the event (see cancel()).

**enter**( delay, priority, action, argument)
Schedule an event for delay more time units. Other then the relative time, the other arguments, the effect and the return value are the same as those for enterabs().

**cancel**( event)
Remove the event from the queue. If event is not an event currently in the queue, this method will raise a RuntimeError.

**empty**()
Return true if the event queue is empty.

**run**( )
Run all scheduled events. This function will wait (using the delayfunc function passed to the constructor) for the next event, then execute it and so on until there are no more scheduled events.

Either action or delayfunc can raise an exception. In either case, the scheduler will maintain a consistent state and propagate the exception. If an exception is raised by action, the event will not be attempted in future calls.
to run().

If a sequence of events takes longer to run than the time available before the next event, the scheduler will simply fall behind. No events will be dropped; the calling code is responsible for canceling events which are no longer pertinent.
6.13 mutex -- Mutual exclusion support

The mutex module defines a class that allows mutual-exclusion via acquiring and releasing locks. It does not require (or imply) threading or multi-tasking, though it could be useful for those purposes.

The mutex module defines the following class:

```python
class mutex()
    Create a new (unlocked) mutex.

    A mutex has two pieces of state -- a "locked" bit and a queue. When the mutex is not locked, the queue is empty. Otherwise, the queue contains zero or more (function, argument) pairs representing functions (or methods) waiting to acquire the lock. When the mutex is unlocked while the queue is not empty, the first queue entry is removed and its function (argument) pair called, implying it now has the lock.

    Of course, no multi-threading is implied - hence the funny interface for lock(), where a function is called once the lock is acquired.
```

Subsections

- [6.13.1 Mutex Objects](#)

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
6.13.1 Mutex Objects

Mutex objects have following methods:

**test()**
Check whether the mutex is locked.

**testandset()**
``Atomic'' test-and-set, grab the lock if it is not set, and return True, otherwise, return False.

**lock(function, argument)**
Execute function(argument), unless the mutex is locked. In the case it is locked, place the function and argument on the queue. See unlock for explanation of when function(argument) is executed in that case.

**unlock()**
Unlock the mutex if queue is empty, otherwise execute the first element in the queue.
curses
6.14 getpass -- Portable password input

The getpass module provides two functions:

getpass([prompt])

Prompt the user for a password without echoing. The user is prompted using the string prompt, which defaults to 'Password: '. Availability: Macintosh, UNIX, Windows.

getuser()

Return the ``login name'' of the user. Availability: UNIX, Windows.

This function checks the environment variables LOGNAME, USER, LNAME and USERNAME, in order, and returns the value of the first one which is set to a non-empty string. If none are set, the login name from the password database is returned on systems which support the pwd module, otherwise, an exception is raised.
6.15 curses -- Terminal handling for character-cell displays

Changed in version 1.6: Added support for the ncurses library and converted to a package.

The curses module provides an interface to the curses library, the de-facto standard for portable advanced terminal handling.

While curses is most widely used in the UNIX environment, versions are available for DOS, OS/2, and possibly other systems as well. This extension module is designed to match the API of ncurses, an open-source curses library hosted on Linux and the BSD variants of UNIX.

See Also:

Module `curses.ascii`:
Utilities for working with ASCII characters, regardless of your locale settings.

Module `curses.panel`:
A panel stack extension that adds depth to curses windows.

Module `curses.textpad`:
Editable text widget for curses supporting Emacs-like bindings.

Module `curses.wrapper`:
Convenience function to ensure proper terminal setup and resetting on application entry and exit.

*Curses Programming with Python*
Tutorial material on using curses with Python, by Andrew Kuchling and Eric Raymond, is available on the Python Web site.

The Demo/curses/ directory in the Python source distribution contains
some example programs using the curses bindings provided by this module.
6.15.1 Functions

The module curses defines the following exception:

**exception error**

Exception raised when a curses library function returns an error.

**Note:** Whenever \( x \) or \( y \) arguments to a function or a method are optional, they default to the current cursor location. Whenever \( attr \) is optional, it defaults to A_NORMAL.

The module curses defines the following functions:

**baudrate()**

Returns the output speed of the terminal in bits per second. On software terminal emulators it will have a fixed high value. Included for historical reasons; in former times, it was used to write output loops for time delays and occasionally to change interfaces depending on the line speed.

**beep()**

Emit a short attention sound.

**can_change_color()**

Returns true or false, depending on whether the programmer can change the colors displayed by the terminal.

**cbreak()**

Enter cbreak mode. In cbreak mode (sometimes called ``rare'' mode) normal tty line buffering is turned off and characters are available to be read one by one. However, unlike raw mode, special characters (interrupt, quit, suspend, and flow control) retain their effects on the tty driver and calling program. Calling first raw() then cbreak() leaves the terminal in cbreak mode.

**color_content(color_number)**

Returns the intensity of the red, green, and blue (RGB) components in the color color_number, which must be between 0 and COLORS. A 3-tuple is
returned, containing the R,G,B values for the given color, which will be between 0 (no component) and 1000 (maximum amount of component).

**color_pair(color_number)**
Returns the attribute value for displaying text in the specified color. This attribute value can be combined with A_STANDOUT, A_REVERSE, and the other A_* attributes. **pair_number()** is the counterpart to this function.

**curs_set(visibility)**
Sets the cursor state. **visibility** can be set to 0, 1, or 2, for invisible, normal, or very visible. If the terminal supports the visibility requested, the previous cursor state is returned; otherwise, an exception is raised. On many terminals, the "visible" mode is an underline cursor and the "very visible" mode is a block cursor.

**def_prog_mode()**
Saves the current terminal mode as the "program" mode, the mode when the running program is using curses. (Its counterpart is the "shell" mode, for when the program is not in curses.) Subsequent calls to **reset_prog_mode()** will restore this mode.

**def_shell_mode()**
Saves the current terminal mode as the "shell" mode, the mode when the running program is not using curses. (Its counterpart is the "program" mode, when the program is using curses capabilities.) Subsequent calls to **reset_shell_mode()** will restore this mode.

**delay_output(ms)**
Inserts an ms millisecond pause in output.

**doupdate()**
Update the physical screen. The curses library keeps two data structures, one representing the current physical screen contents and a virtual screen representing the desired next state. The doupdate() ground updates the physical screen to match the virtual screen.

The virtual screen may be updated by a noutrefresh() call after write
operations such as `addstr()` have been performed on a window. The normal `refresh()` call is simply `noutrefresh()` followed by `doupdate()`; if you have to update multiple windows, you can speed performance and perhaps reduce screen flicker by issuing `noutrefresh()` calls on all windows, followed by a single `doupdate()`.

**echo()**

Enter echo mode. In echo mode, each character input is echoed to the screen as it is entered.

**endwin()**

De-initialize the library, and return terminal to normal status.

**erasechar()**

Returns the user's current erase character. Under Unix operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

**filter()**

The `filter()` routine, if used, must be called before `initscr()` is called. The effect is that, during those calls, LINES is set to 1; the capabilities clear, cup, cud, cud1, cuu1, cuu, vpa are disabled; and the home string is set to the value of cr. The effect is that the cursor is confined to the current line, and so are screen updates. This may be used for enabling character-at-a-time line editing without touching the rest of the screen.

**flash()**

Flash the screen. That is, change it to reverse-video and then change it back in a short interval. Some people prefer such as `visible bell' to the audible attention signal produced by `beep()`.

**flushinp()**

Flush all input buffers. This throws away any typeahead that has been typed by the user and has not yet been processed by the program.

**getmouse()**
After `getch()` returns `KEY_MOUSE` to signal a mouse event, this method should be called to retrieve the queued mouse event, represented as a 5-tuple `(id, x, y, z, bstate)`. `id` is an ID value used to distinguish multiple devices, and `x, y, z` are the event's coordinates. (`z` is currently unused.). `bstate` is an integer value whose bits will be set to indicate the type of event, and will be the bitwise OR of one or more of the following constants, where `n` is the button number from 1 to 4: `BUTTON_n_PRESSED`, `BUTTON_n_RELEASED`, `BUTTON_n_CLICKED`, `BUTTON_n_DOUBLE_CLICKED`, `BUTTON_n_TRIPLE_CLICKED`, `BUTTON_SHIFT`, `BUTTON_CTRL`, `BUTTON_ALT`.

`getsx()`

Returns the current coordinates of the virtual screen cursor in `y` and `x`. If `leaveok` is currently true, then `-1,-1` is returned.

`getwin(file)`

Reads window related data stored in the file by an earlier `putwin()` call. The routine then creates and initializes a new window using that data, returning the new window object.

`has_colors()`

Returns true if the terminal can display colors; otherwise, it returns false.

`has_ic()`

Returns true if the terminal has insert- and delete- character capabilities. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

`has_il()`

Returns true if the terminal has insert- and delete-line capabilities, or can simulate them using scrolling regions. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

`has_key(ch)`

Takes a key value `ch`, and returns true if the current terminal type recognizes a key with that value.
**halfdelay** (*tenths*)

Used for half-delay mode, which is similar to cbreak mode in that characters typed by the user are immediately available to the program. However, after blocking for *tenths* tenths of seconds, an exception is raised if nothing has been typed. The value of *tenths* must be a number between 1 and 255. Use `nocbreak()` to leave half-delay mode.

**init_color** (*color_number, r, g, b*)

Changes the definition of a color, taking the number of the color to be changed followed by three RGB values (for the amounts of red, green, and blue components). The value of *color_number* must be between 0 and COLORS. Each of *r*, *g*, and *b*, must be a value between 0 and 1000. When `init_color()` is used, all occurrences of that color on the screen immediately change to the new definition. This function is a no-op on most terminals; it is active only if `can_change_color()` returns 1.

**init_pair** (*pair_number, fg, bg*)

Changes the definition of a color-pair. It takes three arguments: the number of the color-pair to be changed, the foreground color number, and the background color number. The value of *pair_number* must be between 1 and COLOR_PAIRS - 1 (the 0 color pair is wired to white on black and cannot be changed). The value of *fg* and *bg* arguments must be between 0 and COLORS. If the color-pair was previously initialized, the screen is refreshed and all occurrences of that color-pair are changed to the new definition.

**initscr()**

Initialize the library. Returns a `WindowObject` which represents the whole screen. **Note:** If there is an error opening the terminal, the underlying curses library may cause the interpreter to exit.

**isendwin()**

Returns true if `endwin()` has been called (that is, the curses library has been deinitialized).

**keyname** (*k*)

Return the name of the key numbered *k*. The name of a key generating
printable ASCII character is the key's character. The name of a control-key combination is a two-character string consisting of a caret followed by the corresponding printable ASCII character. The name of an alt-key combination (128-255) is a string consisting of the prefix `M-' followed by the name of the corresponding ASCII character.

**killchar()**

Returns the user's current line kill character. Under UNIX operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

**longname()**

Returns a string containing the terminfo long name field describing the current terminal. The maximum length of a verbose description is 128 characters. It is defined only after the call to initscr().

**meta(yes)**

If yes is 1, allow 8-bit characters to be input. If yes is 0, allow only 7-bit chars.

**mouseinterval( interval)**

Sets the maximum time in milliseconds that can elapse between press and release events in order for them to be recognized as a click, and returns the previous interval value. The default value is 200 msec, or one fifth of a second.

**mousemask( mousemask)**

Sets the mouse events to be reported, and returns a tuple (availmask, oldmask). availmask indicates which of the specified mouse events can be reported; on complete failure it returns 0. oldmask is the previous value of the given window's mouse event mask. If this function is never called, no mouse events are ever reported.

**napms( ms)**

Sleep for ms milliseconds.

**newpad( nlines, ncols)**
Creates and returns a pointer to a new pad data structure with the given number of lines and columns. A pad is returned as a window object.

A pad is like a window, except that it is not restricted by the screen size, and is not necessarily associated with a particular part of the screen. Pads can be used when a large window is needed, and only a part of the window will be on the screen at one time. Automatic refreshes of pads (such as from scrolling or echoing of input) do not occur. The refresh() and noutrefresh() methods of a pad require 6 arguments to specify the part of the pad to be displayed and the location on the screen to be used for the display. The arguments are pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol; the p arguments refer to the upper left corner of the pad region to be displayed and the s arguments define a clipping box on the screen within which the pad region is to be displayed.

newwin([nlines, ncols], begin_y, begin_x)
Return a new window, whose left-upper corner is at (begin_y, begin_x), and whose height/width is nlines/ncols.

By default, the window will extend from the specified position to the lower right corner of the screen.

n1()
Enter newline mode. This mode translates the return key into newline on input, and translates newline into return and line-feed on output. Newline mode is initially on.

nocbreak()
Leave cbreak mode. Return to normal "cooked" mode with line buffering.

noecho()
Leave echo mode. Echoing of input characters is turned off.

nonl()
Leave newline mode. Disable translation of return into newline on input, and disable low-level translation of newline into newline/return on output (but this does not change the behavior of addch('\n'), which always does the equivalent of return and line feed on the virtual screen). With
translation off, curses can sometimes speed up vertical motion a little; also, it will be able to detect the return key on input.

**noqiflush()**

When the noqiflush routine is used, normal flush of input and output queues associated with the INTR, QUIT and SUSP characters will not be done. You may want to call noqiflush() in a signal handler if you want output to continue as though the interrupt had not occurred, after the handler exits.

**noraw()**

Leave raw mode. Return to normal ``cooked'' mode with line buffering.

**pair_content(pair_number)**

Returns a tuple \((fg, bg)\) containing the colors for the requested color pair. The value of \(pair\_number\) must be between 1 and \(COLOR\_PAIRS - 1\).

**pair_number(attr)**

Returns the number of the color-pair set by the attribute value \(attr\). color_pair() is the counterpart to this function.

**putp(string)**

Equivalent to tputs(str, 1, putchar); emits the value of a specified terminfo capability for the current terminal. Note that the output of putp always goes to standard output.

**qiflush([flag])**

If \(flag\) is false, the effect is the same as calling noqiflush(). If \(flag\) is true, or no argument is provided, the queues will be flushed when these control characters are read.

**raw()**

Enter raw mode. In raw mode, normal line buffering and processing of interrupt, quit, suspend, and flow control keys are turned off; characters are presented to curses input functions one by one.

**reset_prog_mode()**
Restores the terminal to "program" mode, as previously saved by def_prog_mode().

`reset_shell_mode()`
Restores the terminal to "shell" mode, as previously saved by def_shell_mode().

`setsyx(y, x)`
Sets the virtual screen cursor to y, x. If y and x are both -1, then leaveok is set.

`setupterm([termstr, fd])`
Initializes the terminal. `termstr` is a string giving the terminal name; if omitted, the value of the TERM environment variable will be used. `fd` is the file descriptor to which any initialization sequences will be sent; if not supplied, the file descriptor for `sys.stdout` will be used.

`start_color()`
Must be called if the programmer wants to use colors, and before any other color manipulation routine is called. It is good practice to call this routine right after `initscr()`.

`start_color()` initializes eight basic colors (black, red, green, yellow, blue, magenta, cyan, and white), and two global variables in the curses module, COLORS and COLOR_PAIRS, containing the maximum number of colors and color-pairs the terminal can support. It also restores the colors on the terminal to the values they had when the terminal was just turned on.

`termattrs()`
Returns a logical OR of all video attributes supported by the terminal. This information is useful when a curses program needs complete control over the appearance of the screen.

`termname()`
Returns the value of the environment variable TERM, truncated to 14 characters.
tigetflag(capname)
Returns the value of the Boolean capability corresponding to the terminfo capability name capname. The value -1 is returned if capname is not a Boolean capability, or 0 if it is canceled or absent from the terminal description.

tigetnum(capname)
Returns the value of the numeric capability corresponding to the terminfo capability name capname. The value -2 is returned if capname is not a numeric capability, or -1 if it is canceled or absent from the terminal description.

tigetstr(capname)
Returns the value of the string capability corresponding to the terminfo capability name capname. None is returned if capname is not a string capability, or is canceled or absent from the terminal description.

tparm(str[,...])
Instantiates the string str with the supplied parameters, where str should be a parameterized string obtained from the terminfo database. E.g. tparm(tigetstr("cup"), 5, 3) could result in '\033[6;4H', the exact result depending on terminal type.

typeahead(fd)
Specifies that the file descriptor fd be used for typeahead checking. If fd is -1, then no typeahead checking is done.

The curses library does ``line-breakout optimization'' by looking for typeahead periodically while updating the screen. If input is found, and it is coming from a tty, the current update is postponed until refresh or doupdate is called again, allowing faster response to commands typed in advance. This function allows specifying a different file descriptor for typeahead checking.

unctrl(ch)
Returns a string which is a printable representation of the character ch. Control characters are displayed as a caret followed by the character, for
example as ^C. Printing characters are left as they are.

ungetch(ch)
Push ch so the next getch() will return it. **Note:** Only one ch can be pushed before getch() is called.

ungetmouse(id, x, y, z, bstate)
Push a KEY_MOUSE event onto the input queue, associating the given state data with it.

use_env(flag)
If used, this function should be called before initscr() or newterm are called. When flag is false, the values of lines and columns specified in the terminfo database will be used, even if environment variables LINES and COLUMNS (used by default) are set, or if curses is running in a window (in which case default behavior would be to use the window size if LINES and COLUMNS are not set).

use_default_colors()
Allow use of default values for colors on terminals supporting this feature. Use this to support transparency in your application. The default color is assigned to the color number -1. After calling this function, init_pair(x, curses.COLOR_RED, -1) initializes, for instance, color pair x to a red foreground color on the default background.
6.15.2 Window Objects

Window objects, as returned by `initscr()` and `newwin()` above, have the following methods:

`addch([y, x[, ch[, attr]]])`

Note: A character means a C character (an ASCII code), rather than a Python character (a string of length 1). (This note is true whenever the documentation mentions a character.) The built-in `ord()` is handy for conveying strings to codes.

Paint character `ch` at `(y, x)` with attributes `attr`, overwriting any character previously painter at that location. By default, the character position and attributes are the current settings for the window object.

`addnstr([y, x[, str[, n[, attr]]]])`

Paint at most `n` characters of the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

`addstr([y, x[, str[, attr]]])`

Paint the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

`attroff(attr)`

Remove attribute `attr` from the ```background`` set applied to all writes to the current window.

`attron(attr)`

Add attribute `attr` from the ```background`` set applied to all writes to the current window.

`attrset(attr)`

Set the ```background`` set of attributes to `attr`. This set is initially 0 (no attributes).

`bkgd(`
Sets the background property of the window to the character \textit{ch}, with attributes \textit{attr}. The change is then applied to every character position in that window:

- The attribute of every character in the window is changed to the new background attribute.
- Wherever the former background character appears, it is changed to the new background character.

\textbf{bkgdset}( \textit{ch[, attr]} )

Sets the window's background. A window's background consists of a character and any combination of attributes. The attribute part of the background is combined (OR'ed) with all non-blank characters that are written into the window. Both the character and attribute parts of the background are combined with the blank characters. The background becomes a property of the character and moves with the character through any scrolling and insert/delete line/character operations.

\textbf{border}( [ls[, rs[, ts[, bs[, tl[, tr[, bl[, br]]]]]]]])

Draw a border around the edges of the window. Each parameter specifies the character to use for a specific part of the border; see the table below for more details. The characters can be specified as integers or as one-character strings.

\textbf{Note:} A 0 value for any parameter will cause the default character to be used for that parameter. Keyword parameters can \textit{not} be used. The defaults are listed in this table:

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>\textit{ls}</td>
<td>Left side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td>\textit{rs}</td>
<td>Right side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td>\textit{ts}</td>
<td>Top</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td>\textit{bs}</td>
<td>Bottom</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td>\textit{tl}</td>
<td>Upper-left corner</td>
<td>ACS_ULCORNER</td>
</tr>
<tr>
<td>\textit{tr}</td>
<td>Upper-right corner</td>
<td>ACS_URCORNER</td>
</tr>
<tr>
<td>\textit{bl}</td>
<td>Bottom-left corner</td>
<td>ACS_LLCORNER</td>
</tr>
<tr>
<td>\textit{br}</td>
<td>Bottom-right corner</td>
<td>ACS_LRCORNER</td>
</tr>
</tbody>
</table>
box([vertch, horch])
    Similar to border(), but both ls and rs are vertch and both ts and bs are horch. The default corner characters are always used by this function.

clear()
    Like erase(), but also causes the whole window to be repainted upon next call to refresh().

clearok(yes)
    If yes is 1, the next call to refresh() will clear the window completely.

clrtobot()
    Erase from cursor to the end of the window: all lines below the cursor are deleted, and then the equivalent of clrtoeol() is performed.

clrtoeol()
    Erase from cursor to the end of the line.

cursyncup()
    Updates the current cursor position of all the ancestors of the window to reflect the current cursor position of the window.

delch([y, x])
    Delete any character at (y, x).

deleteln()
    Delete the line under the cursor. All following lines are moved up by 1 line.

derwin([nlines, ncols], begin_y, begin_x)
    An abbreviation for `derive window`, derwin() is the same as calling subwin(), except that begin_y and begin_x are relative to the origin of the window, rather than relative to the entire screen. Returns a window object for the derived window.

echochar(ch[, attr])
Add character \textit{ch} with attribute \textit{attr}, and immediately call \texttt{refresh()} on the window.

\textbf{enclose}(y, x)
Tests whether the given pair of screen-relative character-cell coordinates are enclosed by the given window, returning true or false. It is useful for determining what subset of the screen windows enclose the location of a mouse event.

\textbf{erase()}
Clear the window.

\textbf{getbegyx()}
Return a tuple \((y, x)\) of co-ordinates of upper-left corner.

\textbf{getch}( [y, x])
Get a character. Note that the integer returned does \textit{not} have to be in ASCII range: function keys, keypad keys and so on return numbers higher than 256. In no-delay mode, \(-1\) is returned if there is no input.

\textbf{getkey}( [y, x])
Get a character, returning a string instead of an integer, as \texttt{getch()} does. Function keys, keypad keys and so on return a multibyte string containing the key name. In no-delay mode, an exception is raised if there is no input.

\textbf{getmaxyx()}
Return a tuple \((y, x)\) of the height and width of the window.

\textbf{getparyx()}
Returns the beginning coordinates of this window relative to its parent window into two integer variables \(y\) and \(x\). Returns \(-1, -1\) if this window has no parent.

\textbf{getstr}( [y, x])
Read a string from the user, with primitive line editing capacity.

\textbf{getyx()}

Return a tuple \((y, x)\) of current cursor position relative to the window's upper-left corner.

\[\text{hline}([y, x], ch, n)\]
Display a horizontal line starting at \((y, x)\) with length \(n\) consisting of the character \(ch\).

\[\text{idcok}(\text{flag})\]
If \(\text{flag}\) is false, curses no longer considers using the hardware insert/delete character feature of the terminal; if \(\text{flag}\) is true, use of character insertion and deletion is enabled. When curses is first initialized, use of character insert/delete is enabled by default.

\[\text{idlok}(\text{yes})\]
If called with \(\text{yes}\) equal to 1, \texttt{curses} will try and use hardware line editing facilities. Otherwise, line insertion/deletion are disabled.

\[\text{immedok}(\text{flag})\]
If \(\text{flag}\) is true, any change in the window image automatically causes the window to be refreshed; you no longer have to call \texttt{refresh()}\) yourself. However, it may degrade performance considerably, due to repeated calls to \texttt{wrefresh}. This option is disabled by default.

\[\text{inch}([y, x])\]
Return the character at the given position in the window. The bottom 8 bits are the character proper, and upper bits are the attributes.

\[\text{insch}([y, x], ch[, attr])\]
Paint character \(ch\) at \((y, x)\) with attributes \(attr\), moving the line from position \(x\) right by one character.

\[\text{insdelln}(nlines)\]
Inserts \(nlines\) lines into the specified window above the current line. The \(nlines\) bottom lines are lost. For negative \(nlines\), delete \(nlines\) lines starting with the one under the cursor, and move the remaining lines up. The bottom \(nlines\) lines are cleared. The current cursor position remains the same.
insertln()
Insert a blank line under the cursor. All following lines are moved down by 1 line.

insnstr([y, x], str, n, [, attr])
Insert a character string (as many characters as will fit on the line) before the character under the cursor, up to n characters. If n is zero or negative, the entire string is inserted. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to y, x, if specified).

insstr([y, x], str [, attr])
Insert a character string (as many characters as will fit on the line) before the character under the cursor. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to y, x, if specified).

instr([y, x] [, n])
Returns a string of characters, extracted from the window starting at the current cursor position, or at y, x if specified. Attributes are stripped from the characters. If n is specified, instr() returns return a string at most n characters long (exclusive of the trailing NUL).

is_linetouched(line)
Returns true if the specified line was modified since the last call to refresh(); otherwise returns false. Raises a curses.error exception if line is not valid for the given window.

is_wintouched()
Returns true if the specified window was modified since the last call to refresh(); otherwise returns false.

keypad(yes)
If yes is 1, escape sequences generated by some keys (keypad, function keys) will be interpreted by curses. If yes is 0, escape sequences will be left as is in the input stream.
**leaveok(yes)**

If yes is 1, cursor is left where it is on update, instead of being at ``cursor position.''' This reduces cursor movement where possible. If possible the cursor will be made invisible.

If yes is 0, cursor will always be at ``cursor position'' after an update.

**move(new_y, new_x)**

Move cursor to \((new_y, \ new_x)\).

**mvderwin(y, x)**

Moves the window inside its parent window. The screen-relative parameters of the window are not changed. This routine is used to display different parts of the parent window at the same physical position on the screen.

**mvwin(new_y, new_x)**

Move the window so its upper-left corner is at \((new_y, \ new_x)\).

**nodelay(yes)**

If yes is 1, `getch()` will be non-blocking.

**notimeout(yes)**

If yes is 1, escape sequences will not be timed out.

If yes is 0, after a few milliseconds, an escape sequence will not be interpreted, and will be left in the input stream as is.

**noutrefresh()**

Mark for refresh but wait. This function updates the data structure representing the desired state of the window, but does not force an update of the physical screen. To accomplish that, call `doupdate()`.

**overlay(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])**

Overlay the window on top of `destwin`. The windows need not be the same size, only the overlapping region is copied. This copy is non-destructive, which means that the current background character does not overwrite the old contents of `destwin`. 
To get fine-grained control over the copied region, the second form of `overlay()` can be used. `sminrow` and `smicol` are the upper-left coordinates of the source window, and the other variables mark a rectangle in the destination window.

```plaintext
overwrite (destwin[, sminrow, smicol, dminrow, dmincol, dmaxrow, dmaxcol])
```

Overwrite the window on top of `destwin`. The windows need not be the same size, in which case only the overlapping region is copied. This copy is destructive, which means that the current background character overwrites the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overwrite()` can be used. `sminrow` and `smicol` are the upper-left coordinates of the source window, the other variables mark a rectangle in the destination window.

```plaintext
putwin (file)
```

Writes all data associated with the window into the provided file object. This information can be later retrieved using the `getwin()` function.

```plaintext
redrawln (beg, num)
```

Indicates that the `num` screen lines, starting at line `beg`, are corrupted and should be completely redrawn on the next `refresh()` call.

```plaintext
redrawwin()
```

Touches the entire window, causing it to be completely redrawn on the next `refresh()` call.

```plaintext
refresh ([pminrow, pmincol, sminrow, smicol, smaxrow, smaxcol])
```

Update the display immediately (sync actual screen with previous drawing/deleting methods).

The 6 optional arguments can only be specified when the window is a pad created with `newpad()`. The additional parameters are needed to indicate what part of the pad and screen are involved. `pminrow` and `pmincol` specify the upper left-hand corner of the rectangle to be displayed in the pad.
sminrow, smincol, smaxrow, and smaxcol specify the edges of the rectangle
to be displayed on the screen. The lower right-hand corner of the rectangle
to be displayed in the pad is calculated from the screen coordinates, since
the rectangles must be the same size. Both rectangles must be entirely
contained within their respective structures. Negative values of pminrow,
pmincol, sminrow, or smincol are treated as if they were zero.

**scroll([lines = 1])**

Scroll the screen or scrolling region upward by lines lines.

**scrollok(flag)**

Controls what happens when the cursor of a window is moved off the edge
of the window or scrolling region, either as a result of a newline action on
the bottom line, or typing the last character of the last line. If flag is false,
the cursor is left on the bottom line. If flag is true, the window is scrolled up
one line. Note that in order to get the physical scrolling effect on the
terminal, it is also necessary to call idlok().

**setscrreg(top, bottom)**

Set the scrolling region from line top to line bottom. All scrolling actions
will take place in this region.

**standend()**

Turn off the standout attribute. On some terminals this has the side effect of
turning off all attributes.

**standout()**

Turn on attribute A_STANDOUT.

**subpad([nlines, ncols], begin_y, begin_x)**

Return a sub-window, whose upper-left corner is at (begin_y, begin_x),
and whose width/height is ncols/nlines.

**subwin([nlines, ncols], begin_y, begin_x)**

Return a sub-window, whose upper-left corner is at (begin_y, begin_x),
and whose width/height is ncols/nlines.
By default, the sub-window will extend from the specified position to the lower right corner of the window.

**syncdown()**

Touches each location in the window that has been touched in any of its ancestor windows. This routine is called by `refresh()`, so it should almost never be necessary to call it manually.

**syncok(flag)**

If called with `flag` set to true, then `syncup()` is called automatically whenever there is a change in the window.

**syncup()**

Touches all locations in ancestors of the window that have been changed in the window.

**timeout(delay)**

Sets blocking or non-blocking read behavior for the window. If `delay` is negative, blocking read is used (which will wait indefinitely for input). If `delay` is zero, then non-blocking read is used, and -1 will be returned by `getch()` if no input is waiting. If `delay` is positive, then `getch()` will block for `delay` milliseconds, and return -1 if there is still no input at the end of that time.

**touchline(start, count)**

Pretend `count` lines have been changed, starting with line `start`.

**touchwin()**

Pretend the whole window has been changed, for purposes of drawing optimizations.

**untouchwin()**

Marks all lines in the window as unchanged since the last call to `refresh()`.

**vline([y, x], ch, n)**

Display a vertical line starting at `(y, x)` with length `n` consisting of the
character `ch`.
6.15.3 Constants

The *curses* module defines the following data members:

**ERR**
Some curses routines that return an integer, such as `getch()`, return **ERR** upon failure.

**OK**
Some curses routines that return an integer, such as `napms()`, return **OK** upon success.

**version**
A string representing the current version of the module. Also available as `__version__`.

Several constants are available to specify character cell attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_ALTCHARSET</td>
<td>Alternate character set mode.</td>
</tr>
<tr>
<td>A_BLINK</td>
<td>Blink mode.</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Bold mode.</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Dim mode.</td>
</tr>
<tr>
<td>A_NORMAL</td>
<td>Normal attribute.</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>Standout mode.</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underline mode.</td>
</tr>
</tbody>
</table>

Keys are referred to by integer constants with names starting with "KEY_". The exact keycaps available are system dependent.

<table>
<thead>
<tr>
<th>Key constant</th>
<th>Key</th>
</tr>
</thead>
<tbody>
<tr>
<td>KEY_MIN</td>
<td>Minimum key value</td>
</tr>
<tr>
<td>KEY_BREAK</td>
<td>Break key (unreliable)</td>
</tr>
<tr>
<td>KEY_DOWN</td>
<td>Down-arrow</td>
</tr>
<tr>
<td>KEY_UP</td>
<td>Up-arrow</td>
</tr>
<tr>
<td>Key Code</td>
<td>Description</td>
</tr>
<tr>
<td>-----------</td>

</tbody>
</table>

On VT100s and their software emulations, such as X terminal emulators, there are normally at least four function keys (KEY_F1, KEY_F2, KEY_F3, KEY_F4) available, and the arrow keys mapped to KEY_UP, KEY_DOWN, KEY_LEFT and KEY_RIGHT in the obvious way. If your machine has a PC keyboard, it is safe to expect arrow keys and twelve function keys (older PC keyboards may have only ten function keys); also, the following keypad mappings are standard:
The following table lists characters from the alternate character set. These are inherited from the VT100 terminal, and will generally be available on software emulations such as X terminals. When there is no graphic available, curses falls back on a crude printable ASCII approximation. **Note:** These are available only after `initscr()` has been called.

<table>

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.16 curses.textpad -- Text input widget for curses programs

New in version 1.6.

The curses.textpad module provides a Textbox class that handles elementary text editing in a curses window, supporting a set of keybindings resembling those of Emacs (thus, also of Netscape Navigator, BBedit 6.x, FrameMaker, and many other programs). The module also provides a rectangle-drawing function useful for framing text boxes or for other purposes.

The module curses.textpad defines the following function:

rectangle (win, uly, ulx, lry, lrx)

Draw a rectangle. The first argument must be a window object; the remaining arguments are coordinates relative to that window. The second and third arguments are the y and x coordinates of the upper left hand corner of the rectangle to be drawn; the fourth and fifth arguments are the y and x coordinates of the lower right hand corner. The rectangle will be drawn using VT100/IBM PC forms characters on terminals that make this possible (including xterm and most other software terminal emulators). Otherwise it will be drawn with ASCII dashes, vertical bars, and plus signs.
6.16.1Textbox objects

You can instantiate a Textbox object as follows:

```
class Textbox( win)
    Return a textbox widget object. The win argument should be a curses WindowObject in which the textbox is to be contained. The edit cursor of the textbox is initially located at the upper left hand corner of the containing window, with coordinates (0, 0). The instance's stripspaces flag is initially on.
```

Textbox objects have the following methods:

```
edit([validator])
    This is the entry point you will normally use. It accepts editing keystrokes until one of the termination keystrokes is entered. If validator is supplied, it must be a function. It will be called for each keystroke entered with the keystroke as a parameter; command dispatch is done on the result. This method returns the window contents as a string; whether blanks in the window are included is affected by the stripspaces member.
```

```
do_command( ch)
    Process a single command keystroke. Here are the supported special keystrokes:
```

<table>
<thead>
<tr>
<th>Keystroke</th>

<tr>
<td>J</td>
<td>Terminate if the window is 1 line, otherwise insert newline.</td>
</tr>
<tr>
<td>K</td>
<td>If line is blank, delete it, otherwise clear to end of line.</td>
</tr>
<tr>
<td>L</td>
<td>Refresh screen.</td>
</tr>
<tr>
<td>N</td>
<td>Cursor down; move down one line.</td>
</tr>
<tr>
<td>O</td>
<td>Insert a blank line at cursor location.</td>
</tr>
<tr>
<td>P</td>
<td>Cursor up; move up one line.</td>
</tr>
</tbody>
</table>

Move operations do nothing if the cursor is at an edge where the movement is not possible. The following synonyms are supported where possible:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Keystroke</th>
</tr>
</thead>
<tbody>
<tr>
<td>KEY_LEFT</td>
<td>Control-B</td>
</tr>
<tr>
<td>KEY_RIGHT</td>
<td>Control-F</td>
</tr>
<tr>
<td>KEY_UP</td>
<td>Control-P</td>
</tr>
<tr>
<td>KEY_DOWN</td>
<td>Control-N</td>
</tr>
<tr>
<td>KEY_BACKSPACE</td>
<td>Control-h</td>
</tr>
</tbody>
</table>

All other keystrokes are treated as a command to insert the given character and move right (with line wrapping).

**gather()**
This method returns the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` member.

**stripspaces**
This data member is a flag which controls the interpretation of blanks in the window. When it is on, trailing blanks on each line are ignored; any cursor
motion that would land the cursor on a trailing blank goes to the end of that line instead, and trailing blanks are stripped when the window contents are gathered.
6.17 curses.wrapper -- Terminal handler for curses programs

New in version 1.6.

This module supplies one function, \texttt{wrapper()}, which runs another function which should be the rest of your curses-using application. If the application raises an exception, \texttt{wrapper()} will restore the terminal to a sane state before re-raising the exception and generating a traceback.

\texttt{wrapper( func, ...)}

Wrapper function that initializes curses and calls another function, \texttt{func}, restoring normal keyboard/screen behavior on error. The callable object \texttt{func} is then passed the main window 'stdscr' as its first argument, followed by any other arguments passed to \texttt{wrapper()}.

Before calling the hook function, \texttt{wrapper()} turns on cbreak mode, turns off echo, enables the terminal keypad, and initializes colors if the terminal has color support. On exit (whether normally or by exception) it restores cooked mode, turns on echo, and disables the terminal keypad.
6.18 curses.ascii -- Utilities for ASCII characters

New in version 1.6.

The `curses.ascii` module supplies name constants for ASCII characters and functions to test membership in various ASCII character classes. The constants supplied are names for control characters as follows:

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>NUL</td>
<td></td>
</tr>
<tr>
<td>SOH</td>
<td>Start of heading, console interrupt</td>
</tr>
<tr>
<td>STX</td>
<td>Start of text</td>
</tr>
<tr>
<td>ETX</td>
<td>End of text</td>
</tr>
<tr>
<td>EOT</td>
<td>End of transmission</td>
</tr>
<tr>
<td>ENQ</td>
<td>Enquiry, goes with ACK flow control</td>
</tr>
<tr>
<td>ACK</td>

</tr>
<tr>
<td>US</td>
<td>Unit separator</td>
</tr>
<tr>
<td>SP</td>
<td>Space</td>
</tr>
<tr>
<td>DEL</td>
<td>Delete</td>
</tr>
</tbody>
</table>

Note that many of these have little practical significance in modern usage. The mnemonics derive from teleprinter conventions that predate digital computers.

The module supplies the following functions, patterned on those in the standard C library:

`isalnum(c)`
Checks for an ASCII alphanumeric character; it is equivalent to "isalpha(c) or isdigit(c)".

`isalpha(c)`
Checks for an ASCII alphabetic character; it is equivalent to "isupper(c) or islower(c)".

`isascii(c)`
Checks for a character value that fits in the 7-bit ASCII set.

`isblank(c)`
Checks for an ASCII whitespace character.

`iscntrl(c)`
Checks for an ASCII control character (in the range 0x00 to 0x1f).

**isdigit(c)**
Checks for an ASCII decimal digit, "0" through "9". This is equivalent to "c in string.digits".

**isgraph(c)**
Checks for ASCII any printable character except space.

**islower(c)**
Checks for an ASCII lower-case character.

**isprint(c)**
Checks for any ASCII printable character including space.

**ispunct(c)**
Checks for any printable ASCII character which is not a space or an alphanumeric character.

**isspace(c)**
Checks for ASCII white-space characters; space, line feed, carriage return, form feed, horizontal tab, vertical tab.

**isupper(c)**
Checks for an ASCII uppercase letter.

**isxdigit(c)**
Checks for an ASCII hexadecimal digit. This is equivalent to "c in string.hexdigits".

**isctrl(c)**
Checks for an ASCII control character (ordinal values 0 to 31).

**ismeta(c)**
Checks for a non-ASCII character (ordinal values 0x80 and above).

These functions accept either integers or strings; when the argument is a string, it
is first converted using the built-in function `ord()`.

Note that all these functions check ordinal bit values derived from the first character of the string you pass in; they do not actually know anything about the host machine's character encoding. For functions that know about the character encoding (and handle internationalization properly) see the `string` module.

The following two functions take either a single-character string or integer byte value; they return a value of the same type.

**ascii(c)**

Return the ASCII value corresponding to the low 7 bits of `c`.

**ctrl(c)**

Return the control character corresponding to the given character (the character bit value is bitwise-anded with 0x1f).

**alt(c)**

Return the 8-bit character corresponding to the given ASCII character (the character bit value is bitwise-ored with 0x80).

The following function takes either a single-character string or integer value; it returns a string.

**unctrl(c)**

Return a string representation of the ASCII character `c`. If `c` is printable, this string is the character itself. If the character is a control character (0x00-0x1f) the string consists of a caret ("^") followed by the corresponding uppercase letter. If the character is an ASCII delete (0x7f) the string is '\?' . If the character has its meta bit (0x80) set, the meta bit is stripped, the preceding rules applied, and "!" prepended to the result.

**controlnames**

A 33-element string array that contains the ASCII mnemonics for the thirty-two ASCII control characters from 0 (NUL) to 0x1f (US), in order, plus the mnemonic "SP" for the space character.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.19 curses.panel -- A panel stack extension for curses.

Panels are windows with the added feature of depth, so they can be stacked on top of each other, and only the visible portions of each window will be displayed. Panels can be added, moved up or down in the stack, and removed.

Subsections

- 6.19.1 Functions
- 6.19.2 Panel Objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.19.1 Functions

The module `curses.panel` defines the following functions:

**bottom_panel()**
Returns the bottom panel in the panel stack.

**new_panel (win)**
Returns a panel object, associating it with the given window `win`. Be aware that you need to keep the returned panel object referenced explicitly. If you don't, the panel object is garbage collected and removed from the panel stack.

**top_panel()**
Returns the top panel in the panel stack.

**update_panels()**
Updates the virtual screen after changes in the panel stack. This does not call `curses.doupdate()`, so you'll have to do this yourself.
6.19.2 Panel Objects

Panel objects, as returned by `new_panel()` above, are windows with a stacking order. There's always a window associated with a panel which determines the content, while the panel methods are responsible for the window's depth in the panel stack.

Panel objects have the following methods:

- **above()**
  Returns the panel above the current panel.

- **below()**
  Returns the panel below the current panel.

- **bottom()**
  Push the panel to the bottom of the stack.

- **hidden()**
  Returns true if the panel is hidden (not visible), false otherwise.

- **hide()**
  Hide the panel. This does not delete the object, it just makes the window on screen invisible.

- **move(y, x)**
  Move the panel to the screen coordinates \((y, x)\).

- **replace(win)**
  Change the window associated with the panel to the window `win`.

- **set_userptr(obj)**
  Set the panel's user pointer to `obj`. This is used to associate an arbitrary piece of data with the panel, and can be any Python object.

- **show()**
Display the panel (which might have been hidden).

**top()**
Push panel to the top of the stack.

**userptr()**
Returns the user pointer for the panel. This might be any Python object.

**window()**
Returns the window object associated with the panel.
6.20 getopt -- Parser for command line options

This module helps scripts to parse the command line arguments in `sys.argv`. It supports the same conventions as the UNIX `getopt()` function (including the special meanings of arguments of the form `'-`-`' and `'- -'`). Long options similar to those supported by GNU software may be used as well via an optional third argument. This module provides a single function and an exception:

```python
getopt(args, options[, long_options])
```

Parses command line options and parameter list. `args` is the argument list to be parsed, without the leading reference to the running program. Typically, this means "`sys.argv[1:]`". `options` is the string of option letters that the script wants to recognize, with options that require an argument followed by a colon (":"; i.e., the same format that UNIX `getopt()` uses).

**Note:** Unlike GNU `getopt()`, after a non-option argument, all further arguments are considered also non-options. This is similar to the way non-GNU UNIX systems work.

`long_options`, if specified, must be a list of strings with the names of the long options which should be supported. The leading ' - - ' characters should not be included in the option name. Long options which require an argument should be followed by an equal sign ("="). To accept only long options, `options` should be an empty string. Long options on the command line can be recognized so long as they provide a prefix of the option name that matches exactly one of the accepted options. For example, if `long_options` is `[ 'foo', 'frob' ]`, the option `--fo` will match as `--foo`, but `--f` will not match uniquely, so `GetoptError` will be raised.

The return value consists of two elements: the first is a list of `(option, value)` pairs; the second is the list of program arguments left after the option list was stripped (this is a trailing slice of `args`). Each option-and-value pair returned has the option as its first element, prefixed with a hyphen for short options (e.g., ' -x ') or two hyphens for long options (e.g.,
'--long-option'), and the option argument as its second element, or an empty string if the option has no argument. The options occur in the list in the same order in which they were found, thus allowing multiple occurrences. Long and short options may be mixed.

**gnu_getopt** *(args, options[, long_options]*)

This function works like **getopt()**, except that GNU style scanning mode is used by default. This means that option and non-option arguments may be intermixed. The **getopt()** function stops processing options as soon as a non-option argument is encountered.

If the first character of the option string is `+`, or if the environment variable **POSIXLY_CORRECT** is set, then option processing stops as soon as a non-option argument is encountered.

New in version 2.3.

**exception GetoptError**

This is raised when an unrecognized option is found in the argument list or when an option requiring an argument is given none. The argument to the exception is a string indicating the cause of the error. For long options, an argument given to an option which does not require one will also cause this exception to be raised. The attributes **msg** and **opt** give the error message and related option; if there is no specific option to which the exception relates, **opt** is an empty string.

Changed in version 1.6: Introduced **GetoptError** as a synonym for **error**.

**exception error**

Alias for **GetoptError**; for backward compatibility.

An example using only **UNIX** style options:

```python
>>> import getopt
>>> args = '-a -b -cfoo -d bar a1 a2'.split()
>>> args
['-a', '-b', '-cfoo', '-d', 'bar', 'a1', 'a2']
>>> optlist, args = getopt.getopt(args, 'abc:d: ')
>>> optlist
[('-a', ''), ('-b', ''), ('-c', 'foo'), ('-d', 'bar')]
```
Using long option names is equally easy:

```python
>>> s = '--condition=foo --testing --output-file abc.def -x a1 a2
>>> args = s.split()
>>> args
['--condition=foo', '--testing', '--output-file', 'abc.def', '-x', '
>>> optlist, args = getopt.getopt(args, 'x', [ ...    'condition=', 'output-file=', 'testing'])
>>> optlist
[('--condition', 'foo'), ('--testing', ''), ('--output-file', 'abc.def')] >>> args
['a1', 'a2']
```

In a script, typical usage is something like this:

```python
import getopt, sys

def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], "ho:v", ["help", "o"
except getopt.GetoptError:
    # print help information and exit:
    usage()
    sys.exit(2)
output = None
verbose = False
for o, a in opts:
    if o == "-v":
        verbose = True
    if o in ("-h", "--help"):
        usage()
        sys.exit() if o in ("-o", "--output"):
            output = a
    
    if __name__ == "__main__":
        main()
```

See About this document... for information on suggesting changes.
6.21 optparse -- More powerful command line option parser

New in version 2.3.

optparse is a more convenient, flexible, and powerful library for parsing command-line options than getopt. optparse uses a more declarative style of command-line parsing: you create an instance of OptionParser, populate it with options, and parse the command line. optparse allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here's an example of using optparse in a simple script:

```python
from optparse import OptionParser

parser = OptionParser()
parser.add_option("-f", "--file", dest="filename",
                  help="write report to FILE", metavar="FILE")
parser.add_option("-q", "--quiet",
                  action="store_false", dest="verbose", default=True,
                  help="don't print status messages to stdout")

(options, args) = parser.parse_args()
```

With these few lines of code, users of your script can now do the `usual thing` on the command-line, for example:

```bash
<yourscript> --file=outfile -q
```

As it parses the command line, optparse sets attributes of the options object returned by parse_args() based on user-supplied command-line values. When parse_args() returns from parsing this command line, options.filename will be "outfile" and options.verbose will be False. optparse supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:
Additionally, users can run one of

```bash
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script's options:

```
usage: <yourscript> [options]

options:
  -h, --help                      show this help message and exit
  -f FILE, --file=FILE           write report to FILE
  -q, --quiet                    don't print status messages to stdout
```

where the value of `yourscript` is determined at runtime (normally from `sys.argv[0]`).

6.21.5.2 Adding new actions
6.21.5.3 Other reasons to extend optparse
6.21.1 Background

optparse was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

Subsections

- 6.21.1.1 Terminology

- 6.21.1.3 What are positional arguments for?
6.21.2 Tutorial

While optparse is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any optparse-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```python
from optparse import OptionParser

parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```python
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as "-f" or "--file", and several option attributes that tell optparse what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```python
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to add_option() are effectively labels for the option defined by that call. For brevity, we will frequently refer to encountering an option on the command line; in reality, optparse encounters option strings and looks up options from them.

Once all of your options are defined, instruct optparse to parse your program's command line:

```python
(options, args) = parser.parse_args()
```
(If you like, you can pass a custom argument list to `parse_args()`, but that's rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- `options`, an object containing values for all of your options—e.g. if "-file" takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option

- `args`, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: `action`, `type`, `dest` (destination), and `help`. Of these, `action` is the most fundamental.

6.21.4 Option Callbacks

When `optparse`'s built-in actions and types aren't quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the `callback` action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

Adding new types
6.21.5 Extending optparse

Since the two major controlling factors in how optparse interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

Also, the examples/ directory of the source distribution includes several demonstrations of extending optparse in different ways: e.g. a case-insensitive option parser, or two kinds of option parsers that implement `required options`.

6.22 tempfile -- Generate temporary files and directories

This module generates temporary files and directories. It works on all supported platforms.

In version 2.3 of Python, this module was overhauled for enhanced security. It now provides three new functions, NamedTemporaryFile(), mkstemp(), and mkdtemp(), which should eliminate all remaining need to use the insecure mktemp() function. Temporary file names created by this module no longer contain the process ID; instead a string of six random characters is used.

Also, all the user-callable functions now take additional arguments which allow direct control over the location and name of temporary files. It is no longer necessary to use the global tempdir and template variables. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable functions:

**TemporaryFile**([`mode='w+b'`, `bufsize=-1`, `suffix`, `prefix`, `dir`])

Return a file (or file-like) object that can be used as a temporary storage area. The file is created using mkstemp. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under UNIX, the directory entry for the file is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function having or not having a visible name in the file system.

The mode parameter defaults to 'w+b' so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. bufsize defaults to -1, meaning that the operating system default is used.

The dir, prefix and suffix parameters are passed to mkstemp().
NamedTemporaryFile([mode='w+b', bufsize=-1, suffix=, prefix=, dir=])

This function operates exactly as TemporaryFile() does, except that the file is guaranteed to have a visible name in the file system (on UNIX, the directory entry is not unlinked). That name can be retrieved from the name member of the file object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on UNIX; it cannot on Windows NT or later). New in version 2.3.

mkstemp([suffix=, prefix=, dir=, text=])

Creates a temporary file in the most secure manner possible. There are no race conditions in the file's creation, assuming that the platform properly implements the O_EXCL flag for os.open(). The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike TemporaryFile(), the user of mkstemp() is responsible for deleting the temporary file when done with it.

If suffix is specified, the file name will end with that suffix, otherwise there will be no suffix. mkstemp() does not put a dot between the file name and the suffix; if you need one, put it at the beginning of suffix.

If prefix is specified, the file name will begin with that prefix; otherwise, a default prefix is used.

If dir is specified, the file will be created in that directory; otherwise, a default directory is used.

If text is specified, it indicates whether to open the file in binary mode (the default) or text mode. On some platforms, this makes no difference.

mkstemp() returns a tuple containing an OS-level handle to an open file (as would be returned by os.open()) and the absolute pathname of that file, in that order. New in version 2.3.
**mkdtemp([suffix[, prefix[, dir]]])**

Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory's creation. The directory is readable, writable, and searchable only by the creating user ID.

The user of `mkdtemp()` is responsible for deleting the temporary directory and its contents when done with it.

The *prefix, suffix, and dir* arguments are the same as for `mkstemp()`.

`mkdtemp()` returns the absolute pathname of the new directory. New in version 2.3.

**mktemp([suffix[, prefix[, dir]]])**

*Deprecated since release 2.3.* Use `mkstemp()` instead.

Return an absolute pathname of a file that did not exist at the time the call is made. The *prefix, suffix, and dir* arguments are the same as for `mkstemp()`.

**Warning:** Use of this function may introduce a security hole in your program. By the time you get around to doing anything with the file name it returns, someone else may have beaten you to the punch.

The module uses two global variables that tell it how to construct a temporary name. They are initialized at the first call to any of the functions above. The caller may change them, but this is discouraged; use the appropriate function arguments, instead.

**tempdir**

When set to a value other than `None`, this variable defines the default value for the *dir* argument to all the functions defined in this module.

If `tempdir` is unset or `None` at any call to any of the above functions, Python searches a standard list of directories and sets `tempdir` to the first one which the calling user can create files in. The list is:

1. The directory named by the TMPDIR environment variable.
2. The directory named by the TEMP environment variable.
3. The directory named by the TMP environment variable.
4. A platform-specific location:
   - On RiscOS, the directory named by the Wimp$ScrapDir environment variable.
   - On Windows, the directories C:TEMP, C:TMP, TEMP, and TMP, in that order.
   - On all other platforms, the directories /tmp, /var/tmp, and /usr/tmp, in that order.
5. As a last resort, the current working directory.

`gettempdir()`
Return the directory currently selected to create temporary files in. If `tempdir` is not `None`, this simply returns its contents; otherwise, the search described above is performed, and the result returned.

`template`
*Deprecated since release 2.0.* Use `gettempprefix()` instead.

When set to a value other than `None`, this variable defines the prefix of the final component of the filenames returned by `mktemp()`. A string of six random letters and digits is appended to the prefix to make the filename unique. On Windows, the default prefix is ~T; on all other systems it is tmp.

Older versions of this module used to require that `template` be set to `None` after a call to `os.fork()`; this has not been necessary since version 1.5.2.

`gettempprefix()`
Return the filename prefix used to create temporary files. This does not contain the directory component. Using this function is preferred over reading the `template` variable directly. New in version 1.5.2.
See About this document... for information on suggesting changes.
6.23 errno -- Standard errno system symbols

This module makes available standard errno system symbols. The value of each symbol is the corresponding integer value. The names and descriptions are borrowed from linux/include/errno.h, which should be pretty all-inclusive.

**errorcode**

Dictionary providing a mapping from the errno value to the string name in the underlying system. For instance, errno.errorcode[errno.EPERM] maps to 'EPERM'.

To translate a numeric error code to an error message, use os.strerror().

Of the following list, symbols that are not used on the current platform are not defined by the module. The specific list of defined symbols is available as errno.errorcode.keys(). Symbols available can include:

**EPERM**

Operation not permitted

**ENOENT**

No such file or directory

**ESRCH**

No such process

**EINTR**

Interrupted system call

**EIO**

I/O error

**ENXIO**

No such device or address

**E2BIG**
Arg list too long

ENOEXEC
    Exec format error

EBADF
    Bad file number

ECHILD
    No child processes

EAGAIN
    Try again

ENOMEM
    Out of memory

EACCES
    Permission denied

EFAULT
    Bad address

ENOTBLK
    Block device required

EBUSY
    Device or resource busy

EEXIST
    File exists

EXDEV
    Cross-device link

ENODEV
    No such device

ENOTDIR
    Not a directory
**EISDIR**
Is a directory

**EINVAL**
Invalid argument

**ENFILE**
File table overflow

**EMFILE**
Too many open files

**ENOTTY**
Not a typewriter

**ETXTBSY**
Text file busy

**EFBIG**
File too large

**ENOSPC**
No space left on device

**ESPIPE**
Illegal seek

**EROFS**
Read-only file system

**EMLINK**
Too many links

**EPIPE**
Broken pipe

**EDOM**
Math argument out of domain of func

**ERANGE**
Math result not representable

**EDEADLK**
Resource deadlock would occur

**ENAMETOOLONG**
File name too long

**ENOLCK**
No record locks available

**ENOSYS**
Function not implemented

**ENOTEMPTY**
Directory not empty

**ELOOP**
Too many symbolic links encountered

**EWOULDBLOCK**
Operation would block

**ENOMSG**
No message of desired type

**EIDRM**
Identifier removed

**ECHRNG**
Channel number out of range

**EL2NSYNC**
Level 2 not synchronized

**EL3HLT**
Level 3 halted

**EL3RST**
Level 3 reset
**ELNRNG**
Link number out of range

**EUNATCH**
Protocol driver not attached

**ENOCSI**
No CSI structure available

**EL2HLT**
Level 2 halted

**EBADE**
Invalid exchange

**EBADR**
Invalid request descriptor

**EXFULL**
Exchange full

**ENOANO**
No anode

**EBADRQC**
Invalid request code

**EBADSLT**
Invalid slot

**EDEADLOCK**
File locking deadlock error

**EBFONT**
Bad font file format

**ENOSTR**
Device not a stream

**ENODATA**
No data available

**ETIME**
Timer expired

**ENOSR**
Out of streams resources

**ENONET**
Machine is not on the network

**ENOPKG**
Package not installed

**EREMOTE**
Object is remote

**ENOLINK**
Link has been severed

**EADV**
Advertise error

**ESRMNT**
Srmount error

**ECOMM**
Communication error on send

**EPROTO**
Protocol error

**EMULTIHOP**
Multihop attempted

**EDOTDOT**
RFS specific error

**EBADMSG**
Not a data message
**EOVERFLOW**
Value too large for defined data type

**ENOTUNIQ**
Name not unique on network

**EBADFD**
File descriptor in bad state

**EREMCHG**
Remote address changed

**ELIBACC**
Can not access a needed shared library

**ELIBBAD**
Accessing a corrupted shared library

**ELIBSCN**
.lib section in a.out corrupted

**ELIBMAX**
Attempting to link in too many shared libraries

**ELIBEXEC**
Cannot exec a shared library directly

**EILSEQ**
Illegal byte sequence

**ERESTART**
Interrupted system call should be restarted

**ESTRPIPE**
Streams pipe error

**EUSERS**
Too many users

**ENOTSOCK**
Socket operation on non-socket

**EDESTADDRREQ**
Destination address required

**EMSGSIZE**
Message too long

**EPROTOTYPE**
Protocol wrong type for socket

**ENOPROTOOPT**
Protocol not available

**EPROTONOSUPPORT**
Protocol not supported

**ESOCKTNOSUPPORT**
Socket type not supported

**EOPNOTSUPP**
Operation not supported on transport endpoint

**EPFNOSUPPORT**
Protocol family not supported

**EAFNOSUPPORT**
Address family not supported by protocol

**EADDRINUSE**
Address already in use

**EADDRNOTAVAIL**
Cannot assign requested address

**ENETDOWN**
Network is down

**ENETUNREACH**
Network is unreachable
ENETRESET
   Network dropped connection because of reset

ECONNABORTED
   Software caused connection abort

ECONNRESET
   Connection reset by peer

ENOBUFFS
   No buffer space available

EISCONN
   Transport endpoint is already connected

ENOTCONN
   Transport endpoint is not connected

ESHUTDOWN
   Cannot send after transport endpoint shutdown

ETOOMANYREFS
   Too many references: cannot splice

ETIMEDOUT
   Connection timed out

ECONNREFUSED
   Connection refused

EHOSTDOWN
   Host is down

EHOSTUNREACH
   No route to host

EALREADY
   Operation already in progress

EINPROGRESS
Operation now in progress

**ESTALE**
Stale NFS file handle

**EUCLEAN**
Structure needs cleaning

**ENOTNAM**
Not a XENIX named type file

**ENAVAIL**
No XENIX semaphores available

**EISNAM**
Is a named type file

**EREMOTEIO**
Remote I/O error

**EDQUOT**
Quota exceeded
6.24 glob -- UNIX style pathname pattern expansion

The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the UNIX shell. No tilde expansion is done, but *, ?, and character ranges expressed with [] will be correctly matched. This is done by using the `os.listdir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

`glob(pathname)`

Returns a possibly-empty list of path names that match `pathname`, which must be a string containing a path specification. `pathname` can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../../Tools/*/*.gif`), and can contain shell-style wildcards. Broken symlinks are included in the results (as in the shell).

For example, consider a directory containing only the following files: 1.gif, 2.txt, and card.gif. `glob()` will produce the following results. Notice how any leading components of the path are preserved.

```python
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
>>> glob.glob('*.gif')
['1.gif', 'card.gif']
>>> glob.glob('?.gif')
['1.gif']
```

See Also:

Module `fnmatch`:

Shell-style filename (not path) expansion.
Release 2.4.4c1, documentation updated on 11 October 2006.  
See About this document... for information on suggesting changes.
6.25 fnmatch -- U\textsc{NIX} filename pattern matching

This module provides support for \textsc{UNIX} shell-style wildcards, which are \textit{not} the same as regular expressions (which are documented in the \texttt{re} module). The special characters used in shell-style wildcards are:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>matches everything</td>
</tr>
<tr>
<td>?</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[seq]</td>
<td>matches any character in seq</td>
</tr>
<tr>
<td>[!seq]</td>
<td>matches any character not in seq</td>
</tr>
</tbody>
</table>

Note that the filename separator ('/' on \textsc{UNIX}) is \textit{not} special to this module. See module \texttt{glob} for pathname expansion (\texttt{glob} uses \texttt{fnmatch()} to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the * and ? patterns.

\begin{verbatim}
fnmatch(filename, pattern)
\end{verbatim}

Test whether the \texttt{filename} string matches the \texttt{pattern} string, returning true or false. If the operating system is case-insensitive, then both parameters will be normalized to all lower- or upper-case before the comparison is performed. If you require a case-sensitive comparison regardless of whether that's standard for your operating system, use \texttt{fnmatchcase()} instead.

\begin{verbatim}
fnmatchcase(filename, pattern)
\end{verbatim}

Test whether \texttt{filename} matches \texttt{pattern}, returning true or false; the comparison is case-sensitive.

\begin{verbatim}
filter(names, pattern)
\end{verbatim}

Return the subset of the list of \texttt{names} that match \texttt{pattern}. It is the same as \[n \text{ for } n \text{ in } \texttt{names} \text{ if } \texttt{fnmatch(n, pattern)}\], but implemented more efficiently. New in version 2.2.
See Also:

Module **glob**:  
UNIX shell-style path expansion.
6.26 shutil -- High-level file operations

The shutil module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal.

Caveat: On MacOS, the resource fork and other metadata are not used. For file copies, this means that resources will be lost and file type and creator codes will not be correct.

copyfile( src, dst)
Copy the contents of the file named src to a file named dst. The destination location must be writable; otherwise, an IOError exception will be raised. If dst already exists, it will be replaced. Special files such as character or block devices and pipes cannot be copied with this function. src and dst are path names given as strings.

copyfileobj( fsrc, fdst[, length])
Copy the contents of the file-like object fsrc to the file-like object fdst. The integer length, if given, is the buffer size. In particular, a negative length value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption.

copymode( src, dst)
Copy the permission bits from src to dst. The file contents, owner, and group are unaffected. src and dst are path names given as strings.

copystat( src, dst)
Copy the permission bits, last access time, and last modification time from src to dst. The file contents, owner, and group are unaffected. src and dst are path names given as strings.

copy( src, dst)
Copy the file `src` to the file or directory `dst`. If `dst` is a directory, a file with the same basename as `src` is created (or overwritten) in the directory specified. Permission bits are copied. `src` and `dst` are path names given as strings.

`copy2(src, dst)`

Similar to `copy()`, but last access time and last modification time are copied as well. This is similar to the UNIX command `cp -p`.

`copytree(src, dst[, symlinks])`

Recursively copy an entire directory tree rooted at `src`. The destination directory, named by `dst`, must not already exist; it will be created. Individual files are copied using `copy2()`. If `symlinks` is true, symbolic links in the source tree are represented as symbolic links in the new tree; if false or omitted, the contents of the linked files are copied to the new tree. If exception(s) occur, an Error is raised with a list of reasons.

The source code for this should be considered an example rather than a tool. Changed in version 2.3: Error is raised if any exceptions occur during copying, rather than printing a message.

`rmtree(path[, ignore_errors[, onerror]])`

Delete an entire directory tree. If `ignore_errors` is true, errors resulting from failed removals will be ignored; if false or omitted, such errors are handled by calling a handler specified by `onerror` or, if that is omitted, they raise an exception.

If `onerror` is provided, it must be a callable that accepts three parameters: `function`, `path`, and `excinfo`. The first parameter, `function`, is the function which raised the exception; it will be `os.listdir()`, `os.remove()` or `os.rmdir()`. The second parameter, `path`, will be the path name passed to `function`. The third parameter, `excinfo`, will be the exception information return by `sys.exc_info()`. Exceptions raised by `onerror` will not be caught.

`move(src, dst)`

Recursively move a file or directory to another location.
If the destination is on our current filesystem, then simply use rename. Otherwise, copy src to the dst and then remove src.

New in version 2.3.

**exception Error**

This exception collects exceptions that raised during a mult-file operation. For `copytree`, the exception argument is a list of 3-tuples (`srcname`, `dstname`, `exception`).

New in version 2.3.
6.26.1 Example

This example is the implementation of the `copytree()` function, described above, with the docstring omitted. It demonstrates many of the other functions provided by this module.

```python
def copytree(src, dst, symlinks=0):
    names = os.listdir(src)
    os.mkdir(dst)
    for name in names:
        srcname = os.path.join(src, name)
        dstname = os.path.join(dst, name)
        try:
            if symlinks and os.path.islink(srcname):
                linkto = os.readlink(srcname)
                os.symlink(linkto, dstname)
            elif os.path.isdir(srcname):
                copytree(srcname, dstname, symlinks)
            else:
                copy2(srcname, dstname)
        except (IOError, os.error), why:
            print "Can't copy %s to %s: %s" % (`srcname`, `dstname`,
```

Python Library Reference

Previous: 6.26 shutil  Up: 6.26 shutil  Next: 6.27 locale

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.27 locale -- Internationalization services

The `locale` module opens access to the POSIX locale database and functionality. The POSIX locale mechanism allows programmers to deal with certain cultural issues in an application, without requiring the programmer to know all the specifics of each country where the software is executed.

The `locale` module is implemented on top of the `_locale` module, which in turn uses an ANSI C locale implementation if available.

The `locale` module defines the following exception and functions:

**exception Error**
Exception raised when `setlocale()` fails.

**setlocale**( `category`, `locale` )

If `locale` is specified, it may be a string, a tuple of the form `(language code, encoding)`, or `None`. If it is a tuple, it is converted to a string using the locale aliasing engine. If `locale` is given and not `None`, `setlocale()` modifies the locale setting for the `category`. The available categories are listed in the data description below. The value is the name of a locale. An empty string specifies the user's default settings. If the modification of the locale fails, the exception `Error` is raised. If successful, the new locale setting is returned.

If `locale` is omitted or `None`, the current setting for `category` is returned.

`setlocale()` is not thread safe on most systems. Applications typically start with a call of

```
import locale
locale.setlocale(locale.LC_ALL, '')
```

This sets the locale for all categories to the user's default setting (typically specified in the LANG environment variable). If the locale is not changed
thereafter, using multithreading should not cause problems.

Changed in version 2.0: Added support for tuple values of the `locale` parameter.

`localeconv()`

Returns the database of the local conventions as a dictionary. This dictionary has the following strings as keys:

<table>
<thead>
<tr>
<th>Key</th>
<th>Category</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>LC_NUMERIC</td>
<td>'decimal_point'</td>
<td>Decimal point character.</td>
</tr>
<tr>
<td></td>
<td>'grouping'</td>
<td>Sequence of numbers specifying which relative positions the</td>
</tr>
<tr>
<td></td>
<td></td>
<td>'thousands_sep' is expected. If the sequence is terminated with</td>
</tr>
<tr>
<td></td>
<td></td>
<td>CHAR_MAX, no further grouping is performed. If the sequence terminates</td>
</tr>
<tr>
<td></td>
<td></td>
<td>with a 0, the last group size is repeatedly used.</td>
</tr>
<tr>
<td></td>
<td>'thousands_sep'</td>
<td>Character used between groups.</td>
</tr>
<tr>
<td>LC_MONETARY</td>
<td>'int_curr_symbol'</td>
<td>International currency symbol.</td>
</tr>
<tr>
<td></td>
<td>'currency_symbol'</td>
<td>Local currency symbol.</td>
</tr>
<tr>
<td></td>
<td>'mon_decimal_point'</td>
<td>Decimal point used for monetary values.</td>
</tr>
<tr>
<td></td>
<td>'mon_thousands_sep'</td>
<td>Group separator used for monetary values.</td>
</tr>
<tr>
<td></td>
<td>'mon_grouping'</td>
<td>Equivalent to 'grouping', used for monetary values.</td>
</tr>
<tr>
<td></td>
<td>'positive_sign'</td>
<td>Symbol used to annotate a positive monetary</td>
</tr>
</tbody>
</table>
The possible values for 'p_sign_posn' and 'n_sign_posn' are given below.

<table>
<thead>
<tr>
<th>Value</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Currency and value are surrounded by parentheses.</td>
</tr>
<tr>
<td>1</td>
<td>The sign should precede the value and currency symbol.</td>
</tr>
<tr>
<td>2</td>
<td>The sign should follow the value and currency symbol.</td>
</tr>
<tr>
<td>3</td>
<td>The sign should immediately precede the value.</td>
</tr>
<tr>
<td>4</td>
<td>The sign should immediately follow the value.</td>
</tr>
<tr>
<td>LC_MAX</td>
<td>Nothing is specified in this locale.</td>
</tr>
</tbody>
</table>

**nl_langinfo**( option )

Return some locale-specific information as a string. This function is not available on all systems, and the set of possible options might also vary across platforms. The possible argument values are numbers, for which symbolic constants are available in the locale module.

**getdefaultlocale**([envvars])

Tries to determine the default locale settings and returns them as a tuple of the form (language code, encoding).

According to POSIX, a program which has not called `setlocale(LC_ALL, '')` runs using the portable 'C' locale. Calling
setlocale(LC_ALL, '') lets it use the default locale as defined by the LANG variable. Since we do not want to interfere with the current locale setting we thus emulate the behavior in the way described above.

To maintain compatibility with other platforms, not only the LANG variable is tested, but a list of variables given as envvars parameter. The first found to be defined will be used. envvars defaults to the search path used in GNU gettext; it must always contain the variable name "LANG". The GNU gettext search path contains 'LANGUAGE', 'LC_ALL', 'LC_CTYPE', and 'LANG', in that order.

Except for the code 'C', the language code corresponds to RFC 1766. language code and encoding may be None if their values cannot be determined. New in version 2.0.

getlocale([category])

Returns the current setting for the given locale category as sequence containing language code, encoding. category may be one of the LC_* values except LC_ALL. It defaults to LC_CTYPE.

Except for the code 'C', the language code corresponds to RFC 1766. language code and encoding may be None if their values cannot be determined. New in version 2.0.

getpreferredencoding([do_setlocale])

Return the encoding used for text data, according to user preferences. User preferences are expressed differently on different systems, and might not be available programmatically on some systems, so this function only returns a guess.

On some systems, it is necessary to invoke setlocale to obtain the user preferences, so this function is not thread-safe. If invoking setlocale is not necessary or desired, do_setlocale should be set to False.

New in version 2.3.

normalize(localename)

Returns a normalized locale code for the given locale name. The returned
locale code is formatted for use with `setlocale()`. If normalization fails, the original name is returned unchanged.

If the given encoding is not known, the function defaults to the default encoding for the locale code just like `setlocale()`. New in version 2.0.

```plaintext
resetlocale([category])
Sets the locale for category to the default setting.

The default setting is determined by calling `getdefaultlocale()`. category defaults to LC_ALL. New in version 2.0.
```

```plaintext
strcoll(string1, string2)
Compares two strings according to the current LC_COLLATE setting. As any other compare function, returns a negative, or a positive value, or 0, depending on whether string1 collates before or after string2 or is equal to it.
```

```plaintext
strxfrm(string)
Transforms a string to one that can be used for the built-in function `cmp()`, and still returns locale-aware results. This function can be used when the same string is compared repeatedly, e.g. when collating a sequence of strings.
```

```plaintext
format(format, val[, grouping])
Formats a number val according to the current LC_NUMERIC setting. The format follows the conventions of the % operator. For floating point values, the decimal point is modified if appropriate. If grouping is true, also takes the grouping into account.
```

```plaintext
str(float)
Formats a floating point number using the same format as the built-in function `str(float)`, but takes the decimal point into account.
```

```plaintext
atof(string)
Converts a string to a floating point number, following the LC_NUMERIC settings.
```
**atoi( string)**
Converts a string to an integer, following the **LC_NUMERIC** conventions.

**LC_CTYPE**
Locale category for the character type functions. Depending on the settings of this category, the functions of module **string** dealing with case change their behaviour.

**LC_COLLATE**
Locale category for sorting strings. The functions **strcoll()** and **strxfrm()** of the **locale** module are affected.

**LC_TIME**
Locale category for the formatting of time. The function **time.strftime()** follows these conventions.

**LC_MONETARY**
Locale category for formatting of monetary values. The available options are available from the **localeconv()** function.

**LC_MESSAGES**
Locale category for message display. Python currently does not support application specific locale-aware messages. Messages displayed by the operating system, like those returned by **os.strerror()** might be affected by this category.

**LC_NUMERIC**
Locale category for formatting numbers. The functions **format()**, **atoi()**, **atof()** and **str()** of the **locale** module are affected by that category. All other numeric formatting operations are not affected.

**LC_ALL**
Combination of all locale settings. If this flag is used when the locale is changed, setting the locale for all categories is attempted. If that fails for any category, no category is changed at all. When the locale is retrieved using this flag, a string indicating the setting for all categories is returned. This string can be later used to restore the settings.

**CHAR_MAX**
This is a symbolic constant used for different values returned by localeconv().

The nl_langinfo function accepts one of the following keys. Most descriptions are taken from the corresponding description in the GNU C library.

**CODESET**
Return a string with the name of the character encoding used in the selected locale.

**D_T_FMT**
Return a string that can be used as a format string for strftime(3) to represent time and date in a locale-specific way.

**D_FMT**
Return a string that can be used as a format string for strftime(3) to represent a date in a locale-specific way.

**T_FMT**
Return a string that can be used as a format string for strftime(3) to represent a time in a locale-specific way.

**T_FMT_AMPM**
The return value can be used as a format string for `strftime' to represent time in the am/pm format.

**DAY_1 ... DAY_7**
Return name of the n-th day of the week. **Warning:** This follows the US convention of DAY_1 being Sunday, not the international convention (ISO 8601) that Monday is the first day of the week.

**ABDAY_1 ... ABDAY_7**
Return abbreviated name of the n-th day of the week.

**MON_1 ... MON_12**
Return name of the n-th month.

**ABMON_1 ... ABMON_12**
Return abbreviated name of the n-th month.
RADIXCHAR
Return radix character (decimal dot, decimal comma, etc.)

THOUSEP
Return separator character for thousands (groups of three digits).

YESEXPR
Return a regular expression that can be used with the regex function to recognize a positive response to a yes/no question. **Warning:** The expression is in the syntax suitable for the `regex()` function from the C library, which might differ from the syntax used in `re`.

NOEXPR
Return a regular expression that can be used with the regex(3) function to recognize a negative response to a yes/no question.

CRNCYSTR
Return the currency symbol, preceded by "-" if the symbol should appear before the value, "+" if the symbol should appear after the value, or "." if the symbol should replace the radix character.

ERA
The return value represents the era used in the current locale.

Most locales do not define this value. An example of a locale which does define this value is the Japanese one. In Japan, the traditional representation of dates includes the name of the era corresponding to the then-emperor's reign.

Normally it should not be necessary to use this value directly. Specifying the E modifier in their format strings causes the strftime function to use this information. The format of the returned string is not specified, and therefore you should not assume knowledge of it on different systems.

ERA_YEAR
The return value gives the year in the relevant era of the locale.

ERA_D_T_FMT
This return value can be used as a format string for strftime to represent dates and times in a locale-specific era-based way.
ERA_D_FMT
This return value can be used as a format string for strftime to represent time in a locale-specific era-based way.

ALT_DIGITS
The return value is a representation of up to 100 values used to represent the values 0 to 99.

Example:

```python
>>> import locale
>>> loc = locale.getlocale(locale.LC_ALL) # get current locale
>>> locale.setlocale(locale.LC_ALL, 'de_DE') # use German locale; na
>>> locale.strcoll('f\xe4n', 'foo') # compare a string containing an
>>> locale.setlocale(locale.LC_ALL, '') # use user's preferred local
>>> locale.setlocale(locale.LC_ALL, 'C') # use default (C) locale
>>> locale.setlocale(locale.LC_ALL, loc) # restore saved locale
```

6.27.1 Background, details, hints, tips and caveats

The C standard defines the locale as a program-wide property that may be relatively expensive to change. On top of that, some implementation are broken in such a way that frequent locale changes may cause core dumps. This makes the locale somewhat painful to use correctly.

Initially, when a program is started, the locale is the "C" locale, no matter what the user’s preferred locale is. The program must explicitly say that it wants the user's preferred locale settings by calling `setlocale(LC_ALL, '')`.

It is generally a bad idea to call `setlocale()` in some library routine, since as a side effect it affects the entire program. Saving and restoring it is almost as bad: it is expensive and affects other threads that happen to run before the settings have been restored.

If, when coding a module for general use, you need a locale independent version of an operation that is affected by the locale (such as `string.lower()`, or certain formats used with `time.strftime()`), you will have to find a way to do it without using the standard library routine. Even better is convincing yourself that using locale settings is okay. Only as a last resort should you document that your module is not compatible with non-"C" locale settings.

The case conversion functions in the `string` module are affected by the locale settings. When a call to the `setlocale()` function changes the `LC_CTYPE` settings, the variables `string.lowercase`, `string.uppercase` and `string.letters` are recalculated. Note that this code that uses these variable through `from ... import ...`, e.g. `from string import letters`, is not affected by subsequent `setlocale()` calls.

The only way to perform numeric operations according to the locale is to use the special functions defined by this module: `atof()`, `atoi()`, `format()`, `str()`.
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
6.27.2 For extension writers and programs that embed Python

Extension modules should never call setlocale(), except to find out what the current locale is. But since the return value can only be used portably to restore it, that is not very useful (except perhaps to find out whether or not the locale is "C").

When Python code uses the locale module to change the locale, this also affects the embedding application. If the embedding application doesn't want this to happen, it should remove the _locale extension module (which does all the work) from the table of built-in modules in the config.c file, and make sure that the _locale module is not accessible as a shared library.
6.27.3 Access to message catalogs

The locale module exposes the C library's gettext interface on systems that provide this interface. It consists of the functions gettext(), dgettext(), dcgettext(), textdomain(), bindtextdomain(), and bind_textdomain_codeset(). These are similar to the same functions in the gettext module, but use the C library's binary format for message catalogs, and the C library's search algorithms for locating message catalogs.

Python applications should normally find no need to invoke these functions, and should use gettext instead. A known exception to this rule are applications that link use additional C libraries which internally invoke gettext() or dcgettext(). For these applications, it may be necessary to bind the text domain, so that the libraries can properly locate their message catalogs.
6.28 gettext -- Multilingual internationalization services

The gettext module provides internationalization (I18N) and localization (L10N) services for your Python modules and applications. It supports both the GNU gettext message catalog API and a higher level, class-based API that may be more appropriate for Python files. The interface described below allows you to write your module and application messages in one natural language, and provide a catalog of translated messages for running under different natural languages.

Some hints on localizing your Python modules and applications are also given.

Python Library Reference

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.28.1 GNU gettext API

The `gettext` module defines the following API, which is very similar to the GNU `gettext` API. If you use this API you will affect the translation of your entire application globally. Often this is what you want if your application is monolingual, with the choice of language dependent on the locale of your user. If you are localizing a Python module, or if your application needs to switch languages on the fly, you probably want to use the class-based API instead.

`bindtextdomain(domain[, localedir])`

Bind the `domain` to the locale directory `localedir`. More concretely, `gettext` will look for binary `.mo` files for the given domain using the path (on UNIX): `localedir/language/LC_MESSAGES/domain.mo`, where `languages` is searched for in the environment variables `LANGUAGE`, `LC_ALL`, `LC_MESSAGES`, and `LANG` respectively.

If `localedir` is omitted or `None`, then the current binding for `domain` is returned.\(^6.2\)

`bind_textdomain_codeset(domain[, codeset])`

Bind the `domain` to `codeset`, changing the encoding of strings returned by the `gettext()` family of functions. If `codeset` is omitted, then the current binding is returned.

New in version 2.4.

`textdomain([domain])`

Change or query the current global domain. If `domain` is `None`, then the current global domain is returned, otherwise the global domain is set to `domain`, which is returned.

`gettext(message)`

Return the localized translation of `message`, based on the current global domain, language, and locale directory. This function is usually aliased as `_` in the local namespace (see examples below).
\texttt{lgettext}(message)
Equivalent to \texttt{gettext()}, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with \texttt{bind_textdomain_codeset()}.

New in version 2.4.

\texttt{dgettext}(domain, message)
Like \texttt{gettext()}, but look the message up in the specified \textit{domain}.

\texttt{ldgettext}(domain, message)
Equivalent to \texttt{dgettext()}, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with \texttt{bind_textdomain_codeset()}.

New in version 2.4.

\texttt{ngettext}(singular, plural, n)
Like \texttt{gettext()}, but consider plural forms. If a translation is found, apply the plural formula to \textit{n}, and return the resulting message (some languages have more than two plural forms). If no translation is found, return \textit{singular} if \textit{n} is 1; return \textit{plural} otherwise.

The Plural formula is taken from the catalog header. It is a C or Python expression that has a free variable \textit{n}; the expression evaluates to the index of the plural in the catalog. See the GNU gettext documentation for the precise syntax to be used in .po files, and the formulas for a variety of languages.

New in version 2.3.

\texttt{lngettext}(singular, plural, n)
Equivalent to \texttt{ngettext()}, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with \texttt{bind_textdomain_codeset()}.

New in version 2.4.
\texttt{dngettext}( \textit{domain, singular, plural, n})

Like \texttt{ngettext()}, but look the message up in the specified \textit{domain}.

New in version 2.3.

\texttt{ldngettext}( \textit{domain, singular, plural, n})

Equivalent to \texttt{dngettext()}, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with \texttt{bind_textdomain_codeset()}

New in version 2.4.

Note that GNU \texttt{gettext} also defines a \texttt{dcgettext()} method, but this was deemed not useful and so it is currently unimplemented.

Here's an example of typical usage for this API:

\begin{verbatim}
import gettext
gettext.bindtextdomain('myapplication', '/path/to/my/language/directory')
gettext.textdomain('myapplication')
_ = gettext.gettext
# ...
print _('This is a translatable string.')
\end{verbatim}

---

\textbf{Footnotes}

... returned \ref{6.2}

The default locale directory is system dependent; for example, on RedHat Linux it is \texttt{/usr/share/locale}, but on Solaris it is \texttt{/usr/lib/locale}. The \texttt{gettext} module does not try to support these system dependent defaults; instead its default is \texttt{sys.prefix/share/locale}. For this reason, it is always best to call \texttt{bindtextdomain()} with an explicit absolute path at the start of your application.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.28.2 Class-based API

The class-based API of the gettext module gives you more flexibility and greater convenience than the GNU gettext API. It is the recommended way of localizing your Python applications and modules. gettext defines a "translations" class which implements the parsing of GNU .mo format files, and has methods for returning either standard 8-bit strings or Unicode strings. Instances of this "translations" class can also install themselves in the built-in namespace as the function _( ).

find( domain[, localedir[, languages[, all]]])

This function implements the standard .mo file search algorithm. It takes a domain, identical to what textdomain() takes. Optional localedir is as in bindtextdomain() Optional languages is a list of strings, where each string is a language code.

If localedir is not given, then the default system locale directory is used. If languages is not given, then the following environment variables are searched: LANGUAGE, LC_ALL, LC_MESSAGES, and LANG. The first one returning a non-empty value is used for the languages variable. The environment variables should contain a colon separated list of languages, which will be split on the colon to produce the expected list of language code strings.

find() then expands and normalizes the languages, and then iterates through them, searching for an existing file built of these components:

localedir/language/LC_MESSAGES/domain.mo

The first such file name that exists is returned by find(). If no such file is found, then None is returned. If all is given, it returns a list of all file names, in the order in which they appear in the languages list or the environment variables.

translation( domain[, localedir[, languages[, class[, fallback[, codeset]]]]])
Return a Translations instance based on the domain, localedir, and languages, which are first passed to find() to get a list of the associated .mo file paths. Instances with identical .mo file names are cached. The actual class instantiated is either class_ if provided, otherwise GNUTranslations. The class's constructor must take a single file object argument. If provided, codeset will change the charset used to encode translated strings.

If multiple files are found, later files are used as fallbacks for earlier ones. To allow setting the fallback, copy.copy is used to clone each translation object from the cache; the actual instance data is still shared with the cache.

If no .mo file is found, this function raises IOError if fallback is false (which is the default), and returns a NullTranslations instance if fallback is true.

Changed in version 2.4: Added the codeset parameter.

install( domain[, localedir[, unicode [, codeset]]]])

This installs the function _ in Python's builtin namespace, based on domain, localedir, and codeset which are passed to the function translation(). The unicode flag is passed to the resulting translation object's install method.

As seen below, you usually mark the strings in your application that are candidates for translation, by wrapping them in a call to the _() function, like this:

    print _('This string will be translated.')

For convenience, you want the _() function to be installed in Python's builtin namespace, so it is easily accessible in all modules of your application.

    Changed in version 2.4: Added the codeset parameter.

Footnotes
... used. See the footnote for bindtextdomain() above.

6.28.3 Internationalizing your programs and modules

Internationalization (I18N) refers to the operation by which a program is made aware of multiple languages. Localization (L10N) refers to the adaptation of your program, once internationalized, to the local language and cultural habits. In order to provide multilingual messages for your Python programs, you need to take the following steps:

1. prepare your program or module by specially marking translatable strings
2. run a suite of tools over your marked files to generate raw messages catalogs
3. create language specific translations of the message catalogs
4. use the gettext module so that message strings are properly translated

In order to prepare your code for I18N, you need to look at all the strings in your files. Any string that needs to be translated should be marked by wrapping it in `_(...' -- that is, a call to the function `_()`. For example:

```python
filename = 'mylog.txt'
message = _('writing a log message')
fp = open(filename, 'w')
fp.write(message)
fp.close()
```

In this example, the string 'writing a log message' is marked as a candidate for translation, while the strings 'mylog.txt' and 'w' are not.

The Python distribution comes with two tools which help you generate the message catalogs once you've prepared your source code. These may or may not be available from a binary distribution, but they can be found in a source distribution, in the Tools/i18n directory.

The `pygettext` program scans all your Python source code looking for the strings you previously marked as translatable. It is similar to the GNU gettext program except that it understands all the intricacies of Python source code, but knows nothing about C or C++ source code. You don't need GNU gettext unless you're also going to be translating C code (such as C extension modules).
**pygettext** generates textual Uniforum-style human readable message catalog .pot files, essentially structured human readable files which contain every marked string in the source code, along with a placeholder for the translation strings. **pygettext** is a command line script that supports a similar command line interface as `xgettext`; for details on its use, run:

```
pygettext.py --help
```

Copies of these .pot files are then handed over to the individual human translators who write language-specific versions for every supported natural language. They send you back the filled in language-specific versions as a .po file. Using the `msgfmt.py` program (in the Tools/i18n directory), you take the .po files from your translators and generate the machine-readable .mo binary catalog files. The .mo files are what the `gettext` module uses for the actual translation processing during run-time.

How you use the `gettext` module in your code depends on whether you are internationalizing your entire application or a single module.

---

**Footnotes**

...pygettext
François Pinard has written a program called `xpot` which does a similar job. It is available as part of his `po-utils` package at [http://po-utils.progiciels-bpi.ca/](http://po-utils.progiciels-bpi.ca/).

...msgfmt.py
`msgfmt.py` is binary compatible with GNU `msgfmt` except that it provides a simpler, all-Python implementation. With this and `pygettext.py`, you generally won’t need to install the GNU `gettext` package to internationalize your Python applications.

6.29 logging -- Logging facility for Python

New in version 2.3. This module defines functions and classes which implement a flexible error logging system for applications.

Logging is performed by calling methods on instances of the Logger class (hereafter called loggers). Each instance has a name, and they are conceptually arranged in a name space hierarchy using dots (periods) as separators. For example, a logger named "scan" is the parent of loggers "scan.text", "scan.html" and "scan.pdf". Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

Logged messages also have levels of importance associated with them. The default levels provided are DEBUG, INFO, WARNING, ERROR and CRITICAL. As a convenience, you indicate the importance of a logged message by calling an appropriate method of Logger. The methods are debug(), info(), warning(), error() and critical(), which mirror the default levels. You are not constrained to use these levels: you can specify your own and use a more general Logger method, log(), which takes an explicit level argument.

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CRITICAL</td>
<td>50</td>
</tr>
<tr>
<td>ERROR</td>
<td>40</td>
</tr>
<tr>
<td>WARNING</td>
<td>30</td>
</tr>
<tr>
<td>INFO</td>
<td>20</td>
</tr>
<tr>
<td>DEBUG</td>
<td>10</td>
</tr>
<tr>
<td>NOTSET</td>
<td>0</td>
</tr>
</tbody>
</table>
Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger's level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the LogRecord class. When a logger decides to actually log an event, a LogRecord instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of handlers, which are instances of subclasses of the Handler class. Handlers are responsible for ensuring that a logged message (in the form of a LogRecord) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed LogRecord instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the addHandler( ) method of Logger). In addition to any handlers directly associated with a logger, all handlers associated with all ancestors of the logger are called to dispatch the message.

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the emit( ) method is used to send the message to its destination. Most user-defined subclasses of Handler will need to override this emit().

In addition to the base Handler class, many useful subclasses are provided:

1. StreamHandler instances send error messages to streams (file-like objects).
2. FileHandler instances send error messages to disk files.
3. BaseRotatingHandler is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use RotatingFileHandler or TimedRotatingFileHandler.
4. **RotatingFileHandler** instances send error messages to disk files, with support for maximum log file sizes and log file rotation.

5. **TimedRotatingFileHandler** instances send error messages to disk files rotating the log file at certain timed intervals.

6. **SocketHandler** instances send error messages to TCP/IP sockets.

7. **DatagramHandler** instances send error messages to UDP sockets.

8. **SMTPHandler** instances send error messages to a designated email address.

9. **SysLogHandler** instances send error messages to a **UNIX** syslog daemon, possibly on a remote machine.

10. **NTEventLogHandler** instances send error messages to a Windows NT/2000/XP event log.

11. **MemoryHandler** instances send error messages to a buffer in memory, which is flushed whenever specific criteria are met.

12. **HTTPHandler** instances send error messages to an HTTP server using either "GET" or "POST" semantics.

The **StreamHandler** and **FileHandler** classes are defined in the core logging package. The other handlers are defined in a sub-module, **logging.handlers**. (There is also another sub-module, **logging.config**, for configuration functionality.)

Logged messages are formatted for presentation through instances of the **Formatter** class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of **BufferingFormatter** can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough,
instances of **Filter** can be added to both **Logger** and **Handler** instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic **Filter** functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.

In addition to the classes described above, there are a number of module-level functions.

**getLogger([name])**

Return a logger with the specified name or, if no name is specified, return a logger which is the root logger of the hierarchy. If specified, the name is typically a dot-separated hierarchical name like "a", "a.b" or "a.b.c.d". Choice of these names is entirely up to the developer who is using logging.

All calls to this function with a given name return the same logger instance. This means that logger instances never need to be passed between different parts of an application.

**getLoggerClass()**

Return either the standard **Logger** class, or the last class passed to `setLoggerClass()`. This function may be called from within a new class definition, to ensure that installing a customised **Logger** class will not undo customisations already applied by other code. For example:

```python
class MyLogger(logging.getLoggerClass()):
    # ... override behaviour here
```

**debug(msg[, *args[, **kwargs]])**

Logs a message with level **DEBUG** on the root logger. The `msg` is the message format string, and the `args` are the arguments which are merged into `msg`. The only keyword argument in `kwargs` which is inspected is `exc_info` which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by `sys.exc_info()` is provided, it is used; otherwise, `sys.exc_info()` is called to get the exception information.
**info**(*msg*, *args*, **kwargs*)
Logs a message with level INFO on the root logger. The arguments are interpreted as for **debug**().

**warning**(*msg*, *args*, **kwargs*)
Logs a message with level WARNING on the root logger. The arguments are interpreted as for **debug**().

**error**(*msg*, *args*, **kwargs*)
Logs a message with level ERROR on the root logger. The arguments are interpreted as for **debug**().

**critical**(*msg*, *args*, **kwargs*)
Logs a message with level CRITICAL on the root logger. The arguments are interpreted as for **debug**().

**exception**(*msg*, *args*)
Logs a message with level ERROR on the root logger. The arguments are interpreted as for **debug**(). Exception info is added to the logging message. This function should only be called from an exception handler.

**log**(*level*, *msg*, *args*, **kwargs*)
Logs a message with level **level** on the root logger. The other arguments are interpreted as for **debug**().

**disable**(*lvl*)
Provides an overriding level **lvl** for all loggers which takes precedence over the logger's own level. When the need arises to temporarily throttle logging output down across the whole application, this function can be useful.

**addLevelName**(*lvl*, **levelName**)
Associates level **lvl** with text **levelName** in an internal dictionary, which is used to map numeric levels to a textual representation, for example when a **Formatter** formats a message. This function can also be used to define your own levels. The only constraints are that all levels used must be
registered using this function, levels should be positive integers and they should increase in increasing order of severity.

**getLevelName**(*lvl*)

Returns the textual representation of logging level *lvl*. If the level is one of the predefined levels CRITICAL, ERROR, WARNING, INFO or DEBUG then you get the corresponding string. If you have associated levels with names using **addLevelName()** then the name you have associated with *lvl* is returned. If a numeric value corresponding to one of the defined levels is passed in, the corresponding string representation is returned. Otherwise, the string "Level %s" % *lvl* is returned.

**makeLogRecord**(*attrdict*)

Creates and returns a new LogRecord instance whose attributes are defined by *attrdict*. This function is useful for taking a pickled LogRecord attribute dictionary, sent over a socket, and reconstituting it as a LogRecord instance at the receiving end.

**basicConfig**(*[**kwargs]*)

Does basic configuration for the logging system by creating a StreamHandler with a default Formatter and adding it to the root logger. The functions **debug()**, **info()**, **warning()**, **error()** and **critical()** will call **basicConfig()** automatically if no handlers are defined for the root logger.

Changed in version 2.4: Formerly, **basicConfig** did not take any keyword arguments.

The following keyword arguments are supported.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>filename</td>
<td>Specifies that a FileHandler be created, using the specified filename, rather than a StreamHandler.</td>
</tr>
<tr>
<td>filemode</td>
<td>Specifies the mode to open the file, if filename is specified (if filemode is unspecified, it defaults to 'a').</td>
</tr>
<tr>
<td>format</td>
<td>Use the specified format string for the handler.</td>
</tr>
<tr>
<td>datefmt</td>
<td>Use the specified date/time format.</td>
</tr>
<tr>
<td>level</td>
<td>Set the root logger level to the specified level.</td>
</tr>
<tr>
<td>---------------</td>
<td>--------------------------------------------------</td>
</tr>
<tr>
<td>stream</td>
<td>Use the specified stream to initialize the StreamHandler. Note that this argument is incompatible with 'filename' - if both are present, 'stream' is ignored.</td>
</tr>
</tbody>
</table>

**shutdown()**
Informs the logging system to perform an orderly shutdown by flushing and closing all handlers.

**setLoggerClass( klass)***
Tells the logging system to use the class `klass` when instantiating a logger. The class should define `__init__()` such that only a name argument is required, and the `__init__()` should call `Logger.__init__()`. This function is typically called before any loggers are instantiated by applications which need to use custom logger behavior.

**See Also:**

**PEP 282, A Logging System**
The proposal which described this feature for inclusion in the Python standard library.

**Original Python logging package**
This is the original source for the `logging` package. The version of the package available from this site is suitable for use with Python 1.5.2, 2.1.x and 2.2.x, which do not include the `logging` package in the standard library.

6.29.1 Logger Objects

Loggers have the following attributes and methods. Note that Loggers are never instantiated directly, but always through the module-level function `logging.getLogger(name)`.

**propagate**

If this evaluates to false, logging messages are not passed by this logger or by child loggers to higher level (ancestor) loggers. The constructor sets this attribute to 1.

**setLevel**(lvl)

Sets the threshold for this logger to lvl. Logging messages which are less severe than lvl will be ignored. When a logger is created, the level is set to NOTSET (which causes all messages to be processed when the logger is the root logger, or delegation to the parent when the logger is a non-root logger). Note that the root logger is created with level WARNING.

The term "delegation to the parent" means that if a logger has a level of NOTSET, its chain of ancestor loggers is traversed until either an ancestor with a level other than NOTSET is found, or the root is reached.

If an ancestor is found with a level other than NOTSET, then that ancestor's level is treated as the effective level of the logger where the ancestor search began, and is used to determine how a logging event is handled.

If the root is reached, and it has a level of NOTSET, then all messages will be processed. Otherwise, the root's level will be used as the effective level.

**isEnabledFor**(lvl)

Indicates if a message of severity lvl would be processed by this logger. This method checks first the module-level level set by `logging.disable(lvl)` and then the logger's effective level as determined by `getEffectiveLevel()`.

**getEffectiveLevel()**

Indicates the effective level for this logger. If a value other than NOTSET
has been set using `setLevel()`), it is returned. Otherwise, the hierarchy is traversed towards the root until a value other than `NOTSET` is found, and that value is returned.

**debug**(*msg*, *args[, **kwargs]*)
Logs a message with level DEBUG on this logger. The *msg* is the message format string, and the *args* are the arguments which are merged into *msg*. The only keyword argument in *kwargs* which is inspected is *exc_info* which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (as provided by `sys.exc_info()`) is provided, it is used; otherwise, `sys.exc_info()` is called to get the exception information.

**info**(*msg*, *args[, **kwargs]*)
Logs a message with level INFO on this logger. The arguments are interpreted as for `debug()`.

**warning**(*msg*, *args[, **kwargs]*)
Logs a message with level WARNING on this logger. The arguments are interpreted as for `debug()`.

**error**(*msg*, *args[, **kwargs]*)
Logs a message with level ERROR on this logger. The arguments are interpreted as for `debug()`.

**critical**(*msg*, *args[, **kwargs]*)
Logs a message with level CRITICAL on this logger. The arguments are interpreted as for `debug()`.

**log**(*lvl*, *msg*, *args[, **kwargs]*)
Logs a message with integer level *lvl* on this logger. The other arguments are interpreted as for `debug()`.

**exception**(*msg*, *args*)
Logs a message with level ERROR on this logger. The arguments are interpreted as for `debug()`). Exception info is added to the logging
message. This method should only be called from an exception handler.

addFilter( filt)
    Adds the specified filter filt to this logger.

removeFilter( filt)
    Removes the specified filter filt from this logger.

filter( record)
    Applies this logger's filters to the record and returns a true value if the record is to be processed.

addHandler( hdlr)
    Adds the specified handler hdlr to this logger.

removeHandler( hdlr)
    Removes the specified handler hdlr from this logger.

findCaller()
    Finds the caller's source filename and line number. Returns the filename and line number as a 2-element tuple.

handle( record)
    Handles a record by passing it to all handlers associated with this logger and its ancestors (until a false value of propagate is found). This method is used for unpickled records received from a socket, as well as those created locally. Logger-level filtering is applied using filter().

makeRecord( name, lvl, fn, lno, msg, args, exc_info)
    This is a factory method which can be overridden in subclasses to create specialized LogRecord instances.
6.29.2 Basic example

Changed in version 2.4: formerly `basicConfig` did not take any keyword arguments.

The `logging` package provides a lot of flexibility, and its configuration can appear daunting. This section demonstrates that simple use of the logging package is possible.

The simplest example shows logging to the console:

```python
import logging
logging.debug('A debug message')
logging.info('Some information')
logging.warning('A shot across the bows')
```

If you run the above script, you'll see this:

```
WARNING:root:A shot across the bows
```

Because no particular logger was specified, the system used the root logger. The debug and info messages didn't appear because by default, the root logger is configured to only handle messages with a severity of WARNING or above. The message format is also a configuration default, as is the output destination of the messages - `sys.stderr`. The severity level, the message format and destination can be easily changed, as shown in the example below:

```python
import logging
logging.basicConfig(level=logging.DEBUG,
                    format='%('asctime)s %('levelname)s %('message)s',
                    filename='/tmp/myapp.log',
                    filemode='w')
logging.debug('A debug message')
logging.info('Some information')
logging.warning('A shot across the bows')
```

The `basicConfig()` method is used to change the configuration defaults, which results in output (written to `/tmp/myapp.log`) which should look something like the following:
This time, all messages with a severity of DEBUG or above were handled, and the format of the messages was also changed, and output went to the specified file rather than the console.

Formatting uses standard Python string formatting - see section 2.3.6. The format string takes the following common specifiers. For a complete list of specifiers, consult the Formatter documentation.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>%(name)s</td>
<td>Name of the logger (logging channel).</td>
</tr>
<tr>
<td>% (levelname)s</td>
<td>Text logging level for the message ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL').</td>
</tr>
<tr>
<td>%(asctime)s</td>
<td>Human-readable time when the LogRecord was created. By default this is of the form <code>2003-07-08 16:49:45,896</code> (the numbers after the comma are millisecond portion of the time).</td>
</tr>
<tr>
<td>%(message)s</td>
<td>The logged message.</td>
</tr>
</tbody>
</table>

To change the date/time format, you can pass an additional keyword parameter, *datefmt*, as in the following:

```python
import logging

logging.basicConfig(level=logging.DEBUG,
                     format='%(asctime)s %(levelname)-8s %(message)s',
                     datefmt='%a, %d %b %Y %H:%M:%S',
                     filename='/temp/myapp.log',
                     filemode='w')

logging.debug('A debug message')
logging.info('Some information')
logging.warning('A shot across the bows')
```

which would result in output like

```
Fri, 02 Jul 2004 13:06:18 DEBUG     A debug message
Fri, 02 Jul 2004 13:06:18 INFO    Some information
Fri, 02 Jul 2004 13:06:18 WARNING A shot across the bows
```

The date format string follows the requirements of *strftime()* - see the
documentation for the `time` module.

If, instead of sending logging output to the console or a file, you'd rather use a file-like object which you have created separately, you can pass it to `basicConfig()` using the `stream` keyword argument. Note that if both `stream` and `filename` keyword arguments are passed, the `stream` argument is ignored.

Of course, you can put variable information in your output. To do this, simply have the message be a format string and pass in additional arguments containing the variable information, as in the following example:

```python
import logging

logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(levelname)-8s %(message)s',
                    datefmt='%a, %d %b %Y %H:%M:%S',
                    filename='/temp/myapp.log',
                    filemode='w')

logging.error('Pack my box with %d dozen %s', 5, 'liquor jugs')
```

which would result in

```
Wed, 21 Jul 2004 15:35:16 ERROR Pack my box with 5 dozen liquor jugs
```
6.29.3 Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```python
import logging

# set up logging to file - see previous section for more details
logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s	%(name)-12s	%(levelname)-8s	%(message)s',
    datefmt='%m-%d	%H:%M',
    filename='/temp/myapp.log',
    filemode='w')

# define a Handler which writes INFO messages or higher to the sys.stderr
console = logging.StreamHandler()
console.setLevel(logging.INFO)

# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s:	%(levelname)-8s	%(message)s')

# tell the handler to use this format
console.setFormatter(formatter)

# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger. First the
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might represent areas
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see:

```
root : INFO  Jackdaws love my big sphinx of quartz.
myapp.area1 : INFO  How quickly daft jumping zebras vex.
myapp.area2 : WARNING  Jail zesty vixen who grabbed pay from quack.
myapp.area2 : ERROR  The five boxing wizards jump quickly.
```
and in the file you will see something like

<table>
<thead>
<tr>
<th>Time</th>
<th>UserID</th>
<th>Level</th>
<th>Message</th>
</tr>
</thead>
<tbody>
<tr>
<td>10-22</td>
<td>root</td>
<td>INFO</td>
<td>Jackdaws love my big sphinx of quartz.</td>
</tr>
<tr>
<td>10-22</td>
<td>myapp.area1</td>
<td>DEBUG</td>
<td>Quick zephyrs blow, vexing daft Jim.</td>
</tr>
<tr>
<td>10-22</td>
<td>myapp.area1</td>
<td>INFO</td>
<td>How quickly daft jumping zebras vex.</td>
</tr>
<tr>
<td>10-22</td>
<td>myapp.area2</td>
<td>WARNING</td>
<td>Jail zesty vixen who grabbed pay f.</td>
</tr>
<tr>
<td>10-22</td>
<td>myapp.area2</td>
<td>ERROR</td>
<td>The five boxing wizards jump quickly.</td>
</tr>
</tbody>
</table>

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.
6.29.4 Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```python
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
                                            logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler sends the ev
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger. First the
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might represent areas
# application:
logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.
logger1.info('How quickly daft jumping zebras vex.
logger2.warning('Jail zesty vixen who grabbed pay from quack.
logger2.error('The five boxing wizards jump quickly.

At the receiving end, you can set up a receiver using the `SocketServer` module. Here is a basic working example:

```python
import cPickle
import logging
import logging.handlers
import SocketServer
import struct

class LogRecordStreamHandler(SocketServer.StreamRequestHandler):
    """Handler for a streaming logging request.

    This basically logs the record using whatever logging policy is configured locally.
```
def handle(self):
    
    Handle multiple requests - each expected to be a 4-byte length followed by the LogRecord in pickle format. Logs the record according to whatever policy is configured locally.
    
    while 1:
        chunk = self.connection.recv(4)
        if len(chunk) < 4:
            break
        slen = struct.unpack('>L', chunk)[0]
        chunk = self.connection.recv(slen)
        while len(chunk) < slen:
            chunk = chunk + self.connection.recv(slen - len(chunk))
        obj = self.unPickle(chunk)
        record = logging.makeLogRecord(obj)
        self.handleLogRecord(record)

def unPickle(self, data):
    return cPickle.loads(data)

def handleLogRecord(self, record):
    # if a name is specified, we use the named logger rather than implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because Logger.handle is normally called AFTER logger-level filtering. If you want to do filtering, do it at the client end to save wasting cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(SocketServer.ThreadingTCPServer):
    
    """simple TCP socket-based logging receiver suitable for testing""
    
    allow_reuse_address = 1
    
def __init__(self, host='localhost',
                 port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
                 handler=LogRecordStreamHandler):
        SocketServer.ThreadingTCPServer.__init__(self, (host, port),
                                                 self.abort = 0,
                                                 self.timeout = 1,
                                                 self.logname = None
        self.handle_until_stopped(self):
import select
abort = 0
while not abort:
    rd, wr, ex = select.select([self.socket.fileno()], [], [], self.timeout)
    if rd:
        self.handle_request()
    abort = self.abort

def main():
    logging.basicConfig(
        format="%s
        tcpserver = LogRecordSocketReceiver()
        tcpserver.serve_until_stopped()

    if __name__ == "__main__":
        main()

First run the server, and then the client. On the client side, nothing is printed on
the console; on the server side, you should see something like:

About to start TCP server...
59 root INFO Jackdaws love my big sphinx of quartz
59 myapp.area1 DEBUG Quick zephyrs blow, vexing daft Jim.
69 myapp.area1 INFO How quickly daft jumping zebras vex.
69 myapp.area2 WARNING Jail zesty vixen who grabbed pay from
69 myapp.area2 ERROR The five boxing wizards jump quickly.

Python Library Reference
Previous: 6.29.3 Logging to multiple Up: 6.29 logging Next: 6.29.5 Handler
Objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.29.5 Handler Objects

Handlers have the following attributes and methods. Note that Handler is never instantiated directly; this class acts as a base for more useful subclasses. However, the __init__() method in subclasses needs to call Handler.__init__().

__init__(level=NOTSET)
Initializes the Handler instance by setting its level, setting the list of filters to the empty list and creating a lock (using createLock()) for serializing access to an I/O mechanism.

createLock()
Initializes a thread lock which can be used to serialize access to underlying I/O functionality which may not be threadsafe.

acquire()
Acquires the thread lock created with createLock().

release()
Releases the thread lock acquired with acquire().

setLevel(lvl)
Sets the threshold for this handler to lvl. Logging messages which are less severe than lvl will be ignored. When a handler is created, the level is set to NOTSET (which causes all messages to be processed).

setFormatter(form)
Sets the Formatter for this handler to form.

addFilter(filt)
Adds the specified filter filt to this handler.

removeFilter(filt)
Removes the specified filter filt from this handler.
**filter** (*record*)  
Applies this handler's filters to the record and returns a true value if the record is to be processed.

**flush**()  
Ensure all logging output has been flushed. This version does nothing and is intended to be implemented by subclasses.

**close**()  
Tidy up any resources used by the handler. This version does nothing and is intended to be implemented by subclasses.

**handle** (*record*)  
Conditionally emits the specified logging record, depending on filters which may have been added to the handler. Wraps the actual emission of the record with acquisition/release of the I/O thread lock.

**handleError** (*record*)  
This method should be called from handlers when an exception is encountered during an emit() call. By default it does nothing, which means that exceptions get silently ignored. This is what is mostly wanted for a logging system - most users will not care about errors in the logging system, they are more interested in application errors. You could, however, replace this with a custom handler if you wish. The specified record is the one which was being processed when the exception occurred.

**format** (*record*)  
Do formatting for a record - if a formatter is set, use it. Otherwise, use the default formatter for the module.

**emit** (*record*)  
Do whatever it takes to actually log the specified logging record. This version is intended to be implemented by subclasses and so raises a `NotImplementedError`.
6.29.5.1 StreamHandler
6.29.5.2 FileHandler
6.29.5.3 RotatingFileHandler
6.29.5.4 TimedRotatingFileHandler

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.29.6 Formatter Objects

Formatters have the following attributes and methods. They are responsible for converting a LogRecord to (usually) a string which can be interpreted by either a human or an external system. The base Formatter allows a formatting string to be specified. If none is supplied, the default value of '%(message)s' is used.

A Formatter can be initialized with a format string which makes use of knowledge of the LogRecord attributes - such as the default value mentioned above making use of the fact that the user's message and arguments are pre-formatted into a LogRecord's message attribute. This format string contains standard python %-style mapping keys. See section 2.3.6, ``String Formatting Operations,'' for more information on string formatting.

Currently, the useful mapping keys in a LogRecord are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>%(name)s</td>
<td>Name of the logger (logging channel).</td>
</tr>
<tr>
<td>%(levelname)s</td>
<td>Text logging level for the message ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL').</td>
</tr>
<tr>
<td>%(pathname)s</td>
<td>Full pathname of the source file where the logging call was issued (if available).</td>
</tr>
<tr>
<td>%(filename)s</td>
<td>Filename portion of pathname.</td>
</tr>
<tr>
<td>%(module)s</td>
<td>Module (name portion of filename).</td>
</tr>
<tr>
<td>%(lineno)d</td>
<td>Source line number where the logging call was issued (if available).</td>
</tr>
<tr>
<td>%(asctime)s</td>
<td>Time when the LogRecord was created (as returned by time.time()).</td>
</tr>
<tr>
<td>%(created)f</td>
<td>Human-readable time when the LogRecord was created. By default this is of the form ``2003-07-08 16:49:45,896'' (the numbers after the comma are millisecond portion of the time).</td>
</tr>
<tr>
<td>Format</td>
<td>Description</td>
</tr>
<tr>
<td>--------</td>
<td>-------------</td>
</tr>
<tr>
<td>%(msecs)d</td>
<td>Millisecond portion of the time when the LogRecord was created.</td>
</tr>
<tr>
<td>%(thread)d</td>
<td>Thread ID (if available).</td>
</tr>
<tr>
<td>% (threadName)s</td>
<td>Thread name (if available).</td>
</tr>
<tr>
<td>%(process)d</td>
<td>Process ID (if available).</td>
</tr>
<tr>
<td>%(message)s</td>
<td>The logged message, computed as msg % args.</td>
</tr>
</tbody>
</table>

**class Formatter(** *[fmt[, datefmt]]*)**

Returns a new instance of the Formatter class. The instance is initialized with a format string for the message as a whole, as well as a format string for the date/time portion of a message. If no fmt is specified, '% (message)s' is used. If no datefmt is specified, the ISO8601 date format is used.

**format(record)**

The record's attribute dictionary is used as the operand to a string formatting operation. Returns the resulting string. Before formatting the dictionary, a couple of preparatory steps are carried out. The message attribute of the record is computed using msg % args. If the formatting string contains '(asctime)', formatTime() is called to format the event time. If there is exception information, it is formatted using formatException() and appended to the message.

**formatTime(record[, datefmt])**

This method should be called from format() by a formatter which wants to make use of a formatted time. This method can be overridden in formatters to provide for any specific requirement, but the basic behavior is as follows: if datefmt (a string) is specified, it is used with time.strftime() to format the creation time of the record. Otherwise, the ISO8601 format is used. The resulting string is returned.

**formatException(exc_info)**

Formats the specified exception information (a standard exception tuple as returned by sys.exc_info()) as a string. This default implementation just uses traceback.print_exception(). The resulting string is
returned.
6.29.7 Filter Objects

Filters can be used by Handlers and Loggers for more sophisticated filtering than is provided by levels. The base filter class only allows events which are below a certain point in the logger hierarchy. For example, a filter initialized with "A.B" will allow events logged by loggers "A.B", "A.B.C", "A.B.C.D", "A.B.D" etc. but not "A.BB", "B.A.B" etc. If initialized with the empty string, all events are passed.

class Filter([name])

Returns an instance of the Filter class. If name is specified, it names a logger which, together with its children, will have its events allowed through the filter. If no name is specified, allows every event.

filter(record)

Is the specified record to be logged? Returns zero for no, nonzero for yes. If deemed appropriate, the record may be modified in-place by this method.
6.29.8 LogRecord Objects

LogRecord instances are created every time something is logged. They contain all the information pertinent to the event being logged. The main information passed in is in msg and args, which are combined using msg % args to create the message field of the record. The record also includes information such as when the record was created, the source line where the logging call was made, and any exception information to be logged.

class LogRecord( name, lvl, pathname, lineno, msg, args, exc_info)

Returns an instance of LogRecord initialized with interesting information. The name is the logger name; lvl is the numeric level; pathname is the absolute pathname of the source file in which the logging call was made; lineno is the line number in that file where the logging call is found; msg is the user-supplied message (a format string); args is the tuple which, together with msg, makes up the user message; and exc_info is the exception tuple obtained by calling sys.exc_info() (or None, if no exception information is available).

getMessage()

Returns the message for this LogRecord instance after merging any user-supplied arguments with the message.
6.29.9 Thread Safety

The logging module is intended to be thread-safe without any special work needing to be done by its clients. It achieves this though using threading locks; there is one lock to serialize access to the module's shared data, and each handler also creates a lock to serialize access to its underlying I/O.
6.29.10 Configuration

Subsections

- [6.29.10.1 Configuration functions](#)
- [6.29.10.2 Configuration file format](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

6.30 platform -- Access to underlying platform's identifying data.

New in version 2.3.

**Note:** Specific platforms listed alphabetically, with Linux included in the UNIX section.

Subsections

- 6.30.1 Cross Platform
- 6.30.2 Java Platform
- 6.30.3 Windows Platform
  - 6.30.3.1 Win95/98 specific
- 6.30.4 Mac OS Platform
- 6.30.5 UNIX Platforms

Python Library Reference

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
6.30.1 Cross Platform

**architecture**(executable=sys.executable, bits='', linkage=')
Queries the given executable (defaults to the Python interpreter binary) for various architecture information.

Returns a tuple (bits, linkage) which contain information about the bit architecture and the linkage format used for the executable. Both values are returned as strings.

Values that cannot be determined are returned as given by the parameter presets. If bits is given as '', the sizeof(pointer) (or sizeof(long) on Python version < 1.5.2) is used as indicator for the supported pointer size.

The function relies on the system's file command to do the actual work. This is available on most if not all UNIX platforms and some non-UNIX platforms and then only if the executable points to the Python interpreter. Reasonable defaults are used when the above needs are not met.

**machine()**

Returns the machine type, e.g. 'i386'. An empty string is returned if the value cannot be determined.

**node()**

Returns the computer's network name (may not be fully qualified!). An empty string is returned if the value cannot be determined.

**platform**(aliased=0, terse=0)

Returns a single string identifying the underlying platform with as much useful information as possible.

The output is intended to be human readable rather than machine parseable. It may look different on different platforms and this is intended.

If aliased is true, the function will use aliases for various platforms that report system names which differ from their common names, for example
SunOS will be reported as Solaris. The `system_alias()` function is used to implement this.

Setting `terse` to true causes the function to return only the absolute minimum information needed to identify the platform.

**processor()**
Returns the (real) processor name, e.g. 'amdk6'.

An empty string is returned if the value cannot be determined. Note that many platforms do not provide this information or simply return the same value as for `machine()`. NetBSD does this.

**python_build()**
Returns a tuple (`buildno, builddate`) stating the Python build number and date as strings.

**python_compiler()**
Returns a string identifying the compiler used for compiling Python.

**python_version()**
Returns the Python version as string 'major.minor.patchlevel'

Note that unlike the Python `sys.version`, the returned value will always include the patchlevel (it defaults to 0).

**python_version_tuple()**
Returns the Python version as tuple (`major, minor, patchlevel`) of strings.

Note that unlike the Python `sys.version`, the returned value will always include the patchlevel (it defaults to '0').

**release()**
Returns the system's release, e.g. '2.2.0' or 'NT'. An empty string is returned if the value cannot be determined.

**system()**
Returns the system/OS name, e.g. 'Linux', 'Windows', or 'Java'. An empty string is returned if the value cannot be determined.

**system_alias**( system, release, version)

Returns (system, release, version) aliased to common marketing names used for some systems. It also does some reordering of the information in some cases where it would otherwise cause confusion.

**version()**

Returns the system's release version, e.g. '#3 on degas'. An empty string is returned if the value cannot be determined.

**uname()**

Fairly portable uname interface. Returns a tuple of strings (system, node, release, version, machine, processor) identifying the underlying platform.

Note that unlike the os.uname() function this also returns possible processor information as additional tuple entry.

Entries which cannot be determined are set to ''.
6.30.2 Java Platform

`java_ver( release='', vendor='', vminfo=('', ''), osinfo=('', '', ''))`

Version interface for JPython.

Returns a tuple `(release, vendor, vminfo, osinfo)` with `vminfo` being a tuple `(vm_name, vm_release, vm_vendor)` and `osinfo` being a tuple `(os_name, os_version, os_arch)`. Values which cannot be determined are set to the defaults given as parameters (which all default to '').
6.30.3 Windows Platform

`win32_ver(release=", version=", csd=", ptype=")`

Get additional version information from the Windows Registry and return a tuple `(version, csd, ptype)` referring to version number, CSD level and OS type (multi/single processor).

As a hint: `ptype` is 'Uniprocessor Free' on single processor NT machines and 'Multiprocessor Free' on multi processor machines. The 'Free' refers to the OS version being free of debugging code. It could also state 'Checked' which means the OS version uses debugging code, i.e. code that checks arguments, ranges, etc.

**Note:** This function only works if Mark Hammond's `win32all` package is installed and (obviously) only runs on Win32 compatible platforms.

Previous: [6.30.2 Java Platform](#)  Up: [6.30 platform](#)  Next: [6.30.3.1 Win95/98 specific](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
6.30.4 Mac OS Platform

mac_ver( release='', versioninfo=('','',''), machine='' )

Get Mac OS version information and return it as tuple (release, versioninfo, machine) with versioninfo being a tuple (version, dev_stage, non_release_version).

Entries which cannot be determined are set to ''. All tuple entries are strings.

Documentation for the underlying gestalt() API is available online at http://www.rgaros.nl/gestalt/.
6.30.5 UNIX Platforms

```
dist(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake'))
```

Tries to determine the name of the OS distribution name. Returns a tuple
`distname`, `version`, `id`) which defaults to the args given as parameters.

```
libc_ver(executable=sys.executable, lib='', version='', chunksize=2048)
```

Tries to determine the libc version against which the file executable
(defaults to the Python interpreter) is linked. Returns a tuple of strings
`(lib, version)` which default to the given parameters in case the lookup
fails.

Note that this function has intimate knowledge of how different libc
versions add symbols to the executable is probably only useable for
executables compiled using gcc.

The file is read and scanned in chunks of chunksize bytes.
7. Optional Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on selected operating systems only. The interfaces are generally modeled after the Unix or C interfaces but they are available on some other systems as well (e.g. Windows or NT). Here's an overview:

- **signal**
  - Set handlers for asynchronous events.

- **socket**
  - Low-level networking interface.

- **select**
  - Wait for I/O completion on multiple streams.

- **thread**
  - Create multiple threads of control within one interpreter.

- **threading**
  - Higher-level threading interface.

- **dummy_thread**
  - Drop-in replacement for the `thread` module.

- **dummy_threading**
  - Drop-in replacement for the `threading` module.

- **Queue**
  - A synchronized queue class.

- **mmap**
  - Interface to memory-mapped files for Unix and Windows.

- **anydbm**
  - Generic interface to DBM-style database modules.

- **dbhash**
  - DBM-style interface to the BSD database library.

- **whichdb**
  - Guess which DBM-style module created a given database.

- **bsddb**
  - Interface to Berkeley DB database library.

- **dumbdbm**
  - Portable implementation of the simple DBM interface.

- **zlib**
  - Low-level interface to compression and decompression routines compatible with `gzip`.

- **gzip**
  - Interfaces for `gzip` compression and decompression using file objects.

- **bz2**
  - Interface to compression and decompression routines compatible with `bzip2`.

- **zipfile**
  - Read and write ZIP-format archive files.
**tarfile**
Read and write tar-format archive files.

**readline**
GNU readline support for Python.

**rlcompleter**
Python identifier completion for the GNU readline library.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
This module provides mechanisms to use signal handlers in Python. Some general rules for working with signals and their handlers:

- A handler for a particular signal, once set, remains installed until it is explicitly reset (Python emulates the BSD style interface regardless of the underlying implementation), with the exception of the handler for SIGCHLD, which follows the underlying implementation.

- There is no way to ``block'' signals temporarily from critical sections (since this is not supported by all UNIX flavors).

- Although Python signal handlers are called asynchronously as far as the Python user is concerned, they can only occur between the ``atomic'' instructions of the Python interpreter. This means that signals arriving during long calculations implemented purely in C (such as regular expression matches on large bodies of text) may be delayed for an arbitrary amount of time.

- When a signal arrives during an I/O operation, it is possible that the I/O operation raises an exception after the signal handler returns. This is dependent on the underlying UNIX system's semantics regarding interrupted system calls.

- Because the C signal handler always returns, it makes little sense to catch synchronous errors like SIGFPE or SIGSEGV.

- Python installs a small number of signal handlers by default: SIGPIPE is ignored (so write errors on pipes and sockets can be reported as ordinary Python exceptions) and SIGINT is translated into a KeyboardInterrupt exception. All of these can be overridden.

- Some care must be taken if both signals and threads are used in the same program. The fundamental thing to remember in using signals and threads
simultaneously is: always perform `signal()` operations in the main thread of execution. Any thread can perform an `alarm()`, `getsignal()`, or `pause()`; only the main thread can set a new signal handler, and the main thread will be the only one to receive signals (this is enforced by the Python `signal` module, even if the underlying thread implementation supports sending signals to individual threads). This means that signals can't be used as a means of inter-thread communication. Use locks instead.

The variables defined in the `signal` module are:

**SIG_DFL**
This is one of two standard signal handling options; it will simply perform the default function for the signal. For example, on most systems the default action for `SIGQUIT` is to dump core and exit, while the default action for `SIGCLD` is to simply ignore it.

**SIG_IGN**
This is another standard signal handler, which will simply ignore the given signal.

**SIG***
All the signal numbers are defined symbolically. For example, the hangup signal is defined as `signal.SIGHUP`; the variable names are identical to the names used in C programs, as found in `<signal.h>`. The UNIX man page for `signal()` lists the existing signals (on some systems this is `signal(2)`, on others the list is in `signal(7)`). Note that not all systems define the same set of signal names; only those names defined by the system are defined by this module.

**NSIG**
One more than the number of the highest signal number.

The `signal` module defines the following functions:

**alarm(time)**
If `time` is non-zero, this function requests that a `SIGALRM` signal be sent to the process in `time` seconds. Any previously scheduled alarm is canceled (only one alarm can be scheduled at any time). The returned value is then
the number of seconds before any previously set alarm was to have been
delivered. If time is zero, no alarm is scheduled, and any scheduled alarm is
canceled. The return value is the number of seconds remaining before a
previously scheduled alarm. If the return value is zero, no alarm is currently
scheduled. (See the UNIX man page alarm(2).) Availability: UNIX.

getsignal( signalnum)
Return the current signal handler for the signal signalnum. The returned
value may be a callable Python object, or one of the special values
signal.SIG_IGN, signal.SIG_DFL or None. Here,
signal.SIG_IGN means that the signal was previously ignored,
signal.SIG_DFL means that the default way of handling the signal was
previously in use, and None means that the previous signal handler was not
installed from Python.

pause()
Cause the process to sleep until a signal is received; the appropriate handler
will then be called. Returns nothing. Not on Windows. (See the UNIX man
page signal(2).)

signal( signalnum, handler)
Set the handler for signal signalnum to the function handler. handler can be
a callable Python object taking two arguments (see below), or one of the
special values signal.SIG_IGN or signal.SIG_DFL. The previous
signal handler will be returned (see the description of getsignal() above). (See the UNIX man page signal(2).)

When threads are enabled, this function can only be called from the main
thread; attempting to call it from other threads will cause a ValueError
exception to be raised.

The handler is called with two arguments: the signal number and the
current stack frame (None or a frame object; for a description of frame
objects, see the reference manual section on the standard type hierarchy or
see the attribute descriptions in the inspect module).

Subsections
7.1.1 Example

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.1.1 Example

Here is a minimal example program. It uses the `alarm()` function to limit the time spent waiting to open a file; this is useful if the file is for a serial device that may not be turned on, which would normally cause the `os.open()` to hang indefinitely. The solution is to set a 5-second alarm before opening the file; if the operation takes too long, the alarm signal will be sent, and the handler raises an exception.

```python
import signal, os

def handler(signum, frame):
    print 'Signal handler called with signal', signum
    raise IOError, "Couldn't open device!"

# Set the signal handler and a 5-second alarm
signal.signal(signal.SIGALRM, handler)
signal.alarm(5)

# This open() may hang indefinitely
fd = os.open('/dev/ttyS0', os.O_RDWR)

signal.alarm(0)        # Disable the alarm
```

**Python Library Reference**

Previous: [7.1 signal](#)  Up: [7.1 signal](#)  Next: [7.2 socket](#)

Release 2.4.4c1, documentation updated on 11 October 2006.  
See [About this document...](#) for information on suggesting changes.
7.2 socket -- Low-level networking interface

This module provides access to the BSD socket interface. It is available on all modern UNIX systems, Windows, MacOS, BeOS, OS/2, and probably additional platforms. **Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs.

For an introduction to socket programming (in C), see the following papers: An Introductory 4.3BSD Interprocess Communication Tutorial, by Stuart Sechrest and An Advanced 4.3BSD Interprocess Communication Tutorial, by Samuel J. Leffler et al, both in the UNIX Programmer's Manual, Supplementary Documents 1 (sections PS1:7 and PS1:8). The platform-specific reference material for the various socket-related system calls are also a valuable source of information on the details of socket semantics. For UNIX, refer to the manual pages; for Windows, see the WinSock (or Winsock 2) specification. For IPv6-ready APIs, readers may want to refer to [RFC 2553](https://tools.ietf.org/html/rfc2553) titled Basic Socket Interface Extensions for IPv6.

The Python interface is a straightforward transliteration of the UNIX system call and library interface for sockets to Python's object-oriented style: the `socket()` function returns a *socket object* whose methods implement the various socket system calls. Parameter types are somewhat higher-level than in the C interface: as with `read()` and `write()` operations on Python files, buffer allocation on receive operations is automatic, and buffer length is implicit on send operations.

Socket addresses are represented as follows: A single string is used for the AF_UNIX address family. A pair `(host, port)` is used for the AF_INET address family, where `host` is a string representing either a hostname in Internet domain notation like 'daring.cwi.nl' or an IPv4 address like '100.50.200.5', and `port` is an integral port number. For AF_INET6 address family, a four-tuple `(host, port, flowinfo, scopeid)` is used, where `flowinfo` and `scopeid` represents `sin6_flowinfo` and `sin6_scope_id` member in `struct sockaddr_in6` in C. For socket module methods, `flowinfo` and `scopeid` can be omitted just for backward compatibility. Note,
however, omission of scopeid can cause problems in manipulating scoped IPv6 addresses. Other address families are currently not supported. The address format required by a particular socket object is automatically selected based on the address family specified when the socket object was created.

For IPv4 addresses, two special forms are accepted instead of a host address: the empty string represents INADDR_ANY, and the string '<broadcast>' represents INADDR_BROADCAST. The behavior is not available for IPv6 for backward compatibility, therefore, you may want to avoid these if you intend to support IPv6 with your Python programs.

If you use a hostname in the host portion of IPv4/v6 socket address, the program may show a nondeterministic behavior, as Python uses the first address returned from the DNS resolution. The socket address will be resolved differently into an actual IPv4/v6 address, depending on the results from DNS resolution and/or the host configuration. For deterministic behavior use a numeric address in host portion.

All errors raise exceptions. The normal exceptions for invalid argument types and out-of-memory conditions can be raised; errors related to socket or address semantics raise the error socket.error.

Non-blocking mode is supported through setblocking(). A generalization of this based on timeouts is supported through settimeout().

The module socket exports the following constants and functions:

**exception error**

This exception is raised for socket-related errors. The accompanying value is either a string telling what went wrong or a pair (errno, string) representing an error returned by a system call, similar to the value accompanying os.error. See the module errno, which contains names for the error codes defined by the underlying operating system.

**exception herror**

This exception is raised for address-related errors, i.e. for functions that use h_errno in the C API, including gethostbyname_ex() and gethostbyaddr().
The accompanying value is a pair \((h\textunderscore errno, \textit{string})\) representing an error returned by a library call. \textit{string} represents the description of \(h\textunderscore errno\), as returned by the \texttt{hstrerror()} C function.

**exception gaierror**

This exception is raised for address-related errors, for \texttt{getaddrinfo()} and \texttt{getnameinfo()}. The accompanying value is a pair \((\textit{error}, \textit{string})\) representing an error returned by a library call. \textit{string} represents the description of \textit{error}, as returned by the \texttt{gai\textunderscore strerror()} C function. The \textit{error} value will match one of the \texttt{EAI\_\*} constants defined in this module.

**exception timeout**

This exception is raised when a timeout occurs on a socket which has had timeouts enabled via a prior call to \texttt{settimeout()}. The accompanying value is a string whose value is currently always ``timed out''. New in version 2.3.

**AF\_UNIX**
**AF\_INET**
**AF\_INET6**

These constants represent the address (and protocol) families, used for the first argument to \texttt{socket()}. If the \texttt{AF\_UNIX} constant is not defined then this protocol is unsupported.

**SOCK\_STREAM**
**SOCK\_DGRAM**
**SOCK\_RAW**
**SOCK\_RDM**
**SOCK\_SEQPACKET**

These constants represent the socket types, used for the second argument to \texttt{socket()}. (Only \texttt{SOCK\_STREAM} and \texttt{SOCK\_DGRAM} appear to be generally useful.)

**SO\_\***
**SOMAXCONN**
**MSG\_\***
**SOL\_\***
**IPPROTO\_\*"
Many constants of these forms, documented in the UNIX documentation on sockets and/or the IP protocol, are also defined in the socket module. They are generally used in arguments to the \texttt{setsockopt()} and \texttt{getsockopt()} methods of socket objects. In most cases, only those symbols that are defined in the UNIX header files are defined; for a few symbols, default values are provided.

\texttt{has_ipv6}

This constant contains a boolean value which indicates if IPv6 is supported on this platform. New in version 2.3.

\texttt{getaddrinfo}(host, port[, family[, socktype[, proto[, flags]]]])

Resolves the \texttt{host/port} argument, into a sequence of 5-tuples that contain all the necessary argument for the sockets manipulation. \texttt{host} is a domain name, a string representation of IPv4/v6 address or \texttt{None}. \texttt{port} is a string service name (like 'http'), a numeric port number or \texttt{None}.

The rest of the arguments are optional and must be numeric if specified. For \texttt{host} and \texttt{port}, by passing either an empty string or \texttt{None}, you can pass NULL to the C API. The \texttt{getaddrinfo()} function returns a list of 5-tuples with the following structure:

\texttt{(family, socktype, proto, canonname, sockaddr)}

\texttt{family}, \texttt{socktype}, \texttt{proto} are all integer and are meant to be passed to the \texttt{socket()} function. \texttt{canonname} is a string representing the canonical name of the \texttt{host}. It can be a numeric IPv4/v6 address when \texttt{AI_CANONNAME} is specified for a numeric \texttt{host}. \texttt{sockaddr} is a tuple describing a socket address, as described above. See the source for the \texttt{httpplib} and other library modules for a typical usage of the function.
New in version 2.2.

getfqdn([name])

Return a fully qualified domain name for name. If name is omitted or empty, it is interpreted as the local host. To find the fully qualified name, the hostname returned by gethostbyaddr() is checked, then aliases for the host, if available. The first name which includes a period is selected. In case no fully qualified domain name is available, the hostname as returned by gethostname() is returned. New in version 2.0.

gethostbyname(hostname)

Translate a host name to IPv4 address format. The IPv4 address is returned as a string, such as '100.50.200.5'. If the host name is an IPv4 address itself it is returned unchanged. See gethostbyname_ex() for a more complete interface. gethostbyname() does not support IPv6 name resolution, and getaddrinfo() should be used instead for IPv4/v6 dual stack support.

gethostbyname_ex(hostname)

Translate a host name to IPv4 address format, extended interface. Return a triple (hostname, aliaslist, ipaddrlist) where hostname is the primary host name responding to the given ip_address, aliaslist is a (possibly empty) list of alternative host names for the same address, and ipaddrlist is a list of IPv4 addresses for the same interface on the same host (often but not always a single address). gethostbyname_ex() does not support IPv6 name resolution, and getaddrinfo() should be used instead for IPv4/v6 dual stack support.

gethostname()

Return a string containing the hostname of the machine where the Python interpreter is currently executing. If you want to know the current machine's IP address, you may want to use gethostbyname(gethostname()). This operation assumes that there is a valid address-to-host mapping for the host, and the assumption does not always hold. Note: gethostname() doesn't always return the fully qualified domain name; use gethostbyaddr(gethostname()) (see below).
**gethostbyaddr( ip_address)**

Return a triple \((hostname, \ aliaslist, \ ipaddrlist)\) where \(hostname\) is the primary host name responding to the given \(ip\_address\), \(aliaslist\) is a (possibly empty) list of alternative host names for the same address, and \(ipaddrlist\) is a list of IPv4/v6 addresses for the same interface on the same host (most likely containing only a single address). To find the fully qualified domain name, use the function \(getfqdn()\). \(gethostbyaddr\) supports both IPv4 and IPv6.

**getnameinfo( sockaddr, flags)**

Translate a socket address sockaddr into a 2-tuple \((host, port)\).
Depending on the settings of \(flags\), the result can contain a fully-qualified domain name or numeric address representation in \(host\). Similarly, \(port\) can contain a string port name or a numeric port number. New in version 2.2.

**getprotobynumber( protocolname)**

Translate an Internet protocol name (for example, '\icmp\') to a constant suitable for passing as the (optional) third argument to the \(socket()\) function. This is usually only needed for sockets opened in "raw" mode (SOCK_RAW); for the normal socket modes, the correct protocol is chosen automatically if the protocol is omitted or zero.

**getservbyname( servicename[, protocolname])**

Translate an Internet service name and protocol name to a port number for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

**getservbyport( port[, protocolname])**

Translate an Internet port number and protocol name to a service name for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

**socket([family[, type[, proto]]])**

Create a new socket using the given address family, socket type and protocol number. The address family should be AF_INET (the default), AF_INET6 or AF_UNIX. The socket type should be SOCK_STREAM (the default), SOCK_DGRAM or perhaps one of the other "SOCK_" constants.
The protocol number is usually zero and may be omitted in that case.

**ssl** *(sock, keyfile, certfile)*

Initiate a SSL connection over the socket *sock*. *keyfile* is the name of a PEM formatted file that contains your private key. *certfile* is a PEM formatted certificate chain file. On success, a new **SSLObject** is returned.

**Warning:** This does not do any certificate verification!

**socketpair** *(family, type, proto)]*

Build a pair of connected socket objects using the given address family, socket type, and protocol number. Address family, socket type, and protocol number are as for the **socket** function above. The default family is **AF_UNIX** if defined on the platform; otherwise, the default is **AF_INET**. Availability: **Unix**. New in version 2.4.

**fromfd** *(fd, family, type, proto)]*

Duplicate the file descriptor *fd* (an integer as returned by a file object's **fileno** method) and build a socket object from the result. Address family, socket type and protocol number are as for the **socket** function above. The file descriptor should refer to a socket, but this is not checked -- subsequent operations on the object may fail if the file descriptor is invalid. This function is rarely needed, but can be used to get or set socket options on a socket passed to a program as standard input or output (such as a server started by the **Unix** inet daemon). The socket is assumed to be in blocking mode. Availability: **Unix**.

**ntohl** *(x)*

Convert 32-bit integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

**ntohs** *(x)*

Convert 16-bit integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.
htonl(x)
Convert 32-bit integers from host to network byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

htons(x)
Convert 16-bit integers from host to network byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

inet_aton(ip_string)
Convert an IPv4 address from dotted-quad string format (for example, '123.45.67.89') to 32-bit packed binary format, as a string four characters in length. This is useful when conversing with a program that uses the standard C library and needs objects of type struct in_addr, which is the C type for the 32-bit packed binary this function returns.

If the IPv4 address string passed to this function is invalid, socket.error will be raised. Note that exactly what is valid depends on the underlying C implementation of inet_aton().

inet_aton() does not support IPv6, and getnameinfo() should be used instead for IPv4/v6 dual stack support.

inet_ntoa(packed_ip)
Convert a 32-bit packed IPv4 address (a string four characters in length) to its standard dotted-quad string representation (for example, '123.45.67.89'). This is useful when conversing with a program that uses the standard C library and needs objects of type struct in_addr, which is the C type for the 32-bit packed binary data this function takes as an argument.

If the string passed to this function is not exactly 4 bytes in length, socket.error will be raised. inet_ntoa() does not support IPv6, and getnameinfo() should be used instead for IPv4/v6 dual stack support.

inet_pton(address_family, ip_string)
Convert an IP address from its family-specific string format to a packed,
binary format. `inet_pton()` is useful when a library or network protocol calls for an object of type `struct in_addr` (similar to `inet_aton()`) or `struct in6_addr`.

Supported values for `address_family` are currently `AF_INET` and `AF_INET6`. If the IP address string `ip_string` is invalid, `socket.error` will be raised. Note that exactly what is valid depends on both the value of `address_family` and the underlying implementation of `inet_pton()`.

Availability: UNIX (maybe not all platforms). New in version 2.3.

`inet_ntop( address_family, packed_ip)`
Convert a packed IP address (a string of some number of characters) to its standard, family-specific string representation (for example, '7.10.0.5' or '5aef:2b::8') `inet_ntop()` is useful when a library or network protocol returns an object of type `struct in_addr` (similar to `inet_ntoa()`) or `struct in6_addr`.

Supported values for `address_family` are currently `AF_INET` and `AF_INET6`. If the string `packed_ip` is not the correct length for the specified address family, `ValueError` will be raised. A `socket.error` is raised for errors from the call to `inet_ntop()`.

Availability: UNIX (maybe not all platforms). New in version 2.3.

`getdefaulttimeout()`
Return the default timeout in floating seconds for new socket objects. A value of `None` indicates that new socket objects have no timeout. When the socket module is first imported, the default is `None`. New in version 2.3.

`setdefaulttimeout( timeout)`
Set the default timeout in floating seconds for new socket objects. A value of `None` indicates that new socket objects have no timeout. When the socket module is first imported, the default is `None`. New in version 2.3.

`SocketType`
This is a Python type object that represents the socket object type. It is the same as `type(socket(...))`.

Module **SocketServer**: Classes that simplify writing network servers.

Subsections

- 7.2.1 Socket Objects
- 7.2.2 SSL Objects
- 7.2.3 Example

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
7.2.1 Socket Objects

Socket objects have the following methods. Except for makefile() these correspond to UNIX system calls applicable to sockets.

accept()
Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair (conn, address) where conn is a new socket object usable to send and receive data on the connection, and address is the address bound to the socket on the other end of the connection.

bind(address)
Bind the socket to address. The socket must not already be bound. (The format of address depends on the address family -- see above.) Note: This method has historically accepted a pair of parameters for AF_INET addresses instead of only a tuple. This was never intentional and is no longer available in Python 2.0 and later.

close()
Close the socket. All future operations on the socket object will fail. The remote end will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

connect(address)
Connect to a remote socket at address. (The format of address depends on the address family -- see above.) Note: This method has historically accepted a pair of parameters for AF_INET addresses instead of only a tuple. This was never intentional and is no longer available in Python 2.0 and later.

connect_ex(address)
Like connect(address), but return an error indicator instead of raising an exception for errors returned by the C-level connect() call (other problems, such as ``host not found,'' can still raise exceptions). The error indicator is 0 if the operation succeeded, otherwise the value of the errno
variable. This is useful to support, for example, asynchronous connects.

**Note:** This method has historically accepted a pair of parameters for AF_INET addresses instead of only a tuple. This was never intentional and is no longer available in Python 2.0 and later.

### fileno()

Return the socket's file descriptor (a small integer). This is useful with `select.select()`.

Under Windows the small integer returned by this method cannot be used where a file descriptor can be used (such as `os.fdopen()`). **Unix** does not have this limitation.

### getpeername()

Return the remote address to which the socket is connected. This is useful to find out the port number of a remote IPv4/v6 socket, for instance. (The format of the address returned depends on the address family -- see above.) On some systems this function is not supported.

### getsockname()

Return the socket's own address. This is useful to find out the port number of an IPv4/v6 socket, for instance. (The format of the address returned depends on the address family -- see above.)

### getsockopt( `level`, `optname`[, `buflen`])

Return the value of the given socket option (see the **Unix** man page `getsockopt(2)`). The needed symbolic constants (SO_* etc.) are defined in this module. If `buflen` is absent, an integer option is assumed and its integer value is returned by the function. If `buflen` is present, it specifies the maximum length of the buffer used to receive the option in, and this buffer is returned as a string. It is up to the caller to decode the contents of the buffer (see the optional built-in module `struct` for a way to decode C structures encoded as strings).

### listen( `backlog`)

Listen for connections made to the socket. The `backlog` argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).
**makefile**([`mode[, bufsize]`])

Return a file object associated with the socket. (File objects are described in 2.3.9, ``File Objects``.) The file object references a dupe()ped version of the socket file descriptor, so the file object and socket object may be closed or garbage-collected independently. The socket must be in blocking mode. The optional mode and bufsize arguments are interpreted the same way as by the built-in file() function; see ``Built-in Functions`` (section 2.1) for more information.

**recv**([`bufsize[, flags]`])

Receive data from the socket. The return value is a string representing the data received. The maximum amount of data to be received at once is specified by bufsize. See the UNIX manual page recv(2) for the meaning of the optional argument flags; it defaults to zero. **Note:** For best match with hardware and network realities, the value of bufsize should be a relatively small power of 2, for example, 4096.

**recvfrom**([`bufsize[, flags]`])

Receive data from the socket. The return value is a pair (`string, address`) where string is a string representing the data received and address is the address of the socket sending the data. The optional flags argument has the same meaning as for recv() above. (The format of address depends on the address family -- see above.)

**send**([`string[, flags]`])

Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for recv() above. Returns the number of bytes sent. Applications are responsible for checking that all data has been sent; if only some of the data was transmitted, the application needs to attempt delivery of the remaining data.

**sendall**([`string[, flags]`])

Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for recv() above. Unlike send(), this method continues to send data from string until either all data has been sent or an error occurs. **None** is returned on success. On error, an exception is raised, and there is no way to determine how much
data, if any, was successfully sent.

**sendto**( string[, flags], address)
Send data to the socket. The socket should not be connected to a remote socket, since the destination socket is specified by address. The optional flags argument has the same meaning as for recv() above. Return the number of bytes sent. (The format of address depends on the address family -- see above.)

**setblocking**( flag)
Set blocking or non-blocking mode of the socket: if flag is 0, the socket is set to non-blocking, else to blocking mode. Initially all sockets are in blocking mode. In non-blocking mode, if a recv() call doesn't find any data, or if a send() call can't immediately dispose of the data, a error exception is raised; in blocking mode, the calls block until they can proceed. s.setblocking(0) is equivalent to s.settimeout(0); s.setblocking(1) is equivalent to s.settimeout(None).

**settimeout**( value)
Set a timeout on blocking socket operations. The value argument can be a nonnegative float expressing seconds, or None. If a float is given, subsequent socket operations will raise an timeout exception if the timeout period value has elapsed before the operation has completed. Setting a timeout of None disables timeouts on socket operations. s.settimeout(0.0) is equivalent to s.setblocking(0); s.settimeout(None) is equivalent to s.setblocking(1). New in version 2.3.

**gettimeout**( )
Returns the timeout in floating seconds associated with socket operations, or None if no timeout is set. This reflects the last call to setblocking() or settimeout(). New in version 2.3.

Some notes on socket blocking and timeouts: A socket object can be in one of three modes: blocking, non-blocking, or timeout. Sockets are always created in blocking mode. In blocking mode, operations block until complete. In non-blocking mode, operations fail (with an error that is unfortunately system-
dependent) if they cannot be completed immediately. In timeout mode, operations fail if they cannot be completed within the timeout specified for the socket. The setblocking() method is simply a shorthand for certain settimeout() calls.

Timeout mode internally sets the socket in non-blocking mode. The blocking and timeout modes are shared between file descriptors and socket objects that refer to the same network endpoint. A consequence of this is that file objects returned by the makefile() method must only be used when the socket is in blocking mode; in timeout or non-blocking mode file operations that cannot be completed immediately will fail.

Note that the connect() operation is subject to the timeout setting, and in general it is recommended to call settimeout() before calling connect().

**setsockopt**( level, optname, value)

Set the value of the given socket option (see the UNIX manual page setsockopt(2)). The needed symbolic constants are defined in the socket module (SO_* etc.). The value can be an integer or a string representing a buffer. In the latter case it is up to the caller to ensure that the string contains the proper bits (see the optional built-in module struct for a way to encode C structures as strings).

**shutdown**( how)

Shut down one or both halves of the connection. If how is SHUT_RD, further receives are disallowed. If how is SHUT_WR, further sends are disallowed. If how is SHUT_RDWR, further sends and receives are disallowed.

Note that there are no methods read() or write(); use recv() and send() without flags argument instead.
7.2.2 SSL Objects

SSL objects have the following methods.

**write**(s)

Writes the string s to the on the object's SSL connection. The return value is the number of bytes written.

**read**([n])

If n is provided, read n bytes from the SSL connection, otherwise read until EOF. The return value is a string of the bytes read.
7.2.3 Example

Here are four minimal example programs using the TCP/IP protocol: a server that echoes all data that it receives back (servicing only one client), and a client using it. Note that a server must perform the sequence `socket()`, `bind()`, `listen()`, `accept()` (possibly repeating the `accept()` to service more than one client), while a client only needs the sequence `socket()`, `connect()`. Also note that the server does not `send()`/`recv()` on the socket it is listening on but on the new socket returned by `accept()`.

The first two examples support IPv4 only.

```python
# Echo server program
import socket

HOST = ''  # Symbolic name meaning the local host
PORT = 50007  # Arbitrary non-privileged port
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.bind((HOST, PORT))
s.listen(1)
conn, addr = s.accept()
print 'Connected by', addr
while 1:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()
```

```python
# Echo client program
import socket

HOST = 'daring.cwi.nl'  # The remote host
PORT = 50007  # The same port as used by the server
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.connect((HOST, PORT))
s.send('Hello, world')
data = s.recv(1024)
s.close()
print 'Received', repr(data)
```

The next two examples are identical to the above two, but support both IPv4 and IPv6. The server side will listen to the first address family available (it should listen to both instead). On most of IPv6-ready systems, IPv6 will take precedence and the server may not accept IPv4 traffic. The client side will try to
connect to the all addresses returned as a result of the name resolution, and sends traffic to the first one connected successfully.

```python
# Echo server program
import socket
import sys

HOST = ''  # Symbolic name meaning the local host
PORT = 50007  # Arbitrary non-privileged port
s = None
for res in socket.getaddrinfo(HOST, PORT, socket.AF_UNSPEC, socket.SOCK_STREAM, 0, socket.AI_PASSIVE):
    af, socktype, proto, canonname, sa = res
    try:
        s = socket.socket(af, socktype, proto)
    except socket.error, msg:
        s = None
        continue
    try:
        s.bind(sa)
        s.listen(1)
    except socket.error, msg:
        s.close()
        s = None
        continue
    break
if s is None:
    print 'could not open socket'
    sys.exit(1)
conn, addr = s.accept()
print 'Connected by', addr
while 1:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()

# Echo client program
import socket
import sys

HOST = 'daring.cwi.nl'  # The remote host
PORT = 50007  # The same port as used by the server
s = None
for res in socket.getaddrinfo(HOST, PORT, socket.AF_UNSPEC, socket.SOCK_STREAM):
    af, socktype, proto, canonname, sa = res
    try:
        s = socket.socket(af, socktype, proto)
    except socket.error, msg:
        s = None
        continue
    break
if s is None:
    print 'could not open socket'
    sys.exit(1)
    conn = s.accept()
    addr = conn[1]
print 'Connected by', addr
while 1:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()
```

```python
s.connect(sa)
except socket.error, msg:
s.close()
s = None
continue
break
if s is None:
    print 'could not open socket'
sys.exit(1)
s.send('Hello, world')
data = s.recv(1024)
s.close()
print 'Received', repr(data)
```
7.3 select -- Waiting for I/O completion

This module provides access to the `select()` and `poll()` functions available in most operating systems. Note that on Windows, it only works for sockets; on other operating systems, it also works for other file types (in particular, on UNIX, it works on pipes). It cannot be used on regular files to determine whether a file has grown since it was last read.

The module defines the following:

**exception error**

The exception raised when an error occurs. The accompanying value is a pair containing the numeric error code from `errno` and the corresponding string, as would be printed by the C function `perror()`.

**poll()**

(Not supported by all operating systems.) Returns a polling object, which supports registering and unregistering file descriptors, and then polling them for I/O events; see section 7.3.1 below for the methods supported by polling objects.

**select( iwtd, owtd, ewtd[, timeout])**

This is a straightforward interface to the UNIX `select()` system call. The first three arguments are sequences of `waitable objects`: either integers representing file descriptors or objects with a parameterless method named `fileno()` returning such an integer. The three sequences of waitable objects are for input, output and `exceptional conditions`, respectively. Empty sequences are allowed, but acceptance of three empty sequences is platform-dependent. (It is known to work on UNIX but not on Windows.) The optional `timeout` argument specifies a time-out as a floating point number in seconds. When the `timeout` argument is omitted the function blocks until at least one file descriptor is ready. A time-out value of zero specifies a poll and never blocks.
The return value is a triple of lists of objects that are ready: subsets of the first three arguments. When the time-out is reached without a file descriptor becoming ready, three empty lists are returned.

Among the acceptable object types in the sequences are Python file objects (e.g. `sys.stdin`, or objects returned by `open()` or `os.popen()`), socket objects returned by `socket.socket()`. You may also define a wrapper class yourself, as long as it has an appropriate `fileno()` method (that really returns a file descriptor, not just a random integer). Note: File objects on Windows are not acceptable, but sockets are. On Windows, the underlying `select()` function is provided by the WinSock library, and does not handle file descriptors that don't originate from WinSock.
7.3.1 Polling Objects

The `poll()` system call, supported on most Unix systems, provides better scalability for network servers that service many, many clients at the same time. `poll()` scales better because the system call only requires listing the file descriptors of interest, while `select()` builds a bitmap, turns on bits for the fds of interest, and then afterward the whole bitmap has to be linearly scanned again. `select()` is $O(\text{highest file descriptor})$, while `poll()` is $O(\text{number of file descriptors})$.

`register(fd[, eventmask])`

Register a file descriptor with the polling object. Future calls to the `poll()` method will then check whether the file descriptor has any pending I/O events. `fd` can be either an integer, or an object with a `fileno()` method that returns an integer. File objects implement `fileno()`, so they can also be used as the argument.

`eventmask` is an optional bitmask describing the type of events you want to check for, and can be a combination of the constants `POLLIN`, `POLLPRI`, and `POLLOUT`, described in the table below. If not specified, the default value used will check for all 3 types of events.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLIN</td>
<td>There is data to read</td>
</tr>
<tr>
<td>POLLPRI</td>
<td>There is urgent data to read</td>
</tr>
<tr>
<td>POLLOUT</td>
<td>Ready for output: writing will not block</td>
</tr>
<tr>
<td>POLLERR</td>
<td>Error condition of some sort</td>
</tr>
<tr>
<td>POLLHUP</td>
<td>Hung up</td>
</tr>
<tr>
<td>POLLNVAL</td>
<td>Invalid request: descriptor not open</td>
</tr>
</tbody>
</table>

Registering a file descriptor that's already registered is not an error, and has the same effect as registering the descriptor exactly once.

`unregister(fd)`

Remove a file descriptor being tracked by a polling object. Just like the
register() method, *fd* can be an integer or an object with a *fileno()* method that returns an integer.

Attempting to remove a file descriptor that was never registered causes a *KeyError* exception to be raised.

**poll**([*timeout]*)
Polls the set of registered file descriptors, and returns a possibly-empty list containing (*fd*, *event*) 2-tuples for the descriptors that have events or errors to report. *fd* is the file descriptor, and *event* is a bitmask with bits set for the reported events for that descriptor -- *POLLIN* for waiting input, *POLLOUT* to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If *timeout* is given, it specifies the length of time in milliseconds which the system will wait for events before returning. If *timeout* is omitted, negative, or *None*, the call will block until there is an event for this poll object.
7.4 thread -- Multiple threads of control

This module provides low-level primitives for working with multiple threads (a.k.a. light-weight processes or tasks) -- multiple threads of control sharing their global data space. For synchronization, simple locks (a.k.a. mutexes or binary semaphores) are provided.

The module is optional. It is supported on Windows, Linux, SGI IRIX, Solaris 2.x, as well as on systems that have a POSIX thread (a.k.a. "pthread") implementation. For systems lacking the thread module, the dummy_thread module is available. It duplicates this module's interface and can be used as a drop-in replacement.

It defines the following constant and functions:

**exception error**

Raised on thread-specific errors.

**LockType**

This is the type of lock objects.

**start_new_thread** *(function, args[, kwargs])*  
Start a new thread and return its identifier. The thread executes the function *function* with the argument list *args* (which must be a tuple). The optional *kwargs* argument specifies a dictionary of keyword arguments. When the function returns, the thread silently exits. When the function terminates with an unhandled exception, a stack trace is printed and then the thread exits (but other threads continue to run).

**interrupt_main()**  
Raise a KeyboardInterrupt exception in the main thread. A subthread can use this function to interrupt the main thread. New in version 2.3.

**exit()**
Raise the `SystemExit` exception. When not caught, this will cause the thread to exit silently.

**allocate_lock()**

Return a new lock object. Methods of locks are described below. The lock is initially unlocked.

**get_ident()**

Return the `thread identifier` of the current thread. This is a nonzero integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

Lock objects have the following methods:

**acquire([waitflag])**

Without the optional argument, this method acquires the lock unconditionally, if necessary waiting until it is released by another thread (only one thread at a time can acquire a lock -- that's their reason for existence). If the integer `waitflag` argument is present, the action depends on its value: if it is zero, the lock is only acquired if it can be acquired immediately without waiting, while if it is nonzero, the lock is acquired unconditionally as before. The return value is `True` if the lock is acquired successfully, `False` if not.

**release()**

Releases the lock. The lock must have been acquired earlier, but not necessarily by the same thread.

**locked()**

Return the status of the lock: `True` if it has been acquired by some thread, `False` if not.

**Caveats:**

- Threads interact strangely with interrupts: the `KeyboardInterrupt` exception will be received by an arbitrary thread. (When the `signal` module is available, interrupts always go to the main thread.)
• Calling `sys.exit()` or raising the `SystemExit` exception is equivalent to calling `exit()`.

• Not all built-in functions that may block waiting for I/O allow other threads to run. (The most popular ones (`time.sleep()`, `file.read()`, `select.select()`) work as expected.)

• It is not possible to interrupt the `acquire()` method on a lock -- the `KeyboardInterrupt` exception will happen after the lock has been acquired.

• When the main thread exits, it is system defined whether the other threads survive. On SGI IRIX using the native thread implementation, they survive. On most other systems, they are killed without executing `try ... finally` clauses or executing object destructors.

• When the main thread exits, it does not do any of its usual cleanup (except that `try ... finally` clauses are honored), and the standard I/O files are not flushed.
This module constructs higher-level threading interfaces on top of the lower level `thread` module.

The `dummy_threading` module is provided for situations where `threading` cannot be used because `thread` is missing.

This module defines the following functions and objects:

**activeCount()**
Return the number of currently active `Thread` objects. The returned count is equal to the length of the list returned by `enumerate()`. A function that returns the number of currently active threads.

**Condition()**
A factory function that returns a new condition variable object. A condition variable allows one or more threads to wait until they are notified by another thread.

**currentThread()**
Return the current `Thread` object, corresponding to the caller's thread of control. If the caller's thread of control was not created through the `threading` module, a dummy thread object with limited functionality is returned.

**enumerate()**
Return a list of all currently active `Thread` objects. The list includes daemonic threads, dummy thread objects created by `currentThread()`, and the main thread. It excludes terminated threads and threads that have not yet been started.

**Event()**
A factory function that returns a new event object. An event manages a flag
that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true.

**class local**
A class that represents thread-local data. Thread-local data are data whose values are thread specific. To manage thread-local data, just create an instance of `local` (or a subclass) and store attributes on it:

```python
  mydata = threading.local()
  mydata.x = 1
```

The instance's values will be different for separate threads.

For more details and extensive examples, see the documentation string of the `_threading_local` module.

New in version 2.4.

**Lock()**
A factory function that returns a new primitive lock object. Once a thread has acquired it, subsequent attempts to acquire it block, until it is released; any thread may release it.

**RLock()**
A factory function that returns a new reentrant lock object. A reentrant lock must be released by the thread that acquired it. Once a thread has acquired a reentrant lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

**Semaphore([value])**
A factory function that returns a new semaphore object. A semaphore manages a counter representing the number of `release()` calls minus the number of `acquire()` calls, plus an initial value. The `acquire()` method blocks if necessary until it can return without making the counter negative. If not given, `value` defaults to 1.

**BoundedSemaphore([value])**
A factory function that returns a new bounded semaphore object. A bounded semaphore checks to make sure its current value doesn't exceed its
initial value. If it does, `ValueError` is raised. In most situations
semaphores are used to guard resources with limited capacity. If the
semaphore is released too many times it's a sign of a bug. If not given,
`value` defaults to 1.

class **Thread**
A class that represents a thread of control. This class can be safely
subclassed in a limited fashion.

class **Timer**
A thread that executes a function after a specified interval has passed.

**settrace**(func)
Set a trace function for all threads started from the `threading` module.
The `func` will be passed to `sys.settrace()` for each thread, before its
`run()` method is called. New in version 2.3.

**setprofile**(func)
Set a profile function for all threads started from the `threading` module.
The `func` will be passed to `sys.setprofile()` for each thread, before
its `run()` method is called. New in version 2.3.

Detailed interfaces for the objects are documented below.

The design of this module is loosely based on Java's threading model. However,
where Java makes locks and condition variables basic behavior of every object,
they are separate objects in Python. Python's **Thread** class supports a subset of
the behavior of Java's Thread class; currently, there are no priorities, no thread
groups, and threads cannot be destroyed, stopped, suspended, resumed, or
interrupted. The static methods of Java's Thread class, when implemented, are
mapped to module-level functions.

All of the methods described below are executed atomically.

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
### 7.5.1 Lock Objects

A primitive lock is a synchronization primitive that is not owned by a particular thread when locked. In Python, it is currently the lowest level synchronization primitive available, implemented directly by the `thread` extension module.

A primitive lock is in one of two states, "locked" or "unlocked". It is created in the unlocked state. It has two basic methods, `acquire()` and `release()`. When the state is unlocked, `acquire()` changes the state to locked and returns immediately. When the state is locked, `acquire()` blocks until a call to `release()` in another thread changes it to unlocked, then the `acquire()` call resets it to locked and returns. The `release()` method should only be called in the locked state; it changes the state to unlocked and returns immediately. When more than one thread is blocked in `acquire()` waiting for the state to turn to unlocked, only one thread proceeds when a `release()` call resets the state to unlocked; which one of the waiting threads proceeds is not defined, and may vary across implementations.

All methods are executed atomically.

**acquire([blocking = 1])**

Acquire a lock, blocking or non-blocking.

When invoked without arguments, block until the lock is unlocked, then set it to locked, and return true.

When invoked with the `blocking` argument set to true, do the same thing as when called without arguments, and return true.

When invoked with the `blocking` argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

**release()**

Release a lock.

When the lock is locked, reset it to unlocked, and return. If any other
threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

Do not call this method when the lock is unlocked.

There is no return value.
7.5.2 RLock Objects

A reentrant lock is a synchronization primitive that may be acquired multiple times by the same thread. Internally, it uses the concepts of "owning thread" and "recursion level" in addition to the locked/unlocked state used by primitive locks. In the locked state, some thread owns the lock; in the unlocked state, no thread owns it.

To lock the lock, a thread calls its `acquire()` method; this returns once the thread owns the lock. To unlock the lock, a thread calls its `release()` method. `acquire()`/`release()` call pairs may be nested; only the final `release()` (the `release()` of the outermost pair) resets the lock to unlocked and allows another thread blocked in `acquire()` to proceed.

`acquire([blocking = 1])`

Acquire a lock, blocking or non-blocking.

When invoked without arguments: if this thread already owns the lock, increment the recursion level by one, and return immediately. Otherwise, if another thread owns the lock, block until the lock is unlocked. Once the lock is unlocked (not owned by any thread), then grab ownership, set the recursion level to one, and return. If more than one thread is blocked waiting until the lock is unlocked, only one at a time will be able to grab ownership of the lock. There is no return value in this case.

When invoked with the `blocking` argument set to true, do the same thing as when called without arguments, and return true.

When invoked with the `blocking` argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

`release()`

Release a lock, decrementing the recursion level. If after the decrement it is zero, reset the lock to unlocked (not owned by any thread), and if any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed. If after the decrement the recursion level is still
nonzero, the lock remains locked and owned by the calling thread.

Only call this method when the calling thread owns the lock. Do not call this method when the lock is unlocked.

There is no return value.
7.5.3 Condition Objects

A condition variable is always associated with some kind of lock; this can be passed in or one will be created by default. (Passing one in is useful when several condition variables must share the same lock.)

A condition variable has `acquire()` and `release()` methods that call the corresponding methods of the associated lock. It also has a `wait()` method, and `notify()` and `notifyAll()` methods. These three must only be called when the calling thread has acquired the lock.

The `wait()` method releases the lock, and then blocks until it is awakened by a `notify()` or `notifyAll()` call for the same condition variable in another thread. Once awakened, it re-acquires the lock and returns. It is also possible to specify a timeout.

The `notify()` method wakes up one of the threads waiting for the condition variable, if any are waiting. The `notifyAll()` method wakes up all threads waiting for the condition variable.

Note: the `notify()` and `notifyAll()` methods don't release the lock; this means that the thread or threads awakened will not return from their `wait()` call immediately, but only when the thread that called `notify()` or `notifyAll()` finally relinquishes ownership of the lock.

Tip: the typical programming style using condition variables uses the lock to synchronize access to some shared state; threads that are interested in a particular change of state call `wait()` repeatedly until they see the desired state, while threads that modify the state call `notify()` or `notifyAll()` when they change the state in such a way that it could possibly be a desired state for one of the waiters. For example, the following code is a generic producer-consumer situation with unlimited buffer capacity:

```python
# Consume one item
cv.acquire()
while not an_item_is_available():
    cv.wait()
get_an_available_item()
cv.release()
```
To choose between `notify()` and `notifyAll()`, consider whether one state change can be interesting for only one or several waiting threads. E.g. in a typical producer-consumer situation, adding one item to the buffer only needs to wake up one consumer thread.

```python
class Condition([lock])
    If the `lock` argument is given and not `None`, it must be a `Lock` or `RLock` object, and it is used as the underlying lock. Otherwise, a new `RLock` object is created and used as the underlying lock.

acquire(*args)
    Acquire the underlying lock. This method calls the corresponding method on the underlying lock; the return value is whatever that method returns.

release()
    Release the underlying lock. This method calls the corresponding method on the underlying lock; there is no return value.

wait([timeout])
    Wait until notified or until a timeout occurs. This must only be called when the calling thread has acquired the lock.

    This method releases the underlying lock, and then blocks until it is awakened by a `notify()` or `notifyAll()` call for the same condition variable in another thread, or until the optional timeout occurs. Once awakened or timed out, it re-acquires the lock and returns.

    When the `timeout` argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

    When the underlying lock is an `RLock`, it is not released using its
release() method, since this may not actually unlock the lock when it was acquired multiple times recursively. Instead, an internal interface of the RLock class is used, which really unlocks it even when it has been recursively acquired several times. Another internal interface is then used to restore the recursion level when the lock is reacquired.

notify()
Wake up a thread waiting on this condition, if any. This must only be called when the calling thread has acquired the lock.

This method wakes up one of the threads waiting for the condition variable, if any are waiting; it is a no-op if no threads are waiting.

The current implementation wakes up exactly one thread, if any are waiting. However, it's not safe to rely on this behavior. A future, optimized implementation may occasionally wake up more than one thread.

Note: the awakened thread does not actually return from its wait() call until it can reacquire the lock. Since notify() does not release the lock, its caller should.

notifyAll()
Wake up all threads waiting on this condition. This method acts like notify(), but wakes up all waiting threads instead of one.
7.5.4 Semaphore Objects

This is one of the oldest synchronization primitives in the history of computer science, invented by the early Dutch computer scientist Edsger W. Dijkstra (he used $P()$ and $V()$ instead of acquire() and release()).

A semaphore manages an internal counter which is decremented by each acquire() call and incremented by each release() call. The counter can never go below zero; when acquire() finds that it is zero, it blocks, waiting until some other thread calls release().

**class Semaphore([value])**

The optional argument gives the initial value for the internal counter; it defaults to 1.

**acquire([blocking])**

Acquire a semaphore.

When invoked without arguments: if the internal counter is larger than zero on entry, decrement it by one and return immediately. If it is zero on entry, block, waiting until some other thread has called release() to make it larger than zero. This is done with proper interlocking so that if multiple acquire() calls are blocked, release() will wake exactly one of them up. The implementation may pick one at random, so the order in which blocked threads are awakened should not be relied on. There is no return value in this case.

When invoked with blocking set to true, do the same thing as when called without arguments, and return true.

When invoked with blocking set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

**release()**

Release a semaphore, incrementing the internal counter by one. When it was zero on entry and another thread is waiting for it to become larger than
zero again, wake up that thread.

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
7.5.5 Event Objects

This is one of the simplest mechanisms for communication between threads: one thread signals an event and other threads wait for it.

An event object manages an internal flag that can be set to true with the \texttt{set()} method and reset to false with the \texttt{clear()} method. The \texttt{wait()} method blocks until the flag is true.

\begin{verbatim}

\textbf{class Event()}
\end{verbatim}

The internal flag is initially false.

\begin{verbatim}

\textbf{isSet()}
\end{verbatim}

Return true if and only if the internal flag is true.

\begin{verbatim}

\textbf{set()}
\end{verbatim}

Set the internal flag to true. All threads waiting for it to become true are awakened. Threads that call \texttt{wait()} once the flag is true will not block at all.

\begin{verbatim}

\textbf{clear()}
\end{verbatim}

Reset the internal flag to false. Subsequently, threads calling \texttt{wait()} will block until \texttt{set()} is called to set the internal flag to true again.

\begin{verbatim}

\textbf{wait([timeout])}
\end{verbatim}

Block until the internal flag is true. If the internal flag is true on entry, return immediately. Otherwise, block until another thread calls \texttt{set()} to set the flag to true, or until the optional timeout occurs.

When the timeout argument is present and not \texttt{None}, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).
Objects

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
7.5.6 Thread Objects

This class represents an activity that is run in a separate thread of control. There are two ways to specify the activity: by passing a callable object to the constructor, or by overriding the `run()` method in a subclass. No other methods (except for the constructor) should be overridden in a subclass. In other words, *only* override the `__init__() and run()` methods of this class.

Once a thread object is created, its activity must be started by calling the thread's `start()` method. This invokes the `run()` method in a separate thread of control.

Once the thread's activity is started, the thread is considered 'alive' and 'active' (these concepts are almost, but not quite exactly, the same; their definition is intentionally somewhat vague). It stops being alive and active when its `run()` method terminates - either normally, or by raising an unhandled exception. The `isAlive()` method tests whether the thread is alive.

Other threads can call a thread's `join()` method. This blocks the calling thread until the thread whose `join()` method is called is terminated.

A thread has a name. The name can be passed to the constructor, set with the `setName()` method, and retrieved with the `getName()` method.

A thread can be flagged as a ``daemon thread``. The significance of this flag is that the entire Python program exits when only daemon threads are left. The initial value is inherited from the creating thread. The flag can be set with the `setDaemon()` method and retrieved with the `isDaemon()` method.

There is a ``main thread`` object; this corresponds to the initial thread of control in the Python program. It is not a daemon thread.

There is the possibility that ``dummy thread objects`` are created. These are thread objects corresponding to ``alien threads``. These are threads of control started outside the threading module, such as directly from C code. Dummy thread objects have limited functionality; they are always considered alive, active, and daemonic, and cannot be `join()`ed. They are never deleted, since it is impossible to detect the termination of alien threads.
class Thread(
    group=None, target=None, name=None, args=(), kwargs={})
This constructor should always be called with keyword arguments.
Arguments are:

group should be None; reserved for future extension when a
ThreadGroup class is implemented.

target is the callable object to be invoked by the run() method. Defaults
to None, meaning nothing is called.

name is the thread name. By default, a unique name is constructed of the
form ``Thread-N'' where N is a small decimal number.

args is the argument tuple for the target invocation. Defaults to ()

kwargs is a dictionary of keyword arguments for the target invocation.
Defaults to {}.

If the subclass overrides the constructor, it must make sure to invoke the
base class constructor (Thread.__init__()) before doing anything
else to the thread.

start()
Start the thread's activity.

This must be called at most once per thread object. It arranges for the
object's run() method to be invoked in a separate thread of control.

run()
Method representing the thread's activity.

You may override this method in a subclass. The standard run() method
invokes the callable object passed to the object's constructor as the target
argument, if any, with sequential and keyword arguments taken from the
args and kwargs arguments, respectively.

join([timeout])
Wait until the thread terminates. This blocks the calling thread until the
thread whose \texttt{join()} method is called terminates - either normally or through an unhandled exception - or until the optional timeout occurs.

When the \textit{timeout} argument is present and not \texttt{None}, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof). As \texttt{join()} always returns \texttt{None}, you must call \texttt{isAlive()} to decide whether a timeout happened.

When the \textit{timeout} argument is not present or \texttt{None}, the operation will block until the thread terminates.

A thread can be \texttt{join()}ed many times.

A thread cannot join itself because this would cause a deadlock.

It is an error to attempt to \texttt{join()} a thread before it has been started.

\texttt{getName()}  
Return the thread's name.

\texttt{setName(name)}  
Set the thread's name.

The name is a string used for identification purposes only. It has no semantics. Multiple threads may be given the same name. The initial name is set by the constructor.

\texttt{isAlive()}  
Return whether the thread is alive.

Roughly, a thread is alive from the moment the \texttt{start()} method returns until its \texttt{run()} method terminates.

\texttt{isDaemon()}  
Return the thread's daemon flag.

\texttt{setDaemon(daemonic)}  
Set the thread's daemon flag to the Boolean value \textit{daemonic}. This must be
called before \texttt{start()} is called.

The initial value is inherited from the creating thread.

The entire Python program exits when no active non-daemon threads are left.
7.5.7 Timer Objects

This class represents an action that should be run only after a certain amount of time has passed -- a timer. Timer is a subclass of Thread and as such also functions as an example of creating custom threads.

Timers are started, as with threads, by calling their start() method. The timer can be stopped (before its action has begun) by calling the cancel() method. The interval the timer will wait before executing its action may not be exactly the same as the interval specified by the user.

For example:

```python
def hello():
    print "hello, world"

t = Timer(30.0, hello)
t.start() # after 30 seconds, "hello, world" will be printed
```

class Timer( interval, function, args=[], kwargs={} )

Create a timer that will run function with arguments args and keyword arguments kwargs, after interval seconds have passed.

cancel()

Stop the timer, and cancel the execution of the timer's action. This will only work if the timer is still in its waiting stage.
7.6 dummy_thread -- Drop-in replacement for the thread module

This module provides a duplicate interface to the thread module. It is meant to be imported when the thread module is not provided on a platform.

Suggested usage is:

```
try:
    import thread as _thread
except ImportError:
    import dummy_thread as _thread
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
7.7 dummy_threading -- Drop-in replacement for the threading module

This module provides a duplicate interface to the `threading` module. It is meant to be imported when the `thread` module is not provided on a platform.

Suggested usage is:

```python
try:
    import threading as _threading
except ImportError:
    import dummy_threading as _threading
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
7.8 Queue -- A synchronized queue class

The Queue module implements a multi-producer, multi-consumer FIFO queue. It is especially useful in threads programming when information must be exchanged safely between multiple threads. The Queue class in this module implements all the required locking semantics. It depends on the availability of thread support in Python.

The Queue module defines the following class and exception:

```python
class Queue(maxsize)

  Constructor for the class. maxsize is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If maxsize is less than or equal to zero, the queue size is infinite.
```

**exception Empty**

Exception raised when non-blocking get() (or get_nowait()) is called on a Queue object which is empty.

**exception Full**

Exception raised when non-blocking put() (or put_nowait()) is called on a Queue object which is full.

Subsections

- [7.8.1 Queue Objects](#)

---

**Python Library Reference**

Previous: 7.7 dummy_threading Up: 7. Optional Operating System Next: 7.8.1 Queue Objects

*Release 2.4.4c1, documentation updated on 11 October 2006.*
See About this document... for information on suggesting changes.
7.8.1 Queue Objects

Class Queue implements queue objects and has the methods described below. This class can be derived from in order to implement other queue organizations (e.g. stack) but the inheritable interface is not described here. See the source code for details. The public methods are:

qsize()
Return the approximate size of the queue. Because of multithreading semantics, this number is not reliable.

empty()
Return True if the queue is empty, False otherwise. Because of multithreading semantics, this is not reliable.

full()
Return True if the queue is full, False otherwise. Because of multithreading semantics, this is not reliable.

put(item[, block[, timeout]])
Put item into the queue. If optional args block is true and timeout is None (the default), block if necessary until a free slot is available. If timeout is a positive number, it blocks at most timeout seconds and raises the Full exception if no free slot was available within that time. Otherwise (block is false), put an item on the queue if a free slot is immediately available, else raise the Full exception (timeout is ignored in that case).

New in version 2.3: the timeout parameter.

put_nowait(item)
Equivalent to put(item, False).

get([block[, timeout]])
Remove and return an item from the queue. If optional args block is true and timeout is None (the default), block if necessary until an item is available. If timeout is a positive number, it blocks at most timeout seconds
and raises the `Empty` exception if no item was available within that time. Otherwise (`block` is false), return an item if one is immediately available, else raise the `Empty` exception (`timeout` is ignored in that case).

New in version 2.3: the timeout parameter.

**get_nowait()**

Equivalent to `get(False)`. 
7.9 mmap -- Memory-mapped file support

Memory-mapped file objects behave like both strings and like file objects. Unlike normal string objects, however, these are mutable. You can use mmap objects in most places where strings are expected; for example, you can use the re module to search through a memory-mapped file. Since they're mutable, you can change a single character by doing `obj[index] = 'a'`, or change a substring by assigning to a slice: `obj[i1:i2] = '...'`. You can also read and write data starting at the current file position, and `seek()` through the file to different positions.

A memory-mapped file is created by the `mmap()` function, which is different on UNIX and on Windows. In either case you must provide a file descriptor for a file opened for update. If you wish to map an existing Python file object, use its `fileno()` method to obtain the correct value for the `fileno` parameter. Otherwise, you can open the file using the `os.open()` function, which returns a file descriptor directly (the file still needs to be closed when done).

For both the UNIX and Windows versions of the function, `access` may be specified as an optional keyword parameter. `access` accepts one of three values: `ACCESS_READ`, `ACCESS_WRITE`, or `ACCESS_COPY` to specify readonly, write-through or copy-on-write memory respectively. `access` can be used on both UNIX and Windows. If `access` is not specified, Windows mmap returns a write-through mapping. The initial memory values for all three access types are taken from the specified file. Assignment to an `ACCESS_READ` memory map raises a `TypeError` exception. Assignment to an `ACCESS_WRITE` memory map affects both memory and the underlying file. Assignment to an `ACCESS_COPY` memory map affects memory but does not update the underlying file.

```
mmap( fileno, length[, tagname[, access]])
```

(Windows version) Maps `length` bytes from the file specified by the file handle `fileno`, and returns a mmap object. If `length` is larger than the current size of the file, the file is extended to contain `length` bytes. If `length` is 0, the maximum length of the map is the current size of the file, except that if the
file is empty Windows raises an exception (you cannot create an empty mapping on Windows).

*tagname*, if specified and not *None*, is a string giving a tag name for the mapping. Windows allows you to have many different mappings against the same file. If you specify the name of an existing tag, that tag is opened, otherwise a new tag of this name is created. If this parameter is omitted or *None*, the mapping is created without a name. Avoiding the use of the tag parameter will assist in keeping your code portable between *UNIX* and Windows.

```
mmap( fileno, length[, flags[, prot[, access]]])
```

(*UNIX version*) Maps *length* bytes from the file specified by the file descriptor *fileno*, and returns a mmap object.

*flags* specifies the nature of the mapping. *MAP_PRIVATE* creates a private copy-on-write mapping, so changes to the contents of the mmap object will be private to this process, and *MAP_SHARED* creates a mapping that's shared with all other processes mapping the same areas of the file. The default value is *MAP_SHARED*.

*prot*, if specified, gives the desired memory protection; the two most useful values are *PROT_READ* and *PROT_WRITE*, to specify that the pages may be read or written. *prot* defaults to *

*access* may be specified in lieu of *flags* and *prot* as an optional keyword parameter. It is an error to specify both *flags*, *prot* and *access*. See the description of *access* above for information on how to use this parameter.

Memory-mapped file objects support the following methods:

**close()**

Close the file. Subsequent calls to other methods of the object will result in an exception being raised.

**find**( *string*[ , *start*])

Returns the lowest index in the object where the substring *string* is found. Returns -1 on failure. *start* is the index at which the search begins, and
defaults to zero.

**flush([offset, size])**
Flushes changes made to the in-memory copy of a file back to disk. Without use of this call there is no guarantee that changes are written back before the object is destroyed. If offset and size are specified, only changes to the given range of bytes will be flushed to disk; otherwise, the whole extent of the mapping is flushed.

**move(dest, src, count)**
Copy the count bytes starting at offset src to the destination index dest. If the mmap was created with ACCESS_READ, then calls to move will throw a TypeError exception.

**read(num)**
Return a string containing up to num bytes starting from the current file position; the file position is updated to point after the bytes that were returned.

**read_byte()**
Returns a string of length 1 containing the character at the current file position, and advances the file position by 1.

**readline()**
Returns a single line, starting at the current file position and up to the next newline.

**resize(newsize)**
Resizes the map and the underlying file, if any. If the mmap was created with ACCESS_READ or ACCESS_COPY, resizing the map will throw a TypeError exception.

**seek(pos[, whence])**
Set the file's current position. whence argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file's end).
size()
Return the length of the file, which can be larger than the size of the memory-mapped area.

tell()
Returns the current position of the file pointer.

write(string)
Write the bytes in string into memory at the current position of the file pointer; the file position is updated to point after the bytes that were written. If the mmap was created with ACCESS_READ, then writing to it will throw a TypeError exception.

write_byte(byte)
Write the single-character string byte into memory at the current position of the file pointer; the file position is advanced by 1. If the mmap was created with ACCESS_READ, then writing to it will throw a TypeError exception.
7.10 anydbm -- Generic access to DBM-style databases

anydbm is a generic interface to variants of the DBM database -- dbhash (requires bsddb), gdbm, or dbm. If none of these modules is installed, the slow-but-simple implementation in module dumbdbm will be used.

open( filename[, flag[, mode]])
Open the database file filename and return a corresponding object.

If the database file already exists, the whichdb module is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is used.

The optional flag argument can be 'r' to open an existing database for reading only, 'w' to open an existing database for reading and writing, 'c' to create the database if it doesn't exist, or 'n', which will always create a new empty database. If not specified, the default value is 'r'.

The optional mode argument is the UNIX mode of the file, used only when the database has to be created. It defaults to octal 0666 (and will be modified by the prevailing umask).

element error
A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception anydbm.error as the first item -- the latter is used when anydbm.error is raised.

The object returned by open() supports most of the same functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the has_key() and keys() methods are available. Keys and values must always be strings.

See Also:
Module **dbhash**: BSD db database interface.

Module **dbm**: Standard UNIX database interface.

Module **dumbdbm**: Portable implementation of the dbm interface.

Module **gdbm**: GNU database interface, based on the dbm interface.

Module **shelve**: General object persistence built on top of the Python dbm interface.

Module **whichdb**: Utility module used to determine the type of an existing database.
The `dbhash` module provides a function to open databases using the BSD `db` library. This module mirrors the interface of the other Python database modules that provide access to DBM-style databases. The `bsddb` module is required to use `dbhash`.

This module provides an exception and a function:

**exception error**
Exception raised on database errors other than `KeyError`. It is a synonym for `bsddb.error`.

**open( path[, flag[, mode]])**
Open a `db` database and return the database object. The `path` argument is the name of the database file.

The `flag` argument can be `'r'` (the default), `'w'`, `'c'` (which creates the database if it doesn't exist), or `'n'` (which always creates a new empty database). For platforms on which the BSD `db` library supports locking, an "l" can be appended to indicate that locking should be used.

The optional `mode` parameter is used to indicate the `UNIX` permission bits that should be set if a new database must be created; this will be masked by the current umask value for the process.

**See Also:**

Module `anydbm`:
Generic interface to `dbm-style` databases.
Module **bsddb**:  
Lower-level interface to the BSD db library.

Module **whichdb**:  
Utility module used to determine the type of an existing database.
7.11.1 Database Objects

The database objects returned by `open()` provide the methods common to all the DBM-style databases and mapping objects. The following methods are available in addition to the standard methods.

**first()**
It's possible to loop over every key/value pair in the database using this method and the `next()` method. The traversal is ordered by the databases internal hash values, and won't be sorted by the key values. This method returns the starting key.

**last()**
Return the last key/value pair in a database traversal. This may be used to begin a reverse-order traversal; see `previous()`.

**next()**
Returns the key next key/value pair in a database traversal. The following code prints every key in the database `db`, without having to create a list in memory that contains them all:

```
print db.first()
for i in xrange(1, len(db)):
    print db.next()
```

**previous()**
Returns the previous key/value pair in a forward-traversal of the database. In conjunction with `last()`, this may be used to implement a reverse-order traversal.

**sync()**
This method forces any unwritten data to be written to the disk.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.12 whichdb -- Guess which DBM module created a database

The single function in this module attempts to guess which of the several simple database modules available—dbm, gdbm, or dbhash—should be used to open a given file.

**whichdb( filename)**

Returns one of the following values: None if the file can't be opened because it's unreadable or doesn't exist; the empty string (' ') if the file's format can't be guessed; or a string containing the required module name, such as 'dbm' or 'gdbm'.

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.13 bsddb -- Interface to Berkeley DB library

Availability: Unix, Windows.

The bsddb module provides an interface to the Berkeley DB library. Users can create hash, btree or record based library files using the appropriate open call. Bsddb objects behave generally like dictionaries. Keys and values must be strings, however, so to use other objects as keys or to store other kinds of objects the user must serialize them somehow, typically using marshal.dumps or pickle.dumps.

Starting with Python 2.3 the bsddb module requires the Berkeley DB library version 3.2 or later (it is known to work with 3.2 through 4.3 at the time of this writing).

See Also:

http://pybsddb.sourceforge.net/
Website with documentation for the new Python Berkeley DB interface that closely mirrors the object oriented interface provided in Berkeley DB 3 and 4.

http://www.oracle.com/database/berkeley-db/
The Berkeley DB library.

The following is a description of the legacy bsddb interface compatible with the old Python bsddb module. For details about the more modern Db and DbEnv object oriented interface see the above mentioned pybsddb URL.

The bsddb module defines the following functions that create objects that access the appropriate type of Berkeley DB file. The first two arguments of each function are the same. For ease of portability, only the first two arguments should be used in most instances.
hashopen(filename[, flag[, mode[, bsize[, ffactor[, nelem[, cachesize[, hash[, lorder]]]]]]]])

Open the hash format file named filename. Files never intended to be preserved on disk may be created by passing None as the filename. The optional flag identifies the mode used to open the file. It may be "r" (read only), "w" (read-write), "c" (read-write - create if necessary; the default) or "n" (read-write - truncate to zero length). The other arguments are rarely used and are just passed to the low-level dbopen() function. Consult the Berkeley DB documentation for their use and interpretation.

btopen(filename[, flag[, mode[, btflags[, cachesize[, maxkeypage[, minkeypage[, pgsize[, lorder]]]]]]])]

Open the btree format file named filename. Files never intended to be preserved on disk may be created by passing None as the filename. The optional flag identifies the mode used to open the file. It may be "r" (read only), "w" (read-write), "c" (read-write - create if necessary; the default) or "n" (read-write - truncate to zero length). The other arguments are rarely used and are just passed to the low-level dbopen function. Consult the Berkeley DB documentation for their use and interpretation.

rnopen(filename[, flag[, mode[, rnflags[, cachesize[, pgsize[, lorder[, reclen[, bval[, bfname]]]]]]]])]

Open a DB record format file named filename. Files never intended to be preserved on disk may be created by passing None as the filename. The optional flag identifies the mode used to open the file. It may be "r" (read only), "w" (read-write), "c" (read-write - create if necessary; the default) or "n" (read-write - truncate to zero length). The other arguments are rarely used and are just passed to the low-level dbopen function. Consult the Berkeley DB documentation for their use and interpretation.

Note: Beginning in 2.3 some Unix versions of Python may have a bsddb185 module. This is present only to allow backwards compatibility with systems which ship with the old Berkeley DB 1.85 database library. The bsddb185 module
should never be used directly in new code.

Module **dbhash**: DBM-style interface to the **bsddb**.

Subsections

- **7.13.1 Hash, BTree and Record Objects**

*Release 2.4.4c1, documentation updated on 11 October 2006.*

See [About this document...](#) for information on suggesting changes.
7.13.1 Hash, BTree and Record Objects

Once instantiated, hash, btree and record objects support the same methods as dictionaries. In addition, they support the methods listed below. Changed in version 2.3.1: Added dictionary methods.

**close()**
Close the underlying file. The object can no longer be accessed. Since there is no open open method for these objects, to open the file again a new bsddb module open function must be called.

**keys()**
Return the list of keys contained in the DB file. The order of the list is unspecified and should not be relied on. In particular, the order of the list returned is different for different file formats.

**has_key(key)**
Return 1 if the DB file contains the argument as a key.

**set_location(key)**
Set the cursor to the item indicated by key and return a tuple containing the key and its value. For binary tree databases (opened using btopen()), if key does not actually exist in the database, the cursor will point to the next item in sorted order and return that key and value. For other databases, KeyError will be raised if key is not found in the database.

**first()**
Set the cursor to the first item in the DB file and return it. The order of keys in the file is unspecified, except in the case of B-Tree databases. This method raises bsddb.error if the database is empty.

**next()**
Set the cursor to the next item in the DB file and return it. The order of keys in the file is unspecified, except in the case of B-Tree databases.

**previous()**
Set the cursor to the previous item in the DB file and return it. The order of keys in the file is unspecified, except in the case of B-Tree databases. This is not supported on hashtable databases (those opened with hashopen()).

last()
Set the cursor to the last item in the DB file and return it. The order of keys in the file is unspecified. This is not supported on hashtable databases (those opened with hashopen()). This method raises bsddb.error if the database is empty.

sync()
Synchronize the database on disk.

Example:

```python
>>> import bsddb
>>> db = bsddb.btopen('/tmp/spam.db', 'c')
>>> for i in range(10): db['%d'%i] = '%d' % (i*i)
...
>>> db['3']
'9'
>>> db.keys()
['0', '1', '2', '3', '4', '5', '6', '7', '8', '9']
>>> db.first()
('0', '0')
>>> db.next()
('1', '1')
>>> db.last()
('9', '81')
>>> db.set_location('2')
('2', '4')
>>> db.previous()
('1', '1')
>>> for k, v in db.iteritems():
...     print k, v
0 0
1 1
2 4
3 9
4 16
5 25
6 36
7 49
8 64
9 81
>>> '8' in db
True
```
>>> db.sync()
0

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.14 dumbdbm -- Portable DBM implementation

Note: The dumbdbm module is intended as a last resort fallback for the anydbm module when no more robust module is available. The dumbdbm module is not written for speed and is not nearly as heavily used as the other database modules.

The dumbdbm module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as gdbm and bsddb, no external library is required. As with other persistent mappings, the keys and values must always be strings.

The module defines the following:

exception error

Raised on dumbdbm-specific errors, such as I/O errors. KeyError is raised for general mapping errors like specifying an incorrect key.

open( filename[, flag[, mode]])

Open a dumbdbm database and return a dumbdbm object. The filename argument is the basename of the database file (without any specific extensions). When a dumbdbm database is created, files with .dat and .dir extensions are created.

The optional flag argument is currently ignored; the database is always opened for update, and will be created if it does not exist.

The optional mode argument is the UNIX mode of the file, used only when the database has to be created. It defaults to octal 0666 (and will be modified by the prevailing umask). Changed in version 2.2: The mode argument was ignored in earlier versions.

Module **dbm**: Similar interface to the DBM/NDBM library.

Module **gdbm**: Similar interface to the GNU GDBM library.

Module **shelve**: Persistence module which stores non-string data.

Module **whichdb**: Utility module used to determine the type of an existing database.

Subsections

- 7.14.1 Dumbdbm Objects
7.14.1 Dumbdbm Objects

In addition to the methods provided by the `UserDict.DictMixin` class, `dumbdbm` objects provide the following methods.

**sync()**

Synchronize the on-disk directory and data files. This method is called by the `sync` method of `Shelve` objects.
7.15 zlib -- Compression compatible with gzip

For applications that require data compression, the functions in this module allow compression and decompression, using the zlib library. The zlib library has its own home page at http://www.gzip.org/zlib/. There are known incompatibilities between the Python module and versions of the zlib library earlier than 1.1.3; 1.1.3 has a security vulnerability, so we recommend using 1.1.4 or later.

The available exception and functions in this module are:

**exception error**
Exception raised on compression and decompression errors.

**adler32** (string[, value])
Computes a Adler-32 checksum of string. (An Adler-32 checksum is almost as reliable as a CRC32 but can be computed much more quickly.) If value is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several input strings. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

**compress** (string[, level])
Compresses the data in string, returning a string contained compressed data. level is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. The default value is 6. Raises the error exception if any error occurs.

**compressobj** ([level])
Returns a compression object, to be used for compressing data streams that won't fit into memory at once. level is an integer from 1 to 9 controlling the
level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. The default value is 6.

crc32(string[, value])

Computes a CRC (Cyclic Redundancy Check) checksum of string. If value is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several input strings. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

decompress(string[, wbits[, bufsize]])

Decompresses the data in string, returning a string containing the uncompressed data. The wbits parameter controls the size of the window buffer. If bufsize is given, it is used as the initial size of the output buffer. Raises the error exception if any error occurs.

The absolute value of wbits is the base two logarithm of the size of the history buffer (the ``window size") used when compressing data. Its absolute value should be between 8 and 15 for the most recent versions of the zlib library, larger values resulting in better compression at the expense of greater memory usage. The default value is 15. When wbits is negative, the standard gzip header is suppressed; this is an undocumented feature of the zlib library, used for compatibility with unzip's compression file format.

bufsize is the initial size of the buffer used to hold decompressed data. If more space is required, the buffer size will be increased as needed, so you don't have to get this value exactly right; tuning it will only save a few calls to malloc(). The default size is 16384.

decompressobj([wbits])

Returns a decompression object, to be used for decompressing data streams that won't fit into memory at once. The wbits parameter controls the size of the window buffer.

Compression objects support the following methods:
compress( string)
Compress string, returning a string containing compressed data for at least part of the data in string. This data should be concatenated to the output produced by any preceding calls to the compress() method. Some input may be kept in internal buffers for later processing.

flush( [mode])
All pending input is processed, and a string containing the remaining compressed output is returned. mode can be selected from the constants Z_SYNC_FLUSH, Z_FULL_FLUSH, or Z_FINISH, defaulting to Z_FINISH. Z_SYNC_FLUSH and Z_FULL_FLUSH allow compressing further strings of data and are used to allow partial error recovery on decompression, while Z_FINISH finishes the compressed stream and prevents compressing any more data. After calling flush() with mode set to Z_FINISH, the compress() method cannot be called again; the only realistic action is to delete the object.

Decompression objects support the following methods, and two attributes:

unused_data
A string which contains any bytes past the end of the compressed data. That is, this remains "" until the last byte that contains compression data is available. If the whole string turned out to contain compressed data, this is "", the empty string.

The only way to determine where a string of compressed data ends is by actually decompressing it. This means that when compressed data is contained part of a larger file, you can only find the end of it by reading data and feeding it followed by some non-empty string into a decompression object's decompress method until the unused_data attribute is no longer the empty string.

unconsumed_tail
A string that contains any data that was not consumed by the last decompress call because it exceeded the limit for the uncompressed data buffer. This data has not yet been seen by the zlib machinery, so you must feed it (possibly with further data concatenated to it) back to a subsequent decompress method call in order to get correct output.
decompress( string[, max_length])

Decompress string, returning a string containing the uncompressed data corresponding to at least part of the data in string. This data should be concatenated to the output produced by any preceding calls to the decompress() method. Some of the input data may be preserved in internal buffers for later processing.

If the optional parameter max_length is supplied then the return value will be no longer than max_length. This may mean that not all of the compressed input can be processed; and unconsumed data will be stored in the attribute unconsumed_tail. This string must be passed to a subsequent call to decompress() if decompression is to continue. If max_length is not supplied then the whole input is decompressed, and unconsumed_tail is an empty string.

flush([length])

All pending input is processed, and a string containing the remaining uncompressed output is returned. After calling flush(), the decompress() method cannot be called again; the only realistic action is to delete the object.

The optional parameter length sets the initial size of the output buffer.

See About this document... for information on suggesting changes.
7.16 gzip -- Support for gzip files

The data compression provided by the zlib module is compatible with that used by the GNU compression program gzip. Accordingly, the gzip module provides the GzipFile class to read and write gzip-format files, automatically compressing or decompressing the data so it looks like an ordinary file object. Note that additional file formats which can be decompressed by the gzip and gunzip programs, such as those produced by compress and pack, are not supported by this module.

The module defines the following items:

```
class GzipFile([filename[, mode[, compresslevel[, fileobj]]]])
```

Constructor for the GzipFile class, which simulates most of the methods of a file object, with the exception of the readinto() and truncate() methods. At least one of fileobj and filename must be given a non-trivial value.

The new class instance is based on fileobj, which can be a regular file, a StringIO object, or any other object which simulates a file. It defaults to None, in which case filename is opened to provide a file object.

When fileobj is not None, the filename argument is only used to be included in the gzip file header, which may includes the original filename of the uncompressed file. It defaults to the filename of fileobj, if discernible; otherwise, it defaults to the empty string, and in this case the original filename is not included in the header.

The mode argument can be any of 'r', 'rb', 'a', 'ab', 'w', or 'wb', depending on whether the file will be read or written. The default is the mode of fileobj if discernible; otherwise, the default is 'rb'. If not given, the 'b' flag will be added to the mode to ensure the file is opened in binary mode for cross-platform portability.

The compresslevel argument is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, and 9 is
slowest and produces the most compression. The default is 9.

Calling a `GzipFile` object's `close()` method does not close `fileobj`, since you might wish to append more material after the compressed data. This also allows you to pass a `StringIO` object opened for writing as `fileobj`, and retrieve the resulting memory buffer using the `StringIO` object's `getvalue()` method.

```python
open( filename[, mode[, compresslevel]])
```

This is a shorthand for `GzipFile(filename, mode, compresslevel)`. The `filename` argument is required; `mode` defaults to 'rb' and `compresslevel` defaults to 9.

The basic data compression module needed to support the `gzip` file format.
(De)compression of files
7.17 bz2 -- Compression compatible with bzip2

New in version 2.3.

This module provides a comprehensive interface for the bz2 compression library. It implements a complete file interface, one-shot (de)compression functions, and types for sequential (de)compression.

Here is a resume of the features offered by the bz2 module:

- **BZ2File** class implements a complete file interface, including `readline()`, `readlines()`, `writelines()`, `seek()`, etc;
- **BZ2File** class implements emulated `seek()` support;
- **BZ2File** class implements universal newline support;
- **BZ2File** class offers an optimized line iteration using the readahead algorithm borrowed from file objects;
- Sequential (de)compression supported by **BZ2Compressor** and **BZ2Decompressor** classes;
- One-shot (de)compression supported by **compress()** and **decompress()** functions;
- Thread safety uses individual locking mechanism;
- Complete inline documentation;

- [7.17.2 Sequential (de)compression](#)
- [7.17.3 One-shot (de)compression](#)
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.17.1 (De)compression of files

Handling of compressed files is offered by the BZ2File class.

```python
class BZ2File(filename[, mode[, buffering[, compresslevel]]])
```

Open a bz2 file. Mode can be either 'r' or 'w', for reading (default) or writing. When opened for writing, the file will be created if it doesn't exist, and truncated otherwise. If `buffering` is given, 0 means unbuffered, and larger numbers specify the buffer size; the default is 0. If `compresslevel` is given, it must be a number between 1 and 9; the default is 9. Add a "U" to mode to open the file for input with universal newline support. Any line ending in the input file will be seen as a "\n" in Python. Also, a file so opened gains the attribute `newlines`; the value for this attribute is one of `None` (no newline read yet), '\r', '\n', '\r\n' or a tuple containing all the newline types seen. Universal newlines are available only when reading. Instances support iteration in the same way as normal file instances.

```python
    close()
```

Close the file. Sets data attribute `closed` to true. A closed file cannot be used for further I/O operations. `close()` may be called more than once without error.

```python
    read([size])
```

Read at most `size` uncompressed bytes, returned as a string. If the `size` argument is negative or omitted, read until EOF is reached.

```python
    readline([size])
```

Return the next line from the file, as a string, retaining newline. A non-negative `size` argument limits the maximum number of bytes to return (an incomplete line may be returned then). Return an empty string at EOF.

```python
    readlines([size])
```

Return a list of lines read. The optional `size` argument, if given, is an approximate bound on the total number of bytes in the lines returned.
**xreadlines()**

For backward compatibility. BZ2File objects now include the performance optimizations previously implemented in the xreadlines module.

**Deprecated since release 2.3.** This exists only for compatibility with the method by this name on file objects, which is deprecated. Use `for line in file` instead.

**seek**( `offset[, whence]` )

Move to new file position. Argument `offset` is a byte count. Optional argument `whence` defaults to 0 (offset from start of file, offset should be >= 0); other values are 1 (move relative to current position, positive or negative), and 2 (move relative to end of file, usually negative, although many platforms allow seeking beyond the end of a file).

Note that seeking of bz2 files is emulated, and depending on the parameters the operation may be extremely slow.

**tell()**

Return the current file position, an integer (may be a long integer).

**write**( `data` )

Write string `data` to file. Note that due to buffering, `close()` may be needed before the file on disk reflects the data written.

**writelines**( `sequence_of_strings` )

Write the sequence of strings to the file. Note that newlines are not added. The sequence can be any iterable object producing strings. This is equivalent to calling `write()` for each string.
7.17.2 Sequential (de)compression

Sequential compression and decompression is done using the classes BZ2Compressor and BZ2Decompressor.

class BZ2Compressor([compresslevel])

Create a new compressor object. This object may be used to compress data sequentially. If you want to compress data in one shot, use the compress() function instead. The compresslevel parameter, if given, must be a number between 1 and 9; the default is 9.

compress(data)

Provide more data to the compressor object. It will return chunks of compressed data whenever possible. When you've finished providing data to compress, call the flush() method to finish the compression process, and return what is left in internal buffers.

flush()

Finish the compression process and return what is left in internal buffers. You must not use the compressor object after calling this method.

class BZ2Decompressor()

Create a new decompressor object. This object may be used to decompress data sequentially. If you want to decompress data in one shot, use the decompress() function instead.

decompress(data)

Provide more data to the decompressor object. It will return chunks of decompressed data whenever possible. If you try to decompress data after the end of stream is found, EOFError will be raised. If any data was found after the end of stream, it'll be ignored and saved in unused_data attribute.
(de)compression

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.17.3 One-shot (de)compression

One-shot compression and decompression is provided through the `compress()` and `decompress()` functions.

`compress(data[, compresslevel])`
Compress `data` in one shot. If you want to compress data sequentially, use an instance of `BZ2Compressor` instead. The `compresslevel` parameter, if given, must be a number between 1 and 9; the default is 9.

`decompress(data)`
Decompress `data` in one shot. If you want to decompress data sequentially, use an instance of `BZ2Decompressor` instead.
7.18 zipfile -- Work with ZIP archives

New in version 1.6.

The ZIP file format is a common archive and compression standard. This module provides tools to create, read, write, append, and list a ZIP file. Any advanced use of this module will require an understanding of the format, as defined in *PKZIP Application Note*.

This module does not currently handle ZIP files which have appended comments, or multi-disk ZIP files.

The available attributes of this module are:

**exception error**

The error raised for bad ZIP files.

**class ZipFile**

The class for reading and writing ZIP files. See ``ZipFile Objects`` (section 7.18.1) for constructor details.

**class PyZipFile**

Class for creating ZIP archives containing Python libraries.

**class ZipInfo([filename[, date_time]])**

Class used to represent information about a member of an archive. Instances of this class are returned by the getinfo() and infolist() methods of ZipFile objects. Most users of the zipfile module will not need to create these, but only use those created by this module. filename should be the full name of the archive member, and date_time should be a tuple containing six fields which describe the time of the last modification to the file; the fields are described in section 7.18.3, ``ZipInfo Objects``.

**is_zipfile(filename)**

Returns True if filename is a valid ZIP file based on its magic number,
otherwise returns `False`. This module does not currently handle ZIP files which have appended comments.

**ZIP_STORED**

The numeric constant for an uncompressed archive member.

**ZIP_DEFLATED**

The numeric constant for the usual ZIP compression method. This requires the `zlib` module. No other compression methods are currently supported.

**Python Library Reference**

Previous: [7.17.3 One-shot (de)compression](#)  Up: [7. Optional Operating System](#)  Next: [7.18.1 ZipFile Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006. See *About this document...* for information on suggesting changes.
7.18.1 ZipFile Objects

class ZipFile( file[, mode[, compression]])

Open a ZIP file, where file can be either a path to a file (a string) or a file-like object. The mode parameter should be 'r' to read an existing file, 'w' to truncate and write a new file, or 'a' to append to an existing file. For mode is 'a' and file refers to an existing ZIP file, then additional files are added to it. If file does not refer to a ZIP file, then a new ZIP archive is appended to the file. This is meant for adding a ZIP archive to another file, such as python.exe. Using

    cat myzip.zip >> python.exe

also works, and at least WinZip can read such files. compression is the ZIP compression method to use when writing the archive, and should be ZIP_STORED or ZIP_DEFLATED; unrecognized values will cause RuntimeError to be raised. If ZIP_DEFLATED is specified but the zlib module is not available, RuntimeError is also raised. The default is ZIP_STORED.

close()

Close the archive file. You must call close() before exiting your program or essential records will not be written.

getinfo( name)

Return a ZipInfo object with information about the archive member name.

infolist()

Return a list containing a ZipInfo object for each member of the archive. The objects are in the same order as their entries in the actual ZIP file on disk if an existing archive was opened.

namedlist()

Return a list of archive members by name.
printdir()

Print a table of contents for the archive to sys.stdout.

read( name)

Return the bytes of the file in the archive. The archive must be open for read or append.

testzip()

Read all the files in the archive and check their CRC’s. Return the name of the first bad file, or else return None.

write( filename[, arcname[, compress_type]])

Write the file named filename to the archive, giving it the archive name arcname (by default, this will be the same as filename). If given, compress_type overrides the value given for the compression parameter to the constructor for the new entry. The archive must be open with mode 'w' or 'a'.

Note: There is no official file name encoding for ZIP files. If you have unicode file names, please convert them to byte strings in your desired encoding before passing them to write(). WinZip interprets all file names as encoded in CP437, also known as DOS Latin.

Note: Archive names should be relative to the archive root, that is, they should not start with a path separator.

writestr( zinfo_or_arcname, bytes)

Write the string bytes to the archive; zinfo_or_arcname is either the file name it will be given in the archive, or a ZipInfo instance. If it's an instance, at least the filename, date, and time must be given. If it's a name, the date and time is set to the current date and time. The archive must be opened with mode 'w' or 'a'.

The following data attribute is also available:

ddebug

The level of debug output to use. This may be set from 0 (the default, no output) to 3 (the most output). Debugging information is written to
sys.stdout.
7.18.2 PyZipFile Objects

The PyZipFile constructor takes the same parameters as the ZipFile constructor. Instances have one method in addition to those of ZipFile objects.

\texttt{writepy(pathname[, basename])}

Search for files *.py and add the corresponding file to the archive. The corresponding file is a *.pyo file if available, else a *.pyc file, compiling if necessary. If the pathname is a file, the filename must end with .py, and just the (corresponding *.py[co]) file is added at the top level (no path information). If it is a directory, and the directory is not a package directory, then all the files *.py[co] are added at the top level. If the directory is a package directory, then all *.py[oc] are added under the package name as a file path, and if any subdirectories are package directories, all of these are added recursively. \texttt{basename} is intended for internal use only. The \texttt{writepy()} method makes archives with file names like this:

```
string.pyc                   # Top level name
 test/__init__.pyc           # Package directory
 test/testall.pyc            # Module test.test
 test/bogus/__init__.pyc     # Subpackage directory
 test/bogus/myfile.pyc       # Submodule test.
```
7.18.3 ZipInfo Objects

Instances of the ZipInfo class are returned by the getinfo() and infolist() methods of ZipFile objects. Each object stores information about a single member of the ZIP archive.

Instances have the following attributes:

**filename**
   Name of the file in the archive.

**date_time**
   The time and date of the last modification to the archive member. This is a tuple of six values:

<table>
<thead>
<tr>
<th>Index</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Year</td>
</tr>
<tr>
<td>1</td>
<td>Month (one-based)</td>
</tr>
<tr>
<td>2</td>
<td>Day of month (one-based)</td>
</tr>
<tr>
<td>3</td>
<td>Hours (zero-based)</td>
</tr>
<tr>
<td>4</td>
<td>Minutes (zero-based)</td>
</tr>
<tr>
<td>5</td>
<td>Seconds (zero-based)</td>
</tr>
</tbody>
</table>

**compress_type**
   Type of compression for the archive member.

**comment**
   Comment for the individual archive member.

**extra**
   Expansion field data. The PKZIP Application Note contains some comments on the internal structure of the data contained in this string.

**create_system**
   System which created ZIP archive.

**create_version**
PKZIP version which created ZIP archive.

**extract_version**
PKZIP version needed to extract archive.

**reserved**
Must be zero.

**flag_bits**
ZIP flag bits.

**volume**
Volume number of file header.

**internal_attr**
Internal attributes.

**external_attr**
External file attributes.

**header_offset**
Byte offset to the file header.

**file_offset**
Byte offset to the start of the file data.

**CRC**
CRC-32 of the uncompressed file.

**compress_size**
Size of the compressed data.

**file_size**
Size of the uncompressed file.
See About this document... for information on suggesting changes.
7.19 tarfile -- Read and write tar archive files

New in version 2.3.

The tarfile module makes it possible to read and create tar archives. Some facts and figures:

- reads and writes gzip and bzip2 compressed archives.
- creates POSIX 1003.1-1990 compliant or GNU tar compatible archives.
- reads GNU tar extensions longname, longlink and sparse.
- stores pathnames of unlimited length using GNU tar extensions.
- handles directories, regular files, hardlinks, symbolic links, fifos, character devices and block devices and is able to acquire and restore file information like timestamp, access permissions and owner.
- can handle tape devices.

```
open([name[, mode[, fileobj[, bufsize]]]])
```

Return a TarFile object for the pathname name. For detailed information on TarFile objects, see TarFile Objects (section 7.19.1).

*mode* has to be a string of the form 'filemode[:compression]', it defaults to 'r'. Here is a full list of mode combinations:

<table>
<thead>
<tr>
<th>mode</th>
<th>action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open for reading with transparent compression (recommended).</td>
</tr>
<tr>
<td>'r:'</td>
<td>Open for reading exclusively without compression.</td>
</tr>
<tr>
<td>'r:gz'</td>
<td>Open for reading with gzip compression.</td>
</tr>
<tr>
<td>'r:bz2'</td>
<td>Open for reading with bzip2 compression.</td>
</tr>
<tr>
<td>'a' or 'a:'</td>
<td>Open for appending with no compression.</td>
</tr>
<tr>
<td>'w' or 'w:'</td>
<td>Open for uncompressed writing.</td>
</tr>
</tbody>
</table>
'w:gz' Open for gzip compressed writing.

'w:bz2' Open for bzip2 compressed writing.

Note that 'a:gz' or 'a:bz2' is not possible. If mode is not suitable to open a certain (compressed) file for reading, ReadError is raised. Use mode 'r' to avoid this. If a compression method is not supported, CompressionError is raised.

If fileobj is specified, it is used as an alternative to a file object opened for name.

For special purposes, there is a second format for mode: 'filemode|compression'. open() will return a TarFile object that processes its data as a stream of blocks. No random seeking will be done on the file. If given, fileobj may be any object that has a read() or write() method (depending on the mode). bufsize specifies the blocksize and defaults to 20 * 512 bytes. Use this variant in combination with e.g. sys.stdin, a socket file object or a tape device. However, such a TarFile object is limited in that it does not allow to be accessed randomly, see ``Examples'' (section 7.19.3). The currently possible modes:

<table>
<thead>
<tr>
<th>Mode</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open a stream of uncompressed tar blocks for reading.</td>
</tr>
<tr>
<td>'r</td>
<td>gz'</td>
</tr>
<tr>
<td>'r</td>
<td>bz2'</td>
</tr>
<tr>
<td>'w'</td>
<td>Open an uncompressed stream for writing.</td>
</tr>
<tr>
<td>'w</td>
<td>gz'</td>
</tr>
<tr>
<td>'w</td>
<td>bz2'</td>
</tr>
</tbody>
</table>

**class TarFile**

Class for reading and writing tar archives. Do not use this class directly, better use open() instead. See ``TarFile Objects'' (section 7.19.1).

**is_tarfile(name)**

Return True if name is a tar archive file, that the tarfile module can read.
class TarFileCompat(filename[, mode[, compression]])
    Class for limited access to tar archives with a zipfile-like interface.
    Please consult the documentation of the zipfile module for more details.
    compression must be one of the following constants:
    TAR_PLAIN
        Constant for an uncompressed tar archive.
    TAR_GZIPPED
        Constant for a gzip compressed tar archive.

exception TarError
    Base class for all tarfile exceptions.

exception ReadError
    Is raised when a tar archive is opened, that either cannot be handled by the
    tarfile module or is somehow invalid.

exception CompressionError
    Is raised when a compression method is not supported or when the data
    cannot be decoded properly.

exception StreamError
    Is raised for the limitations that are typical for stream-like TarFile
    objects.

exception ExtractError
    Is raised for non-fatal errors when using extract(), but only if
    TarFile.errorlevel == 2.

See Also:

Module zipfile:
    Documentation of the zipfile standard module.

GNU tar manual, Basic Tar Format
    Documentation for tar archive files, including GNU tar extensions.
7.19.1 TarFile Objects

The `TarFile` object provides an interface to a tar archive. A tar archive is a sequence of blocks. An archive member (a stored file) is made up of a header block followed by data blocks. It is possible, to store a file in a tar archive several times. Each archive member is represented by a `TarInfo` object, see `TarInfo Objects` (section 7.19.2) for details.

```python
class TarFile([name[, mode[, fileobj]]])
    Open an (uncompressed) tar archive `name`. `mode` is either 'r' to read from an existing archive, 'a' to append data to an existing file or 'w' to create a new file overwriting an existing one. `mode` defaults to 'r'.

    If `fileobj` is given, it is used for reading or writing data. If it can be determined, `mode` is overridden by `fileobj`'s mode.

    Note: `fileobj` is not closed, when `TarFile` is closed.
```

```python
open(...)
    Alternative constructor. The `open()` function on module level is actually a shortcut to this classmethod. See section 7.19 for details.
```

```python
getmember(name)
    Return a `TarInfo` object for member `name`. If `name` can not be found in the archive, `KeyError` is raised.

    Note: If a member occurs more than once in the archive, its last occurrence is assumed to be the most up-to-date version.
```

```python
getmembers()
    Return the members of the archive as a list of `TarInfo` objects. The list has the same order as the members in the archive.
```
getnames()
Return the members as a list of their names. It has the same order as the list returned by getmembers().

list( verbose=True)
Print a table of contents to sys.stdout. If verbose is False, only the names of the members are printed. If it is True, output similar to that of ls -l is produced.

next()
Return the next member of the archive as a TarInfo object, when TarFile is opened for reading. Return None if there is no more available.

extract( member[, path])
Extract a member from the archive to the current working directory, using its full name. Its file information is extracted as accurately as possible. member may be a filename or a TarInfo object. You can specify a different directory using path.

extractfile( member)
Extract a member from the archive as a file object. member may be a filename or a TarInfo object. If member is a regular file, a file-like object is returned. If member is a link, a file-like object is constructed from the link's target. If member is none of the above, None is returned.

Note: The file-like object is read-only and provides the following methods: read(), readline(), readlines(), seek(), tell().

add( name[, arcname[, recursive]])
Add the file name to the archive. name may be any type of file (directory, fifo, symbolic link, etc.). If given, arcname specifies an alternative name for the file in the archive. Directories are added recursively by default. This can be avoided by setting recursive to False; the default is True.

addfile( tarinfo[, fileobj])
Add the TarInfo object `tarinfo` to the archive. If `fileobj` is given, `tarinfo.size` bytes are read from it and added to the archive. You can create TarInfo objects using `gettarinfo()`.

**Note:** On Windows platforms, `fileobj` should always be opened with mode `'rb'` to avoid irritation about the file size.

`gettarinfo([name[, arcname[, fileobj]]])`
Create a TarInfo object for either the file name or the file object `fileobj` (using `os.fstat()` on its file descriptor). You can modify some of the TarInfo's attributes before you add it using `addfile()`. If given, `arcname` specifies an alternative name for the file in the archive.

`close()`
Close the TarFile. In write mode, two finishing zero blocks are appended to the archive.

`posix`
If true, create a POSIX 1003.1-1990 compliant archive. GNU extensions are not used, because they are not part of the POSIX standard. This limits the length of filenames to at most 256, link names to 100 characters and the maximum file size to 8 gigabytes. A `ValueError` is raised if a file exceeds this limit. If false, create a GNU tar compatible archive. It will not be POSIX compliant, but can store files without any of the above restrictions. Changed in version 2.4: `posix` defaults to `False`.

`dereference`
If false, add symbolic and hard links to archive. If true, add the content of the target files to the archive. This has no effect on systems that do not support symbolic links.

`ignore_zeros`
If false, treat an empty block as the end of the archive. If true, skip empty (and invalid) blocks and try to get as many members as possible. This is only useful for concatenated or damaged archives.
**debug=0**

To be set from 0 (no debug messages; the default) up to 3 (all debug messages). The messages are written to `sys.stderr`.

**errorlevel**

If 0 (the default), all errors are ignored when using `extract()`. Nevertheless, they appear as error messages in the debug output, when debugging is enabled. If 1, all *fatal* errors are raised as `OSError` or `IOError` exceptions. If 2, all *non-fatal* errors are raised as `TarError exceptions as well.*
7.19.2 TarInfo Objects

A TarInfo object represents one member in a TarFile. Aside from storing all required attributes of a file (like file type, size, time, permissions, owner etc.), it provides some useful methods to determine its type. It does not contain the file's data itself.

TarInfo objects are returned by TarFile's methods getmember(), getmembers() and gettarinfo().

class TarInfo([name])
    Create a TarInfo object.

frombuf()
    Create and return a TarInfo object from a string buffer.

tobuf()
    Create a string buffer from a TarInfo object.

A TarInfo object has the following public data attributes:

name
    Name of the archive member.

size
    Size in bytes.

mtime
    Time of last modification.

mode
    Permission bits.

type
    File type. type is usually one of these constants: REGTYPE, AREGTYPE, LNKTYPE, SYMTYPE, DIRTYPE, FIFOTYPE, CONTTYPE, CHRTYPE, BLKTYPE, GNUTYPE_SPARSE. To determine the type of a TarInfo
object more conveniently, use the `is_*()` methods below.

**linkname**
Name of the target file name, which is only present in `TarInfo` objects of type LNKTYPE and SYMTYPE.

**uid**
User ID of the user who originally stored this member.

**gid**
Group ID of the user who originally stored this member.

**uname**
User name.

**gname**
Group name.

A `TarInfo` object also provides some convenient query methods:

**isfile()**
Return `True` if the `TarInfo` object is a regular file.

**isreg()**
Same as `isfile()`.

**isdir()**
Return `True` if it is a directory.

**issym()**
Return `True` if it is a symbolic link.

**islnk()**
Return `True` if it is a hard link.

**ischr()**
Return `True` if it is a character device.
**isblk()**

Return True if it is a block device.

**isfifo()**

Return True if it is a FIFO.

**isdev()**

Return True if it is one of character device, block device or FIFO.
**7.19.3 Examples**

How to create an uncompressed tar archive from a list of filenames:

```python
import tarfile
tar = tarfile.open("sample.tar", "w")
for name in ["foo", "bar", "quux"]:
    tar.add(name)
tar.close()
```

How to read a gzip compressed tar archive and display some member information:

```python
import tarfile
tar = tarfile.open("sample.tar.gz", "r:gz")
for tarinfo in tar:
    print tarinfo.name, "is", tarinfo.size, "bytes in size and is",
    if tarinfo.isreg():
        print "a regular file."
    elif tarinfo.isdir():
        print "a directory."
    else:
        print "something else."
tar.close()
```

How to create a tar archive with faked information:

```python
import tarfile
tar = tarfile.open("sample.tar.gz", "w:gz")
for name in namelist:
    tarinfo = tar.gettarinfo(name, "fakeproj-1.0/" + name)
    tarinfo.uid = 123
    tarinfo.gid = 456
    tarinfo.uname = "johndoe"
    tarinfo.gname = "fake"
    tar.addfile(tarinfo, file(name))
tar.close()
```

The only way to extract an uncompressed tar stream from `sys.stdin`:

```python
import sys
import tarfile
tar = tarfile.open(mode="r|", fileobj=sys.stdin)
for tarinfo in tar:
    tar.extract(tarinfo)
tar.close()
```
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.20 readline -- GNU readline interface

Availability: Unix.

The readline module defines a number of functions used either directly or from the rlcompleter module to facilitate completion and history file read and write from the Python interpreter.

The readline module defines the following functions:

**parse_and_bind**( string)
Parse and execute single line of a readline init file.

**get_line_buffer**( )
Return the current contents of the line buffer.

**insert_text**( string)
Insert text into the command line.

**read_init_file**( [filename])
Parse a readline initialization file. The default filename is the last filename used.

**read_history_file**( [filename])
Load a readline history file. The default filename is ~/.history.

**write_history_file**( [filename])
Save a readline history file. The default filename is ~/.history.

**clear_history**( )
Clear the current history. (Note: this function is not available if the installed version of GNU readline doesn't support it.) New in version 2.4.
get_history_length()
Return the desired length of the history file. Negative values imply unlimited history file size.

set_history_length( length)
Set the number of lines to save in the history file.
write_history_file() uses this value to truncate the history file when saving. Negative values imply unlimited history file size.

get_current_history_length()
Return the number of lines currently in the history. (This is different from get_history_length(), which returns the maximum number of lines that will be written to a history file.) New in version 2.3.

get_history_item( index)
Return the current contents of history item at index. New in version 2.3.

remove_history_item( pos)
Remove history item specified by its position from the history. New in version 2.4.

replace_history_item( pos, line)
Replace history item specified by its position with the given line. New in version 2.4.

redisplay()
Change what's displayed on the screen to reflect the current contents of the line buffer. New in version 2.3.

set_startup_hook([function])
Set or remove the startup_hook function. If function is specified, it will be used as the new startup_hook function; if omitted or None, any hook function already installed is removed. The startup_hook function is called with no arguments just before readline prints the first prompt.

set_pre_input_hook([function])
Set or remove the pre_input_hook function. If function is specified, it will
be used as the new pre_input_hook function; if omitted or None, any hook function already installed is removed. The pre_input_hook function is called with no arguments after the first prompt has been printed and just before readline starts reading input characters.

**set_completer**([*function*])
Set or remove the completer function. If *function* is specified, it will be used as the new completer function; if omitted or None, any completer function already installed is removed. The completer function is called as *function*(text, state), for state in 0, 1, 2, ..., until it returns a non-string value. It should return the next possible completion starting with text.

**get_completer**()
Get the completer function, or None if no completer function has been set. New in version 2.3.

**get_begidx**()
Get the beginning index of the readline tab-completion scope.

**get_endidx**()
Get the ending index of the readline tab-completion scope.

**set_completer_delims**(*string*)
Set the readline word delimiters for tab-completion.

**get_completer_delims**()
Get the readline word delimiters for tab-completion.

**add_history**(*line*)
Append a line to the history buffer, as if it was the last line typed.

### See Also:

Module [rlcompleter](#):
Completion of Python identifiers at the interactive prompt.
7.20.1 Example

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.20.1 Example

The following example demonstrates how to use the `readline` module's history reading and writing functions to automatically load and save a history file named `.pyhist` from the user's home directory. The code below would normally be executed automatically during interactive sessions from the user's PYTHONSTARTUP file.

```python
import os
histfile = os.path.join(os.environ["HOME"], ".pyhist")
try:
    readline.read_history_file(histfile)
except IOError:
    pass
import atexit
atexit.register(readline.write_history_file, histfile)
del os, histfile
```

The following example extends the `code.InteractiveConsole` class to support history save/restore.

```python
import code
import readline
import atexit
import os

class HistoryConsole(code.InteractiveConsole):
    def __init__(self, locals=None, filename="<console>",
                 histfile=os.path.expanduser("~/console-history"),):
        code.InteractiveConsole.__init__(self)
        self.init_history(histfile)

    def init_history(self, histfile):
        readline.parse_and_bind("tab: complete")
        if hasattr(readline, "read_history_file"):
            try:
                readline.read_history_file(histfile)
            except IOError:
                pass
        atexit.register(self.save_history, histfile)

    def save_history(self, histfile):
        readline.write_history_file(histfile)
```

---

**Python Library Reference**
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.21 rlcompleter -- Completion function for GNU readline

Availability: Unix.

The rlcompleter module defines a completion function for the readline module by completing valid Python identifiers and keywords.

This module is Unix-specific due to its dependence on the readline module.

The rlcompleter module defines the Completer class.

Example:

```python
>>> import rlcompleter
global import readline
>>> readline.parse_and_bind("tab: complete")
```

The rlcompleter module is designed for use with Python's interactive mode. A user can add the following lines to his or her initialization file (identified by the PYTHONSTARTUP environment variable) to get automatic Tab completion:

```python
try:
    import readline
except ImportError:
    print "Module readline not available."
else:
    import rlcompleter
    readline.parse_and_bind("tab: complete")
```

Subsections

- [7.21.1 Completer Objects](#)
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
7.21.1 Completer Objects

Completer objects have the following method:

\texttt{complete}(\textit{text, state})

Return the \textit{state}th completion for \textit{text}.

If called for \textit{text} that doesn't include a period character ("."), it will complete from names currently defined in \texttt{\_\_main\_}, \texttt{\_\_builtin\_} and keywords (as defined by the \texttt{keyword} module).

If called for a dotted name, it will try to evaluate anything without obvious side-effects (functions will not be evaluated, but it can generate calls to \texttt{\_\_getattr\_}()) up to the last part, and find matches for the rest via the \texttt{dir()} function.
8. Unix Specific Services

The modules described in this chapter provide interfaces to features that are unique to the Unix operating system, or in some cases to some or many variants of it. Here's an overview:

- **posix**: The most common POSIX system calls (normally used via module `os`).
- **pwd**: The password database (`getpwnam()` and friends).
- **grp**: The group database (`getgrnam()` and friends).
- **crypt**: The `crypt()` function used to check Unix passwords.
- **dl**: Call C functions in shared objects.
- **dbm**: The standard ```database''` interface, based on ndbm.
- **gdbm**: GNU's reinterpretation of dbm.
- **termios**: POSIX style tty control.
- **tty**: Utility functions that perform common terminal control operations.
- **pty**: Pseudo-Terminal Handling for SGI and Linux.
- **fcntl**: The `fcntl()` and `ioctl()` system calls.
- **pipes**: A Python interface to Unix shell pipelines.
- **posixfile**: A file-like object with support for locking.
- **resource**: An interface to provide resource usage information on the current process.
- **nis**: Interface to Sun's NIS (Yellow Pages) library.
- **syslog**: An interface to the Unix syslog library routines.
- **commands**: Utility functions for running external commands.
See *About this document...* for information on suggesting changes.
8.1 posix -- The most common POSIX system calls

Availability: Unix.

This module provides access to operating system functionality that is standardized by the C Standard and the POSIX standard (a thinly disguised UNIX interface).

**Do not import this module directly.** Instead, import the module os, which provides a portable version of this interface. On UNIX, the os module provides a superset of the posix interface. On non-UNIX operating systems the posix module is not available, but a subset is always available through the os interface. Once os is imported, there is no performance penalty in using it instead of posix. In addition, os provides some additional functionality, such as automatically calling `putenv()` when an entry in os.environ is changed.

The descriptions below are very terse; refer to the corresponding UNIX manual (or POSIX documentation) entry for more information. Arguments called path refer to a pathname given as a string.

Errors are reported as exceptions; the usual exceptions are given for type errors, while errors reported by the system calls raise error (a synonym for the standard exception OSError), described below.

---

Subsections

- [8.1.1 Large File Support](#)
- [8.1.2 Module Contents](#)

---

Python Library Reference

Previous: 8. Unix Specific Services  Up: 8. Unix Specific Services  Next: 8.1.1 Large File Support
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
8.1.1 Large File Support

Several operating systems (including AIX, HPUX, Irix and Solaris) provide support for files that are larger than 2 Gb from a C programming model where `int` and `long` are 32-bit values. This is typically accomplished by defining the relevant size and offset types as 64-bit values. Such files are sometimes referred to as large files.

Large file support is enabled in Python when the size of an `off_t` is larger than a `long` and the `long long` type is available and is at least as large as an `off_t`. Python longs are then used to represent file sizes, offsets and other values that can exceed the range of a Python int. It may be necessary to configure and compile Python with certain compiler flags to enable this mode. For example, it is enabled by default with recent versions of Irix, but with Solaris 2.6 and 2.7 you need to do something like:

```
CFLAGS="`getconf LFS_CFLAGS`" OPT="-g -O2 $CFLAGS" \
./configure
```

On large-file-capable Linux systems, this might work:

```
CFLAGS='`-D_LARGEFILE64_SOURCE -D_FILE_OFFSET_BITS=64`' OPT="-g -O2 $CFLAGS" \
./configure
```

---

Python Library Reference

Previous: 8.1 posix  Up: 8.1 posix  Next: 8.1.2 Module Contents
8.1.2 Module Contents

Module posix defines the following data item:

envir on

A dictionary representing the string environment at the time the interpreter was started. For example, environ ['HOME'] is the pathname of your home directory, equivalent to getenv("HOME") in C.

Modifying this dictionary does not affect the string environment passed on by execv(), popen() or system(); if you need to change the environment, pass environ to execve() or add variable assignments and export statements to the command string for system() or popen().

Note: The os module provides an alternate implementation of environ which updates the environment on modification. Note also that updating os.environ will render this dictionary obsolete. Use of the os module version of this is recommended over direct access to the posix module.

Additional contents of this module should only be accessed via the os module; refer to the documentation for that module for further information.
8.2 pwd -- The password database

Availability: Unix.

This module provides access to the Unix user account and password database. It is available on all Unix versions.

Password database entries are reported as a tuple-like object, whose attributes correspond to the members of the passwd structure (Attribute field below, see <pwd.h>):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>pw_name</td>
<td>Login name</td>
</tr>
<tr>
<td>1</td>
<td>pw_passwd</td>
<td>Optional encrypted password</td>
</tr>
<tr>
<td>2</td>
<td>pw_uid</td>
<td>Numerical user ID</td>
</tr>
<tr>
<td>3</td>
<td>pw_gid</td>
<td>Numerical group ID</td>
</tr>
<tr>
<td>4</td>
<td>pw_gecos</td>
<td>User name or comment field</td>
</tr>
<tr>
<td>5</td>
<td>pw_dir</td>
<td>User home directory</td>
</tr>
<tr>
<td>6</td>
<td>pw_shell</td>
<td>User command interpreter</td>
</tr>
</tbody>
</table>

The uid and gid items are integers, all others are strings. KeyError is raised if the entry asked for cannot be found.

Note: In traditional Unix the field pw_passwd usually contains a password encrypted with a DES derived algorithm (see module crypt). However most modern unices use a so-called shadow password system. On those unices the pw_passwd field only contains an asterisk ('*') or the letter "x" where the encrypted password is stored in a file /etc/shadow which is not world readable. Whether the pw_passwd field contains anything useful is system-dependent.

It defines the following items:

getpwuid(uid)

Return the password database entry for the given numeric user ID.
**getpwnam** (*name*)

Return the password database entry for the given user name.

**getpwall()**

Return a list of all available password database entries, in arbitrary order.

### See Also:

Module **grp**:  
An interface to the group database, similar to this.
8.3 grp -- The group database

Availability: Unix.

This module provides access to the UNIX group database. It is available on all UNIX versions.

Group database entries are reported as a tuple-like object, whose attributes correspond to the members of the group structure (Attribute field below, see </pwd.h>):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>gr_name</td>
<td>the name of the group</td>
</tr>
<tr>
<td>1</td>
<td>gr_passwd</td>
<td>the (encrypted) group password; often empty</td>
</tr>
<tr>
<td>2</td>
<td>gr_gid</td>
<td>the numerical group ID</td>
</tr>
<tr>
<td>3</td>
<td>gr_mem</td>
<td>all the group member's user names</td>
</tr>
</tbody>
</table>

The gid is an integer, name and password are strings, and the member list is a list of strings. (Note that most users are not explicitly listed as members of the group they are in according to the password database. Check both databases to get complete membership information.)

It defines the following items:

**getgrgid**(gid)
- Return the group database entry for the given numeric group ID. `KeyError` is raised if the entry asked for cannot be found.

**getgrnam**(name)
- Return the group database entry for the given group name. `KeyError` is raised if the entry asked for cannot be found.

**getgrall**()
- Return a list of all available group entries, in arbitrary order.
See Also:

Module `pwd`:

An interface to the user database, similar to this.
8.4 crypt -- Function to check \textsc{unix} passwords

Availability: \textsc{unix}.

This module implements an interface to the \texttt{crypt}(3) routine, which is a one-way hash function based upon a modified DES algorithm; see the \textsc{unix} man page for further details. Possible uses include allowing Python scripts to accept typed passwords from the user, or attempting to crack \textsc{unix} passwords with a dictionary.

Notice that the behavior of this module depends on the actual implementation of the \texttt{crypt}(3) routine in the running system. Therefore, any extensions available on the current implementation will also be available on this module.

\texttt{crypt( word, salt)}

\textit{word} will usually be a user's password as typed at a prompt or in a graphical interface. \textit{salt} is usually a random two-character string which will be used to perturb the DES algorithm in one of 4096 ways. The characters in \textit{salt} must be in the set [./a-zA-Z0-9]. Returns the hashed password as a string, which will be composed of characters from the same alphabet as the salt (the first two characters represent the salt itself).

Since a few \texttt{crypt}(3) extensions allow different values, with different sizes in the \textit{salt}, it is recommended to use the full crypted password as salt when checking for a password.

A simple example illustrating typical use:

\begin{verbatim}
import crypt, getpass, pwd

def login():
    username = raw_input('Python login:')
    cryptedpasswd = pwd.getpwnam(username)[1]
    if cryptedpasswd:
        if cryptedpasswd == 'x' or cryptedpasswd == '*':
            raise "Sorry, currently no support for shadow passwords"
        cleartext = getpass.getpass()
        return crypt.crypt(cleartext, cryptedpasswd) == cryptedpasswd
\end{verbatim}
else:
    return 1
8.5 d1 -- Call C functions in shared objects

Availability: Unix.

The d1 module defines an interface to the dlopen() function, which is the most common interface on UNIX platforms for handling dynamically linked libraries. It allows the program to call arbitrary functions in such a library.

**Warning:** The d1 module bypasses the Python type system and error handling. If used incorrectly it may cause segmentation faults, crashes or other incorrect behaviour.

**Note:** This module will not work unless sizeof(int) == sizeof(long) == sizeof(char *). If this is not the case, SystemError will be raised on import.

The d1 module defines the following function:

```python
open( name[, mode = RTLD_LAZY])
```

Open a shared object file, and return a handle. Mode signifies late binding (RTLD_LAZY) or immediate binding (RTLD_NOW). Default is RTLD_LAZY. Note that some systems do not support RTLD_NOW.

Return value is a dlobject.

The d1 module defines the following constants:

**RTLD_LAZY**

Useful as an argument to open().

**RTLD_NOW**

Useful as an argument to open(). Note that on systems which do not support immediate binding, this constant will not appear in the module. For maximum portability, use hasattr() to determine if the system supports immediate binding.
The `dl` module defines the following exception:

**exception error**

Exception raised when an error has occurred inside the dynamic loading and linking routines.

Example:

```python
>>> import dl, time
>>> a=dl.open('/lib/libc.so.6')
>>> a.call('time'), time.time()
(929723914, 929723914.498)
```

This example was tried on a Debian GNU/Linux system, and is a good example of the fact that using this module is usually a bad alternative.
8.5.1 DL Objects

DL objects, as returned by open( ) above, have the following methods:

**close( )**
Free all resources, except the memory.

**sym( name)**
Return the pointer for the function named *name*, as a number, if it exists in the referenced shared object, otherwise *None*. This is useful in code like:

```python
>>> if a.sym('time):
    ...    a.call('time')
>>> else:
    ...    time.time()
```

(Note that this function will return a non-zero number, as zero is the NULL pointer)

**call( name[, arg1[, arg2...]] )**
Call the function named *name* in the referenced shared object. The arguments must be either Python integers, which will be passed as is, Python strings, to which a pointer will be passed, or *None*, which will be passed as NULL. Note that strings should only be passed to functions as *const char* *, as Python will not like its string mutated.

There must be at most 10 arguments, and arguments not given will be treated as *None*. The function's return value must be a C *long*, which is a Python integer.
8.6 dbm -- Simple "`database" interface

Availability: **Unix**.

The dbm module provides an interface to the **Unix** (n)dbm library. Dbm objects behave like mappings (dictionaries), except that keys and values are always strings. Printing a dbm object doesn't print the keys and values, and the `items()` and `values()` methods are not supported.

This module can be used with the "classic" ndbm interface, the BSD DB compatibility interface, or the GNU GDBM compatibility interface. On **Unix**, the `configure` script will attempt to locate the appropriate header file to simplify building this module.

The module defines the following:

**exception error**

Raised on dbm-specific errors, such as I/O errors. **KeyError** is raised for general mapping errors like specifying an incorrect key.

**library**

Name of the ndbm implementation library used.

**open( filename[, flag[, mode]])**

Open a dbm database and return a dbm object. The `filename` argument is the name of the database file (without the .dir or .pag extensions; note that the BSD DB implementation of the interface will append the extension .db and only create one file).

The optional `flag` argument must be one of these values:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
</tbody>
</table>
'c' | Open database for reading and writing, creating it if it doesn't exist

'n' | Always create a new, empty database, open for reading and writing

The optional *mode* argument is the UNIX mode of the file, used only when the database has to be created. It defaults to octal 0666.

### See Also:

Module **anydbm:**
Generic interface to dbm-style databases.

Module **gdbm:**
Similar interface to the GNU GDBM library.

Module **whichdb:**
Utility module used to determine the type of an existing database.
8.7 gdbm -- GNU's reinterpretation of dbm

Availability: Unix.

This module is quite similar to the dbm module, but uses gdbm instead to provide some additional functionality. Please note that the file formats created by gdbm and dbm are incompatible.

The gdbm module provides an interface to the GNU DBM library. gdbm objects behave like mappings (dictionaries), except that keys and values are always strings. Printing a gdbm object doesn't print the keys and values, and the items() and values() methods are not supported.

The module defines the following constant and functions:

**exception error**

Raised on gdbm-specific errors, such as I/O errors. KeyError is raised for general mapping errors like specifying an incorrect key.

**open( filename, [flag, [mode]])**

Open a gdbm database and return a gdbm object. The filename argument is the name of the database file.

The optional flag argument can be 'r' (to open an existing database for reading only -- default), 'w' (to open an existing database for reading and writing), 'c' (which creates the database if it doesn't exist), or 'n' (which always creates a new empty database).

The following additional characters may be appended to the flag to control how the database is opened:

- 'f' -- Open the database in fast mode. Writes to the database will not be synchronized.
- 's' -- Synchronized mode. This will cause changes to the database will be immediately written to the file.
• 'u' -- Do not lock database.

Not all flags are valid for all versions of gdbm. The module constant openflags is a string of supported flag characters. The exception error is raised if an invalid flag is specified.

The optional mode argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0666.

In addition to the dictionary-like methods, gdbm objects have the following methods:

**firstkey()**
It's possible to loop over every key in the database using this method and the nextkey() method. The traversal is ordered by gdbm's internal hash values, and won't be sorted by the key values. This method returns the starting key.

**nextkey(key)**
Returns the key that follows key in the traversal. The following code prints every key in the database db, without having to create a list in memory that contains them all:

```python
k = db.firstkey()
while k != None:
    print k
    k = db.nextkey(k)
```

**reorganize()**
If you have carried out a lot of deletions and would like to shrink the space used by the gdbm file, this routine will reorganize the database. gdbm will not shorten the length of a database file except by using this reorganization; otherwise, deleted file space will be kept and reused as new (key, value) pairs are added.

**sync()**
When the database has been opened in fast mode, this method forces any unwritten data to be written to the disk.

Module **anydbm**: Generic interface to dbm-style databases.

Module **whichdb**: Utility module used to determine the type of an existing database.
### 8.8 termios -- POSIX style tty control

**Availability:** Unix.

This module provides an interface to the POSIX calls for tty I/O control. For a complete description of these calls, see the POSIX or UNIX manual pages. It is only available for those UNIX versions that support POSIX termios style tty I/O control (and then only if configured at installation time).

All functions in this module take a file descriptor `fd` as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or a file object, such as `sys.stdin` itself.

This module also defines all the constants needed to work with the functions provided here; these have the same name as their counterparts in C. Please refer to your system documentation for more information on using these terminal control interfaces.

The module defines the following functions:

**tcgetattr**( `fd` )
Return a list containing the tty attributes for file descriptor `fd`, as follows: `[iflag, oflag, cflag, lflag, ispeed, ospeed, cc]` where `cc` is a list of the tty special characters (each a string of length 1, except the items with indices VMIN and VTIME, which are integers when these fields are defined). The interpretation of the flags and the speeds as well as the indexing in the `cc` array must be done using the symbolic constants defined in the termios module.

**tcsetattr**( `fd`, `when`, `attributes` )
Set the tty attributes for file descriptor `fd` from the `attributes`, which is a list like the one returned by `tcgetattr()`. The `when` argument determines when the attributes are changed: TCSANOW to change immediately, TCSADRAIN to change after transmitting all queued output, or
TCSAFLUSH to change after transmitting all queued output and discarding all queued input.

\texttt{tcsendbreak}(fd, duration)

Send a break on file descriptor \textit{fd}. A zero \textit{duration} sends a break for 0.25-0.5 seconds; a nonzero \textit{duration} has a system dependent meaning.

\texttt{tcdrain}(fd)

Wait until all output written to file descriptor \textit{fd} has been transmitted.

\texttt{tcflush}(fd, queue)

Discard queued data on file descriptor \textit{fd}. The \textit{queue} selector specifies which queue: TCIFLUSH for the input queue, TCOFLUSH for the output queue, or TCI0FLUSH for both queues.

\texttt{tcflow}(fd, action)

Suspend or resume input or output on file descriptor \textit{fd}. The \textit{action} argument can be TCOOFF to suspend output, TCOON to restart output, TCI0FF to suspend input, or TCI0N to restart input.

\textbf{See Also:}

Module \texttt{tty}:

Convenience functions for common terminal control operations.

\textbf{Subsections}

- \textbf{8.8.1 Example}

\textbf{Python Library Reference}

Previous: \texttt{8.7 gdbm} Up: \texttt{8. Unix Specific Services} Next: \texttt{8.8.1 Example}

Release 2.4.4c1, documentation updated on 11 October 2006.
See \texttt{About this document...} for information on suggesting changes.
8.8.1 Example

Here's a function that prompts for a password with echoing turned off. Note the technique using a separate `tcgetattr()` call and a `try ... finally` statement to ensure that the old tty attributes are restored exactly no matter what happens:

```python
def getpass(prompt = "Password: "):
    import termios, sys
    fd = sys.stdin.fileno()
    old = termios.tcgetattr(fd)
    new = termios.tcgetattr(fd)
    try:
        termios.tcsetattr(fd, termios.TCSADRAIN, new)
        passwd = raw_input(prompt)
    finally:
        termios.tcsetattr(fd, termios.TCSADRAIN, old)
    return passwd
```

Python Library Reference

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
8.9 tty -- Terminal control functions

Availability: Unix.

The tty module defines functions for putting the tty into cbreak and raw modes.

Because it requires the termios module, it will work only on UNIX.

The tty module defines the following functions:

**setraw(fd[, when])**

Change the mode of the file descriptor `fd` to raw. If `when` is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

**setcbreak(fd[, when])**

Change the mode of file descriptor `fd` to cbreak. If `when` is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

See Also:

Module **termios**: Low-level terminal control interface.
8.10 pty -- Pseudo-terminal utilities

Availability: IRIX, Linux.

The pty module defines operations for handling the pseudo-terminal concept: starting another process and being able to write to and read from its controlling terminal programmatically.

Because pseudo-terminal handling is highly platform dependant, there is code to do it only for SGI and Linux. (The Linux code is supposed to work on other platforms, but hasn't been tested yet.)

The pty module defines the following functions:

`fork()`
Fork. Connect the child's controlling terminal to a pseudo-terminal. Return value is `(pid, fd)`. Note that the child gets `pid 0`, and the `fd` is invalid. The parent's return value is the `pid` of the child, and `fd` is a file descriptor connected to the child's controlling terminal (and also to the child's standard input and output).

`openpty()`
Open a new pseudo-terminal pair, using `os.openpty()` if possible, or emulation code for SGI and generic UNIX systems. Return a pair of file descriptors (`master`, `slave`), for the master and the slave end, respectively.

`spawn(argv[, master_read[, stdin_read]])`
Spawn a process, and connect its controlling terminal with the current process's standard io. This is often used to baffle programs which insist on reading from the controlling terminal.

The functions `master_read` and `stdin_read` should be functions which read from a file-descriptor. The defaults try to read 1024 bytes each time they are called.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
8.11 fcntl -- The fcntl() and ioctl() system calls

Availability: Unix.

This module performs file control and I/O control on file descriptors. It is an interface to the fcntl() and ioctl() UNIX routines.

All functions in this module take a file descriptor `fd` as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or a file object, such as `sys.stdin` itself, which provides a `fileno()` which returns a genuine file descriptor.

The module defines the following functions:

```python
fcntl(fd, op[, arg])
```

Perform the requested operation on file descriptor `fd` (file objects providing a `fileno()` method are accepted as well). The operation is defined by `op` and is operating system dependent. These codes are also found in the fcntl module. The argument `arg` is optional, and defaults to the integer value 0. When present, it can either be an integer value, or a string. With the argument missing or an integer value, the return value of this function is the integer return value of the C `fcntl()` call. When the argument is a string it represents a binary structure, e.g. created by `struct.pack()`. The binary data is copied to a buffer whose address is passed to the C `fcntl()` call. The return value after a successful call is the contents of the buffer, converted to a string object. The length of the returned string will be the same as the length of the `arg` argument. This is limited to 1024 bytes. If the information returned in the buffer by the operating system is larger than 1024 bytes, this is most likely to result in a segmentation violation or a more subtle data corruption.

If the `fcntl()` fails, an IOError is raised.

```python
ioctl(fd, op[, arg[, mutate_flag]])
```
This function is identical to the `fcntl()` function, except that the operations are typically defined in the library module `termios` and the argument handling is even more complicated.

The parameter `arg` can be one of an integer, absent (treated identically to the integer 0), an object supporting the read-only buffer interface (most likely a plain Python string) or an object supporting the read-write buffer interface.

In all but the last case, behaviour is as for the `fcntl()` function.

If a mutable buffer is passed, then the behaviour is determined by the value of the `mutate_flag` parameter.

If it is false, the buffer's mutability is ignored and behaviour is as for a read-only buffer, except that the 1024 byte limit mentioned above is avoided - so long as the buffer you pass is longer than what the operating system wants to put there, things should work.

If `mutate_flag` is true, then the buffer is (in effect) passed to the underlying `ioctl()` system call, the latter's return code is passed back to the calling Python, and the buffer's new contents reflect the action of the `ioctl()`.

This is a slight simplification, because if the supplied buffer is less than 1024 bytes long it is first copied into a static buffer 1024 bytes long which is then passed to `ioctl()` and copied back into the supplied buffer.

If `mutate_flag` is not supplied, then in 2.3 it defaults to false. This is planned to change over the next few Python versions: in 2.4 failing to supply `mutate_flag` will get a warning but the same behavior and in versions later than 2.5 it will default to true.

An example:

```python
>>> import array, fcntl, struct, termios, os
>>> os.getpgrp()
13341
>>> struct.unpack('h', fcntl.ioctl(0, termios.TIOCGPGRP, 
          
" "))
13341
>>> buf = array.array('h', [0])
>>> fcntl.ioctl(0, termios.TIOCGPGRP, buf, 1)
0
>>> buf
```
**flock** \((fd, op)\)
Perform the lock operation \(op\) on file descriptor \(fd\) (file objects providing a `fileno()` method are accepted as well). See the UNIX manual `flock(3)` for details. (On some systems, this function is emulated using `fcntl()`.)

**lockf** \((fd, operation, [length, [start, [whence]]])\)
This is essentially a wrapper around the `fcntl()` locking calls. \(fd\) is the file descriptor of the file to lock or unlock, and `operation` is one of the following values:

- `LOCK_UN` - unlock
- `LOCK_SH` - acquire a shared lock
- `LOCK_EX` - acquire an exclusive lock

When `operation` is `LOCK_SH` or `LOCK_EX`, it can also be bit-wise OR'd with `LOCK_NB` to avoid blocking on lock acquisition. If `LOCK_NB` is used and the lock cannot be acquired, an `IOError` will be raised and the exception will have an `errno` attribute set to `EACCES` or `EAGAIN` (depending on the operating system; for portability, check for both values). On at least some systems, `LOCK_EX` can only be used if the file descriptor refers to a file opened for writing.

`length` is the number of bytes to lock, `start` is the byte offset at which the lock starts, relative to `whence`, and `whence` is as with `fileobj.seek()`, specifically:

- 0 - relative to the start of the file (`SEEK_SET`)
- 1 - relative to the current buffer position (`SEEK_CUR`)
- 2 - relative to the end of the file (`SEEK_END`)

The default for `start` is 0, which means to start at the beginning of the file. The default for `length` is 0 which means to lock to the end of the file. The default for `whence` is also 0.

Examples (all on a SVR4 compliant system):

```python
import struct, fcntl, os
```
```python
f = open(...)
rv = fcntl.fcntl(f, fcntl.F_SETFL, os.O_NDELAY)

lockdata = struct.pack('hhllhh', fcntl.F_WRLCK, 0, 0, 0, 0, 0)
rv = fcntl.fcntl(f, fcntl.F_SETLKW, lockdata)
```

Note that in the first example the return value variable `rv` will hold an integer value; in the second example it will hold a string value. The structure lay-out for the `lockdata` variable is system dependent -- therefore using the `flock()` call may be better.

### See Also:

Module `os`:

The `os.open()` function supports locking flags and is available on a wider variety of platforms than the `lockf()` and `flock()` functions, providing a more platform-independent file locking facility.
8.12 pipes -- Interface to shell pipelines

Availability: Unix.

The pipes module defines a class to abstract the concept of a pipeline -- a sequence of converters from one file to another.

Because the module uses /bin/sh command lines, a POSIX or compatible shell for os.system() and os.popen() is required.

The pipes module defines the following class:

```python
class Template:
    An abstraction of a pipeline.
```

Example:

```python
>>> import pipes
>>> t=pipes.Template()
>>> t.append('tr a-z A-Z', '--')
>>> f=t.open('/tmp/1', 'w')
>>> f.write('hello world')
>>> f.close()
>>> open('/tmp/1').read()
'HELLO WORLD'
```
8.12.1 Template Objects

Template objects following methods:

reset()
   Restore a pipeline template to its initial state.

clone()
   Return a new, equivalent, pipeline template.

debug(flag)
   If flag is true, turn debugging on. Otherwise, turn debugging off. When
   debugging is on, commands to be executed are printed, and the shell is
given set -x command to be more verbose.

append(cmd, kind)
   Append a new action at the end. The cmd variable must be a valid bourne
   shell command. The kind variable consists of two letters.

   The first letter can be either of ' - ' (which means the command reads its
   standard input), ' f ' (which means the commands reads a given file on the
   command line) or ' . ' (which means the commands reads no input, and
   hence must be first.)

   Similarly, the second letter can be either of ' - ' (which means the
   command writes to standard output), ' f ' (which means the command
   writes a file on the command line) or ' . ' (which means the command does
   not write anything, and hence must be last.)

prepend(cmd, kind)
   Add a new action at the beginning. See append() for explanations of the
   arguments.

open(file, mode)
   Return a file-like object, open to file, but read from or written to by the
   pipeline. Note that only one of ' r ', ' w ' may be given.
copy(infile, outfile)

Copy infile to outfile through the pipe.
8.13 posixfile -- File-like objects with locking support

Availability: Unix.

Deprecated since release 1.5. The locking operation that this module provides is done better and more portably by the `fcntl.lockf()` call.

This module implements some additional functionality over the built-in file objects. In particular, it implements file locking, control over the file flags, and an easy interface to duplicate the file object. The module defines a new file object, the posixfile object. It has all the standard file object methods and adds the methods described below. This module only works for certain flavors of UNIX, since it uses `fcntl.fcntl()` for file locking.

To instantiate a posixfile object, use the `open()` function in the `posixfile` module. The resulting object looks and feels roughly the same as a standard file object.

The `posixfile` module defines the following constants:

**SEEK_SET**
Offset is calculated from the start of the file.

**SEEK_CUR**
Offset is calculated from the current position in the file.

**SEEK_END**
Offset is calculated from the end of the file.

The `posixfile` module defines the following functions:

`open( filename[, mode[, bufsize]])`
Create a new posixfile object with the given filename and mode. The `filename`, `mode` and `bufsize` arguments are interpreted the same way as by the built-in `open()` function.
**fileopen**(*fileobject*)

Create a new posixfile object with the given standard file object. The resulting object has the same filename and mode as the original file object.

The posixfile object defines the following additional methods:

**lock**(*fmt, [len[, start[, whence]]]*)

Lock the specified section of the file that the file object is referring to. The format is explained below in a table. The *len* argument specifies the length of the section that should be locked. The default is 0. *start* specifies the starting offset of the section, where the default is 0. The *whence* argument specifies where the offset is relative to. It accepts one of the constants SEEK_SET, SEEK_CUR or SEEK_END. The default is SEEK_SET. For more information about the arguments refer to the *fcntl*(2) manual page on your system.

**flags**([*flags]*)

Set the specified flags for the file that the file object is referring to. The new flags are ORed with the old flags, unless specified otherwise. The format is explained below in a table. Without the *flags* argument a string indicating the current flags is returned (this is the same as the "?" modifier). For more information about the flags refer to the *fcntl*(2) manual page on your system.

**dup**()

Duplicate the file object and the underlying file pointer and file descriptor. The resulting object behaves as if it were newly opened.

**dup2**(*fd*)

Duplicate the file object and the underlying file pointer and file descriptor. The new object will have the given file descriptor. Otherwise the resulting object behaves as if it were newly opened.

**file**()

Return the standard file object that the posixfile object is based on. This is sometimes necessary for functions that insist on a standard file object.
All methods raise `IOError` when the request fails.

Format characters for the `lock()` method have the following meaning:

<table>
<thead>
<tr>
<th>Format</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>u</td>
<td>unlock the specified region</td>
</tr>
<tr>
<td>r</td>
<td>request a read lock for the specified section</td>
</tr>
<tr>
<td>w</td>
<td>request a write lock for the specified section</td>
</tr>
</tbody>
</table>

In addition the following modifiers can be added to the format:

<table>
<thead>
<tr>
<th>Modifier</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>wait until the lock has been granted</td>
<td></td>
</tr>
<tr>
<td>?</td>
<td>return the first lock conflicting with the requested lock, or None if there is no conflict.</td>
<td>(1)</td>
</tr>
</tbody>
</table>

Note:

(1) The lock returned is in the format `(mode, len, start, whence, pid)` where `mode` is a character representing the type of lock ('r' or 'w'). This modifier prevents a request from being granted; it is for query purposes only.

Format characters for the `flags()` method have the following meanings:

<table>
<thead>
<tr>
<th>Format</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>append only flag</td>
</tr>
<tr>
<td>c</td>
<td>close on exec flag</td>
</tr>
<tr>
<td>n</td>
<td>no delay flag (also called non-blocking flag)</td>
</tr>
<tr>
<td>s</td>
<td>synchronization flag</td>
</tr>
</tbody>
</table>

In addition the following modifiers can be added to the format:

<table>
<thead>
<tr>
<th>Modifier</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>!</td>
<td>turn the specified flags 'off', instead of the default 'on'</td>
<td>(1)</td>
</tr>
<tr>
<td>=</td>
<td>replace the flags, instead of the default 'OR' operation</td>
<td>(1)</td>
</tr>
</tbody>
</table>
return a string in which the characters represent the flags that are set.

Notes:

(1) The "!" and "=" modifiers are mutually exclusive.

(2) This string represents the flags after they may have been altered by the same call.

Examples:

```python
import posixfile

file = posixfile.open('/tmp/test', 'w')
file.lock('w|')

file.lock('u')
file.close()
```
8.14 resource -- Resource usage information

Availability: Unix.

This module provides basic mechanisms for measuring and controlling system resources utilized by a program.

Symbolic constants are used to specify particular system resources and to request usage information about either the current process or its children.

A single exception is defined for errors:

**exception error**

The functions described below may raise this error if the underlying system call failures unexpectedly.

**Subsections**

- 8.14.1 Resource Limits
- 8.14.2 Resource Usage

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
8.14.1 Resource Limits

Resources usage can be limited using the setrlimit() function described below. Each resource is controlled by a pair of limits: a soft limit and a hard limit. The soft limit is the current limit, and may be lowered or raised by a process over time. The soft limit can never exceed the hard limit. The hard limit can be lowered to any value greater than the soft limit, but not raised. (Only processes with the effective UID of the super-user can raise a hard limit.)

The specific resources that can be limited are system dependent. They are described in the getrlimit(2) man page. The resources listed below are supported when the underlying operating system supports them; resources which cannot be checked or controlled by the operating system are not defined in this module for those platforms.

getrlimit(resource)

Returns a tuple (soft, hard) with the current soft and hard limits of resource. Raises ValueError if an invalid resource is specified, or error if the underlying system call fails unexpectedly.

setrlimit(resource, limits)

Sets new limits of consumption of resource. The limits argument must be a tuple (soft, hard) of two integers describing the new limits. A value of -1 can be used to specify the maximum possible upper limit.

Raises ValueError if an invalid resource is specified, if the new soft limit exceeds the hard limit, or if a process tries to raise its hard limit (unless the process has an effective UID of super-user). Can also raise error if the underlying system call fails.

These symbols define resources whose consumption can be controlled using the setrlimit() and getrlimit() functions described below. The values of these symbols are exactly the constants used by C programs.

The UNIX man page for getrlimit(2) lists the available resources. Note that not all systems use the same symbol or same value to denote the same resource. This module does not attempt to mask platform differences -- symbols not defined for
a platform will not be available from this module on that platform.

**RLIMIT_CORE**
The maximum size (in bytes) of a core file that the current process can create. This may result in the creation of a partial core file if a larger core would be required to contain the entire process image.

**RLIMIT_CPU**
The maximum amount of processor time (in seconds) that a process can use. If this limit is exceeded, a SIGXCPU signal is sent to the process. (See the [signal](#) module documentation for information about how to catch this signal and do something useful, e.g. flush open files to disk.)

**RLIMITFSIZE**
The maximum size of a file which the process may create. This only affects the stack of the main thread in a multi-threaded process.

**RLIMIT_DATA**
The maximum size (in bytes) of the process’s heap.

**RLIMIT_STACK**
The maximum size (in bytes) of the call stack for the current process.

**RLIMIT_RSS**
The maximum resident set size that should be made available to the process.

**RLIMIT_NPROC**
The maximum number of processes the current process may create.

**RLIMIT_NOFILE**
The maximum number of open file descriptors for the current process.

**RLIMIT_OFILE**
The BSD name for RLIMIT_NOFILE.

**RLIMIT_MEMLOCK**
The maximum address space which may be locked in memory.

**RLIMIT_VMEM**
The largest area of mapped memory which the process may occupy.

**RLIMIT_AS**

The maximum area (in bytes) of address space which may be taken by the process.
8.14.2 Resource Usage

These functions are used to retrieve resource usage information:

`getrusage(who)`

This function returns an object that describes the resources consumed by either the current process or its children, as specified by the `who` parameter. The `who` parameter should be specified using one of the `RUSAGE_*` constants described below.

The fields of the return value each describe how a particular system resource has been used, e.g. amount of time spent running is user mode or number of times the process was swapped out of main memory. Some values are dependent on the clock tick internal, e.g. the amount of memory the process is using.

For backward compatibility, the return value is also accessible as a tuple of 16 elements.

The fields `ru_utime` and `ru_stime` of the return value are floating point values representing the amount of time spent executing in user mode and the amount of time spent executing in system mode, respectively. The remaining values are integers. Consult the `getrusage(2)` man page for detailed information about these values. A brief summary is presented here:

<table>
<thead>
<tr>
<th>Index</th>
<th>Field</th>
<th>Resource</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td><code>ru_utime</code></td>
<td>time in user mode (float)</td>
</tr>
<tr>
<td>1</td>
<td><code>ru_stime</code></td>
<td>time in system mode (float)</td>
</tr>
<tr>
<td>2</td>
<td><code>ru_maxrss</code></td>
<td>maximum resident set size</td>
</tr>
<tr>
<td>3</td>
<td><code>ru_ixrss</code></td>
<td>shared memory size</td>
</tr>
<tr>
<td>4</td>
<td><code>ru_idrss</code></td>
<td>unshared memory size</td>
</tr>
<tr>
<td>5</td>
<td><code>ru_isrss</code></td>
<td>unshared stack size</td>
</tr>
<tr>
<td>6</td>
<td><code>ru_minflt</code></td>
<td>page faults not requiring I/O</td>
</tr>
<tr>
<td>7</td>
<td><code>ru_majflt</code></td>
<td>page faults requiring I/O</td>
</tr>
<tr>
<td>8</td>
<td><code>ru_nswap</code></td>
<td>number of swap outs</td>
</tr>
<tr>
<td>9</td>
<td><code>ru_inblock</code></td>
<td>block input operations</td>
</tr>
</tbody>
</table>
This function will raise a `ValueError` if an invalid `who` parameter is specified. It may also raise `error` exception in unusual circumstances.

Changed in version 2.3: Added access to values as attributes of the returned object.

**getpagesize()**

Returns the number of bytes in a system page. (This need not be the same as the hardware page size.) This function is useful for determining the number of bytes of memory a process is using. The third element of the tuple returned by `getrusage()` describes memory usage in pages; multiplying by page size produces number of bytes.

The following `RUSAGE_*` symbols are passed to the `getrusage()` function to specify which processes information should be provided for.

**RUSAGE_SELF**

`RUSAGE_SELF` should be used to request information pertaining only to the process itself.

**RUSAGE_CHILDREN**

Pass to `getrusage()` to request resource information for child processes of the calling process.

**RUSAGE_BOTH**

Pass to `getrusage()` to request resources consumed by both the current process and child processes. May not be available on all systems.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
8.15 nis -- Interface to Sun's NIS (Yellow Pages)

Availability: UNIX.

The nis module gives a thin wrapper around the NIS library, useful for central administration of several hosts.

Because NIS exists only on UNIX systems, this module is only available for UNIX.

The nis module defines the following functions:

**match**(key, mapname)

Return the match for key in map mapname, or raise an error (nis.error) if there is none. Both should be strings, key is 8-bit clean. Return value is an arbitrary array of bytes (may contain NULL and other joys).

Note that mapname is first checked if it is an alias to another name.

**cat**(mapname)

Return a dictionary mapping key to value such that match(key, mapname) == value. Note that both keys and values of the dictionary are arbitrary arrays of bytes.

Note that mapname is first checked if it is an alias to another name.

**maps**()

Return a list of all valid maps.

The nis module defines the following exception:

**exception error**

An error raised when a NIS function returns an error code.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
8.16 syslog -- UNIX syslog library routines

Availability: Unix.

This module provides an interface to the UNIX syslog library routines. Refer to the UNIX manual pages for a detailed description of the syslog facility.

The module defines the following functions:

**syslog([priority,] message)**
- Send the string message to the system logger. A trailing newline is added if necessary. Each message is tagged with a priority composed of a facility and a level. The optional priority argument, which defaults to LOG_INFO, determines the message priority. If the facility is not encoded in priority using logical-or (LOG_INFO | LOG_USER), the value given in the openlog() call is used.

**openlog([ident[, logopt[, facility]]])**
- Logging options other than the defaults can be set by explicitly opening the log file with openlog() prior to calling syslog(). The defaults are (usually) ident = 'syslog', logopt = 0, facility = LOG_USER. The ident argument is a string which is prepended to every message. The optional logopt argument is a bit field - see below for possible values to combine. The optional facility argument sets the default facility for messages which do not have a facility explicitly encoded.

**closelog()**
- Close the log file.

**setlogmask(maskpri)**
- Set the priority mask to maskpri and return the previous mask value. Calls to syslog() with a priority level not set in maskpri are ignored. The default is to log all priorities. The function LOG_MASK(pri) calculates the
mask for the individual priority \textit{pri}. The function \texttt{LOG\_UPTO(\textit{pri})} calculates the mask for all priorities up to and including \textit{pri}.

The module defines the following constants:

**Priority levels (high to low):**

\begin{itemize}
  \item \texttt{LOG\_EMERG, LOG\_ALERT, LOG\_CRIT, LOG\_ERR, LOG\_WARNING,}
  \item \texttt{LOG\_NOTICE, LOG\_INFO, LOG\_DEBUG.}
\end{itemize}

**Facilities:**

\begin{itemize}
  \item \texttt{LOG\_KERN, LOG\_USER, LOG\_MAIL, LOG\_DAEMON, LOG\_AUTH,}
  \item \texttt{LOG\_LPR, LOG\_NEWS, LOG\_UUCP, LOG\_CRON and LOG\_LOCAL0 to}
  \item \texttt{LOG\_LOCAL7.}
\end{itemize}

**Log options:**

\begin{itemize}
  \item \texttt{LOG\_PID, LOG\_CONS, LOG\_NDELAY, LOG\_NOWAIT and LOG\_PERROR}
  \item \texttt{if defined in \textless syslog.h\textgreater.}
\end{itemize}
8.17 commands -- Utilities for running commands

Availability: Unix.

The commands module contains wrapper functions for \texttt{os.popen() which take a system command as a string and return any output generated by the command and, optionally, the exit status.}

The commands module defines the following functions:

\textbf{getstatusoutput}(cmd)

Execute the string \textit{cmd} in a shell with \texttt{os.popen()} and return a 2-tuple \texttt{(status, output). cmd} is actually run as \{ \texttt{cmd ; } \} 2>&1, so that the returned output will contain output or error messages. A trailing newline is stripped from the output. The exit status for the command can be interpreted according to the rules for the C function \texttt{wait()}.  

\textbf{getoutput}(cmd)

Like \texttt{getstatusoutput()}, except the exit status is ignored and the return value is a string containing the command's output.

\textbf{getstatus}(file)

Return the output of "\texttt{ls -ld file}" as a string. This function uses the \texttt{getoutput()} function, and properly escapes backslashes and dollar signs in the argument.

Example:

```python
g>>> import commands
g>>> commands.getstatusoutput('ls /bin/ls')
(0, '/bin/ls')
g>>> commands.getstatusoutput('cat /bin/junk')
(256, 'cat: /bin/junk: No such file or directory')
g>>> commands.getstatusoutput('/bin/junk')
(256, 'sh: /bin/junk: not found')
g>>> commands.getoutput('ls /bin/ls')
'/bin/ls'
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
9. The Python Debugger

The module `pdb` defines an interactive source code debugger for Python programs. It supports setting (conditional) breakpoints and single stepping at the source line level, inspection of stack frames, source code listing, and evaluation of arbitrary Python code in the context of any stack frame. It also supports post-mortem debugging and can be called under program control.

The debugger is extensible -- it is actually defined as the class `Pdb`. This is currently undocumented but easily understood by reading the source. The extension interface uses the modules `bdb` (undocumented) and `cmd`.

The debugger's prompt is "(Pdb) ". Typical usage to run a program under control of the debugger is:

```python
>>> import pdb
>>> import mymodule
>>> pdb.run('mymodule.test()')
> <string>(0)?()
(Pdb) continue
> <string>(1)?()
(Pdb) continue
NameError: 'spam'
> <string>(1)?()
(Pdb)
```

`pdb.py` can also be invoked as a script to debug other scripts. For example:

```
python -m pdb myscript.py
```

When invoked as a script, pdb will automatically enter post-mortem debugging if the program being debugged exits abnormally. After post-mortem debugging (or after normal exit of the program), pdb will restart the program. Automatic restarting preserves pdb's state (such as breakpoints) and in most cases is more useful than quitting the debugger upon program's exit. New in version 2.4: Restarting post-mortem behavior added.

Typical usage to inspect a crashed program is:

```python
>>> import pdb
>>> import mymodule
```
>>> mymodule.test()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "./mymodule.py", line 4, in test
test2()
  File "./mymodule.py", line 3, in test2
    print spam
NameError: spam
>>> pdb.pm()
> ./mymodule.py(3)test2()
-> print spam
(Pdb)

The module defines the following functions; each enters the debugger in a slightly different way:

run( statement[, globals[, locals]])

Execute the statement (given as a string) under debugger control. The debugger prompt appears before any code is executed; you can set breakpoints and type "continue", or you can step through the statement using "step" or "next" (all these commands are explained below). The optional globals and locals arguments specify the environment in which the code is executed; by default the dictionary of the module __main__ is used. (See the explanation of the exec statement or the eval() built-in function.)

runeval( expression[, globals[, locals]])

Evaluate the expression (given as a string) under debugger control. When runeval() returns, it returns the value of the expression. Otherwise this function is similar to run().

runcall( function[, argument, ...])

Call the function (a function or method object, not a string) with the given arguments. When runcall() returns, it returns whatever the function call returned. The debugger prompt appears as soon as the function is entered.

set_trace()

Enter the debugger at the calling stack frame. This is useful to hard-code a breakpoint at a given point in a program, even if the code is not otherwise being debugged (e.g. when an assertion fails).
post_mortem( traceback)

Enter post-mortem debugging of the given traceback object.

pm()

Enter post-mortem debugging of the traceback found in sys.last_traceback.
9.1 Debugger Commands

The debugger recognizes the following commands. Most commands can be abbreviated to one or two letters; e.g. "h(elp)" means that either "h" or "help" can be used to enter the help command (but not "he" or "hel", nor "H" or "Help" or "HELP"). Arguments to commands must be separated by whitespace (spaces or tabs). Optional arguments are enclosed in square brackets ("[]") in the command syntax; the square brackets must not be typed. Alternatives in the command syntax are separated by a vertical bar ("| ").

Entering a blank line repeats the last command entered. Exception: if the last command was a "list" command, the next 11 lines are listed.

Commands that the debugger doesn't recognize are assumed to be Python statements and are executed in the context of the program being debugged. Python statements can also be prefixed with an exclamation point ("! "). This is a powerful way to inspect the program being debugged; it is even possible to change a variable or call a function. When an exception occurs in such a statement, the exception name is printed but the debugger's state is not changed.

Multiple commands may be entered on a single line, separated by "; ;". (A single ";" is not used as it is the separator for multiple commands in a line that is passed to the Python parser.) No intelligence is applied to separating the commands; the input is split at the first "; ;" pair, even if it is in the middle of a quoted string.

The debugger supports aliases. Aliases can have parameters which allows one a certain level of adaptability to the context under examination.

If a file .pdbrc exists in the user's home directory or in the current directory, it is read in and executed as if it had been typed at the debugger prompt. This is particularly useful for aliases. If both files exist, the one in the home directory is read first and aliases defined there can be overridden by the local file.

help [command]

Without argument, print the list of available commands. With a command as
argument, print help about that command. "help pdb" displays the full documentation file; if the environment variable PAGER is defined, the file is piped through that command instead. Since the command argument must be an identifier, "help exec" must be entered to get help on the "!" command.

**w(here)**

Print a stack trace, with the most recent frame at the bottom. An arrow indicates the current frame, which determines the context of most commands.

**d(own)**

Move the current frame one level down in the stack trace (to a newer frame).

**u(p)**

Move the current frame one level up in the stack trace (to an older frame).

**b(reak) \[filename:]lineno | function[, condition]**

With a lineno argument, set a break there in the current file. With a function argument, set a break at the first executable statement within that function. The line number may be prefixed with a filename and a colon, to specify a breakpoint in another file (probably one that hasn't been loaded yet). The file is searched on `sys.path`. Note that each breakpoint is assigned a number to which all the other breakpoint commands refer.

If a second argument is present, it is an expression which must evaluate to true before the breakpoint is honored.

Without argument, list all breaks, including for each breakpoint, the number of times that breakpoint has been hit, the current ignore count, and the associated condition if any.

**tbreak \[filename:]lineno | function[, condition]**

Temporary breakpoint, which is removed automatically when it is first hit.
The arguments are the same as break.

\texttt{cl(ear)} \texttt{[bpnumber [bpnumber ...]]}

With a space separated list of breakpoint numbers, clear those breakpoints. Without argument, clear all breaks (but first ask confirmation).

\texttt{disable} \texttt{[bpnumber [bpnumber ...]]}

Disables the breakpoints given as a space separated list of breakpoint numbers. Disabling a breakpoint means it cannot cause the program to stop execution, but unlike clearing a breakpoint, it remains in the list of breakpoints and can be (re-)enabled.

\texttt{enable} \texttt{[bpnumber [bpnumber ...]]}

Enables the breakpoints specified.

\texttt{ignore} \texttt{bpnumber [count]}

Sets the ignore count for the given breakpoint number. If count is omitted, the ignore count is set to 0. A breakpoint becomes active when the ignore count is zero. When non-zero, the count is decremented each time the breakpoint is reached and the breakpoint is not disabled and any associated condition evaluates to true.

\texttt{condition} \texttt{bpnumber [condition]}

Condition is an expression which must evaluate to true before the breakpoint is honored. If condition is absent, any existing condition is removed; i.e., the breakpoint is made unconditional.

\texttt{s(tep)}

Execute the current line, stop at the first possible occasion (either in a function that is called or on the next line in the current function).

\texttt{n(ext)}

Continue execution until the next line in the current function is reached or it
returns. (The difference between "next" and "step" is that "step" stops inside a called function, while "next" executes called functions at (nearly) full speed, only stopping at the next line in the current function.)

**r(eturn)**

Continue execution until the current function returns.

**c(ont(inue))**

Continue execution, only stop when a breakpoint is encountered.

**j(ump) lineno**

Set the next line that will be executed. Only available in the bottom-most frame. This lets you jump back and execute code again, or jump forward to skip code that you don't want to run.

It should be noted that not all jumps are allowed -- for instance it is not possible to jump into the middle of a for loop or out of a finally clause.

**l(ist) [first[, last]]**

List source code for the current file. Without arguments, list 11 lines around the current line or continue the previous listing. With one argument, list 11 lines around at that line. With two arguments, list the given range; if the second argument is less than the first, it is interpreted as a count.

**a(rgs)**

Print the argument list of the current function.

**p expression**

Evaluate the expression in the current context and print its value. **Note:** "print" can also be used, but is not a debugger command -- this executes the Python print statement.

**pp expression**
Like the "p" command, except the value of the expression is pretty-printed using the `pprint` module.

**alias [name [command]]**

Creates an alias called `name` that executes `command`. The command must *not* be enclosed in quotes. Replaceable parameters can be indicated by "%1", "%2", and so on, while "%*" is replaced by all the parameters. If no command is given, the current alias for `name` is shown. If no arguments are given, all aliases are listed.

Aliases may be nested and can contain anything that can be legally typed at the pdb prompt. Note that internal pdb commands *can* be overridden by aliases. Such a command is then hidden until the alias is removed. Aliasing is recursively applied to the first word of the command line; all other words in the line are left alone.

As an example, here are two useful aliases (especially when placed in the .pdbrc file):

```python
# Print instance variables (usage "pi classInst")
alias pi for k in %1.__dict__.keys(): print "%1.",k,"=",%1.__dict__[k]
# Print instance variables in self
alias ps pi self
```

**unalias name**

Deletes the specified alias.

**[!]statement**

Execute the (one-line) `statement` in the context of the current stack frame. The exclamation point can be omitted unless the first word of the statement resembles a debugger command. To set a global variable, you can prefix the assignment command with a "global" command on the same line, e.g.:

```python
(Pdb) global list_options; list_options = ['-l']
(Pdb)
```

**quit**
Quit from the debugger. The program being executed is aborted.
9.2 How It Works

Some changes were made to the interpreter:

- `sys.settrace(func)` sets the global trace function
- there can also a local trace function (see later)

Trace functions have three arguments: `frame`, `event`, and `arg`. `frame` is the current stack frame. `event` is a string: 'call', 'line', 'return', 'exception', 'c_call', 'c_return', or 'c_exception'. `arg` depends on the event type.

The global trace function is invoked (with `event` set to 'call') whenever a new local scope is entered; it should return a reference to the local trace function to be used that scope, or `None` if the scope shouldn't be traced.

The local trace function should return a reference to itself (or to another function for further tracing in that scope), or `None` to turn off tracing in that scope.

Instance methods are accepted (and very useful!) as trace functions.

The events have the following meaning:

'call'
A function is called (or some other code block entered). The global trace function is called; `arg` is `None`; the return value specifies the local trace function.

'line'
The interpreter is about to execute a new line of code (sometimes multiple line events on one line exist). The local trace function is called; `arg` is `None`; the return value specifies the new local trace function.

'return'
A function (or other code block) is about to return. The local trace function is called; `arg` is the value that will be returned. The trace function's return value is ignored.
'exception'
An exception has occurred. The local trace function is called; arg is a triple
(exception, value, traceback); the return value specifies the new local
trace function.

'c_call'
A C function is about to be called. This may be an extension function or a
builtin. arg is the C function object.

'c_return'
A C function has returned. arg is None.

'c_exception'
A C function has thrown an exception. arg is None.

Note that as an exception is propagated down the chain of callers, an
'exception' event is generated at each level.

For more information on code and frame objects, refer to the Python Reference
Manual.

The profiler was written after only programming in Python for 3 weeks. As a result, it is probably clumsy code, but I don't know for sure yet 'cause I'm a beginner :-). I did work hard to make the code run fast, so that profiling would be a reasonable thing to do. I tried not to repeat code fragments, but I'm sure I did some stuff in really awkward ways at times. Please send suggestions for improvements to: jar@netscape.com. I won't promise any support. ...but I'd appreciate the feedback.
Footnotes

10.1 Introduction to the profiler

A profiler is a program that describes the run time performance of a program, providing a variety of statistics. This documentation describes the profiler functionality provided in the modules profile and pstats. This profiler provides deterministic profiling of any Python programs. It also provides a series of report generation tools to allow users to rapidly examine the results of a profile operation.
10.2 How Is This Profiler Different From The Old Profiler?

(This section is of historical importance only; the old profiler discussed here was last seen in Python 1.1.)

The big changes from old profiling module are that you get more information, and you pay less CPU time. It's not a trade-off, it's a trade-up.

To be specific:

**Bugs removed:**
Local stack frame is no longer molested, execution time is now charged to correct functions.

**Accuracy increased:**
Profiler execution time is no longer charged to user's code, calibration for platform is supported, file reads are not done by profiler *during* profiling (and charged to user's code!).

**Speed increased:**
Overhead CPU cost was reduced by more than a factor of two (perhaps a factor of five), lightweight profiler module is all that must be loaded, and the report generating module (*pstats*) is not needed during profiling.

**Recursive functions support:**
Cumulative times in recursive functions are correctly calculated; recursive entries are counted.

**Large growth in report generating UI:**
Distinct profiles runs can be added together forming a comprehensive report; functions that import statistics take arbitrary lists of files; sorting criteria is now based on keywords (instead of 4 integer options); reports shows what functions were profiled as well as what profile file was referenced; output format has been improved.
10.3 Instant Users Manual

This section is provided for users that "don't want to read the manual." It provides a very brief overview, and allows a user to rapidly perform profiling on an existing application.

To profile an application with a main entry point of `foo()`, you would add the following to your module:

```python
import profile
profile.run('foo()')
```

The above action would cause `foo()` to be run, and a series of informative lines (the profile) to be printed. The above approach is most useful when working with the interpreter. If you would like to save the results of a profile into a file for later examination, you can supply a file name as the second argument to the `run()` function:

```python
import profile
profile.run('foo()', 'fooprof')
```

The file `profile.py` can also be invoked as a script to profile another script. For example:

```bash
python -m profile myscript.py
```

`profile.py` accepts two optional arguments on the command line:

```bash
profile.py [-o output_file] [-s sort_order]
```

`-s` only applies to standard output (`-o` is not supplied). Look in the `Stats` documentation for valid sort values.

When you wish to review the profile, you should use the methods in the `pstats` module. Typically you would load the statistics data as follows:

```python
import pstats
p = pstats.Stats('fooprof')
```

The class `Stats` (the above code just created an instance of this class) has a
variety of methods for manipulating and printing the data that was just read into p. When you ran `profile.run()` above, what was printed was the result of three method calls:

\[ \text{p.strip_dirs().sort_stats(-1).print_stats()} \]

The first method removed the extraneous path from all the module names. The second method sorted all the entries according to the standard module/line/name string that is printed (this is to comply with the semantics of the old profiler). The third method printed out all the statistics. You might try the following sort calls:

\[ \text{p.sort_stats('name')} \]
\[ \text{p.print_stats()} \]

The first call will actually sort the list by function name, and the second call will print out the statistics. The following are some interesting calls to experiment with:

\[ \text{p.sort_stats('cumulative').print_stats(10)} \]

This sorts the profile by cumulative time in a function, and then only prints the ten most significant lines. If you want to understand what algorithms are taking time, the above line is what you would use.

If you were looking to see what functions were looping a lot, and taking a lot of time, you would do:

\[ \text{p.sort_stats('time').print_stats(10)} \]

to sort according to time spent within each function, and then print the statistics for the top ten functions.

You might also try:

\[ \text{p.sort_stats('file').print_stats('\_\_init\_\_')} \]

This will sort all the statistics by file name, and then print out statistics for only the class init methods (since they are spelled with `\_\_init\_\_` in them). As one final example, you could try:

\[ \text{p.sort_stats('time', 'cum').print_stats(.5, 'init')} \]
This line sorts statistics with a primary key of time, and a secondary key of cumulative time, and then prints out some of the statistics. To be specific, the list is first culled down to 50% (re: ".5") of its original size, then only lines containing init are maintained, and that sub-sub-list is printed.

If you wondered what functions called the above functions, you could now (p is still sorted according to the last criteria) do:

```
p.print_callers(.5, 'init')
```

and you would get a list of callers for each of the listed functions.

If you want more functionality, you're going to have to read the manual, or guess what the following functions do:

```
p.print_callees()
p.add('fooprof')
```

Invoked as a script, the pstats module is a statistics browser for reading and examining profile dumps. It has a simple line-oriented interface (implemented using cmd) and interactive help.
10.4 What Is Deterministic Profiling?

_Deterministic profiling_ is meant to reflect the fact that all _function call, function return_, and _exception_ events are monitored, and precise timings are made for the intervals between these events (during which time the user's code is executing). In contrast, _statistical profiling_ (which is not done by this module) randomly samples the effective instruction pointer, and deduces where time is being spent. The latter technique traditionally involves less overhead (as the code does not need to be instrumented), but provides only relative indications of where time is being spent.

In Python, since there is an interpreter active during execution, the presence of instrumented code is not required to do deterministic profiling. Python automatically provides a _hook_ (optional callback) for each event. In addition, the interpreted nature of Python tends to add so much overhead to execution, that deterministic profiling tends to only add small processing overhead in typical applications. The result is that deterministic profiling is not that expensive, yet provides extensive run time statistics about the execution of a Python program.

Call count statistics can be used to identify bugs in code (surprising counts), and to identify possible inline-expansion points (high call counts). Internal time statistics can be used to identify "hot loops" that should be carefully optimized. Cumulative time statistics should be used to identify high level errors in the selection of algorithms. Note that the unusual handling of cumulative times in this profiler allows statistics for recursive implementations of algorithms to be directly compared to iterative implementations.
The Stats Class
10.5 Reference Manual

The primary entry point for the profiler is the global function `profile.run()`. It is typically used to create any profile information. The reports are formatted and printed using methods of the class `pstats.Stats`. The following is a description of all of these standard entry points and functions. For a more in-depth view of some of the code, consider reading the later section on Profiler Extensions, which includes discussion of how to derive "better" profilers from the classes presented, or reading the source code for these modules.

```python
run(command[, filename])
```

This function takes a single argument that has can be passed to the `exec` statement, and an optional file name. In all cases this routine attempts to `exec` its first argument, and gather profiling statistics from the execution. If no file name is present, then this function automatically prints a simple profiling report, sorted by the standard name string (file/line/function-name) that is presented in each line. The following is a typical output from such a call:

```
main()
2706 function calls (2004 primitive calls) in 4.504 CPU sec
Ordered by: standard name
ncalls  tottime  percall  cumtime  percall  filename:lineno(function)
2    0.006    0.003    0.953    0.477  pobject.py:75(save_objects)
43/3  0.533    0.012    0.749    0.250  pobject.py:99(evaluate)
...
```

The first line indicates that this profile was generated by the call: `profile.run('main()')`, and hence the exec'ed string is 'main()'. The second line indicates that 2706 calls were monitored. Of those calls, 2004 were primitive. We define primitive to mean that the call was not induced via recursion. The next line: `Ordered by: standard name`, indicates that the text string in the far right column was used to sort the output. The column headings include:
ncalls
for the number of calls,

tottime
for the total time spent in the given function (and excluding time made in calls to sub-functions),

percall
is the quotient of tottime divided by ncalls

cumtime
is the total time spent in this and all subfunctions (from invocation till exit). This figure is accurate even for recursive functions.

percall
is the quotient of cumtime divided by primitive calls

filename:lineno(function)
provides the respective data of each function

When there are two numbers in the first column (for example, "43/3"), then the latter is the number of primitive calls, and the former is the actual number of calls. Note that when the function does not recurse, these two values are the same, and only the single figure is printed.

runctx(command, globals, locals[, filename])
This function is similar to profile.run(), with added arguments to supply the globals and locals dictionaries for the command string.

Analysis of the profiler data is done using this class from the pstats module:

class Stats(filename[, ...])
This class constructor creates an instance of a ```statistics object``` from a filename (or set of filenames). Stats objects are manipulated by methods, in order to print useful reports.

The file selected by the above constructor must have been created by the corresponding version of profile. To be specific, there is no file compatibility guaranteed with future versions of this profiler, and there is
no compatibility with files produced by other profilers (such as the old system profiler).

If several files are provided, all the statistics for identical functions will be coalesced, so that an overall view of several processes can be considered in a single report. If additional files need to be combined with data in an existing \texttt{Stats} object, the \texttt{add()} method can be used.
10.5.1 The Stats Class

Stats objects have the following methods:

**strip_dirs()**
This method for the Stats class removes all leading path information from file names. It is very useful in reducing the size of the printout to fit within (close to) 80 columns. This method modifies the object, and the stripped information is lost. After performing a strip operation, the object is considered to have its entries in a ``random`` order, as it was just after object initialization and loading. If **strip_dirs()** causes two function names to be indistinguishable (they are on the same line of the same filename, and have the same function name), then the statistics for these two entries are accumulated into a single entry.

**add(filename[, ...])**
This method of the Stats class accumulates additional profiling information into the current profiling object. Its arguments should refer to filenames created by the corresponding version of **profile.run()**. Statistics for identically named (re: file, line, name) functions are automatically accumulated into single function statistics.

**dump_stats(filename)**
Save the data loaded into the Stats object to a file named filename. The file is created if it does not exist, and is overwritten if it already exists. This is equivalent to the method of the same name on the profile.Profile class. New in version 2.3.

**sort_stats(key[, ...])**
This method modifies the Stats object by sorting it according to the supplied criteria. The argument is typically a string identifying the basis of a sort (example: 'time' or 'name').

When more than one key is provided, then additional keys are used as secondary criteria when there is equality in all keys selected before them. For example, **sort_stats('name', 'file')** will sort all the entries
according to their function name, and resolve all ties (identical function names) by sorting by file name.

Abbreviations can be used for any key names, as long as the abbreviation is unambiguous. The following are the keys currently defined:

<table>
<thead>
<tr>
<th>Valid Arg</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'calls'</td>
<td>call count</td>
</tr>
<tr>
<td>'cumulative'</td>
<td>cumulative time</td>
</tr>
<tr>
<td>'file'</td>
<td>file name</td>
</tr>
<tr>
<td>'module'</td>
<td>file name</td>
</tr>
<tr>
<td>'pcalls'</td>
<td>primitive call count</td>
</tr>
<tr>
<td>'line'</td>
<td>line number</td>
</tr>
<tr>
<td>'name'</td>
<td>function name</td>
</tr>
<tr>
<td>'nfl'</td>
<td>name/file/line</td>
</tr>
<tr>
<td>'stdname'</td>
<td>standard name</td>
</tr>
<tr>
<td>'time'</td>
<td>internal time</td>
</tr>
</tbody>
</table>

Note that all sorts on statistics are in descending order (placing most time consuming items first), where as name, file, and line number searches are in ascending order (alphabetical). The subtle distinction between 'nfl' and 'stdname' is that the standard name is a sort of the name as printed, which means that the embedded line numbers get compared in an odd way. For example, lines 3, 20, and 40 would (if the file names were the same) appear in the string order 20, 3 and 40. In contrast, 'nfl' does a numeric compare of the line numbers. In fact, `sort_stats('nfl')` is the same as `sort_stats('name', 'file', 'line')`.

For compatibility with the old profiler, the numeric arguments -1, 0, 1, and 2 are permitted. They are interpreted as 'stdname', 'calls', 'time', and 'cumulative' respectively. If this old style format (numeric) is used, only one sort key (the numeric key) will be used, and additional arguments will be silently ignored.

**reverse_order()**

This method for the Stats class reverses the ordering of the basic list within the object. This method is provided primarily for compatibility with
the old profiler. Its utility is questionable now that ascending vs descending order is properly selected based on the sort key of choice.

print_stats([restriction, ...])
This method for the Stats class prints out a report as described in the profile.run() definition.

The order of the printing is based on the last sort_stats() operation done on the object (subject to caveats in add() and strip_dirs()).

The arguments provided (if any) can be used to limit the list down to the significant entries. Initially, the list is taken to be the complete set of profiled functions. Each restriction is either an integer (to select a count of lines), or a decimal fraction between 0.0 and 1.0 inclusive (to select a percentage of lines), or a regular expression (to pattern match the standard name that is printed; as of Python 1.5b1, this uses the Perl-style regular expression syntax defined by the re module). If several restrictions are provided, then they are applied sequentially. For example:

```
pattern Stats
```

```
print_stats(.1, 'foo:')
```

would first limit the printing to first 10% of list, and then only print functions that were part of filename .*foo:. In contrast, the command:

```
pattern Stats
```

```
print_stats('foo:', .1)
```

would limit the list to all functions having file names .*foo:, and then proceed to only print the first 10% of them.

print_callers([restriction, ...])
This method for the Stats class prints a list of all functions that called each function in the profiled database. The ordering is identical to that provided by print_stats(), and the definition of the restricting argument is also identical. For convenience, a number is shown in parentheses after each caller to show how many times this specific call was made. A second non-parenthesized number is the cumulative time spent in the function at the right.

print_callees([restriction, ...])
This method for the Stats class prints a list of all function that were called by the indicated function. Aside from this reversal of direction of calls (re: called vs was called by), the arguments and ordering are identical to the print_callers() method.

**ignore()**

**Deprecated since release 1.5.1.** This is not needed in modern versions of Python.¹⁰²

---

### Footnotes

... Python.¹⁰²

This was once necessary, when Python would print any unused expression result that was not `None`. The method is still defined for backward compatibility.

---

*Python Library Reference*

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
10.6 Limitations

One limitation has to do with accuracy of timing information. There is a fundamental problem with deterministic profilers involving accuracy. The most obvious restriction is that the underlying ``clock'' is only ticking at a rate (typically) of about .001 seconds. Hence no measurements will be more accurate than the underlying clock. If enough measurements are taken, then the ``error'' will tend to average out. Unfortunately, removing this first error induces a second source of error.

The second problem is that it ``takes a while'' from when an event is dispatched until the profiler's call to get the time actually gets the state of the clock. Similarly, there is a certain lag when exiting the profiler event handler from the time that the clock's value was obtained (and then squirreled away), until the user's code is once again executing. As a result, functions that are called many times, or call many functions, will typically accumulate this error. The error that accumulates in this fashion is typically less than the accuracy of the clock (less than one clock tick), but it can accumulate and become very significant. This profiler provides a means of calibrating itself for a given platform so that this error can be probabilistically (on the average) removed. After the profiler is calibrated, it will be more accurate (in a least square sense), but it will sometimes produce negative numbers (when call counts are exceptionally low, and the gods of probability work against you :-). ) Do not be alarmed by negative numbers in the profile. They should only appear if you have calibrated your profiler, and the results are actually better than without calibration.
10.7 Calibration

The profiler subtracts a constant from each event handling time to compensate for the overhead of calling the time function, and socking away the results. By default, the constant is 0. The following procedure can be used to obtain a better constant for a given platform (see discussion in section Limitations above).

```python
import profile
pr = profile.Profile()
for i in range(5):
    print pr.calibrate(10000)
```

The method executes the number of Python calls given by the argument, directly and again under the profiler, measuring the time for both. It then computes the hidden overhead per profiler event, and returns that as a float. For example, on an 800 MHz Pentium running Windows 2000, and using Python’s time.clock() as the timer, the magical number is about 12.5e-6.

The object of this exercise is to get a fairly consistent result. If your computer is very fast, or your timer function has poor resolution, you might have to pass 100000, or even 1000000, to get consistent results.

When you have a consistent answer, there are three ways you can use it:

```python
import profile

# 1. Apply computed bias to all Profile instances created hereafter.
profile.Profile.bias = your_computed_bias

# 2. Apply computed bias to a specific Profile instance.
pr = profile.Profile()
pr.bias = your_computed_bias

# 3. Specify computed bias in instance constructor.
pr = profile.Profile(bias=your_computed_bias)
```

If you have a choice, you are better off choosing a smaller constant, and then your results will `\`less often" show up as negative in profile statistics.
Footnotes

... it: 10.3

Prior to Python 2.2, it was necessary to edit the profiler source code to embed the bias as a literal number. You still can, but that method is no longer described, because no longer needed.
10.8 Extensions -- Deriving Better Profilers

The Profile class of module profile was written so that derived classes could be developed to extend the profiler. The details are not described here, as doing this successfully requires an expert understanding of how the Profile class works internally. Study the source code of module profile carefully if you want to pursue this.

If all you want to do is change how current time is determined (for example, to force use of wall-clock time or elapsed process time), pass the timing function you want to the Profile class constructor:

```
pr = profile.Profile(your_time_func)
```

The resulting profiler will then call `your_time_func()`. The function should return a single number, or a list of numbers whose sum is the current time (like what `os.times()` returns). If the function returns a single time number, or the list of returned numbers has length 2, then you will get an especially fast version of the dispatch routine.

Be warned that you should calibrate the profiler class for the timer function that you choose. For most machines, a timer that returns a lone integer value will provide the best results in terms of low overhead during profiling. `(os.times())` is pretty bad, as it returns a tuple of floating point values). If you want to substitute a better timer in the cleanest fashion, derive a class and hardwire a replacement dispatch method that best handles your timer call, along with the appropriate calibration constant.
10.9 hotshot -- High performance logging profiler

New in version 2.2.

This module provides a nicer interface to the _hotshot C module. Hotshot is a replacement for the existing profile module. As it's written mostly in C, it should result in a much smaller performance impact than the existing profile module.

Warning: The hotshot profiler does not yet work well with threads. It is useful to use an unthreaded script to run the profiler over the code you're interested in measuring if at all possible.

class Profile( logfile[, lineevents[, linetimings]])
The profiler object. The argument logfile is the name of a log file to use for logged profile data. The argument lineevents specifies whether to generate events for every source line, or just on function call/return. It defaults to 0 (only log function call/return). The argument linetimings specifies whether to record timing information. It defaults to 1 (store timing information).

Subsections

- 10.9.1 Profile Objects
- 10.9.2 Using hotshot data
- 10.9.3 Example Usage

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
10.9.1 Profile Objects

Profile objects have the following methods:

**addinfo**(key, value)

Add an arbitrary labelled value to the profile output.

**close**( )

Close the logfile and terminate the profiler.

**fileno**( )

Return the file descriptor of the profiler's log file.

**run**(cmd)

Profile an exec-compatible string in the script environment. The globals from the **main** module are used as both the globals and locals for the script.

**runcall**(func, *args, **keywords)

Profile a single call of a callable. Additional positional and keyword arguments may be passed along; the result of the call is returned, and exceptions are allowed to propagate cleanly, while ensuring that profiling is disabled on the way out.

**runctx**(cmd, globals, locals)

Evaluate an exec-compatible string in a specific environment. The string is compiled before profiling begins.

**start**( )

Start the profiler.

**stop**( )

Stop the profiler.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
10.9.2 Using hotshot data

New in version 2.2.

This module loads hotshot profiling data into the standard `pstats` Stats objects.

```
load(filename)
```

Load hotshot data from `filename`. Returns an instance of the `pstats.Stats` class.

See Also:

Module `profile`:
The `profile` module's `Stats` class.
### 10.9.3 Example Usage

Note that this example runs the python `"benchmark"` pystones. It can take some time to run, and will produce large output files.

```python
>>> import hotshot, hotshot.stats, test.pystone
>>> prof = hotshot.Profile("stones.prof")
>>> benchtime, stones = prof.runcall(test.pystone.pystones)
>>> prof.close()
>>> stats = hotshot.stats.load("stones.prof")
>>> stats.strip_dirs()
>>> stats.sort_stats('time', 'calls')
>>> stats.print_stats(20)

850004 function calls in 10.090 CPU seconds

Ordered by: internal time, call count

Previous: [10.9.2 Using hotshot data](#) Up: [10.9 hotshot](#) Next: [10.10 timeit](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.*

*See [About this document...](#) for information on suggesting changes.*
10.10 timeit -- Measure execution time of small code snippets

New in version 2.3.

This module provides a simple way to time small bits of Python code. It has both command line as well as callable interfaces. It avoids a number of common traps for measuring execution times. See also Tim Peters' introduction to the "Algorithms" chapter in the Python Cookbook, published by O'Reilly.

The module defines the following public class:

```python
class Timer([stmt='pass' [, setup='pass' [, timer=<timer function>]]])
    Class for timing execution speed of small code snippets.
    The constructor takes a statement to be timed, an additional statement used for setup, and a timer function. Both statements default to 'pass'; the timer function is platform-dependent (see the module doc string). The statements may contain newlines, as long as they don't contain multi-line string literals.
    To measure the execution time of the first statement, use the timeit() method. The repeat() method is a convenience to call timeit() multiple times and return a list of results.
```

```python
print_exc([file=None])
    Helper to print a traceback from the timed code.
```

Typical use:

```python
t = Timer(...)  # outside the try/except
try:
    t.timeit(...)  # or t.repeat(...)
except:
    t.print_exc()
```
The advantage over the standard traceback is that source lines in the compiled template will be displayed. The optional file argument directs where the traceback is sent; it defaults to sys.stderr.

```
repeat([repeat=3, number=1000000])
```

Call `timeit()` a few times.

This is a convenience function that calls the `timeit()` repeatedly, returning a list of results. The first argument specifies how many times to call `timeit()`. The second argument specifies the `number` argument for `timeit()`.

```
Note: It's tempting to calculate mean and standard deviation from the result vector and report these. However, this is not very useful. In a typical case, the lowest value gives a lower bound for how fast your machine can run the given code snippet; higher values in the result vector are typically not caused by variability in Python's speed, but by other processes interfering with your timing accuracy. So the min() of the result is probably the only number you should be interested in. After that, you should look at the entire vector and apply common sense rather than statistics.
```

```
timeit([number=1000000])
```

Time `number` executions of the main statement. This executes the setup statement once, and then returns the time it takes to execute the main statement a number of times, measured in seconds as a float. The argument is the number of times through the loop, defaulting to one million. The main statement, the setup statement and the timer function to be used are passed to the constructor.

```
Note: By default, `timeit()` temporarily turns off garbage collection during the timing. The advantage of this approach is that it makes independent timings more comparable. This disadvantage is that GC may be an
important component of the performance of the function being measured. If so, GC can be re-enabled as the first statement in the setup string. For example:

```python
timeit.Timer('for i in xrange(10): oct(i)', 'gc.enable()').timeit()
```
Section 10.10.1: Command Line Interface

When called as a program from the command line, the following form is used:

```
python timeit.py [-n N] [-r N] [-s S] [-t] [-c] [-h] [statement ...]
```

where the following options are understood:

- `-n N`/`--number=N`
  how many times to execute 'statement'

- `-r N`/`--repeat=N`
  how many times to repeat the timer (default 3)

- `-s S`/`--setup=S`
  statement to be executed once initially (default 'pass')

- `-t`/`--time`
  use `time.time()` (default on all platforms but Windows)

- `-c`/`--clock`
  use `time.clock()` (default on Windows)

- `-v`/`--verbose`
  print raw timing results; repeat for more digits precision

- `-h`/`--help`
  print a short usage message and exit

A multi-line statement may be given by specifying each line as a separate statement argument; indented lines are possible by enclosing an argument in quotes and using leading spaces. Multiple `-s` options are treated similarly.

If `-n` is not given, a suitable number of loops is calculated by trying successive powers of 10 until the total time is at least 0.2 seconds.

The default timer function is platform dependent. On Windows, `time.clock()` has microsecond granularity but `time.time()`'s granularity is 1/60th of a second; on UNIX, `time.clock()` has 1/100th of a second granularity and `time.time()` is much more precise. On either platform, the default timer functions measure wall clock time, not the CPU time. This means that other processes running on the same computer may interfere with the timing. The best thing to do when accurate timing is necessary is to repeat the timing a few times and use the best time. The `-r` option is good for this; the
default of 3 repetitions is probably enough in most cases. On UNIX, you can use `time.clock()` to measure CPU time.

**Note:** There is a certain baseline overhead associated with executing a pass statement. The code here doesn't try to hide it, but you should be aware of it. The baseline overhead can be measured by invoking the program without arguments.

The baseline overhead differs between Python versions! Also, to fairly compare older Python versions to Python 2.3, you may want to use Python's `-O` option for the older versions to avoid timing `SET_LINENO` instructions.
10.10.2 Examples

Here are two example sessions (one using the command line, one using the module interface) that compare the cost of using `hasattr()` vs. `try/except` to test for missing and present object attributes.

```python
% timeit.py 'try:' '		str.__nonzero__' 'except AttributeError:' '	pass'
100000 loops, best of 3: 15.7 usec per loop
% timeit.py 'if hasattr(str, "__nonzero__"): pass'
100000 loops, best of 3: 4.26 usec per loop
% timeit.py 'try:' '		int.__nonzero__' 'except AttributeError:' '	pass'
1000000 loops, best of 3: 1.43 usec per loop
% timeit.py 'if hasattr(int, "__nonzero__"): pass'
100000 loops, best of 3: 2.23 usec per loop

>>> import timeit
>>> s = """\n... try:
... 	str.__nonzero__
... except AttributeError:
... 	pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000
17.09 usec/pass
>>> s = """\n... if hasattr(str, '__nonzero__'): pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000
4.85 usec/pass
>>> s = """\n... try:
... 	int.__nonzero__
... except AttributeError:
... 	pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000
1.97 usec/pass
>>> s = """\n... if hasattr(int, '__nonzero__'): pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000
3.15 usec/pass
```

To give the `timeit` module access to functions you define, you can pass a
setup parameter which contains an import statement:

```python
def test():
    "Stupid test function"
    L = []
    for i in range(100):
        L.append(i)

if __name__=='__main__':
    from timeit import Timer
    t = Timer("test()", "from __main__ import test")
    print t.timeit()
```

Python Library Reference

Previous: 10.10.1 Command Line Interface    Up: 10.10 timeit    Next: 11. Internet Protocols and

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11. Internet Protocols and Support

The modules described in this chapter implement Internet protocols and support for related technology. They are all implemented in Python. Most of these modules require the presence of the system-dependent module `socket`, which is currently supported on most popular platforms. Here is an overview:

- **webbrowser**
  Easy-to-use controller for Web browsers.

- **cgi**
  Common Gateway Interface support, used to interpret forms in server-side scripts.

- **cgitb**
  Configurable traceback handler for CGI scripts.

- **urllib**
  Open an arbitrary network resource by URL (requires sockets).

- **urllib2**
  An extensible library for opening URLs using a variety of protocols

- **httplib**
  HTTP and HTTPS protocol client (requires sockets).

- **ftplib**
  FTP protocol client (requires sockets).

- **gopherlib**
  Gopher protocol client (requires sockets).

- **poplib**
  POP3 protocol client (requires sockets).

- **imaplib**
  IMAP4 protocol client (requires sockets).

- **nntplib**
  NNTP protocol client (requires sockets).

- **smtplib**
  SMTP protocol client (requires sockets).

- **smtpd**
  Implement a flexible SMTP server

- **telnetlib**
  Telnet client class.

- **urlparse**
  Parse URLs into components.

- **SocketServer**
  A framework for network servers.

- **BaseHTTPServer**
  Basic HTTP server (base class for SimpleHTTPServer and CGIHTTPServer).

- **SimpleHTTPServer**
  This module provides a basic request handler for HTTP servers.

- **CGIHTTPServer**
  This module provides a request handler for HTTP servers which can run CGI scripts.
**cookielib**

Cookie handling for HTTP clients

**Cookie**

Support for HTTP state management (cookies).

**xmlrpclib**

XML-RPC client access.

**SimpleXMLRPCServer**

Basic XML-RPC server implementation.

**DocXMLRPCServer**

Self-documenting XML-RPC server implementation.

**asyncore**

A base class for developing asynchronous socket handling services.

**asynchat**

Support for asynchronous command/response protocols.

---

Previous: 10.10.2 Examples  Up: Python Library Reference  Next: 11.1

webbrowser

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.1 webbrowser -- Convenient Web-browser controller

The webbrowser module provides a very high-level interface to allow displaying Web-based documents to users. The controller objects are easy to use and are platform-independent. Under most circumstances, simply calling the `open()` function from this module will do the right thing.

Under **UNIX**, graphical browsers are preferred under X11, but text-mode browsers will be used if graphical browsers are not available or an X11 display isn't available. If text-mode browsers are used, the calling process will block until the user exits the browser.

Under **UNIX**, if the environment variable BROWSER exists, it is interpreted to override the platform default list of browsers, as a colon-separated list of browsers to try in order. When the value of a list part contains the string `%s`, then it is interpreted as a literal browser command line to be used with the argument URL substituted for the `%s`; if the part does not contain `%s`, it is simply interpreted as the name of the browser to launch.

For non-**UNIX** platforms, or when X11 browsers are available on **UNIX**, the controlling process will not wait for the user to finish with the browser, but allow the browser to maintain its own window on the display.

The following exception is defined:

**exception Error**

Exception raised when a browser control error occurs.

The following functions are defined:

```python
open(url[, new=0][, autoraise=1])
```

Display `url` using the default browser. If `new` is true, a new browser window is opened if possible. If `autoraise` is true, the window is raised if possible (note that under many window managers this will occur regardless of the setting of this variable).
open_new(url)
Open url in a new window of the default browser, if possible, otherwise, open url in the only browser window.

get([name])
Return a controller object for the browser type name. If name is empty, return a controller for a default browser appropriate to the caller's environment.

register(name, constructor[, instance])
Register the browser type name. Once a browser type is registered, the get() function can return a controller for that browser type. If instance is not provided, or is None, constructor will be called without parameters to create an instance when needed. If instance is provided, constructor will never be called, and may be None.

This entry point is only useful if you plan to either set the BROWSER variable or call get with a nonempty argument matching the name of a handler you declare.

A number of browser types are predefined. This table gives the type names that may be passed to the get() function and the corresponding instantiations for the controller classes, all defined in this module.

<table>
<thead>
<tr>
<th>Type Name</th>
<th>Class Name</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'mozilla'</td>
<td>Netscape('mozilla')</td>
<td></td>
</tr>
<tr>
<td>'netscape'</td>
<td>Netscape('netscape')</td>
<td></td>
</tr>
<tr>
<td>'mosaic'</td>
<td>GenericBrowser('mosaic %s &amp;')</td>
<td></td>
</tr>
<tr>
<td>'kfm'</td>
<td>Konqueror()</td>
<td>(1)</td>
</tr>
<tr>
<td>'grail'</td>
<td>Grail()</td>
<td></td>
</tr>
<tr>
<td>'links'</td>
<td>GenericBrowser('links %s')</td>
<td></td>
</tr>
<tr>
<td>'lynx'</td>
<td>GenericBrowser('lynx %s')</td>
<td></td>
</tr>
<tr>
<td>'w3m'</td>
<td>GenericBrowser('w3m %s')</td>
<td></td>
</tr>
<tr>
<td>'windows-default'</td>
<td>WindowsDefault</td>
<td>(2)</td>
</tr>
</tbody>
</table>
Notes:

(1) ``Konqueror'' is the file manager for the KDE desktop environment for UNIX, and only makes sense to use if KDE is running. Some way of reliably detecting KDE would be nice; the KDEDIR variable is not sufficient. Note also that the name ``kfm'' is used even when using the konqueror command with KDE 2 --- the implementation selects the best strategy for running Konqueror.

(2) Only on Windows platforms; requires the common extension modules win32api and win32con.

(3) Only on MacOS platforms; requires the standard MacPython ic module, described in the Macintosh Library Modules manual.
11.1.1 Browser Controller Objects

Browser controllers provide two methods which parallel two of the module-level convenience functions:

**open** *(url[, new])*
Display *url* using the browser handled by this controller. If *new* is true, a new browser window is opened if possible.

**open_new** *(url)*
Open *url* in a new window of the browser handled by this controller, if possible, otherwise, open *url* in the only browser window.
11.2 cgi -- Common Gateway Interface support.

Support module for Common Gateway Interface (CGI) scripts.

This module defines a number of utilities for use by CGI scripts written in Python.

Subsections

- 11.2.1 Introduction
- 11.2.2 Using the cgi module
- 11.2.3 Higher Level Interface
- 11.2.4 Old classes
- 11.2.5 Functions
- 11.2.6 Caring about security
- 11.2.7 Installing your CGI script on a UNIX system
- 11.2.8 Testing your CGI script
- 11.2.9 Debugging CGI scripts
- 11.2.10 Common problems and solutions

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.2.1 Introduction

A CGI script is invoked by an HTTP server, usually to process user input submitted through an HTML `<FORM>` or `<ISINDEX>` element.

Most often, CGI scripts live in the server's special `cgi-bin` directory. The HTTP server places all sorts of information about the request (such as the client's hostname, the requested URL, the query string, and lots of other goodies) in the script's shell environment, executes the script, and sends the script's output back to the client.

The script's input is connected to the client too, and sometimes the form data is read this way; at other times the form data is passed via the ``query string'' part of the URL. This module is intended to take care of the different cases and provide a simpler interface to the Python script. It also provides a number of utilities that help in debugging scripts, and the latest addition is support for file uploads from a form (if your browser supports it).

The output of a CGI script should consist of two sections, separated by a blank line. The first section contains a number of headers, telling the client what kind of data is following. Python code to generate a minimal header section looks like this:

```python
print "Content-Type: text/html"  # HTML is following
print ""  # blank line, end of headers
```

The second section is usually HTML, which allows the client software to display nicely formatted text with header, in-line images, etc. Here's Python code that prints a simple piece of HTML:

```python
print "<TITLE>CGI script output</TITLE>"
print "<H1>This is my first CGI script</H1>"
print "Hello, world!"
```
11.2.2 Using the cgi module

Begin by writing "import cgi". Do not use "from cgi import *" -- the module defines all sorts of names for its own use or for backward compatibility that you don't want in your namespace.

When you write a new script, consider adding the line:

   import cgitb; cgitb.enable()

This activates a special exception handler that will display detailed reports in the Web browser if any errors occur. If you'd rather not show the guts of your program to users of your script, you can have the reports saved to files instead, with a line like this:

   import cgitb; cgitb.enable(display=0, logdir="/tmp")

It's very helpful to use this feature during script development. The reports produced by cgitb provide information that can save you a lot of time in tracking down bugs. You can always remove the cgitb line later when you have tested your script and are confident that it works correctly.

To get at submitted form data, it's best to use the FieldStorage class. The other classes defined in this module are provided mostly for backward compatibility. Instantiate it exactly once, without arguments. This reads the form contents from standard input or the environment (depending on the value of various environment variables set according to the CGI standard). Since it may consume standard input, it should be instantiated only once.

The FieldStorage instance can be indexed like a Python dictionary, and also supports the standard dictionary methods has_key() and keys(). The built-in len() is also supported. Form fields containing empty strings are ignored and do not appear in the dictionary; to keep such values, provide a true value for the optional keep_blank_values keyword parameter when creating the FieldStorage instance.

For instance, the following code (which assumes that the Content-Type: header and blank line have already been printed) checks that the fields name and addr
are both set to a non-empty string:

    form = cgi.FieldStorage()
    if not (form.has_key("name") and form.has_key("addr")):
        print "<H1>Error</H1>"
        print "Please fill in the name and addr fields."
        return
    print "<p>name: ", form["name"].value
    print "<p>addr: ", form["addr"].value
    ...

Here the fields, accessed through "form[key]", are themselves instances of FieldStorage (or MiniFieldStorage, depending on the form encoding). The value attribute of the instance yields the string value of the field. The getValue() method returns this string value directly; it also accepts an optional second argument as a default to return if the requested key is not present.

If the submitted form data contains more than one field with the same name, the object retrieved by "form[key]" is not a FieldStorage or MiniFieldStorage instance but a list of such instances. Similarly, in this situation, "form.getValue(key)" would return a list of strings. If you expect this possibility (when your HTML form contains multiple fields with the same name), use the getlist() function, which always returns a list of values (so that you do not need to special-case the single item case). For example, this code concatenates any number of username fields, separated by commas:

    value = form.getlist("username")
    usernames = ",".join(value)

If a field represents an uploaded file, accessing the value via the value attribute or the getValue() method reads the entire file in memory as a string. This may not be what you want. You can test for an uploaded file by testing either the filename attribute or the file attribute. You can then read the data at leisure from the file attribute:

    fileitem = form["userfile"]
    if fileitem.file:
        # It's an uploaded file; count lines
        linecount = 0
        while 1:
            line = fileitem.file.readline()
            if not line: break
            linecount = linecount + 1
The file upload draft standard entertains the possibility of uploading multiple files from one field (using a recursive multipart/* encoding). When this occurs, the item will be a dictionary-like FieldStorage item. This can be determined by testing its type attribute, which should be multipart/form-data (or perhaps another MIME type matching multipart/*). In this case, it can be iterated over recursively just like the top-level form object.

When a form is submitted in the ``old'' format (as the query string or as a single data part of type application/x-www-form-urlencoded), the items will actually be instances of the class MiniFieldStorage. In this case, the list, file, and filename attributes are always None.
11.2.3 Higher Level Interface

New in version 2.2.

The previous section explains how to read CGI form data using the FieldStorage class. This section describes a higher level interface which was added to this class to allow one to do it in a more readable and intuitive way. The interface doesn't make the techniques described in previous sections obsolete -- they are still useful to process file uploads efficiently, for example.

The interface consists of two simple methods. Using the methods you can process form data in a generic way, without the need to worry whether only one or more values were posted under one name.

In the previous section, you learned to write following code anytime you expected a user to post more than one value under one name:

```python
item = form.getvalue("item")
if isinstance(item, list):
    # The user is requesting more than one item.
else:
    # The user is requesting only one item.
```

This situation is common for example when a form contains a group of multiple checkboxes with the same name:

```html
<input type="checkbox" name="item" value="1" />
<input type="checkbox" name="item" value="2" />
```

In most situations, however, there's only one form control with a particular name in a form and then you expect and need only one value associated with this name. So you write a script containing for example this code:

```python
user = form.getvalue("user").upper()
```

The problem with the code is that you should never expect that a client will provide valid input to your scripts. For example, if a curious user appends another "user=foo" pair to the query string, then the script would crash, because in this situation the `getvalue("user")` method call returns a list instead of a string. Calling the `toupper()` method on a list is not valid (since
lists do not have a method of this name) and results in an `AttributeError` exception.

Therefore, the appropriate way to read form data values was to always use the code which checks whether the obtained value is a single value or a list of values. That's annoying and leads to less readable scripts.

A more convenient approach is to use the methods `getfirst()` and `getlist()` provided by this higher level interface.

**getfirst**( *name*, *default* )

This method always returns only one value associated with form field *name*. The method returns only the first value in case that more values were posted under such name. Please note that the order in which the values are received may vary from browser to browser and should not be counted on.

If no such form field or value exists then the method returns the value specified by the optional parameter *default*. This parameter defaults to `None` if not specified.

**getlist**( *name* )

This method always returns a list of values associated with form field *name*. The method returns an empty list if no such form field or value exists for *name*. It returns a list consisting of one item if only one such value exists.

Using these methods you can write nice compact code:

```python
import cgi
form = cgi.FieldStorage()
user = form.getfirst("user", "").upper()  # This way it's safe.
for item in form.getlist("item"):
    do_something(item)
```

---

**Footnotes**

... on.

Note that some recent versions of the HTML specification do state what order the field values should be supplied in, but knowing whether a request was received from a conforming browser, or even from a browser at all, is
tedious and error-prone.
11.2.4 Old classes

These classes, present in earlier versions of the `cgi` module, are still supported for backward compatibility. New applications should use the `FieldStorage` class.

`SvFormContentDict` stores single value form content as dictionary; it assumes each field name occurs in the form only once.

`FormContentDict` stores multiple value form content as a dictionary (the form items are lists of values). Useful if your form contains multiple fields with the same name.

Other classes (`FormContent`, `InterpFormContentDict`) are present for backwards compatibility with really old applications only. If you still use these and would be inconvenienced when they disappeared from a next version of this module, drop me a note.
11.2.5 Functions

These are useful if you want more control, or if you want to employ some of the algorithms implemented in this module in other circumstances.

```
parse(fp[, keep_blank_values[, strict_parsing]])
```

Parse a query in the environment or from a file (the file defaults to `sys.stdin`). The `keep_blank_values` and `strict_parsing` parameters are passed to `parse_qs()` unchanged.

```
parse_qs(qs[, keep_blank_values[, strict_parsing]])
```

Parse a query string given as a string argument (data of type `application/x-www-form-urlencoded`). Data are returned as a dictionary. The dictionary keys are the unique query variable names and the values are lists of values for each name.

The optional argument `keep_blank_values` is a flag indicating whether blank values in URL encoded queries should be treated as blank strings. A true value indicates that blanks should be retained as blank strings. The default false value indicates that blank values are to be ignored and treated as if they were not included.

The optional argument `strict_parsing` is a flag indicating what to do with parsing errors. If false (the default), errors are silently ignored. If true, errors raise a `ValueError` exception.

Use the `urllib.urlencode()` function to convert such dictionaries into query strings.

```
parse_qsl(qs[, keep_blank_values[, strict_parsing]])
```

Parse a query string given as a string argument (data of type `application/x-www-form-urlencoded`). Data are returned as a list of name, value pairs.

The optional argument `keep_blank_values` is a flag indicating whether blank values in URL encoded queries should be treated as blank strings. A true value indicates that blanks should be retained as blank strings. The default false value indicates that blank values are to be ignored and treated
as if they were not included.

The optional argument `strict_parsing` is a flag indicating what to do with parsing errors. If false (the default), errors are silently ignored. If true, errors raise a `ValueError` exception.

Use the `urllib.urlencode()` function to convert such lists of pairs into query strings.

**parse_multipart**\( (fp, pdict) \)
Parse input of type `multipart/form-data` (for file uploads). Arguments are `fp` for the input file and `pdict` for a dictionary containing other parameters in the Content-Type: header.

Returns a dictionary just like `parse_qs()` keys are the field names, each value is a list of values for that field. This is easy to use but not much good if you are expecting megabytes to be uploaded -- in that case, use the `FieldStorage` class instead which is much more flexible.

Note that this does not parse nested multipart parts -- use `FieldStorage` for that.

**parse_header**\( (string) \)
Parse a MIME header (such as Content-Type:) into a main value and a dictionary of parameters.

**test()**
Robust test CGI script, usable as main program. Writes minimal HTTP headers and formats all information provided to the script in HTML form.

**print_environ()**
Format the shell environment in HTML.

**print_form**(form)
Format a form in HTML.

**print_directory()**
Format the current directory in HTML.
print_environ_usage()
Print a list of useful (used by CGI) environment variables in HTML.

escape(s[, quote])
Convert the characters "&", "<" and ">" in string s to HTML-safe sequences. Use this if you need to display text that might contain such characters in HTML. If the optional flag quote is true, the double-quote character ("""") is also translated; this helps for inclusion in an HTML attribute value, as in <A HREF="...">. If the value to be quoted might include single- or double-quote characters, or both, consider using the quoteattr() function in the xml.sax.saxutils module instead.
11.2.6 Caring about security

There's one important rule: if you invoke an external program (via the `os.system()` or `os.popen()` functions or others with similar functionality), make very sure you don't pass arbitrary strings received from the client to the shell. This is a well-known security hole whereby clever hackers anywhere on the Web can exploit a gullible CGI script to invoke arbitrary shell commands. Even parts of the URL or field names cannot be trusted, since the request doesn't have to come from your form!

To be on the safe side, if you must pass a string gotten from a form to a shell command, you should make sure the string contains only alphanumeric characters, dashes, underscores, and periods.
11.2.7 Installing your CGI script on a UNIX system

Read the documentation for your HTTP server and check with your local system administrator to find the directory where CGI scripts should be installed; usually this is in a directory cgi-bin in the server tree.

Make sure that your script is readable and executable by ``others''; the UNIX file mode should be 0755 octal (use "chmod 0755 filename"). Make sure that the first line of the script contains #! starting in column 1 followed by the pathname of the Python interpreter, for instance:

```bash
#!/usr/local/bin/python
```

Make sure the Python interpreter exists and is executable by ``others''.

Make sure that any files your script needs to read or write are readable or writable, respectively, by ``others'' -- their mode should be 0644 for readable and 0666 for writable. This is because, for security reasons, the HTTP server executes your script as user ``nobody'', without any special privileges. It can only read (write, execute) files that everybody can read (write, execute). The current directory at execution time is also different (it is usually the server's cgi-bin directory) and the set of environment variables is also different from what you get when you log in. In particular, don't count on the shell's search path for executables (PATH) or the Python module search path (PYTHONPATH) to be set to anything interesting.

If you need to load modules from a directory which is not on Python's default module search path, you can change the path in your script, before importing other modules. For example:

```python
import sys
sys.path.insert(0, "/usr/home/joe/lib/python")
sys.path.insert(0, "/usr/local/lib/python")
```

(This way, the directory inserted last will be searched first!)

Instructions for non-UNIX systems will vary; check your HTTP server's documentation (it will usually have a section on CGI scripts).
11.2.8 Testing your CGI script

Unfortunately, a CGI script will generally not run when you try it from the command line, and a script that works perfectly from the command line may fail mysteriously when run from the server. There's one reason why you should still test your script from the command line: if it contains a syntax error, the Python interpreter won't execute it at all, and the HTTP server will most likely send a cryptic error to the client.

Assuming your script has no syntax errors, yet it does not work, you have no choice but to read the next section.
11.2.9 Debugging CGI scripts

First of all, check for trivial installation errors -- reading the section above on installing your CGI script carefully can save you a lot of time. If you wonder whether you have understood the installation procedure correctly, try installing a copy of this module file (cgi.py) as a CGI script. When invoked as a script, the file will dump its environment and the contents of the form in HTML form. Give it the right mode etc, and send it a request. If it's installed in the standard cgi-bin directory, it should be possible to send it a request by entering a URL into your browser of the form:

http://yourhostname/cgi-bin/cgi.py?name=Joe+Blow&addr=At+Home

If this gives an error of type 404, the server cannot find the script - perhaps you need to install it in a different directory. If it gives another error, there's an installation problem that you should fix before trying to go any further. If you get a nicely formatted listing of the environment and form content (in this example, the fields should be listed as ``addr'' with value ``At Home'' and ``name'' with value ``Joe Blow''), the cgi.py script has been installed correctly. If you follow the same procedure for your own script, you should now be able to debug it.

The next step could be to call the cgi module's test() function from your script: replace its main code with the single statement

cgi.test()

This should produce the same results as those gotten from installing the cgi.py file itself.

When an ordinary Python script raises an unhandled exception (for whatever reason: of a typo in a module name, a file that can't be opened, etc.), the Python interpreter prints a nice traceback and exits. While the Python interpreter will still do this when your CGI script raises an exception, most likely the traceback will end up in one of the HTTP server's log files, or be discarded altogether.

Fortunately, once you have managed to get your script to execute some code, you can easily send tracebacks to the Web browser using the cgitb module. If you
haven't done so already, just add the line:

   import cgitb; cgitb.enable()

to the top of your script. Then try running it again; when a problem occurs, you should see a detailed report that will likely make apparent the cause of the crash.

If you suspect that there may be a problem in importing the `cgitb` module, you can use an even more robust approach (which only uses built-in modules):

   import sys
   sys.stderr = sys.stdout
   print "Content-Type: text/plain"
   print
   ...your code here...

This relies on the Python interpreter to print the traceback. The content type of the output is set to plain text, which disables all HTML processing. If your script works, the raw HTML will be displayed by your client. If it raises an exception, most likely after the first two lines have been printed, a traceback will be displayed. Because no HTML interpretation is going on, the traceback will be readable.
11.2.10 Common problems and solutions

- Most HTTP servers buffer the output from CGI scripts until the script is completed. This means that it is not possible to display a progress report on the client's display while the script is running.

- Check the installation instructions above.

- Check the HTTP server's log files. ("tail -f logfile" in a separate window may be useful!)

- Always check a script for syntax errors first, by doing something like "python script.py".

- If your script does not have any syntax errors, try adding "import cgitb; cgitb.enable()" to the top of the script.

- When invoking external programs, make sure they can be found. Usually, this means using absolute path names -- PATH is usually not set to a very useful value in a CGI script.

- When reading or writing external files, make sure they can be read or written by the userid under which your CGI script will be running: this is typically the userid under which the web server is running, or some explicitly specified userid for a web server's "suexec" feature.

- Don't try to give a CGI script a set-uid mode. This doesn't work on most systems, and is a security liability as well.
11.3 cgitb -- Traceback manager for CGI scripts

New in version 2.2.

The cgitb module provides a special exception handler for Python scripts. (Its name is a bit misleading. It was originally designed to display extensive traceback information in HTML for CGI scripts. It was later generalized to also display this information in plain text.) After this module is activated, if an uncaught exception occurs, a detailed, formatted report will be displayed. The report includes a traceback showing excerpts of the source code for each level, as well as the values of the arguments and local variables to currently running functions, to help you debug the problem. Optionally, you can save this information to a file instead of sending it to the browser.

To enable this feature, simply add one line to the top of your CGI script:

```
import cgitb; cgitb.enable()
```

The options to the `enable()` function control whether the report is displayed in the browser and whether the report is logged to a file for later analysis.

```
enable([display[, logdir[, context[, format]]]])
```

This function causes the `cgitb` module to take over the interpreter's default handling for exceptions by setting the value of `sys.excepthook`.

The optional argument `display` defaults to 1 and can be set to 0 to suppress sending the traceback to the browser. If the argument `logdir` is present, the traceback reports are written to files. The value of `logdir` should be a directory where these files will be placed. The optional argument `context` is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5. If the optional argument `format` is "html", the output is formatted as HTML. Any other value forces plain text output. The default value is "html".

```
handler([info])
```
This function handles an exception using the default settings (that is, show a report in the browser, but don't log to a file). This can be used when you've caught an exception and want to report it using cgitb. The optional info argument should be a 3-tuple containing an exception type, exception value, and traceback object, exactly like the tuple returned by \texttt{sys.exc_info()}. If the info argument is not supplied, the current exception is obtained from \texttt{sys.exc_info()}.

11.4 urllib -- Open arbitrary resources by URL

This module provides a high-level interface for fetching data across the World Wide Web. In particular, the `urlopen()` function is similar to the built-in function `open()`, but accepts Universal Resource Locators (URLs) instead of filenames. Some restrictions apply -- it can only open URLs for reading, and no seek operations are available.

It defines the following public functions:

`urlopen(url[, data[, proxies]])`

Open a network object denoted by a URL for reading. If the URL does not have a scheme identifier, or if it has `file:` as its scheme identifier, this opens a local file (without universal newlines); otherwise it opens a socket to a server somewhere on the network. If the connection cannot be made the IOError exception is raised. If all went well, a file-like object is returned. This supports the following methods: `read()`, `readline()`, `readlines()`, `fileno()`, `close()`, `info()` and `geturl()`. It also has proper support for the iterator protocol. One caveat: the `read()` method, if the size argument is omitted or negative, may not read until the end of the data stream; there is no good way to determine that the entire stream from a socket has been read in the general case.

Except for the `info()` and `geturl()` methods, these methods have the same interface as for file objects -- see section 2.3.9 in this manual. (It is not a built-in file object, however, so it can't be used at those few places where a true built-in file object is required.)

The `info()` method returns an instance of the class `mimetools.Message` containing meta-information associated with the URL. When the method is HTTP, these headers are those returned by the server at the head of the retrieved HTML page (including Content-Length and Content-Type). When the method is FTP, a Content-Length header will be present if (as is now usual) the server passed back a file length in
response to the FTP retrieval request. A Content-Type header will be present if the MIME type can be guessed. When the method is local-file, returned headers will include a Date representing the file's last-modified time, a Content-Length giving file size, and a Content-Type containing a guess at the file's type. See also the description of the mimetools module.

The geturl() method returns the real URL of the page. In some cases, the HTTP server redirects a client to another URL. The urlopen() function handles this transparently, but in some cases the caller needs to know which URL the client was redirected to. The geturl() method can be used to get at this redirected URL.

If the url uses the http: scheme identifier, the optional data argument may be given to specify a POST request (normally the request type is GET). The data argument must be in standard application/x-www-form-urlencoded format; see the urlencode() function below.

The urlopen() function works transparently with proxies which do not require authentication. In a UNIX or Windows environment, set the http_proxy, ftp_proxy or gopher_proxy environment variables to a URL that identifies the proxy server before starting the Python interpreter. For example (the "%" is the command prompt):

```
% http_proxy="http://www.someproxy.com:3128"
% export http_proxy
% python...
```

In a Windows environment, if no proxy environment variables are set, proxy settings are obtained from the registry's Internet Settings section.

In a Macintosh environment, urlopen() will retrieve proxy information from Internet Config.

Alternatively, the optional proxies argument may be used to explicitly specify proxies. It must be a dictionary mapping scheme names to proxy URLs, where an empty dictionary causes no proxies to be used, and None (the default value) causes environmental proxy settings to be used as discussed above. For example:

```
# Use http://www.someproxy.com:3128 for http proxying
```
proxies = {'http': 'http://www.someproxy.com:3128'}
filehandle = urllib.urlopen(some_url, proxies=proxies)
# Don't use any proxies
filehandle = urllib.urlopen(some_url, proxies={})
# Use proxies from environment - both versions are equivalent
filehandle = urllib.urlopen(some_url, proxies=None)
filehandle = urllib.urlopen(some_url)

The `urlopen()` function does not support explicit proxy specification. If you need to override environmental proxy settings, use `URLopener`, or a subclass such as `FancyURLopener`.

Proxies which require authentication for use are not currently supported; this is considered an implementation limitation.

Changed in version 2.3: Added the `proxies` support.

`urlretrieve( url[, filename[, reporthook[, data]]])`

Copy a network object denoted by a URL to a local file, if necessary. If the URL points to a local file, or a valid cached copy of the object exists, the object is not copied. Return a tuple `(filename, headers)` where `filename` is the local file name under which the object can be found, and `headers` is whatever the `info()` method of the object returned by `urlopen()` returned (for a remote object, possibly cached). Exceptions are the same as for `urlopen()`.

The second argument, if present, specifies the file location to copy to (if absent, the location will be a tempfile with a generated name). The third argument, if present, is a hook function that will be called once on establishment of the network connection and once after each block read thereafter. The hook will be passed three arguments; a count of blocks transferred so far, a block size in bytes, and the total size of the file. The third argument may be `-1` on older FTP servers which do not return a file size in response to a retrieval request.

If the `url` uses the http: scheme identifier, the optional `data` argument may be given to specify a POST request (normally the request type is GET). The `data` argument must in standard `application/x-www-form-urlencoded` format; see the `urlencode()` function below.

`_urlopener`
The public functions `urlopen()` and `urlretrieve()` create an instance of the `FancyURLopener` class and use it to perform their requested actions. To override this functionality, programmers can create a subclass of `URLopener` or `FancyURLopener`, then assign an instance of that class to the `urllib._urlopener` variable before calling the desired function. For example, applications may want to specify a different User-Agent: header than `URLopener` defines. This can be accomplished with the following code:

```python
import urllib

class AppURLopener(urllib.FancyURLopener):
    version = "App/1.7"

    urllib._urlopener = AppURLopener()
```

`urlcleanup()`

Clear the cache that may have been built up by previous calls to `urlretrieve()`.

`quote(string[, safe])`

Replace special characters in `string` using the "%XX" escape. Letters, digits, and the characters "_.-" are never quoted. The optional `safe` parameter specifies additional characters that should not be quoted -- its default value is '/'.

Example: `quote('/~connolly/')` yields '/%7econnolly/'.

`quote_plus(string[, safe])`

Like `quote()`, but also replaces spaces by plus signs, as required for quoting HTML form values. Plus signs in the original string are escaped unless they are included in `safe`. It also does not have `safe` default to '/'.

`unquote(string)`

Replace "%XX" escapes by their single-character equivalent.

Example: `unquote('/%7Econnolly/')` yields '/~connolly/'.

`unquote_plus(string)`
Like unquote(), but also replaces plus signs by spaces, as required for unquoting HTML form values.

urlencode(query[, doseq])
Convert a mapping object or a sequence of two-element tuples to a "url-encoded" string, suitable to pass to urlopen() above as the optional data argument. This is useful to pass a dictionary of form fields to a POST request. The resulting string is a series of key=value pairs separated by "&" characters, where both key and value are quoted using quote_plus() above. If the optional parameter doseq is present and evaluates to true, individual key=value pairs are generated for each element of the sequence. When a sequence of two-element tuples is used as the query argument, the first element of each tuple is a key and the second is a value. The order of parameters in the encoded string will match the order of parameter tuples in the sequence. The cgi module provides the functions parse_qs() and parse_qsl() which are used to parse query strings into Python data structures.

pathname2url(path)
Convert the pathname path from the local syntax for a path to the form used in the path component of a URL. This does not produce a complete URL. The return value will already be quoted using the quote() function.

url2pathname(path)
Convert the path component path from an encoded URL to the local syntax for a path. This does not accept a complete URL. This function uses unquote() to decode path.

class URLopener([proxies[, **x509]])
Base class for opening and reading URLs. Unless you need to support opening objects using schemes other than http:, ftp:, gopher: or file:, you probably want to use FancyURLopener.

By default, the URLopener class sends a User-Agent: header of "urllib/VVV", where VVV is the urllib version number. Applications can define their own User-Agent: header by subclassing URLopener or FancyURLopener and setting the class attribute version to an
appropriate string value in the subclass definition.

The optional *proxies* parameter should be a dictionary mapping scheme names to proxy URLs, where an empty dictionary turns proxies off completely. Its default value is *None*, in which case environmental proxy settings will be used if present, as discussed in the definition of *urlopen()*, above.

Additional keyword parameters, collected in *x509*, are used for authentication with the *https:* scheme. The keywords *key_file* and *cert_file* are supported; both are needed to actually retrieve a resource at an *https:* URL.

*URLopener* objects will raise an *IOError* exception if the server returns an error code.

**class FancyURLopener( ...)**

*FancyURLopener* subclasses *URLopener* providing default handling for the following HTTP response codes: 301, 302, 303, 307 and 401. For the 30x response codes listed above, the *Location:* header is used to fetch the actual URL. For 401 response codes (authentication required), basic HTTP authentication is performed. For the 30x response codes, recursion is bounded by the value of the *maxtries* attribute, which defaults to 10.

For all other response codes, the method *http_error_default()* is called which you can override in subclasses to handle the error appropriately.

**Note:** According to the letter of *RFC 2616*, 301 and 302 responses to POST requests must not be automatically redirected without confirmation by the user. In reality, browsers do allow automatic redirection of these responses, changing the POST to a GET, and *urllib* reproduces this behaviour.

The parameters to the constructor are the same as those for *URLopener*.

**Note:** When performing basic authentication, a *FancyURLopener* instance calls its *prompt_user_passwd()* method. The default implementation asks the users for the required information on the controlling terminal. A subclass may override this method to support more
appropriate behavior if needed.

Restrictions:

- Currently, only the following protocols are supported: HTTP, (versions 0.9 and 1.0), Gopher (but not Gopher-+), FTP, and local files.

- The caching feature of urlretrieve() has been disabled until I find the time to hack proper processing of Expiration time headers.

- There should be a function to query whether a particular URL is in the cache.

- For backward compatibility, if a URL appears to point to a local file but the file can't be opened, the URL is re-interpreted using the FTP protocol. This can sometimes cause confusing error messages.

- The urlopen() and urlretrieve() functions can cause arbitrarily long delays while waiting for a network connection to be set up. This means that it is difficult to build an interactive Web client using these functions without using threads.

- The data returned by urlopen() or urlretrieve() is the raw data returned by the server. This may be binary data (e.g. an image), plain text or (for example) HTML. The HTTP protocol provides type information in the reply header, which can be inspected by looking at the Content-Type: header. For the Gopher protocol, type information is encoded in the URL; there is currently no easy way to extract it. If the returned data is HTML, you can use the module htmllib to parse it.

- The code handling the FTP protocol cannot differentiate between a file and a directory. This can lead to unexpected behavior when attempting to read a URL that points to a file that is not accessible. If the URL ends in a /, it is assumed to refer to a directory and will be handled accordingly. But if an attempt to read a file leads to a 550 error (meaning the URL cannot be found or is not accessible, often for permission reasons), then the path is treated as a directory in order to handle the case when a directory is specified by a URL but the trailing / has been left off. This can cause misleading results when you try to fetch a file whose read permissions
make it inaccessible; the FTP code will try to read it, fail with a 550 error, and then perform a directory listing for the unreadable file. If fine-grained control is needed, consider using the \texttt{ftplib} module, subclassing \texttt{FancyURLopener}, or changing \_\texttt{urlopen}
er to meet your needs.

- This module does not support the use of proxies which require authentication. This may be implemented in the future.

- Although the \texttt{urllib} module contains (undocumented) routines to parse and unpars

\texttt{URL} strings, the recommended interface for URL manipulation is in module \texttt{urlparse}.

- 11.4.1 URLopener Objects
- 11.4.2 Examples

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See \texttt{About this document...} for information on suggesting changes.
11.4.1 URLopener Objects

URLopener and FancyURLopener objects have the following attributes.

**open**(*fullurl[, data]*)
Open *fullurl* using the appropriate protocol. This method sets up cache and proxy information, then calls the appropriate open method with its input arguments. If the scheme is not recognized, **open Unknown**() is called. The *data* argument has the same meaning as the *data* argument of urlopen().

**open Unknown**(*fullurl[, data]*)
Overridable interface to open unknown URL types.

**retrieve**(*url[, filename[, reporthook[, data]]]*)
Retrieves the contents of *url* and places it in *filename*. The return value is a tuple consisting of a local filename and either a mimetools.Message object containing the response headers (for remote URLs) or None (for local URLs). The caller must then open and read the contents of *filename*. If *filename* is not given and the URL refers to a local file, the input filename is returned. If the URL is non-local and *filename* is not given, the filename is the output of tempfile.mktemp() with a suffix that matches the suffix of the last path component of the input URL. If *reporthook* is given, it must be a function accepting three numeric parameters. It will be called after each chunk of data is read from the network. *reporthook* is ignored for local URLs.

If the *url* uses the http: scheme identifier, the optional *data* argument may be given to specify a POST request (normally the request type is GET). The *data* argument must in standard application/x-www-form-urlencoded format; see the urllib encode() function below.

**version**
Variable that specifies the user agent of the opener object. To get urllib to tell servers that it is a particular user agent, set this in a subclass as a class variable or in the constructor before calling the base constructor.
The **FancyURLopener** class offers one additional method that should be overloaded to provide the appropriate behavior:

```python
prompt_user_passwd( host, realm)
```

Return information needed to authenticate the user at the given host in the specified security realm. The return value should be a tuple, \( \text{user, password} \), which can be used for basic authentication.

The implementation prompts for this information on the terminal; an application should override this method to use an appropriate interaction model in the local environment.
11.4.2 Examples

Here is an example session that uses the "GET" method to retrieve a URL containing parameters:

```python
>>> import urllib
>>> params = urllib.urlencode({'spam': 1, 'eggs': 2, 'bacon': 0})
>>> f = urllib.urlopen("http://www.musical.com/cgi-bin/query?%s" %
>>> print f.read()
```

The following example uses the "POST" method instead:

```python
>>> import urllib
>>> params = urllib.urlencode({'spam': 1, 'eggs': 2, 'bacon': 0})
>>> f = urllib.urlopen("http://www.musical.com/cgi-bin/query", para
>>> print f.read()
```

The following example uses an explicitly specified HTTP proxy, overriding environment settings:

```python
>>> import urllib
>>> proxies = {'http': 'http://proxy.example.com:8080/'}
>>> opener = urllib.FancyURLopener(proxies)
>>> f = opener.open("http://www.python.org")
>>> f.read()
```

The following example uses no proxies at all, overriding environment settings:

```python
>>> import urllib
>>> opener = urllib.FancyURLopener({})
>>> f = opener.open("http://www.python.org")
>>> f.read()
```
11.5 urllib2 -- extensible library for opening URLs

The urllib2 module defines functions and classes which help in opening URLs (mostly HTTP) in a complex world -- basic and digest authentication, redirections, cookies and more.

The urllib2 module defines the following functions:

**urlopen**( *url[, data]*)

Open the URL *url*, which can be either a string or a Request object.

*data* may be a string specifying additional data to send to the server. Currently HTTP requests are the only ones that use *data*; the HTTP request will be a POST instead of a GET when the *data* parameter is provided. *data* should be a buffer in the standard application/x-www-form-urlencoded format. The urllib.urlencode() function takes a mapping or sequence of 2-tuples and returns a string in this format.

This function returns a file-like object with two additional methods:

- **geturl()** -- return the URL of the resource retrieved
- **info()** -- return the meta-information of the page, as a dictionary-like object

Raises URLError on errors.

Note that None may be returned if no handler handles the request (though the default installed global OpenerDirector uses UnknownHandler to ensure this never happens).

**install_opener**( *opener*)

Install an OpenerDirector instance as the default global opener. Installing an opener is only necessary if you want urlopen to use that opener; otherwise, simply call OpenerDirector.open() instead of
urlopen(). The code does not check for a real OpenerDirector, and any class with the appropriate interface will work.

**build_opener([handler, ...])**

Return an OpenerDirector instance, which chains the handlers in the order given. handlers can be either instances of BaseHandler, or subclasses of BaseHandler (in which case it must be possible to call the constructor without any parameters). Instances of the following classes will be in front of the handlers, unless the handlers contain them, instances of them or subclasses of them: ProxyHandler, UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, HTTPErrorProcessor.

If the Python installation has SSL support (socket.ssl() exists), HTTPSHandler will also be added.

Beginning in Python 2.3, a BaseHandler subclass may also change its handler_order member variable to modify its position in the handlers list. Besides ProxyHandler, which has handler_order of 100, all handlers currently have it set to 500.

The following exceptions are raised as appropriate:

**exception URLError**

The handlers raise this exception (or derived exceptions) when they run into a problem. It is a subclass of IOError.

**exception HTTPError**

A subclass of URLError, it can also function as a non-exceptional file-like return value (the same thing that urlopen() returns). This is useful when handling exotic HTTP errors, such as requests for authentication.

**exception GopherError**

A subclass of URLError, this is the error raised by the Gopher handler.

The following classes are provided:
class Request((url[, data][, headers][, origin_req_host][, unverifiable]))

This class is an abstraction of a URL request.

`url` should be a string which is a valid URL. For a description of `data` see the `add_data()` description. `headers` should be a dictionary, and will be treated as if `add_header()` was called with each key and value as arguments.

The final two arguments are only of interest for correct handling of third-party HTTP cookies:

`origin_req_host` should be the request-host of the origin transaction, as defined by RFC 2965. It defaults to `cookielib.request_host(self)`. This is the host name or IP address of the original request that was initiated by the user. For example, if the request is for an image in an HTML document, this should be the request-host of the request for the page containing the image.

`unverifiable` should indicate whether the request is unverifiable, as defined by RFC 2965. It defaults to False. An unverifiable request is one whose URL the user did not have the option to approve. For example, if the request is for an image in an HTML document, and the user had no option to approve the automatic fetching of the image, this should be true.

class OpenerDirector()

The OpenerDirector class opens URLs via BaseHandlers chained together. It manages the chaining of handlers, and recovery from errors.

class BaseHandler()

This is the base class for all registered handlers -- and handles only the simple mechanics of registration.

class HTTPDefaultErrorHandler()

A class which defines a default handler for HTTP error responses; all responses are turned into TypeError exceptions.

class HTTPRedirectHandler()

A class to handle redirections.
class HTTPCookieProcessor([cookiejar])
A class to handle HTTP Cookies.

class ProxyHandler([proxies])
Cause requests to go through a proxy. If proxies is given, it must be a
dictionary mapping protocol names to URLs of proxies. The default is to
read the list of proxies from the environment variables <protocol>_proxy.

class HTTPPasswordMgr()
Keep a database of (realm, uri) -> (user, password) mappings.

class HTTPPasswordMgrWithDefaultRealm()
Keep a database of (realm, uri) -> (user, password) mappings. A
realm of None is considered a catch-all realm, which is searched if no other
realm fits.

class AbstractBasicAuthHandler([password_mgr])
This is a mixin class that helps with HTTP authentication, both to the
remote host and to a proxy. password_mgr, if given, should be something
that is compatible with HTTPPasswordMgr; refer to section 11.5.7 for
information on the interface that must be supported.

class HTTPBasicAuthHandler([password_mgr])
Handle authentication with the remote host. password_mgr, if given, should
be something that is compatible with HTTPPasswordMgr; refer to
section 11.5.7 for information on the interface that must be supported.

class ProxyBasicAuthHandler([password_mgr])
Handle authentication with the proxy. password_mgr, if given, should be
something that is compatible with HTTPPasswordMgr; refer to
section 11.5.7 for information on the interface that must be supported.

class AbstractDigestAuthHandler([password_mgr])
This is a mixin class that helps with HTTP authentication, both to the
remote host and to a proxy. password_mgr, if given, should be something
that is compatible with HTTPPasswordMgr; refer to section 11.5.7 for
information on the interface that must be supported.

class **HTTPDigestAuthHandler**([`password_mgr`])

Handle authentication with the remote host. `password_mgr`, if given, should be something that is compatible with HTTPPasswordMgr; refer to section 11.5.7 for information on the interface that must be supported.

class **ProxyDigestAuthHandler**([`password_mgr`])

Handle authentication with the proxy. `password_mgr`, if given, should be something that is compatible with HTTPPasswordMgr; refer to section 11.5.7 for information on the interface that must be supported.

class **HTTPHandler**()

A class to handle opening of HTTP URLs.

class **HTTPSHandler**()

A class to handle opening of HTTPS URLs.

class **FileHandler**()

Open local files.

class **FTPHandler**()

Open FTP URLs.

class **CacheFTPHandler**()

Open FTP URLs, keeping a cache of open FTP connections to minimize delays.

class **GopherHandler**()

Open gopher URLs.

class **UnknownHandler**()

A catch-all class to handle unknown URLs.

11.5.21 HTTPErrorProcessor Objects
11.5.22 Examples
11.5.1 Request Objects

The following methods describe all of Request's public interface, and so all must be overridden in subclasses.

add_data(data)
Set the Request data to data. This is ignored by all handlers except HTTP handlers -- and there it should be a byte string, and will change the request to be POST rather than GET.

get_method()
Return a string indicating the HTTP request method. This is only meaningful for HTTP requests, and currently always returns 'GET' or 'POST'.

has_data()
Return whether the instance has a non-None data.

get_data()
Return the instance's data.

add_header(key, val)
Add another header to the request. Headers are currently ignored by all handlers except HTTP handlers, where they are added to the list of headers sent to the server. Note that there cannot be more than one header with the same name, and later calls will overwrite previous calls in case the key collides. Currently, this is no loss of HTTP functionality, since all headers which have meaning when used more than once have a (header-specific) way of gaining the same functionality using only one header.

add_unredirected_header(key, header)
Add a header that will not be added to a redirected request. New in version 2.4.

has_header(header)
Return whether the instance has the named header (checks both regular and
unredirected). New in version 2.4.

**get_full_url()**
Return the URL given in the constructor.

**get_type()**
Return the type of the URL -- also known as the scheme.

**get_host()**
Return the host to which a connection will be made.

**get_selector()**
Return the selector -- the part of the URL that is sent to the server.

**set_proxy( host, type)**
Prepare the request by connecting to a proxy server. The *host* and *type* will replace those of the instance, and the instance's selector will be the original URL given in the constructor.

**get_origin_req_host()**
Return the request-host of the origin transaction, as defined by RFC 2965. See the documentation for the Request constructor.

**is_unverifiable()**
Return whether the request is unverifiable, as defined by RFC 2965. See the documentation for the Request constructor.
11.5.2 OpenerDirector Objects

OpenerDirector instances have the following methods:

**add_handler(handler)**

*handler* should be an instance of BaseHandler. The following methods are searched, and added to the possible chains (note that HTTP errors are a special case).

- *protocol_open()* -- signal that the handler knows how to open protocol URLs.
- *http_error_type()* -- signal that the handler knows how to handle HTTP errors with HTTP error code *type*.
- *protocol_error()* -- signal that the handler knows how to handle errors from (non-http) *protocol*.
- *protocol_request()* -- signal that the handler knows how to pre-process *protocol* requests.
- *protocol_response()* -- signal that the handler knows how to post-process *protocol* responses.

**open(url[, data])**

Open the given *url* (which can be a request object or a string), optionally passing the given *data*. Arguments, return values and exceptions raised are the same as those of *urlopen()* (which simply calls the *open()* method on the currently installed global OpenerDirector).

**error(proto[, arg[, ...]])**

Handle an error of the given protocol. This will call the registered error handlers for the given protocol with the given arguments (which are protocol specific). The HTTP protocol is a special case which uses the HTTP response code to determine the specific error handler; refer to the *http_error_*() methods of the handler classes.

Return values and exceptions raised are the same as those of *urlopen()*.

OpenerDirector objects open URLs in three stages:
The order in which these methods are called within each stage is determined by sorting the handler instances.

1. Every handler with a method named like `protocol_request()` has that method called to pre-process the request.

2. Handlers with a method named like `protocol_open()` are called to handle the request. This stage ends when a handler either returns a non-None value (ie. a response), or raises an exception (usually URLError). Exceptions are allowed to propagate.

   In fact, the above algorithm is first tried for methods named `default_open`. If all such methods return None, the algorithm is repeated for methods named like `protocol_open()`. If all such methods return None, the algorithm is repeated for methods named `unknown_open()`.

   Note that the implementation of these methods may involve calls of the parent `OpenerDirector` instance's .open() and .error() methods.

3. Every handler with a method named like `protocol_response()` has that method called to post-process the response.
11.5.3 BaseHandler Objects

BaseHandler objects provide a couple of methods that are directly useful, and others that are meant to be used by derived classes. These are intended for direct use:

**add_parent**( *director*)
Add a director as parent.

**close()**
Remove any parents.

The following members and methods should only be used by classes derived from BaseHandler. **Note:** The convention has been adopted that subclasses defining *protocol_request()* or *protocol_response()* methods are named *Processor*; all others are named *Handler*.

**parent**
A valid OpenerDirector, which can be used to open using a different protocol, or handle errors.

**default_open**( *req*)
This method is *not* defined in BaseHandler, but subclasses should define it if they want to catch all URLs.

This method, if implemented, will be called by the parent OpenerDirector. It should return a file-like object as described in the return value of the *open()* of OpenerDirector, or *None*. It should raise URLError, unless a truly exceptional thing happens (for example, MemoryError should not be mapped to URLError).

This method will be called before any protocol-specific open method.

**protocol_open**( *req*)
This method is *not* defined in BaseHandler, but subclasses should define it if they want to handle URLs with the given protocol.
This method, if defined, will be called by the parent OpenerDirector. Return values should be the same as for default_open().

unknown_open( req)
This method is not defined in BaseHandler, but subclasses should define it if they want to catch all URLs with no specific registered handler to open it.

This method, if implemented, will be called by the parent OpenerDirector. Return values should be the same as for default_open().

http_error_default( req, fp, code, msg, hdrs)
This method is not defined in BaseHandler, but subclasses should override it if they intend to provide a catch-all for otherwise unhandled HTTP errors. It will be called automatically by the OpenerDirector getting the error, and should not normally be called in other circumstances.

req will be a Request object, fp will be a file-like object with the HTTP error body, code will be the three-digit code of the error, msg will be the user-visible explanation of the code and hdrs will be a mapping object with the headers of the error.

Return values and exceptions raised should be the same as those of urlopen().

http_error_nnn( req, fp, code, msg, hdrs)
nnn should be a three-digit HTTP error code. This method is also not defined in BaseHandler, but will be called, if it exists, on an instance of a subclass, when an HTTP error with code nnn occurs.

Subclasses should override this method to handle specific HTTP errors.

Arguments, return values and exceptions raised should be the same as for http_error_default().

protocol_request( req)
This method is not defined in BaseHandler, but subclasses should define
it if they want to pre-process requests of the given protocol.

This method, if defined, will be called by the parent OpenerDirector. 
`req` will be a Request object. The return value should be a Request object.

`protocol_response(req, response)`

This method is *not* defined in BaseHandler, but subclasses should define it if they want to post-process responses of the given protocol.

This method, if defined, will be called by the parent OpenerDirector. 
`req` will be a Request object. `response` will be an object implementing the same interface as the return value of `urlopen()`. The return value should implement the same interface as the return value of `urlopen()`.
11.5.4 HTTPRedirectHandler Objects

**Note:** Some HTTP redirections require action from this module's client code. If this is the case, HTTPError is raised. See RFC 2616 for details of the precise meanings of the various redirection codes.

**redirect_request**( `req`, `fp`, `code`, `msg`, `hdrs`)

Return a Request or None in response to a redirect. This is called by the default implementations of the `http_error_30*()` methods when a redirection is received from the server. If a redirection should take place, return a new Request to allow `http_error_30*()` to perform the redirect. Otherwise, raise HTTPError if no other handler should try to handle this URL, or return None if you can't but another handler might.

**Note:** The default implementation of this method does not strictly follow RFC 2616, which says that 301 and 302 responses to POST requests must not be automatically redirected without confirmation by the user. In reality, browsers do allow automatic redirection of these responses, changing the POST to a GET, and the default implementation reproduces this behavior.

**http_error_301**( `req`, `fp`, `code`, `msg`, `hdrs`)

Redirect to the Location: URL. This method is called by the parent OpenerDirector when getting an HTTP `moved permanently' response.

**http_error_302**( `req`, `fp`, `code`, `msg`, `hdrs`)

The same as `http_error_301()`, but called for the `found' response.

**http_error_303**( `req`, `fp`, `code`, `msg`, `hdrs`)

The same as `http_error_301()`, but called for the `see other' response.

**http_error_307**( `req`, `fp`, `code`, `msg`, `hdrs`)

The same as `http_error_301()`, but called for the `temporary redirect' response.
11.5.5 HTTPCookieProcessor Objects

HTTPCookieProcessor instances have one attribute:

**cookiejar**

The `cookielib.CookieJar` in which cookies are stored.
11.5.6 ProxyHandler Objects

`protocol_open(request)`

The `ProxyHandler` will have a method `protocol_open()` for every `protocol` which has a proxy in the `proxies` dictionary given in the constructor. The method will modify requests to go through the proxy, by calling `request.set_proxy()`, and call the next handler in the chain to actually execute the protocol.
11.5.7 HTTPPasswordMgr Objects

These methods are available on HTTPPasswordMgr and HTTPPasswordMgrWithDefaultRealm objects.

**add_password(realm, uri, user, passwd)**

`uri` can be either a single URI, or a sequence of URIs. `realm, user` and `passwd` must be strings. This causes `(user, passwd)` to be used as authentication tokens when authentication for `realm` and a super-URI of any of the given URIs is given.

**find_user_password(realm, authuri)**

Get user/password for given realm and URI, if any. This method will return `(None, None)` if there is no matching user/password.

For HTTPPasswordMgrWithDefaultRealm objects, the realm `None` will be searched if the given `realm` has no matching user/password.
11.5.8 AbstractBasicAuthHandler Objects

handle_authentication_request( authreq, host, req, headers)
Handle an authentication request by getting a user/password pair, and retrying the request. authreq should be the name of the header where the information about the realm is included in the request, host is the host to authenticate to, req should be the (failed) Request object, and headers should be the error headers.
11.5.9 HTTPBasicAuthHandler Objects

**http_error_401**( req, fp, code, msg, hdrs)

Retry the request with authentication information, if available.
11.5.10 ProxyBasicAuthHandler Objects

`http_error_407(req, fp, code, msg, hdrs)`
Retry the request with authentication information, if available.
11.5.11 AbstractDigestAuthHandler Objects

```python
def handle_authentication_request(authreq, host, req, headers):
    authreq should be the name of the header where the information about the
    realm is included in the request, host should be the host to authenticate to,
    req should be the (failed) Request object, and headers should be the error
    headers.
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.5.12 HTTPDigestAuthHandler Objects

`http_error_401(req, fp, code, msg, hdrs)`

Retry the request with authentication information, if available.
11.5.13 ProxyDigestAuthHandler Objects

`http_error_407(req, fp, code, msg, hdrs)`

Retry the request with authentication information, if available.
11.5.14 HTTPHandler Objects

`http_open(req)`
Send an HTTP request, which can be either GET or POST, depending on `req.has_data()`.
11.5.15 HTTPSHandler Objects

https_open( req)

   Send an HTTPS request, which can be either GET or POST, depending on
   req.has_data().

Previous: 11.5.14 HTTPHandler Objects  Up: 11.5 urllib2  Next: 11.5.16
FileHandler Objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.5.16 FileHandler Objects

`file_open(req)`

Open the file locally, if there is no host name, or the host name is 'localhost'. Change the protocol to `ftp` otherwise, and retry opening it using `parent`.
11.5.17 FTPHandler Objects

`ftp_open(req)`
Open the FTP file indicated by `req`. The login is always done with empty username and password.

Previous: 11.5.16 FileHandler Objects  Up: 11.5 urllib2  Next: 11.5.18 CacheFTPHandler Objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.5.18 CacheFTPHandler Objects

CacheFTPHandler objects are FTPHandler objects with the following additional methods:

**setTimeout**\((t)\)

Set timeout of connections to \(t\) seconds.

**setMaxConns**\((m)\)

Set maximum number of cached connections to \(m\).
11.5.19 GopherHandler Objects

`gopher_open(req)`

Open the gopher resource indicated by `req`.

---

Python Library Reference

Previous: 11.5.18 CacheFTPHandler Objects  Up: 11.5 urllib2  Next: 11.5.20 UnknownHandler Objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.5.20 UnknownHandler Objects

unknown_open()

Raise a URLError exception.
11.5.21 `HTTPErrorProcessor` Objects

New in version 2.4.

`unknown_open()`  
Process HTTP error responses.  

For 200 error codes, the response object is returned immediately.  

For non-200 error codes, this simply passes the job on to the `protocol_error_code()` handler methods, via `OpenerDirector.error()`. Eventually, `urllib2.HTTPDefaultErrorHandler` will raise an `HTTPError` if no other handler handles the error.
11.5.22 Examples

This example gets the python.org main page and displays the first 100 bytes of it:

```python
>>> import urllib2
>>> f = urllib2.urlopen('http://www.python.org/')
>>> print f.read(100)
<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01 Transitional//EN">
<?xml-stylesheet href="./css/ht2html

Here we are sending a data-stream to the stdin of a CGI and reading the data it returns to us. Note that this example will only work when the Python installation supports SSL.

```python
>>> import urllib2
>>> req = urllib2.Request(url='https://localhost/cgi-bin/test.cgi',
...		data='This data is passed to stdin of the
>>> f = urllib2.urlopen(req)
>>> print f.read()
Got Data: "This data is passed to stdin of the CGI"

The code for the sample CGI used in the above example is:

```python
#!/usr/bin/env python
import sys
data = sys.stdin.read()
print 'Content-type: text-plain

Got Data: "%s"' % data
```

Use of Basic HTTP Authentication:

```python
import urllib2
# Create an OpenerDirector with support for Basic HTTP Authenticatio
auth_handler = urllib2.HTTPBasicAuthHandler()
auth_handler.add_password('realm', 'host', 'username', 'password')
 opener = urllib2.build_opener(auth_handler)
# ...and install it globally so it can be used with urlopen.
 urllib2.install_opener(opener)
 urllib2.urlopen('http://www.example.com/login.html')
```

`build_opener()` provides many handlers by default, including a `ProxyHandler`. By default, `ProxyHandler` uses the environment variables named `<scheme>__proxy`, where `<scheme>` is the URL scheme involved. For example, the `http_proxy` environment variable is read to obtain the HTTP
proxy's URL.

This example replaces the default `ProxyHandler` with one that uses programatically-supplied proxy URLs, and adds proxy authorization support with `ProxyBasicAuthHandler`.

```python
go, proxy_handler = urllib2.ProxyHandler({'http': 'http://www.example.com:3128/'}),
go.proxy_auth_handler = urllib2.HTTPBasicAuthHandler()
go.proxy_auth_handler.add_password('realm', 'host', 'username', 'password')
o = urllib2.build_opener(proxy_handler, proxy_auth_handler)
# This time, rather than install the OpenerDirector, we use it direc
o.open('http://www.example.com/login.html')
```

Adding HTTP headers:

Use the `headers` argument to the `Request` constructor, or:

```python
import urllib2
r = urllib2.Request('http://www.example.com/'),
r.add_header('Referer', 'http://www.python.org/'),
r = urllib2.urlopen(r)
```

`OpenerDirector` automatically adds a `User-Agent: header` to every `Request`. To change this:

```python
import urllib2
o = urllib2.build_opener()
o.addheaders = [({'User-agent', 'Mozilla/5.0'})]
o.open('http://www.example.com/')
```

Also, remember that a few standard headers (`Content-Length:`, `Content-Type:` and `Host:`) are added when the `Request` is passed to `urlopen()` (or `OpenerDirector.open()`).
11.6 httpplib -- HTTP protocol client

This module defines classes which implement the client side of the HTTP and HTTPS protocols. It is normally not used directly -- the module urllib uses it to handle URLs that use HTTP and HTTPS.

Note: HTTPS support is only available if the socket module was compiled with SSL support.

Note: The public interface for this module changed substantially in Python 2.0. The HTTP class is retained only for backward compatibility with 1.5.2. It should not be used in new code. Refer to the online docstrings for usage.

The module provides the following classes:

class HTTPConnection( host[, port])

An HTTPConnection instance represents one transaction with an HTTP server. It should be instantiated passing it a host and optional port number. If no port number is passed, the port is extracted from the host string if it has the form host:port, else the default HTTP port (80) is used. For example, the following calls all create instances that connect to the server at the same host and port:

    >>> h1 = httpplib.HTTPConnection('www.cwi.nl')
    >>> h2 = httpplib.HTTPConnection('www.cwi.nl:80')
    >>> h3 = httpplib.HTTPConnection('www.cwi.nl', 80)

New in version 2.0.

class HTTPSConnection( host[, port, key_file, cert_file])

A subclass of HTTPConnection that uses SSL for communication with secure servers. Default port is 443. key_file is the name of a PEM formatted file that contains your private key. cert_file is a PEM formatted
certificate chain file.

**Warning:** This does not do any certificate verification!

New in version 2.0.

```python
class HTTPResponse( sock[, debuglevel=0][, strict=0])
```

Class whose instances are returned upon successful connection. Not instantiated directly by user. New in version 2.0.

The following exceptions are raised as appropriate:

- **exception HTTPException**
  - The base class of the other exceptions in this module. It is a subclass of `Exception`. New in version 2.0.

- **exception NotConnected**
  - A subclass of HTTPException. New in version 2.0.

- **exception InvalidURL**
  - A subclass of HTTPException, raised if a port is given and is either non-numeric or empty. New in version 2.3.

- **exception UnknownProtocol**
  - A subclass of HTTPException. New in version 2.0.

- **exception UnknownTransferEncoding**
  - A subclass of HTTPException. New in version 2.0.

- **exception UnimplementedFileMode**
  - A subclass of HTTPException. New in version 2.0.

- **exception IncompleteRead**
  - A subclass of HTTPException. New in version 2.0.

- **exception ImproperConnectionState**
  - A subclass of HTTPException. New in version 2.0.

- **exception CannotSendRequest**
A subclass of ImproperConnectionState. New in version 2.0.

**exception CannotSendHeader**
A subclass of ImproperConnectionState. New in version 2.0.

**exception ResponseNotReady**
A subclass of ImproperConnectionState. New in version 2.0.

**exception BadStatusLine**
A subclass of HTTPException. Raised if a server responds with a HTTP status code that we don't understand. New in version 2.0.

The constants defined in this module are:

**HTTP_PORT**
The default port for the HTTP protocol (always 80).

**HTTPS_PORT**
The default port for the HTTPS protocol (always 443).

and also the following constants for integer status codes:

*Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.*
11.6.1 HTTPConnection Objects

HTTPConnection instances have the following methods:

`request(method, url[, body[, headers]])`

This will send a request to the server using the HTTP request method `method` and the selector `url`. If the `body` argument is present, it should be a string of data to send after the headers are finished. The header Content-Length is automatically set to the correct value. The `headers` argument should be a mapping of extra HTTP headers to send with the request.

`getresponse()`

Should be called after a request is sent to get the response from the server. Returns an `HTTPResponse` instance. **Note:** Note that you must have read the whole response before you can send a new request to the server.

`set_debuglevel(level)`

Set the debugging level (the amount of debugging output printed). The default debug level is 0, meaning no debugging output is printed.

`connect()`

Connect to the server specified when the object was created.

`close()`

Close the connection to the server.

As an alternative to using the `request()` method described above, you can also send your request step by step, by using the four functions below.

`putrequest(request, selector[, skip_host[, skip_accept_encoding]])`

This should be the first call after the connection to the server has been made. It sends a line to the server consisting of the `request` string, the `selector` string, and the HTTP version (HTTP/1.1). To disable automatic sending of Host: or Accept-Encoding: headers (for example to accept additional content encodings), specify `skip_host` or `skip_accept_encoding` with non-False values. Changed in version 2.4:
skip_accept_encoding argument added.

putheader( header, argument[, ...])
Send an RFC 822-style header to the server. It sends a line to the server consisting of the header, a colon and a space, and the first argument. If more arguments are given, continuation lines are sent, each consisting of a tab and an argument.

endheaders()
Send a blank line to the server, signalling the end of the headers.

send( data)
Send data to the server. This should be used directly only after the endheaders() method has been called and before getresponse() is called.
**11.6.2 HTTPResponse Objects**

HTTPResponse instances have the following methods and attributes:

- **read**([*amt]*)
  Reads and returns the response body, or up to the next *amt* bytes.

- **getheader**(*name[, default]*)
  Get the contents of the header *name*, or *default* if there is no matching header.

- **getheaders()**
  Return a list of (header, value) tuples. New in version 2.4.

- **msg**
  A mimetools.Message instance containing the response headers.

- **version**
  HTTP protocol version used by server. 10 for HTTP/1.0, 11 for HTTP/1.1.

- **status**
  Status code returned by server.

- **reason**
  Reason phrase returned by server.

---

*Python Library Reference*

Previous: 11.6.1 HTTPConnection Objects  Up: 11.6 httplib  Next: 11.6.3 Examples

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.6.3 Examples

Here is an example session that uses the "GET" method:

```python
>>> import httplib
>>> conn = httplib.HTTPConnection("www.python.org")
>>> conn.request("GET", "/index.html")
>>> r1 = conn.getresponse()
>>> print r1.status, r1.reason
200 OK
>>> data1 = r1.read() 
>>> conn.request("GET", "/parrot.spam")
>>> r2 = conn.getresponse()
>>> print r2.status, r2.reason
404 Not Found
>>> data2 = r2.read() 
>>> conn.close()
```

Here is an example session that shows how to "POST" requests:

```python
>>> import httplib, urllib
>>> params = urllib.urlencode({'spam': 1, 'eggs': 2, 'bacon': 0})
>>> headers = {
            "Content-type": "application/x-www-form-urlencoded",
            "Accept": "text/plain"
            }
>>> conn = httplib.HTTPConnection("musi-cal.mojam.com:80")
>>> conn.request("POST", "/cgi-bin/query", params, headers)
>>> response = conn.getresponse()
>>> print response.status, response.reason
200 OK
>>> data = response.read()
>>> conn.close()
```
11.7 ftplib -- FTP protocol client

This module defines the class FTP and a few related items. The FTP class implements the client side of the FTP protocol. You can use this to write Python programs that perform a variety of automated FTP jobs, such as mirroring other ftp servers. It is also used by the module urllib to handle URLs that use FTP. For more information on FTP (File Transfer Protocol), see Internet RFC 959.

Here's a sample session using the ftplib module:

```python
>>> from ftplib import FTP
>>> ftp = FTP('ftp.cwi.nl')  # connect to host, default port
>>> ftp.login()  # user anonymous, passwd anonymous@
>>> ftp.retrlines('LIST')  # list directory contents
total 24418
drwxrwsr-x  5 ftp-usr pdmaint 1536 Mar 20 09:48 .
dr-xr-srwt 105 ftp-usr pdmaint 1536 Mar 21 14:32 ..
-rw-r--r--  1 ftp-usr pdmaint  5305 Mar 20 09:48 INDEX
.
.
>>> ftp.retrbinary('RETR README', open('README', 'wb').write)
'226 Transfer complete.'
>>> ftp.quit()
```

The module defines the following items:

```python
class FTP([host[, user[, passwd[, acct]]]])
```

Return a new instance of the FTP class. When host is given, the method call `connect(host)` is made. When user is given, additionally the method call `login(user, passwd, acct)` is made (where passwd and acct default to the empty string when not given).

```python
all_errors
```

The set of all exceptions (as a tuple) that methods of FTP instances may raise as a result of problems with the FTP connection (as opposed to programming errors made by the caller). This set includes the four exceptions listed below as well as `socket.error` and `IOError`.

```python
exception error_reply
```
Exception raised when an unexpected reply is received from the server.

**exception error_temp**
Exception raised when an error code in the range 400-499 is received.

**exception error_perm**
Exception raised when an error code in the range 500-599 is received.

**exception error_proto**
Exception raised when a reply is received from the server that does not begin with a digit in the range 1-5.

---

**See Also:**

Module **netrc**: Parser for the .netrc file format. The file .netrc is typically used by FTP clients to load user authentication information before prompting the user.

The file Tools/scripts/ftpmirror.py in the Python source distribution is a script that can mirror FTP sites, or portions thereof, using the `ftplib` module. It can be used as an extended example that applies this module.
### 11.7.1 FTP Objects

Several methods are available in two flavors: one for handling text files and another for binary files. These are named for the command which is used followed by "lines" for the text version or "binary" for the binary version.

FTP instances have the following methods:

- **set_debuglevel** *(level)*
  
  Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the control connection.

- **connect** *(host[, port]*)
  
  Connect to the given host and port. The default port number is 21, as specified by the FTP protocol specification. It is rarely needed to specify a different port number. This function should be called only once for each instance; it should not be called at all if a host was given when the instance was created. All other methods can only be used after a connection has been made.

- **getwelcome** *
  
  Return the welcome message sent by the server in reply to the initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

- **login** *[user[, passwd[, acct]]]*
  
  Log in as the given user. The passwd and acct parameters are optional and default to the empty string. If no user is specified, it defaults to 'anonymous'. If user is 'anonymous', the default passwd is 'anonymous@'. This function should be called only once for each instance, after a connection has been established; it should not be called at all if a host and user were given when the instance was created. Most FTP
Commands are only allowed after the client has logged in.

**abort()**

Abort a file transfer that is in progress. Using this does not always work, but it's worth a try.

**sendcmd**( **command** )

Send a simple command string to the server and return the response string.

**voidcmd**( **command** )

Send a simple command string to the server and handle the response. Return nothing if a response code in the range 200-299 is received. Raise an exception otherwise.

**retrbinary**( **command**, **callback** [, **maxblocksize** [, **rest**]])

Retrieve a file in binary transfer mode. **command** should be an appropriate "RETR" command: 'RETR filename'. The **callback** function is called for each block of data received, with a single string argument giving the data block. The optional **maxblocksize** argument specifies the maximum chunk size to read on the low-level socket object created to do the actual transfer (which will also be the largest size of the data blocks passed to **callback**). A reasonable default is chosen. **rest** means the same thing as in the **transfercmd()** method.

**retrlines**( **command** [, **callback**])

Retrieve a file or directory listing in ASCII transfer mode. **command** should be an appropriate "RETR" command (see **retrbinary()**) or a "LIST" command (usually just the string 'LIST'). The **callback** function is called for each line, with the trailing CRLF stripped. The default **callback** prints the line to **sys.stdout**.

**set_pasv**( **boolean**)

Enable ``passive'' mode if **boolean** is true, other disable passive mode. (In Python 2.0 and before, passive mode was off by default; in Python 2.1 and later, it is on by default.)

**storbinary**( **command**, **file** [, **blocksize**])
Store a file in binary transfer mode. `command` should be an appropriate "STOR" command: "STOR filename". `file` is an open file object which is read until EOF using its `read()` method in blocks of size `blocksize` to provide the data to be stored. The `blocksize` argument defaults to 8192. Changed in version 2.1: default for `blocksize` added.

`storlines(command, file)`

Store a file in ASCII transfer mode. `command` should be an appropriate "STOR" command (see `storbinary()`). Lines are read until EOF from the open file object `file` using its `readline()` method to provide the data to be stored.

`transfercmd(cmd[, rest])`

Initiate a transfer over the data connection. If the transfer is active, send a "EPRT" or "PORT" command and the transfer command specified by `cmd`, and accept the connection. If the server is passive, send a "EPSV" or "PASV" command, connect to it, and start the transfer command. Either way, return the socket for the connection.

If optional `rest` is given, a "REST" command is sent to the server, passing `rest` as an argument. `rest` is usually a byte offset into the requested file, telling the server to restart sending the file's bytes at the requested offset, skipping over the initial bytes. Note however that RFC 959 requires only that `rest` be a string containing characters in the printable range from ASCII code 33 to ASCII code 126. The `transfercmd()` method, therefore, converts `rest` to a string, but no check is performed on the string's contents. If the server does not recognize the "REST" command, an `error_reply` exception will be raised. If this happens, simply call `transfercmd()` without a `rest` argument.

`ntransfercmd(cmd[, rest])`

Like `transfercmd()`, but returns a tuple of the data connection and the expected size of the data. If the expected size could not be computed, `None` will be returned as the expected size. `cmd` and `rest` means the same thing as in `transfercmd()`.

`nlst(argument[, ...])`
Return a list of files as returned by the "NLST" command. The optional argument is a directory to list (default is the current server directory). Multiple arguments can be used to pass non-standard options to the "NLST" command.

```
dir( argument[, ...])
```

Produce a directory listing as returned by the "LIST" command, printing it to standard output. The optional argument is a directory to list (default is the current server directory). Multiple arguments can be used to pass non-standard options to the "LIST" command. If the last argument is a function, it is used as a callback function as for retrlines(); the default prints to `sys.stdout`. This method returns None.

```
rename( fromname, toname)
```

Rename file fromname on the server to toname.

```
delete( filename)
```

Remove the file named filename from the server. If successful, returns the text of the response, otherwise raises error_perm on permission errors or error_reply on other errors.

```
cwd( pathname)
```

Set the current directory on the server.

```
mkd( pathname)
```

Create a new directory on the server.

```
pwd()
```

Return the pathname of the current directory on the server.

```
rmd( dirname)
```

Remove the directory named dirname on the server.

```
size( filename)
```

Request the size of the file named filename on the server. On success, the size of the file is returned as an integer, otherwise None is returned. Note that the "SIZE" command is not standardized, but is supported by many
common server implementations.

**quit()**

Send a "QUIT" command to the server and close the connection. This is the "polite" way to close a connection, but it may raise an exception of the server responds with an error to the "QUIT" command. This implies a call to the `close()` method which renders the FTP instance useless for subsequent calls (see below).

**close()**

Close the connection unilaterally. This should not be applied to an already closed connection such as after a successful call to `quit()`. After this call the FTP instance should not be used any more (after a call to `close()` or `quit()` you cannot reopen the connection by issuing another `login()` method).
11.8 gopherlib -- Gopher protocol client

This module provides a minimal implementation of client side of the Gopher protocol. It is used by the module urllib to handle URLs that use the Gopher protocol.

The module defines the following functions:

```python
send_selector(selector, host[, port])
```

Send a `selector` string to the gopher server at `host` and `port` (default 70). Returns an open file object from which the returned document can be read.

```python
send_query(selector, query, host[, port])
```

Send a `selector` string and a `query` string to a gopher server at `host` and `port` (default 70). Returns an open file object from which the returned document can be read.

Note that the data returned by the Gopher server can be of any type, depending on the first character of the selector string. If the data is text (first character of the selector is "0"), lines are terminated by CRLF, and the data is terminated by a line consisting of a single ".", and a leading "." should be stripped from lines that begin with "..". Directory listings (first character of the selector is "1") are transferred using the same protocol.
11.9 poplib -- POP3 protocol client

This module defines a class, POP3, which encapsulates a connection to a POP3 server and implements the protocol as defined in RFC 1725. The POP3 class supports both the minimal and optional command sets. Additionally, this module provides a class POP3_SSL, which provides support for connecting to POP3 servers that use SSL as an underlying protocol layer.

Note that POP3, though widely supported, is obsolescent. The implementation quality of POP3 servers varies widely, and too many are quite poor. If your mailserver supports IMAP, you would be better off using the imaplib IMAP4 class, as IMAP servers tend to be better implemented.

A single class is provided by the poplib module:

```python
class POP3(host[, port])
```

This class implements the actual POP3 protocol. The connection is created when the instance is initialized. If `port` is omitted, the standard POP3 port (110) is used.

```python
class POP3_SSL(host[, port[, keyfile[, certfile]]])
```

This is a subclass of POP3 that connects to the server over an SSL encrypted socket. If `port` is not specified, 995, the standard POP3-over-SSL port is used. `keyfile` and `certfile` are also optional - they can contain a PEM formatted private key and certificate chain file for the SSL connection.

New in version 2.4.

One exception is defined as an attribute of the poplib module:

```python
exception error_proto
```

Exception raised on any errors. The reason for the exception is passed to the constructor as a string.

See Also:
Module **imaplib**: The standard Python IMAP module.

**Frequently Asked Questions About Fetchmail**

The FAQ for the fetchmail POP/IMAP client collects information on POP3 server variations and RFC noncompliance that may be useful if you need to write an application based on the POP protocol.

- [11.9.2 POP3 Example](#)

---

**Python Library Reference**

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.
11.9.1 POP3 Objects

All POP3 commands are represented by methods of the same name, in lowercase; most return the response text sent by the server.

An POP3 instance has the following methods:

**set_debuglevel( level)**
Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the control connection.

**getwelcome()**
Returns the greeting string sent by the POP3 server.

**user( username)**
Send user command, response should indicate that a password is required.

**pass_( password)**
Send password, response includes message count and mailbox size. Note: the mailbox on the server is locked until **quit()** is called.

**apop( user, secret)**
Use the more secure APOP authentication to log into the POP3 server.

**rpop( user)**
Use RPOP authentication (similar to UNIX r-commands) to log into POP3 server.

**stat()**
Get mailbox status. The result is a tuple of 2 integers: *(message count, mailbox size).*
list([*which*])

Request message list, result is in the form ('response', ['msg_num
octets', ...], octets). If *which* is set, it is the message to list.

retr(*which*)

Retrieve whole message number *which*, and set its seen flag. Result is in
form ('response', ['line', ...], octets).

dele(*which*)

Flag message number *which* for deletion. On most servers deletions are not
actually performed until QUIT (the major exception is Eudora QPOP, which
deliberately violates the RFCs by doing pending deletes on any disconnect).

rset()

Remove any deletion marks for the mailbox.

noop()

Do nothing. Might be used as a keep-alive.

quit()

Signoff: commit changes, unlock mailbox, drop connection.

top(*which*, *howmuch*)

Retrieves the message header plus *howmuch* lines of the message after the
header of message number *which*. Result is in form ('response',
['line', ...], octets).

The POP3 TOP command this method uses, unlike the RETR command,
doesn't set the message's seen flag; unfortunately, TOP is poorly specified in
the RFCs and is frequently broken in off-brand servers. Test this method by
hand against the POP3 servers you will use before trusting it.

uidl([*which*])

Return message digest (unique id) list. If *which* is specified, result contains
the unique id for that message in the form 'response msgnum uid',
otherwise result is list ('response', ['msgnum uid', ...],
octets).
Instances of POP3_SSL have no additional methods. The interface of this subclass is identical to its parent.
11.9.2 POP3 Example

Here is a minimal example (without error checking) that opens a mailbox and retrieves and prints all messages:

```python
import getpass, poplib
M = poplib.POP3('localhost')
M.user(getpass.getuser())
M.pass_(getpass.getpass())
numMessages = len(M.list()[1])
for i in range(numMessages):
    for j in M.retr(i+1)[1]:
        print j
```

At the end of the module, there is a test section that contains a more extensive example of usage.
11.10 imaplib -- IMAP4 protocol client

This module defines three classes, IMAP4, IMAP4_SSL and IMAP4_stream, which encapsulate a connection to an IMAP4 server and implement a large subset of the IMAP4rev1 client protocol as defined in RFC 2060. It is backward compatible with IMAP4 (RFC 1730) servers, but note that the "STATUS" command is not supported in IMAP4.

Three classes are provided by the imaplib module, IMAP4 is the base class:

```python
class IMAP4([host[, port]])
```

This class implements the actual IMAP4 protocol. The connection is created and protocol version (IMAP4 or IMAP4rev1) is determined when the instance is initialized. If `host` is not specified, '' (the local host) is used. If `port` is omitted, the standard IMAP4 port (143) is used.

Three exceptions are defined as attributes of the IMAP4 class:

```python
exception IMAP4.error
```

Exception raised on any errors. The reason for the exception is passed to the constructor as a string.

```python
exception IMAP4.abort
```

IMAP4 server errors cause this exception to be raised. This is a sub-class of IMAP4.error. Note that closing the instance and instantiating a new one will usually allow recovery from this exception.

```python
exception IMAP4.readonly
```

This exception is raised when a writable mailbox has its status changed by the server. This is a sub-class of IMAP4.error. Some other client now has write permission, and the mailbox will need to be re-opened to re-obtain write permission.

There's also a subclass for secure connections:
class IMAP4_SSL([host[, port[, keyfile[, certfile]]]])

This is a subclass derived from IMAP4 that connects over an SSL encrypted socket (to use this class you need a socket module that was compiled with SSL support). If host is not specified, '' (the local host) is used. If port is omitted, the standard IMAP4-over-SSL port (993) is used. keyfile and certfile are also optional - they can contain a PEM formatted private key and certificate chain file for the SSL connection.

The second subclass allows for connections created by a child process:

class IMAP4_stream(command)

This is a subclass derived from IMAP4 that connects to the stdin/stdout file descriptors created by passing command to os.popen2(). New in version 2.3.

The following utility functions are defined:

Internaldate2tuple(datestr)

Converts an IMAP4 INTERNALDATE string to Coordinated Universal Time. Returns a time module tuple.

Int2AP(num)

Converts an integer into a string representation using characters from the set [A .. P].

ParseFlags(flagstr)

Converts an IMAP4 "FLAGS" response to a tuple of individual flags.

Time2Internaldate(date_time)

Converts a time module tuple to an IMAP4 "INTERNALDATE" representation. Returns a string in the form: "DD-Mmm-YYYY HH:MM:SS +HHMM" (including double-quotes).

Note that IMAP4 message numbers change as the mailbox changes; in particular, after an "EXPUNGE" command performs deletions the remaining messages are renumbered. So it is highly advisable to use UIDs instead, with the UID command.
At the end of the module, there is a test section that contains a more extensive example of usage.

**See Also:**

Documents describing the protocol, and sources and binaries for servers implementing it, can all be found at the University of Washington's IMAP Information Center ([http://www.cac.washington.edu/imap/](http://www.cac.washington.edu/imap/)).

---

**Subsections**

- 11.10.1 IMAP4 Objects
- 11.10.2 IMAP4 Example

---

*Release 2.4.4c1, documentation updated on 11 October 2006.*

See *About this document...* for information on suggesting changes.
11.10.1 IMAP4 Objects

All IMAP4rev1 commands are represented by methods of the same name, either upper-case or lower-case.

All arguments to commands are converted to strings, except for "AUTHENTICATE", and the last argument to "APPEND" which is passed as an IMAP4 literal. If necessary (the string contains IMAP4 protocol-sensitive characters and isn't enclosed with either parentheses or double quotes) each string is quoted. However, the password argument to the "LOGIN" command is always quoted. If you want to avoid having an argument string quoted (eg: the flags argument to "STORE") then enclose the string in parentheses (eg: r'(\Deleted)').

Each command returns a tuple: (type, [data, ...]) where type is usually 'OK' or 'NO', and data is either the text from the command response, or mandated results from the command. Each data is either a string, or a tuple. If a tuple, then the first part is the header of the response, and the second part contains the data (ie: 'literal' value).

The message_set options to commands below is a string specifying one or more messages to be acted upon. It may be a simple message number ('1'), a range of message numbers ('2:4'), or a group of non-contiguous ranges separated by commas ('1:3, 6:9'). A range can contain an asterisk to indicate an infinite upper bound ('3:*').

An IMAP4 instance has the following methods:

append( mailbox, flags, date_time, message)
Append message to named mailbox.

authenticate( mechanism, authobject)
Authenticate command -- requires response processing.

mechanism specifies which authentication mechanism is to be used - it should appear in the instance variable capabilities in the form AUTH=mechanism.
authobject must be a callable object:

```python
data = authobject(response)
```

It will be called to process server continuation responses. It should return data that will be encoded and sent to server. It should return None if the client abort response "*" should be sent instead.

cellk():
Checkpoint mailbox on server.

cellose():
Close currently selected mailbox. Deleted messages are removed from writable mailbox. This is the recommended command before "LOGOUT".

copy( message_set, new_mailbox)
Copy message_set messages onto end of new_mailbox.

cellreate( mailbox)
Create new mailbox named mailbox.

celldelete( mailbox)
Delete old mailbox named mailbox.

deleleteacl( mailbox, who)
Delete the ACLs (remove any rights) set for who on mailbox. New in version 2.4.

dexpunge():
Permanently remove deleted items from selected mailbox. Generates an "EXPUNGE" response for each deleted message. Returned data contains a list of "EXPUNGE" message numbers in order received.

fetch( message_set, message_parts)
Fetch (parts of) messages. message_parts should be a string of message part names enclosed within parentheses, eg: "(UID BODY[TEXT])". Returned data are tuples of message part envelope and data.
**getacl** (*mailbox*)

Get the "ACL"s for *mailbox*. The method is non-standard, but is supported by the "Cyrus" server.

**getquota** (*root*)

Get the "quotas" root's resource usage and limits. This method is part of the IMAP4 QUOTA extension defined in rfc2087. New in version 2.3.

**getquotaroot** (*mailbox*)

Get the list of "quotas" "roots" for the named *mailbox*. This method is part of the IMAP4 QUOTA extension defined in rfc2087. New in version 2.3.

**list** ([*directory*, *pattern]*)

List mailbox names in *directory* matching *pattern*. *directory* defaults to the top-level mail folder, and *pattern* defaults to match anything. Returned data contains a list of "LIST" responses.

**login** (*user*, *password*)

Identify the client using a plaintext password. The *password* will be quoted.

**login_cram_md5** (*user*, *password*)

Force use of "CRAM-MD5" authentication when identifying the client to protect the password. Will only work if the server "CAPABILITY" response includes the phrase "AUTH=CRAM-MD5". New in version 2.3.

**logout**()

Shutdown connection to server. Returns server "BYE" response.

**lsub** ([*directory*, *pattern]*)

List subscribed mailbox names in directory matching pattern. *directory* defaults to the top level directory and *pattern* defaults to match any mailbox. Returned data are tuples of message part envelope and data.

**myrights** (*mailbox*)

Show my ACLs for a mailbox (i.e. the rights that I have on mailbox). New
in version 2.4.

namespace()
Returns IMAP namespaces as defined in RFC2342. New in version 2.3.

noop()
Send "NOOP" to server.

open( host, port)
Opens socket to port at host. The connection objects established by this method will be used in the read, readline, send, and shutdown methods. You may override this method.

partial( message_num, message_part, start, length)
Fetch truncated part of a message. Returned data is a tuple of message part envelope and data.

proxyauth( user)
Assume authentication as user. Allows an authorised administrator to proxy into any user's mailbox. New in version 2.3.

read( size)
Reads size bytes from the remote server. You may override this method.

readline()
Reads one line from the remote server. You may override this method.

recent()
Prompt server for an update. Returned data is None if no new messages, else value of "RECENT" response.

rename( oldmailbox, newmailbox)
Rename mailbox named oldmailbox to newmailbox.

response( code)
Return data for response code if received, or None. Returns the given code, instead of the usual type.
**search**(charset, criterion[, ...])
Search mailbox for matching messages. `charset` may be `None`, in which case no "CHARSET" will be specified in the request to the server. The IMAP protocol requires that at least one criterion be specified; an exception will be raised when the server returns an error.

Example:
```
# M is a connected IMAP4 instance...
typ, msgnums = M.search(None, 'FROM', '"LDJ"')
# or:
typ, msgnums = M.search(None, '(FROM "LDJ")')
```

**select**(mailbox[, readonly])
Select a mailbox. Returned data is the count of messages in `mailbox` ("EXISTS" response). The default `mailbox` is 'INBOX'. If the `readonly` flag is set, modifications to the mailbox are not allowed.

**send**(data)
Sends `data` to the remote server. You may override this method.

**setacl**(mailbox, who, what)
Set an "ACL" for `mailbox`. The method is non-standard, but is supported by the "Cyrus" server.

**setquota**(root, limits)
Set the "quota" `root`'s resource `limits`. This method is part of the IMAP4 QUOTA extension defined in rfc2087. New in version 2.3.

**shutdown**()
Close connection established in `open`. You may override this method.

**socket**(())
Returns socket instance used to connect to server.

**sort**(sort_criteria, charset, search_criteria[,...])
The `sort` command is a variant of `search` with sorting semantics for the
results. Returned data contains a space separated list of matching message numbers.

Sort has two arguments before the search_criterion argument(s); a parenthesized list of sort_criteria, and the searching charset. Note that unlike search, the searching charset argument is mandatory. There is also a uid sort command which corresponds to sort the way that uid search corresponds to search. The sort command first searches the mailbox for messages that match the given searching criteria using the charset argument for the interpretation of strings in the searching criteria. It then returns the numbers of matching messages.

This is an "IMAP4rev1" extension command.

**status**( mailbox, names)
Request named status conditions for mailbox.

**store**( message_set, command, flag_list)
Alters flag dispositions for messages in mailbox. command is specified by section 6.4.6 of [RFC 2060](https://tools.ietf.org/html/rfc2060) as being one of "FLAGS", "+FLAGS", or "-FLAGS", optionally with a suffix of ".SILENT".

For example, to set the delete flag on all messages:

```python
    typ, data = M.search(None, 'ALL')
    for num in data[0].split():
        M.store(num, '+FLAGS', '\Deleted')
    M.expunge()
```

**subscribe**( mailbox)
Subscribe to new mailbox.

**thread**( threading_algorithm, charset, search_criterion[, ...])
The thread command is a variant of search with threading semantics for the results. Returned data contains a space separated list of thread members.

Thread members consist of zero or more messages numbers, delimited by spaces, indicating successive parent and child.
Thread has two arguments before the search criterion argument(s); a threading algorithm, and the searching charset. Note that unlike search, the searching charset argument is mandatory. There is also a uid thread command which corresponds to thread the way that uid search corresponds to search. The thread command first searches the mailbox for messages that match the given searching criteria using the charset argument for the interpretation of strings in the searching criteria. It then returns the matching messages threaded according to the specified threading algorithm.

This is an "IMAP4rev1" extension command. New in version 2.4.

**uid(command, arg[, ...])**
Execute command args with messages identified by UID, rather than message number. Returns response appropriate to command. At least one argument must be supplied; if none are provided, the server will return an error and an exception will be raised.

**unsubscribe(mailbox)**
Unsubscribe from old mailbox.

**xatom(name[, arg[, ...]])**
Allow simple extension commands notified by server in "CAPABILITY" response.

Instances of IMAP4_SSL have just one additional method:

**ssl()**
Returns SSLObjec instance used for the secure connection with the server.

The following attributes are defined on instances of IMAP4:

**PROTOCOL_VERSION**
The most recent supported protocol in the "CAPABILITY" response from the server.

**debug**
Integer value to control debugging output. The initialize value is taken from
the module variable `Debug`. Values greater than three trace each command.
11.10.2 IMAP4 Example

Here is a minimal example (without error checking) that opens a mailbox and retrieves and prints all messages:

```python
import getpass, imaplib
M = imaplib.IMAP4()
M.login(getpass.getuser(), getpass.getpass())
M.select()
typ, data = M.search(None, 'ALL')
for num in data[0].split():	
    typ, data = M.fetch(num, '(RFC822)')
    print 'Message %s
%s
' % (num, data[0][1])
M.close()
M.logout()
```
11.11 nntplib -- NNTP protocol client

This module defines the class `NNTP` which implements the client side of the NNTP protocol. It can be used to implement a news reader or poster, or automated news processors. For more information on NNTP (Network News Transfer Protocol), see Internet [RFC 977](https://www.rfc-editor.org/info/rfc977).

Here are two small examples of how it can be used. To list some statistics about a newsgroup and print the subjects of the last 10 articles:

```python
>>> s = NNTP('news.cwi.nl')
>>> resp, count, first, last, name = s.group('comp.lang.python')
>>> print 'Group', name, 'has', count, 'articles, range', first, 'to', last
Group comp.lang.python has 59 articles, range 3742 to 3803
>>> resp, subs = s.xhdr('subject', first + '-' + last)
>>> for id, sub in subs[-10:]: print id, sub

3792 Re: Removing elements from a list while iterating...
3793 Re: Who likes Info files?
3794 Emacs and doc strings
3795 a few questions about the Mac implementation
3796 Re: executable python scripts
3797 Re: executable python scripts
3798 Re: a few questions about the Mac implementation
3799 Re: PROPOSAL: A Generic Python Object Interface for Python C Mo
3802 Re: executable python scripts
3803 Re: \
POSIX{} wait and SIGCHLD
```

To post an article from a file (this assumes that the article has valid headers):

```python
>>> s = NNTP('news.cwi.nl')
>>> f = open('/tmp/article')
>>> s.post(f)
'240 Article posted successfully.'
>>> s.quit()
'205 news.cwi.nl closing connection. Goodbye.'
```

The module itself defines the following items:

```python
class NNTP(
```
host[, port [, user[, password [, readermode] [, usenetrc]]]]

Return a new instance of the NNTP class, representing a connection to the NNTP server running on host host, listening at port port. The default port is 119. If the optional user and password are provided, or if suitable credentials are present in /netrc and the optional flag usenetrc is true (the default), the "AUTHINFO USER" and "AUTHINFO PASS" commands are used to identify and authenticate the user to the server. If the optional flag readermode is true, then a "mode reader" command is sent before authentication is performed. Reader mode is sometimes necessary if you are connecting to an NNTP server on the local machine and intend to call reader-specific commands, such as "group". If you get unexpected NNTPPermanentErrors, you might need to set readermode. readermode defaults to None. usenetrc defaults to True.

Changed in version 2.4: usenetrc argument added.

class NNTPError()

Derived from the standard exception Exception, this is the base class for all exceptions raised by the nntplib module.

class NNTPReplyError()

Exception raised when an unexpected reply is received from the server. For backwards compatibility, the exception error_reply is equivalent to this class.

class NNTPTemporaryError()

Exception raised when an error code in the range 400-499 is received. For backwards compatibility, the exception error_temp is equivalent to this class.

class NNTPPermanentError()

Exception raised when an error code in the range 500-599 is received. For backwards compatibility, the exception error_perm is equivalent to this class.

class NNTPProtocolError()

Exception raised when a reply is received from the server that does not
begin with a digit in the range 1-5. For backwards compatibility, the exception `error_proto` is equivalent to this class.

```python
class NNTPDataError():
    Exception raised when there is some error in the response data. For backwards compatibility, the exception `error_data` is equivalent to this class.
```

---

**Subsections**

- [11.11.1 NNTP Objects](#)

---

**Python Library Reference**

Release 2.4.4c1, documentation updated on 11 October 2006. See [About this document...](#) for information on suggesting changes.
11.11.1 NNTP Objects

NNTP instances have the following methods. The response that is returned as the first item in the return tuple of almost all methods is the server's response: a string beginning with a three-digit code. If the server's response indicates an error, the method raises one of the above exceptions.

getwelcome()
Return the welcome message sent by the server in reply to the initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

set_debuglevel( level)
Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request or response. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the connection (including message text).

newgroups( date, time, [file])
Send a "NEWGROUPS" command. The date argument should be a string of the form 'yymmd' indicating the date, and time should be a string of the form 'hhmmss' indicating the time. Return a pair (response, groups) where groups is a list of group names that are new since the given date and time. If the file parameter is supplied, then the output of the "NEWGROUPS" command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

newnews( group, date, time, [file])
Send a "NEWNEWS" command. Here, group is a group name or ' * ', and date and time have the same meaning as for newgroups(). Return a pair (response, articles) where articles is a list of message ids. If the file parameter is supplied, then the output of the "NEWNEWS" command is
stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

**list([file])**

Send a "LIST" command. Return a pair (response, list) where list is a list of tuples. Each tuple has the form (group, last, first, flag), where group is a group name, last and first are the last and first article numbers (as strings), and flag is 'y' if posting is allowed, 'n' if not, and 'm' if the newsgroup is moderated. (Note the ordering: last, first.) If the file parameter is supplied, then the output of the "LIST" command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

**descriptions(grouppattern)**

Send a "LIST NEWSGROUPS" command, where grouppattern is a wildmat string as specified in RFC2980 (it's essentially the same as DOS or UNIX shell wildcard strings). Return a pair (response, list), where list is a list of tuples containing (name, title).

New in version 2.4.

**description(group)**

Get a description for a single group group. If more than one group matches (if 'group' is a real wildmat string), return the first match. If no group matches, return an empty string.

This elides the response code from the server. If the response code is needed, use descriptions().

New in version 2.4.

**group(name)**

Send a "GROUP" command, where name is the group name. Return a tuple (response, count, first, last, name) where count is the (estimated)
number of articles in the group, first is the first article number in the group, last is the last article number in the group, and name is the group name. The numbers are returned as strings.

help([file])
Send a "HELP" command. Return a pair (response, list) where list is a list of help strings. If the file parameter is supplied, then the output of the "HELP" command is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

stat(id)
Send a "STAT" command, where id is the message id (enclosed in "<" and ">") or an article number (as a string). Return a triple (response, number, id) where number is the article number (as a string) and id is the message id (enclosed in "<" and ">").

next()
Send a "NEXT" command. Return as for stat().

last()
Send a "LAST" command. Return as for stat().

head( id)
Send a "HEAD" command, where id has the same meaning as for stat(). Return a tuple (response, number, id, list) where the first three are the same as for stat(), and list is a list of the article's headers (an uninterpreted list of lines, without trailing newlines).

body( id,[file])
Send a "BODY" command, where id has the same meaning as for stat(). If the file parameter is supplied, then the body is stored in a file. If file is a string, then the method will open a file object with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the body. Return as for head(). If file is supplied, then the returned list is an empty list.
**article**(id)
  Send an "ARTICLE" command, where id has the same meaning as for `stat()`. Return as for `head()`.

**slave()**
  Send a "SLAVE" command. Return the server's *response*.

**xhdr**(header, string, [file])
  Send an "XHDR" command. This command is not defined in the RFC but is a common extension. The *header* argument is a header keyword, e.g. 'subject'. The *string* argument should have the form '{first-last}' where *first* and *last* are the first and last article numbers to search. Return a pair (*response*, *list*), where *list* is a list of pairs *(id, text)*, where *id* is an article number (as a string) and *text* is the text of the requested header for that article. If the *file* parameter is supplied, then the output of the "XHDR" command is stored in a file. If *file* is a string, then the method will open a file object with that name, write to it then close it. If *file* is a file object, then it will start calling `write()` on it to store the lines of the command output. If *file* is supplied, then the returned *list* is an empty list.

**post**(file)
  Post an article using the "POST" command. The *file* argument is an open file object which is read until EOF using its `readline()` method. It should be a well-formed news article, including the required headers. The `post()` method automatically escapes lines beginning with ".".

**ihave**(id, file)
  Send an "IHAVE" command. *id* is a message id (enclosed in "<" and ">"). If the response is not an error, treat *file* exactly as for the `post()` method.

**date()**
  Return a triple (*response*, *date*, *time*), containing the current date and time in a form suitable for the `newnews()` and `newgroups()` methods. This is an optional NNTP extension, and may not be supported by all servers.

**xgtitle**(name, [file])
Process an "XGTITLE" command, returning a pair \((response, list)\), where \(list\) is a list of tuples containing \((name, title)\). If the \(file\) parameter is supplied, then the output of the "XGTITLE" command is stored in a file. If \(file\) is a string, then the method will open a file object with that name, write to it then close it. If \(file\) is a file object, then it will start calling \texttt{write()}\ on it to store the lines of the command output. If \(file\) is supplied, then the returned \(list\) is an empty list. This is an optional NNTP extension, and may not be supported by all servers.

RFC2980 says ``It is suggested that this extension be deprecated''. Use \texttt{descriptions()} or \texttt{description()} instead.

\subsection*{\texttt{xover}(start, end, [file])}

Return a pair \((resp, list)\). \texttt{list} is a list of tuples, one for each article in the range delimited by the \texttt{start} and \texttt{end} article numbers. Each tuple is of the form \((article\ number, subject, poster, date, id, references, size, lines)\). If the \texttt{file} parameter is supplied, then the output of the "XOVER" command is stored in a file. If \texttt{file} is a string, then the method will open a file object with that name, write to it then close it. If \texttt{file} is a file object, then it will start calling \texttt{write()}\ on it to store the lines of the command output. If \texttt{file} is supplied, then the returned \texttt{list} is an empty list. This is an optional NNTP extension, and may not be supported by all servers.

\subsection*{\texttt{xpath}(id)}

Return a pair \((resp, path)\), where \texttt{path} is the directory path to the article with message ID \texttt{id}. This is an optional NNTP extension, and may not be supported by all servers.

\subsection*{\texttt{quit}()}\n
Send a "QUIT" command and close the connection. Once this method has been called, no other methods of the NNTP object should be called.
11.12 smtplib -- SMTP protocol client

The smtplib module defines an SMTP client session object that can be used to send mail to any Internet machine with an SMTP or ESMTP listener daemon. For details of SMTP and ESMTP operation, consult RFC 821 (Simple Mail Transfer Protocol) and RFC 1869 (SMTP Service Extensions).

class SMTP([host[, port[, local_hostname]]])

A SMTP instance encapsulates an SMTP connection. It has methods that support a full repertoire of SMTP and ESMTP operations. If the optional host and port parameters are given, the SMTP connect() method is called with those parameters during initialization. An SMTPConnectError is raised if the specified host doesn't respond correctly.

For normal use, you should only require the initialization/connect, sendmail(), and quit() methods. An example is included below.

A nice selection of exceptions is defined as well:

exception SMTPException
    Base exception class for all exceptions raised by this module.

exception SMTPServerDisconnected
    This exception is raised when the server unexpectedly disconnects, or when an attempt is made to use the SMTP instance before connecting it to a server.

exception SMTPResponseException
    Base class for all exceptions that include an SMTP error code. These exceptions are generated in some instances when the SMTP server returns an error code. The error code is stored in the smtp_code attribute of the error, and the smtp_error attribute is set to the error message.
exception **SMTPSenderRefused**
Sender address refused. In addition to the attributes set by on all
SMTPResponseException exceptions, this sets `sender' to the string
that the SMTP server refused.

exception **SMTPRecipientsRefused**
All recipient addresses refused. The errors for each recipient are accessible
through the attribute recipients, which is a dictionary of exactly the
same sort as SMTP.sendmail() returns.

exception **SMTPDataError**
The SMTP server refused to accept the message data.

exception **SMTPConnectError**
Error occurred during establishment of a connection with the server.

exception **SMTPHeloError**
The server refused our "HELO" message.

**Subsections**

- [11.12.1 SMTP Objects](#)
- [11.12.2 SMTP Example](#)
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.12.1 SMTP Objects

An SMTP instance has the following methods:

**set_debuglevel( level)**
Set the debug output level. A true value for `level` results in debug messages for connection and for all messages sent to and received from the server.

**connect([host[, port]])**
Connect to a host on a given port. The defaults are to connect to the local host at the standard SMTP port (25). If the hostname ends with a colon (":"), followed by a number, that suffix will be stripped off and the number interpreted as the port number to use. This method is automatically invoked by the constructor if a host is specified during instantiation.

**docmd(cmd, [argstring])**
Send a command `cmd` to the server. The optional argument `argstring` is simply concatenated to the command, separated by a space.

This returns a 2-tuple composed of a numeric response code and the actual response line (multiline responses are joined into one long line.)

In normal operation it should not be necessary to call this method explicitly. It is used to implement other methods and may be useful for testing private extensions.

If the connection to the server is lost while waiting for the reply, `SMTPServerDisconnected` will be raised.

**helo([hostname])**
Identify yourself to the SMTP server using "HELO". The hostname argument defaults to the fully qualified domain name of the local host.

In normal operation it should not be necessary to call this method explicitly. It will be implicitly called by the `sendmail()` when necessary.
**ehlo([hostname])**

Identify yourself to an ESMTP server using "EHLO". The hostname argument defaults to the fully qualified domain name of the local host. Examine the response for ESMTP option and store them for use by has_extn().

Unless you wish to use has_extn() before sending mail, it should not be necessary to call this method explicitly. It will be implicitly called by sendmail() when necessary.

**has_extn(name)**

Return True if name is in the set of SMTP service extensions returned by the server, False otherwise. Case is ignored.

**verify(address)**

Check the validity of an address on this server using SMTP "VRFY". Returns a tuple consisting of code 250 and a full RFC 822 address (including human name) if the user address is valid. Otherwise returns an SMTP error code of 400 or greater and an error string.

**login(user, password)**

Log in on an SMTP server that requires authentication. The arguments are the username and the password to authenticate with. If there has been no previous "EHLO" or "HELO" command this session, this method tries ESMTP "EHLO" first. This method will return normally if the authentication was successful, or may raise the following exceptions:

- **SMTPHeloError**
  - The server didn't reply properly to the "HELO" greeting.
- **SMTPAuthenticationError**
  - The server didn't accept the username/password combination.
- **SMTPError**
  - No suitable authentication method was found.

**starttls([keyfile[, certfile]])**
Put the SMTP connection in TLS (Transport Layer Security) mode. All SMTP commands that follow will be encrypted. You should then call `ehlo()` again.

If `keyfile` and `certfile` are provided, these are passed to the `socket` module's `ssl()` function.

```python
sendmail(from_addr, to_addrs, msg[, mail_options, rcpt_options])
```

Send mail. The required arguments are an RFC 822 from-address string, a list of RFC 822 to-address strings (a bare string will be treated as a list with 1 address), and a message string. The caller may pass a list of ESMTP options (such as "8bitmime") to be used in "MAIL FROM" commands as `mail_options`. ESMTP options (such as "DSN" commands) that should be used with all "RCPT" commands can be passed as `rcpt_options`. (If you need to use different ESMTP options to different recipients you have to use the low-level methods such as `mail`, `rcpt` and `data` to send the message.)

**Note:** The `from_addr` and `to_addrs` parameters are used to construct the message envelope used by the transport agents. The SMTP does not modify the message headers in any way.

If there has been no previous "EHLO" or "HELO" command this session, this method tries ESMTP "EHLO" first. If the server does ESMTP, message size and each of the specified options will be passed to it (if the option is in the feature set the server advertises). If "EHLO" fails, "HELO" will be tried and ESMTP options suppressed.

This method will return normally if the mail is accepted for at least one recipient. Otherwise it will throw an exception. That is, if this method does not throw an exception, then someone should get your mail. If this method does not throw an exception, it returns a dictionary, with one entry for each recipient that was refused. Each entry contains a tuple of the SMTP error code and the accompanying error message sent by the server.

This method may raise the following exceptions:

**SMTPRecipientsRefused**

All recipients were refused. Nobody got the mail. The `recipients` attribute of the exception object is a dictionary with information about
the refused recipients (like the one returned when at least one recipient was accepted).

**SMTPHeloError**

The server didn't reply properly to the "HELO" greeting.

**SMTPSenderRefused**

The server didn't accept the `from_addr`.

**SMTPDataError**

The server replied with an unexpected error code (other than a refusal of a recipient).

Unless otherwise noted, the connection will be open even after an exception is raised.

**quit()**

Terminate the SMTP session and close the connection.

Low-level methods corresponding to the standard SMTP/ESMTP commands "HELP", "RSET", "NOOP", "MAIL", "RCPT", and "DATA" are also supported. Normally these do not need to be called directly, so they are not documented here. For details, consult the module code.
11.12.2 SMTP Example

This example prompts the user for addresses needed in the message envelope (`To' and `From' addresses), and the message to be delivered. Note that the headers to be included with the message must be included in the message as entered; this example doesn't do any processing of the RFC 822 headers. In particular, the `To' and `From' addresses must be included in the message headers explicitly.

```python
import smtplib

def prompt(prompt):
    return raw_input(prompt).strip()

fromaddr = prompt("From:	")
toaddrs = prompt("To:	").split()
print "Enter message, end with ^D (Unix) or ^Z (Windows):
#
# Add the From: and To: headers at the start!
msg = ("From: %s\r\nTo: %s\r\n\r\n" % (fromaddr, ",	".join(toaddrs)))
while 1:
    try:
        line = raw_input()
    except EOFError:
        break
    if not line:
        break
    msg = msg + line

print "Message length is " + repr(len(msg))

server = smtplib.SMTP('localhost')
server.set_debuglevel(1)
server.sendmail(fromaddr, toaddrs, msg)
server.quit()
```
This module offers several classes to implement SMTP servers. One is a generic do-nothing implementation, which can be overridden, while the other two offer specific mail-sending strategies.

**Subsections**

- 11.13.1 SMTPServer Objects
- 11.13.2 DebuggingServer Objects
- 11.13.3 PureProxy Objects
- 11.13.4 MailmanProxy Objects

Release 2.4.4c1, documentation updated on 11 October 2006.  
See [About this document...](#) for information on suggesting changes.
11.13.1 SMTPServer Objects

**class SMTPServer**( localaddr, remoteaddr)
Create a new SMTPServer object, which binds to local address localaddr. It will treat remoteaddr as an upstream SMTP relayer. It inherits from asyncore.dispatcher, and so will insert itself into asyncore’s event loop on instantiation.

**process_message**( peer, mailfrom, rcpttos, data)
Raise NotImplemented exception. Override this in subclasses to do something useful with this message. Whatever was passed in the constructor as remoteaddr will be available as the _remoteaddr attribute. peer is the remote host's address, mailfrom is the envelope originator, rcpttos are the envelope recipients and data is a string containing the contents of the e-mail (which should be in RFC 2822 format).
class DebuggingServer(localaddr, remoteaddr)

Create a new debugging server. Arguments are as per SMTPServer. Messages will be discarded, and printed on stdout.
11.13.3 PureProxy Objects

class PureProxy(localaddr, remoteaddr)

Create a new pure proxy server. Arguments are as per SMTPServer. Everything will be relayed to remoteaddr. Note that running this has a good chance to make you into an open relay, so please be careful.
11.13.4 MailmanProxy Objects

```python
class MailmanProxy(localaddr, remoteaddr):
    Create a new pure proxy server. Arguments are as per SMTPServer. Everything will be relayed to remoteaddr, unless local mailman configurations knows about an address, in which case it will be handled via mailman. Note that running this has a good chance to make you into an open relay, so please be careful.
```

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
11.14 telnetlib -- Telnet client

The telnetlib module provides a Telnet class that implements the Telnet protocol. See RFC 854 for details about the protocol. In addition, it provides symbolic constants for the protocol characters (see below), and for the telnet options. The symbolic names of the telnet options follow the definitions in arpa/telnet.h, with the leading TELOPT_ removed. For symbolic names of options which are traditionally not included in arpa/telnet.h, see the module source itself.

The symbolic constants for the telnet commands are: IAC, DONT, DO, WONT, WILL, SE (Subnegotiation End), NOP (No Operation), DM (Data Mark), BRK (Break), IP (Interrupt process), AO (Abort output), AYT (Are You There), EC (Erase Character), EL (Erase Line), GA (Go Ahead), SB (Subnegotiation Begin).

**class Telnet([host[, port]])**

Telnet represents a connection to a Telnet server. The instance is initially not connected by default; the open() method must be used to establish a connection. Alternatively, the host name and optional port number can be passed to the constructor, to, in which case the connection to the server will be established before the constructor returns.

Do not reopen an already connected instance.

This class has many read_*() methods. Note that some of them raise EOFError when the end of the connection is read, because they can return an empty string for other reasons. See the individual descriptions below.

---

See Also:

RFC 854, Telnet Protocol Specification
Definition of the Telnet protocol.

---

Subsections
11.14.1 Telnet Objects
11.14.2 Telnet Example
11.14.1 Telnet Objects

Telnet instances have the following methods:

**read_until**(expected[, timeout])

Read until a given string, `expected`, is encountered or until `timeout` seconds have passed.

When no match is found, return whatever is available instead, possibly the empty string. Raise `EOFError` if the connection is closed and no cooked data is available.

**read_all()**

Read all data until EOF; block until connection closed.

**read_some()**

Read at least one byte of cooked data unless EOF is hit. Return `'` if EOF is hit. Block if no data is immediately available.

**read_very_eager()**

Read everything that can be without blocking in I/O (eager).

Raise `EOFError` if connection closed and no cooked data available. Return `'` if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

**read_eager()**

Read readily available data.

Raise `EOFError` if connection closed and no cooked data available. Return `'` if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

**read_lazy()**

Process and return data already in the queues (lazy).
Raise `EOFError` if connection closed and no data available. Return `' ' if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

`read_very_lazy()`
Return any data available in the cooked queue (very lazy).

Raise `EOFError` if connection closed and no data available. Return `' ' if no cooked data available otherwise. This method never blocks.

`read_sb_data()`
Return the data collected between a SB/SE pair (suboption begin/end). The callback should access these data when it was invoked with a SE command. This method never blocks.

New in version 2.3.

`open( host[, port])`
Connect to a host. The optional second argument is the port number, which defaults to the standard Telnet port (23).

Do not try to reopen an already connected instance.

`msg( msg[, *args])`
Print a debug message when the debug level is > 0. If extra arguments are present, they are substituted in the message using the standard string formatting operator.

`set_debuglevel( debuglevel)`
Set the debug level. The higher the value of `debuglevel`, the more debug output you get (on `sys.stdout`).

`close()`
Close the connection.

`get_socket()`
Return the socket object used internally.
fileno()
Return the file descriptor of the socket object used internally.

write(buffer)
Write a string to the socket, doubling any IAC characters. This can block if the connection is blocked. May raise socket.error if the connection is closed.

interact()
Interaction function, emulates a very dumb Telnet client.

mt_interact()
Multithreaded version of interact().

expect(list[, timeout])
Read until one from a list of a regular expressions matches.

The first argument is a list of regular expressions, either compiled (re.RegexObject instances) or uncompiled (strings). The optional second argument is a timeout, in seconds; the default is to block indefinitely.

Return a tuple of three items: the index in the list of the first regular expression that matches; the match object returned; and the text read up till and including the match.

If end of file is found and no text was read, raise EOFError. Otherwise, when nothing matches, return (-1, None, text) where text is the text received so far (may be the empty string if a timeout happened).

If a regular expression ends with a greedy match (such as .* ) or if more than one expression can match the same input, the results are indeterministic, and may depend on the I/O timing.

set_option_negotiation_callback(callback)
Each time a telnet option is read on the input flow, this callback (if set) is called with the following parameters : callback(telnet socket, command (DO/DONT/WILL/WONT), option). No other action is done afterwards by
telnetlib.
11.14.2 Telnet Example

A simple example illustrating typical use:

```python
import getpass
import sys
import telnetlib

HOST = "localhost"
user = raw_input("Enter your remote account: ")
password = getpass.getpass()
	n = telnetlib.Telnet(HOST)
	n.read_until("login: ")

tn.write(user + "\n")

if password:
    tn.read_until("Password: ")
    tn.write(password + "\n")

tn.write("ls\n")

tn.write("exit\n")

print tn.read_all()
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.15 urlparse -- Parse URLs into components

This module defines a standard interface to break Uniform Resource Locator (URL) strings up in components (addressing scheme, network location, path etc.), to combine the components back into a URL string, and to convert a ``relative URL" to an absolute URL given a ``base URL."

The module has been designed to match the Internet RFC on Relative Uniform Resource Locators (and discovered a bug in an earlier draft!). It supports the following URL schemes: file, ftp, gopher, hdl, http, https, imap, mailto, mms, news, nntp, prospero, rsync, rtsp, rtspu, shttp, sip, snews, svn, svn+ssh, telnet, wais.

The urlparse module defines the following functions:

**urlparse** (urlstring[, default_scheme[, allow_fragments]])

Parse a URL into 6 components, returning a 6-tuple: (addressing scheme, network location, path, parameters, query, fragment identifier). This corresponds to the general structure of a URL:

```
scheme: //netloc/path;parameters?query#fragment
```

Each tuple item is a string, possibly empty. The components are not broken up in smaller parts (e.g. the network location is a single string), and % escapes are not expanded. The delimiters as shown above are not part of the tuple items, except for a leading slash in the path component, which is retained if present.

Example:

```
urlparse('http://www.cwi.nl:80/%7Eguido/Python.html')
```

yields the tuple

```
('http', 'www.cwi.nl:80', '/%7Eguido/Python.html', '', '', '')
```

If the default_scheme argument is specified, it gives the default addressing
scheme, to be used only if the URL string does not specify one. The default value for this argument is the empty string.

If the allow_fragments argument is zero, fragment identifiers are not allowed, even if the URL's addressing scheme normally does support them. The default value for this argument is 1.

``urlunparse( tuple)``

Construct a URL string from a tuple as returned by `urlparse()`. This may result in a slightly different, but equivalent URL, if the URL that was parsed originally had redundant delimiters, e.g. a ? with an empty query (the draft states that these are equivalent).

``urlsplit( urlstring[, default_scheme[, allow_fragments]])``

This is similar to `urlparse()`, but does not split the params from the URL. This should generally be used instead of `urlparse()` if the more recent URL syntax allowing parameters to be applied to each segment of the path portion of the URL (see RFC 2396) is wanted. A separate function is needed to separate the path segments and parameters. This function returns a 5-tuple: (addressing scheme, network location, path, query, fragment identifier). New in version 2.2.

``urlunsplit( tuple)``

Combine the elements of a tuple as returned by `urlsplit()` into a complete URL as a string. New in version 2.2.

``urljoin( base, url[, allow_fragments])``

Construct a full (``absolute``) URL by combining a ``base URL`` (base) with a ``relative URL`` (url). Informally, this uses components of the base URL, in particular the addressing scheme, the network location and (part of) the path, to provide missing components in the relative URL.

Example:

``urljoin('http://www.cwi.nl/%7Eguido/Python.html', 'FAQ.html')``

yields the string

'http://www.cwi.nl/%7Eguido/FAQ.html'
The `allow_fragments` argument has the same meaning as for `urlparse()`.

**urldefrag(url)**

If `url` contains a fragment identifier, returns a modified version of `url` with no fragment identifier, and the fragment identifier as a separate string. If there is no fragment identifier in `url`, returns `url` unmodified and an empty string.

This Request For Comments includes the rules for joining an absolute and a relative URL, including a fair number of "Abnormal Examples" which govern the treatment of border cases.

**RFC 2396, Uniform Resource Identifiers (URI): Generic Syntax**

Document describing the generic syntactic requirements for both Uniform Resource Names (URNs) and Uniform Resource Locators (URLs).
11.16 SocketServer -- A framework for network servers

The SocketServer module simplifies the task of writing network servers.

There are four basic server classes: TCPServer uses the Internet TCP protocol, which provides for continuous streams of data between the client and server. UDPServer uses datagrams, which are discrete packets of information that may arrive out of order or be lost while in transit. The more infrequently used UnixStreamServer and UnixDatagramServer classes are similar, but use UNIX domain sockets; they're not available on non-UNIX platforms. For more details on network programming, consult a book such as W. Richard Steven's UNIX Network Programming or Ralph Davis's Win32 Network Programming.

These four classes process requests synchronously; each request must be completed before the next request can be started. This isn't suitable if each request takes a long time to complete, because it requires a lot of computation, or because it returns a lot of data which the client is slow to process. The solution is to create a separate process or thread to handle each request; the ForkingMixIn and ThreadingMixIn mix-in classes can be used to support asynchronous behaviour.

Creating a server requires several steps. First, you must create a request handler class by subclassing the BaseRequestHandler class and overriding its handle() method; this method will process incoming requests. Second, you must instantiate one of the server classes, passing it the server's address and the request handler class. Finally, call the handle_request() or serve_forever() method of the server object to process one or many requests.

When inheriting from ThreadingMixIn for threaded connection behavior, you should explicitly declare how you want your threads to behave on an abrupt shutdown. The ThreadingMixIn class defines an attribute daemon_threads, which indicates whether or not the server should wait for thread termination. You should set the flag explicitly if you would like threads to behave autonomously; the default is False, meaning that Python will not exit until all
threads created by ThreadingMixIn have exited.

Server classes have the same external methods and attributes, no matter what network protocol they use:

---

Subsections

- [11.16.1 Server Creation Notes](#)
- [11.16.2 Server Objects](#)
- [11.16.3 RequestHandler Objects](#)

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See *About this document...* for information on suggesting changes.
11.16.1 Server Creation Notes

There are five classes in an inheritance diagram, four of which represent synchronous servers of four types:

```
+------------+  +-------------+
| BaseServer |  | TCPServer    |
+------------+  +--------------------+
| UIBStreamServer |------>|
+------------------+
| UDPServer      |------>|
| UnixDatagramServer |
+--------------------+
```

Note that UnixDatagramServer derives from UDPServer, not from UnixStreamServer - the only difference between an IP and a Unix stream server is the address family, which is simply repeated in both unix server classes.

Forking and threading versions of each type of server can be created using the ForkingMixIn and ThreadingMixIn mix-in classes. For instance, a threading UDP server class is created as follows:

```
class ThreadingUDPServer(ThreadingMixIn, UDPServer): pass
```

The mix-in class must come first, since it overrides a method defined in UDPServer. Setting the various member variables also changes the behavior of the underlying server mechanism.

To implement a service, you must derive a class from BaseRequestHandler and redefine its handle() method. You can then run various versions of the service by combining one of the server classes with your request handler class. The request handler class must be different for datagram or stream services. This can be hidden by using the handler subclasses StreamRequestHandler or DatagramRequestHandler.

Of course, you still have to use your head! For instance, it makes no sense to use
a forking server if the service contains state in memory that can be modified by
different requests, since the modifications in the child process would never reach
the initial state kept in the parent process and passed to each child. In this case,
you can use a threading server, but you will probably have to use locks to protect
the integrity of the shared data.

On the other hand, if you are building an HTTP server where all data is stored
externally (for instance, in the file system), a synchronous class will essentially
render the service "deaf" while one request is being handled - which may be for
a very long time if a client is slow to receive all the data it has requested. Here a
threading or forking server is appropriate.

In some cases, it may be appropriate to process part of a request synchronously,
but to finish processing in a forked child depending on the request data. This can
be implemented by using a synchronous server and doing an explicit fork in the
request handler class handle() method.

Another approach to handling multiple simultaneous requests in an environment
that supports neither threads nor fork() (or where these are too expensive or
inappropriate for the service) is to maintain an explicit table of partially finished
requests and to use select() to decide which request to work on next (or
whether to handle a new incoming request). This is particularly important for
stream services where each client can potentially be connected for a long time (if
threads or subprocesses cannot be used).
11.16.2 Server Objects

**fileno()**

Return an integer file descriptor for the socket on which the server is listening. This function is most commonly passed to `select.select()`, to allow monitoring multiple servers in the same process.

**handle_request()**

Process a single request. This function calls the following methods in order: `get_request()`, `verify_request()`, and `process_request()`. If the user-provided `handle()` method of the handler class raises an exception, the server's `handle_error()` method will be called.

**serve_forever()**

Handle an infinite number of requests. This simply calls `handle_request()` inside an infinite loop.

**address_family**

The family of protocols to which the server's socket belongs. `socket.AF_INET` and `socket.AF_UNIX` are two possible values.

**RequestHandlerClass**

The user-provided request handler class; an instance of this class is created for each request.

**server_address**

The address on which the server is listening. The format of addresses varies depending on the protocol family; see the documentation for the socket module for details. For Internet protocols, this is a tuple containing a string giving the address, and an integer port number: (`'127.0.0.1', 80`), for example.

**socket**

The socket object on which the server will listen for incoming requests.

The server classes support the following class variables:
**allow_reuse_address**

Whether the server will allow the reuse of an address. This defaults to `False`, and can be set in subclasses to change the policy.

**request_queue_size**

The size of the request queue. If it takes a long time to process a single request, any requests that arrive while the server is busy are placed into a queue, up to `request_queue_size` requests. Once the queue is full, further requests from clients will get a "Connection denied" error. The default value is usually 5, but this can be overridden by subclasses.

**socket_type**

The type of socket used by the server; `socket.SOCK_STREAM` and `socket.SOCK_DGRAM` are two possible values.

There are various server methods that can be overridden by subclasses of base server classes like `TCPServer`; these methods aren't useful to external users of the server object.

**finish_request()**

Actually processes the request by instantiating `RequestHandlerClass` and calling its `handle()` method.

**get_request()**

Must accept a request from the socket, and return a 2-tuple containing the new socket object to be used to communicate with the client, and the client's address.

**handle_error**( `request`, `client_address` )

This function is called if the `RequestHandlerClass's handle()` method raises an exception. The default action is to print the traceback to standard output and continue handling further requests.

**process_request**( `request`, `client_address` )

Calls `finish_request()` to create an instance of the `RequestHandlerClass`. If desired, this function can create a new process or thread to handle the request; the `ForkingMixIn` and `ThreadingMixIn` classes do this.
**server_activate()**

Called by the server's constructor to activate the server. The default behavior just listens to the server's socket. May be overridden.

**server_bind()**

Called by the server's constructor to bind the socket to the desired address. May be overridden.

**verify_request(request, client_address)**

Must return a Boolean value; if the value is True, the request will be processed, and if it's False, the request will be denied. This function can be overridden to implement access controls for a server. The default implementation always returns True.
11.16.3 RequestHandler Objects

The request handler class must define a new handle() method, and can override any of the following methods. A new instance is created for each request.

**finish()**
Called after the handle() method to perform any clean-up actions required. The default implementation does nothing. If setup() or handle() raise an exception, this function will not be called.

**handle()**
This function must do all the work required to service a request. The default implementation does nothing. Several instance attributes are available to it; the request is available as self.request; the client address as self.client_address; and the server instance as self.server, in case it needs access to per-server information.

The type of self.request is different for datagram or stream services. For stream services, self.request is a socket object; for datagram services, self.request is a string. However, this can be hidden by using the request handler subclasses StreamRequestHandler or DatagramRequestHandler, which override the setup() and finish() methods, and provide self.rfile and self.wfile attributes. self.rfile and self.wfile can be read or written, respectively, to get the request data or return data to the client.

**setup()**
Called before the handle() method to perform any initialization actions required. The default implementation does nothing.
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
11.17 BaseHTTPServer -- Basic HTTP server

This module defines two classes for implementing HTTP servers (Web servers). Usually, this module isn't used directly, but is used as a basis for building functioning Web servers. See the SimpleHTTPServer and CGIHTTPServer modules.

The first class, HTTPServer, is a SocketServer.TCPServer subclass. It creates and listens at the HTTP socket, dispatching the requests to a handler. Code to create and run the server looks like this:

```python
def run(server_class=BaseHTTPServer.HTTPServer,
       handler_class=BaseHTTPServer.BaseHTTPRequestHandler):
    server_address = ('', 8000)
    httpd = server_class(server_address, handler_class)
    httpd.serve_forever()
```

**class HTTPServer**( server_address, RequestHandlerClass)

This class builds on the TCPServer class by storing the server address as instance variables named server_name and server_port. The server is accessible by the handler, typically through the handler's server instance variable.

**class BaseHTTPRequestHandler**( request, client_address, server)

This class is used to handle the HTTP requests that arrive at the server. By itself, it cannot respond to any actual HTTP requests; it must be subclassed to handle each request method (e.g. GET or POST). BaseHTTPRequestHandler provides a number of class and instance variables, and methods for use by subclasses.

The handler will parse the request and the headers, then call a method specific to the request type. The method name is constructed from the request. For example, for the request method "SPAM", the do_SPAM() method will be called with no arguments. All of the relevant information is stored in instance variables of the handler. Subclasses should not need to
override or extend the `__init__()` method.

`BaseHTTPRequestHandler` has the following instance variables:

**client_address**
Contains a tuple of the form `(host, port)` referring to the client's address.

**command**
Contains the command (request type). For example, 'GET'.

**path**
Contains the request path.

**request_version**
Contains the version string from the request. For example, 'HTTP/1.0'.

**headers**
Holds an instance of the class specified by the `MessageClass` class variable. This instance parses and manages the headers in the HTTP request.

**rfile**
Contains an input stream, positioned at the start of the optional input data.

**wfile**
Contains the output stream for writing a response back to the client. Proper adherence to the HTTP protocol must be used when writing to this stream.

`BaseHTTPRequestHandler` has the following class variables:

**server_version**
Specifies the server software version. You may want to override this. The format is multiple whitespace-separated strings, where each string is of the form name[/version]. For example, 'BaseHTTP/0.2'.

**sys_version**
Contains the Python system version, in a form usable by the `version_string` method and the `server_version` class variable. For example, 'Python/1.4'.

**error_message_format**
Specifies a format string for building an error response to the client. It uses parenthesized, keyed format specifiers, so the format operand must be a dictionary. The **code** key should be an integer, specifying the numeric HTTP error code value. **message** should be a string containing a (detailed) error message of what occurred, and **explain** should be an explanation of the error code number. Default **message** and **explain** values can found in the **responses** class variable.

**protocol_version**
This specifies the HTTP protocol version used in responses. If set to 'HTTP/1.1', the server will permit HTTP persistent connections; however, your server **must** then include an accurate **Content-Length** header (using **send_header()**) in all of its responses to clients. For backwards compatibility, the setting defaults to 'HTTP/1.0'.

**MessageClass**
Specifies a **rfc822.Message**-like class to parse HTTP headers. Typically, this is not overridden, and it defaults to **mimetools.Message**.

**responses**
This variable contains a mapping of error code integers to two-element tuples containing a short and long message. For example, `{**code**: (**shortmessage**, **longmessage**)}`. The **shortmessage** is usually used as the **message** key in an error response, and **longmessage** as the **explain** key (see the **error_message_format** class variable).

A **BaseHTTPRequestHandler** instance has the following methods:

**handle()**
Calls **handle_one_request()** once (or, if persistent connections are enabled, multiple times) to handle incoming HTTP requests. You should never need to override it; instead, implement appropriate **do_*()** methods.

**handle_one_request()**
This method will parse and dispatch the request to the appropriate **do_*()** method. You should never need to override it.
send_error(code[, message])
Sends and logs a complete error reply to the client. The numeric code specifies the HTTP error code, with message as optional, more specific text. A complete set of headers is sent, followed by text composed using the error_message_format class variable.

send_response(code[, message])
Sends a response header and logs the accepted request. The HTTP response line is sent, followed by Server and Date headers. The values for these two headers are picked up from the version_string() and date_time_string() methods, respectively.

send_header(keyword, value)
Writes a specific HTTP header to the output stream. keyword should specify the header keyword, with value specifying its value.

drop_headers()
Sends a blank line, indicating the end of the HTTP headers in the response.

log_request([code[, size]])
Logs an accepted (successful) request. code should specify the numeric HTTP code associated with the response. If a size of the response is available, then it should be passed as the size parameter.

log_error(...)  
Logs an error when a request cannot be fulfilled. By default, it passes the message to log_message(), so it takes the same arguments (format and additional values).

log_message(format, ...)
Logs an arbitrary message to sys.stderr. This is typically overridden to create custom error logging mechanisms. The format argument is a standard printf-style format string, where the additional arguments to log_message() are applied as inputs to the formatting. The client address and current date and time are prefixed to every message logged.

version_string()
Returns the server software's version string. This is a combination of the server_version and sys_version class variables.

**date_time_string()**
Returns the current date and time, formatted for a message header.

**log_data_time_string()**
Returns the current date and time, formatted for logging.

**address_string()**
Returns the client address, formatted for logging. A name lookup is performed on the client's IP address.

Module **CGIHTTPServer**: Extended request handler that supports CGI scripts.

Module **SimpleHTTPServer**: Basic request handler that limits response to files actually under the document root.
11.18 SimpleHTTPServer -- Simple HTTP request handler

The SimpleHTTPServer module defines a request-handler class, interface-compatible with BaseHTTPServer.BaseHTTPRequestHandler, that serves files only from a base directory.

The SimpleHTTPServer module defines the following class:

```
class SimpleHTTPRequestHandler(request, client_address, server)
```

This class is used to serve files from the current directory and below, directly mapping the directory structure to HTTP requests.

A lot of the work, such as parsing the request, is done by the base class BaseHTTPServer.BaseHTTPRequestHandler. This class implements the do_GET() and do_HEAD() functions.

The SimpleHTTPRequestHandler defines the following member variables:

```
server_version
```

This will be "SimpleHTTP/" + __version__, where __version__ is defined in the module.

```
extensions_map
```

A dictionary mapping suffixes into MIME types. The default is signified by an empty string, and is considered to be application/octet-stream. The mapping is used case-insensitively, and so should contain only lower-cased keys.

The SimpleHTTPRequestHandler defines the following methods:

```
do_HEAD()
```

This method serves the 'HEAD' request type: it sends the headers it would send for the equivalent GET request. See the do_GET() method for a more
complete explanation of the possible headers.

**do_GET()**

The request is mapped to a local file by interpreting the request as a path relative to the current working directory.

If the request was mapped to a directory, the directory is checked for a file named `index.html` or `index.htm` (in that order). If found, the file's contents are returned; otherwise a directory listing is generated by calling the `list_directory()` method. This method uses `os.listdir()` to scan the directory, and returns a 404 error response if the `listdir()` fails.

If the request was mapped to a file, it is opened and the contents are returned. Any `IOError` exception in opening the requested file is mapped to a 404, 'File not found' error. Otherwise, the content type is guessed by calling the `guess_type()` method, which in turn uses the `extensions_map` variable.

A 'Content-type:' header with the guessed content type is output, followed by a blank line signifying the end of the headers, and then the contents of the file are output. If the file's MIME type starts with `text/` the file is opened in text mode; otherwise binary mode is used.

For example usage, see the implementation of the `test()` function.

See About this document... for information on suggesting changes.
11.19 CGIHTTPServer -- CGI-capable HTTP request handler

The CGIHTTPServer module defines a request-handler class, interface compatible with BaseHTTPServer.BaseHTTPRequestHandler and inherits behavior from SimpleHTTPServer.SimpleHTTPRequestHandler but can also run CGI scripts.

Note: This module can run CGI scripts on UNIX and Windows systems; on Mac OS it will only be able to run Python scripts within the same process as itself.

The CGIHTTPServer module defines the following class:

class CGIHTTPRequestHandler( request, client_address, server)

This class is used to serve either files or output of CGI scripts from the current directory and below. Note that mapping HTTP hierarchic structure to local directory structure is exactly as in SimpleHTTPServer.SimpleHTTPRequestHandler.

The class will however, run the CGI script, instead of serving it as a file, if it guesses it to be a CGI script. Only directory-based CGI are used -- the other common server configuration is to treat special extensions as denoting CGI scripts.

The do_GET() and do_HEAD() functions are modified to run CGI scripts and serve the output, instead of serving files, if the request leads to somewhere below the cgi_directories path.

The CGIHTTPRequestHandler defines the following data member:

cgi_directories

This defaults to ['/cgi-bin', '/htbin'] and describes directories to treat as containing CGI scripts.

The CGIHTTPRequestHandler defines the following methods:
**do_POST()**

This method serves the 'POST' request type, only allowed for CGI scripts. Error 501, "Can only POST to CGI scripts", is output when trying to POST to a non-CGI url.

Note that CGI scripts will be run with UID of user nobody, for security reasons. Problems with the CGI script will be translated to error 403.

For example usage, see the implementation of the `test()` function.

See [About this document...](#) for information on suggesting changes.
11.20 cookielib -- Cookie handling for HTTP clients

The cookielib module defines classes for automatic handling of HTTP cookies. It is useful for accessing web sites that require small pieces of data - cookies - to be set on the client machine by an HTTP response from a web server, and then returned to the server in later HTTP requests.

Both the regular Netscape cookie protocol and the protocol defined by RFC 2965 are handled. RFC 2965 handling is switched off by default. RFC 2109 cookies are parsed as Netscape cookies and subsequently treated as RFC 2965 cookies. Note that the great majority of cookies on the Internet are Netscape cookies. cookielib attempts to follow the de-facto Netscape cookie protocol (which differs substantially from that set out in the original Netscape specification), including taking note of the max-age and port cookie-attributes introduced with RFC 2109. Note: The various named parameters found in Set-Cookie: and Set-Cookie2: headers (eg. domain and expires) are conventionally referred to as attributes. To distinguish them from Python attributes, the documentation for this module uses the term cookie-attribute instead.

The module defines the following exception:

exception LoadError

Instances of FileCookieJar raise this exception on failure to load cookies from a file.

The following classes are provided:

class CookieJar(policy=None)

policy is an object implementing the CookiePolicy interface.

The CookieJar class stores HTTP cookies. It extracts cookies from HTTP requests, and returns them in HTTP responses. CookieJar instances automatically expire contained cookies when necessary. Subclasses are also responsible for storing and retrieving cookies from a
file or database.

**class FileCookieJar** *(filename, delayload=None, policy=None)*

`policy` is an object implementing the `CookiePolicy` interface. For the other arguments, see the documentation for the corresponding attributes.

A `CookieJar` which can load cookies from, and perhaps save cookies to, a file on disk. Cookies are **NOT** loaded from the named file until either the `load()` or `revert()` method is called. Subclasses of this class are documented in section 11.20.2.

**class CookiePolicy()**

This class is responsible for deciding whether each cookie should be accepted from / returned to the server.

**class DefaultCookiePolicy** *(blockedDomains=None, allowedDomains=None, netscape=True, rfc2965=False, hidecookie=False, strict_domain=False, strict_rfc2965_unverifiable=False, strict_ns_domain=DefaultCookiePolicy.Default, strict_ns_set_initial_dollar=False, strict_ns_set_path=False)*

Constructor arguments should be passed as keyword arguments only. `blocked_domains` is a sequence of domain names that we never accept cookies from, nor return cookies to. `allowed_domains` if not `None`, this is a sequence of the only domains for which we accept and return cookies. For all other arguments, see the documentation for `CookiePolicy` and `DefaultCookiePolicy` objects.

`DefaultCookiePolicy` implements the standard accept / reject rules for Netscape and RFC 2965 cookies. RFC 2109 cookies (ie. cookies received in a `Set-Cookie:` header with a version cookie-attribute of 1) are treated according to the RFC 2965 rules. `DefaultCookiePolicy` also provides some parameters to allow some fine-tuning of policy.

**class Cookie()**

This class represents Netscape, RFC 2109 and RFC 2965 cookies. It is not expected that users of `cookie` construct their own `Cookie` instances.
Instead, if necessary, call `make_cookies()` on a `CookieJar` instance.

**See Also:**

Module **`urllib2`**: URL opening with automatic cookie handling.

Module **`Cookie`**: HTTP cookie classes, principally useful for server-side code. The `cookielib` and `Cookie` modules do not depend on each other.

[http://wwwsearch.sf.net/ClientCookie/](http://wwwsearch.sf.net/ClientCookie/) Extensions to this module, including a class for reading Microsoft Internet Explorer cookies on Windows.

[http://www.netscape.com/newsref/std/cookie_spec.html](http://www.netscape.com/newsref/std/cookie_spec.html) The specification of the original Netscape cookie protocol. Though this is still the dominant protocol, the 'Netscape cookie protocol' implemented by all the major browsers (and `cookielib`) only bears a passing resemblance to the one sketched out in `cookie_spec.html`.

**RFC 2109, HTTP State Management Mechanism**

**RFC 2965, HTTP State Management Mechanism**
The Netscape protocol with the bugs fixed. Uses Set-Cookie2: in place of Set-Cookie:. Not widely used.

• 11.20.3 CookiePolicy Objects
• 11.20.4 DefaultCookiePolicy Objects
• 11.20.5 Cookie Objects
• 11.20.6 Examples

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.20.1 CookieJar and FileCookieJar Objects

CookieJar objects support the iterator protocol for iterating over contained Cookie objects.

CookieJar has the following methods:

`add_cookie_header(request)`
Add correct Cookie: header to request.

If policy allows (i.e. the rfc2965 and hide_cookie2 attributes of the CookieJar's CookiePolicy instance are true and false respectively), the Cookie2: header is also added when appropriate.

The request object (usually a urllib2.Request instance) must support the methods get_full_url(), get_host(), get_type(), unverifiable(), get_origin_req_host(), has_header(), get_header(), header_items(), and add_unredirected_header(), as documented by urllib2.

`extract_cookies(response, request)`
Extract cookies from HTTP response and store them in the CookieJar, where allowed by policy.

The CookieJar will look for allowable Set-Cookie: and Set-Cookie2: headers in the response argument, and store cookies as appropriate (subject to the CookiePolicy.set_ok() method's approval).

The response object (usually the result of a call to urllib2.urlopen(), or similar) should support an info() method, which returns an object with a getallmatchingheaders() method (usually a mimetools.Message instance).

The request object (usually a urllib2.Request instance) must support the methods get_full_url(), get_host(), unverifiable(), and get_origin_req_host(), as documented by urllib2. The request is used to set default values for cookie-attributes as well as for
checking that the cookie is allowed to be set.

set_policy(policy)
   Set the CookiePolicy instance to be used.

make_cookies(response, request)
   Return sequence of Cookie objects extracted from response object.

   See the documentation for extract_cookies for the interfaces required of the response and request arguments.

set_cookie_if_ok(cookie, request)
   Set a Cookie if policy says it's OK to do so.

set_cookie(cookie)
   Set a Cookie, without checking with policy to see whether or not it should be set.

clear([domain[, path[, name]]])
   Clear some cookies.

   If invoked without arguments, clear all cookies. If given a single argument, only cookies belonging to that domain will be removed. If given two arguments, cookies belonging to the specified domain and URL path are removed. If given three arguments, then the cookie with the specified domain, path and name is removed.

   Raises KeyError if no matching cookie exists.

clear_session_cookies()
   Discard all session cookies.

   Discards all contained cookies that have a true discard attribute (usually because they had either no max-age or expires cookie-attribute, or an explicit discard cookie-attribute). For interactive browsers, the end of a session usually corresponds to closing the browser window.

   Note that the save() method won't save session cookies anyway, unless
you ask otherwise by passing a true ignore_discard argument.

FileCookieJar implements the following additional methods:

**save**(filename=None, ignore_discard=False, ignore_expires=False)

Save cookies to a file.

This base class raises NotImplementedException. Subclasses may leave this method unimplemented.

*filename* is the name of file in which to save cookies. If *filename* is not specified, *self.filename* is used (whose default is the value passed to the constructor, if any); if *self.filename* is None, ValueError is raised.

*ignore_discard*: save even cookies set to be discarded. *ignore_expires*: save even cookies that have expired

The file is overwritten if it already exists, thus wiping all the cookies it contains. Saved cookies can be restored later using the load() or revert() methods.

**load**(filename=None, ignore_discard=False, ignore_expires=False)

Load cookies from a file.

Old cookies are kept unless overwritten by newly loaded ones.

Arguments are as for save().

The named file must be in the format understood by the class, or LoadError will be raised.

**revert**(filename=None, ignore_discard=False, ignore_expires=False)

Clear all cookies and reload cookies from a saved file.

Raises cookielib.LoadError or IOError if reversion is not successful; the object's state will not be altered if this happens.

FileCookieJar instances have the following public attributes:
**filename**

Filename of default file in which to keep cookies. This attribute may be assigned to.

**delayload**

If true, load cookies lazily from disk. This attribute should not be assigned to. This is only a hint, since this only affects performance, not behaviour (unless the cookies on disk are changing). A CookieJar object may ignore it. None of the FileCookieJar classes included in the standard library lazily loads cookies.
11.20.2 FileCookieJar subclasses and cooperation with web browsers

The following CookieJar subclasses are provided for reading and writing. Further CookieJar subclasses, including one that reads Microsoft Internet Explorer cookies, are available at [http://wwwsearch.sf.net/ClientCookie/](http://wwwsearch.sf.net/ClientCookie/).

**class MozillaCookieJar**( `filename`, `delayload=None, policy=None`)  
A FileCookieJar that can load from and save cookies to disk in the Mozilla `cookies.txt` file format (which is also used by the Lynx and Netscape browsers). **Note:** This loses information about RFC 2965 cookies, and also about newer or non-standard cookie-attributes such as `port`.

**Warning:** Back up your cookies before saving if you have cookies whose loss / corruption would be inconvenient (there are some subtleties which may lead to slight changes in the file over a load / save round-trip).

Also note that cookies saved while Mozilla is running will get clobbered by Mozilla.

**class LWPCookieJar**( `filename`, `delayload=None, policy=None`)  
A FileCookieJar that can load from and save cookies to disk in format compatible with the libwww-perl library's `Set-Cookie3` file format. This is convenient if you want to store cookies in a human-readable file.
11.20.3 CookiePolicy Objects

Objects implementing the CookiePolicy interface have the following methods:

**set_ok( cookie, request)**

Return boolean value indicating whether cookie should be accepted from server.

*cookie* is a *cookielib.Cookie* instance. *request* is an object implementing the interface defined by the documentation for *CookieJar.extract_cookies()*.

**return_ok( cookie, request)**

Return boolean value indicating whether cookie should be returned to server.

*cookie* is a *cookielib.Cookie* instance. *request* is an object implementing the interface defined by the documentation for *CookieJar.add_cookie_header()*.

**domain_return_ok( domain, request)**

Return false if cookies should not be returned, given cookie domain.

This method is an optimization. It removes the need for checking every cookie with a particular domain (which might involve reading many files). Returning true from domain_return_ok() and path_return_ok() leaves all the work to return_ok().

If domain_return_ok() returns true for the cookie domain, path_return_ok() is called for the cookie path. Otherwise, path_return_ok() and return_ok() are never called for that cookie domain. If path_return_ok() returns true, return_ok() is called with the Cookie object itself for a full check. Otherwise, return_ok() is never called for that cookie path.

Note that domain_return_ok() is called for every cookie domain, not
just for the request domain. For example, the function might be called with both ".example.com" and "www.example.com" if the request domain is "www.example.com". The same goes for path_return_ok().

The request argument is as documented for return_ok().

path_return_ok(path, request)
Return false if cookies should not be returned, given cookie path.

See the documentation for domain_return_ok().

In addition to implementing the methods above, implementations of the CookiePolicy interface must also supply the following attributes, indicating which protocols should be used, and how. All of these attributes may be assigned to.

netscape
Implement Netscape protocol.

rfc2965
Implement RFC 2965 protocol.

hide_cookie2
Don't add Cookie2: header to requests (the presence of this header indicates to the server that we understand RFC 2965 cookies).

The most useful way to define a CookiePolicy class is by subclassing from DefaultCookiePolicy and overriding some or all of the methods above. CookiePolicy itself may be used as a 'null policy' to allow setting and receiving any and all cookies (this is unlikely to be useful).
11.20.4 DefaultCookiePolicy Objects

Implements the standard rules for accepting and returning cookies.

Both RFC 2965 and Netscape cookies are covered. RFC 2965 handling is switched off by default.

The easiest way to provide your own policy is to override this class and call its methods in your overridden implementations before adding your own additional checks:

```python
import cookielib
class MyCookiePolicy(cookielib.DefaultCookiePolicy):
    def set_ok(self, cookie, request):
        if not cookielib.DefaultCookiePolicy.set_ok(self, cookie, request):
            return False
        if i_dont_want_to_store_this_cookie(cookie):
            return False
        return True
```

In addition to the features required to implement the CookiePolicy interface, this class allows you to block and allow domains from setting and receiving cookies. There are also some strictness switches that allow you to tighten up the rather loose Netscape protocol rules a little bit (at the cost of blocking some benign cookies).

A domain blacklist and whitelist is provided (both off by default). Only domains not in the blacklist and present in the whitelist (if the whitelist is active) participate in cookie setting and returning. Use the blocked_domains constructor argument, and blocked_domains() and set_blocked_domains() methods (and the corresponding argument and methods for allowed_domains). If you set a whitelist, you can turn it off again by setting it to None.

Domains in block or allow lists that do not start with a dot must equal the cookie domain to be matched. For example, "example.com" matches a blacklist entry of "example.com", but "www.example.com" does not. Domains that do start with a dot are matched by more specific domains too. For example, both "www.example.com" and "www.coyote.example.com" match ".example.com" (but "example.com" itself does not). IP addresses are an exception, and must match exactly. For example, if blocked_domains contains
"192.168.1.2" and ".168.1.2", 192.168.1.2 is blocked, but 193.168.1.2 is not.

DefaultCookiePolicy implements the following additional methods:

**blocked_domains()**
Return the sequence of blocked domains (as a tuple).

**set_blocked_domains(blocked_domains)**
Set the sequence of blocked domains.

**is_blocked(domain)**
Return whether domain is on the blacklist for setting or receiving cookies.

**allowed_domains()**
Return None, or the sequence of allowed domains (as a tuple).

**set_allowed_domains(allowed_domains)**
Set the sequence of allowed domains, or None.

**is_not_allowed(domain)**
Return whether domain is not on the whitelist for setting or receiving cookies.

DefaultCookiePolicy instances have the following attributes, which are all initialised from the constructor arguments of the same name, and which may all be assigned to.

General strictness switches:

**strict_domain**
Don't allow sites to set two-component domains with country-code top-level domains like .co.uk, .gov.uk, .co.nz etc. This is far from perfect and isn't guaranteed to work!

RFC 2965 protocol strictness switches:

**strict_rfc2965_unverifiable**
Follow RFC 2965 rules on unverifiable transactions (usually, an unverifiable transaction is one resulting from a redirect or a request for an image hosted on another site). If this is false, cookies are never blocked on the basis of verifiability.

Netscape protocol strictness switches:

**strict_ns_unverifiable**
apply RFC 2965 rules on unverifiable transactions even to Netscape cookies

**strict_ns_domain**
Flags indicating how strict to be with domain-matching rules for Netscape cookies. See below for acceptable values.

**strict_ns_set_initial_dollar**
Ignore cookies in Set-Cookie: headers that have names starting with '$'.

**strict_ns_set_path**
Don't allow setting cookies whose path doesn't path-match request URI.

**strict_ns_domain** is a collection of flags. Its value is constructed by or-ing together (for example, DomainStrictNoDots|DomainStrictNonDomain means both flags are set).

**DomainStrictNoDots**
When setting cookies, the 'host prefix' must not contain a dot (eg. www.foo.bar.com can't set a cookie for .bar.com, because www.foo contains a dot).

**DomainStrictNonDomain**
Cookies that did not explicitly specify a domain cookie-attribute can only be returned to a domain equal to the domain that set the cookie (eg. spam.example.com won't be returned cookies from example.com that had no domain cookie-attribute).

**DomainRFC2965Match**
When setting cookies, require a full RFC 2965 domain-match.
The following attributes are provided for convenience, and are the most useful combinations of the above flags:

**DomainLiberal**

Equivalent to 0 (ie. all of the above Netscape domain strictness flags switched off).

**DomainStrict**

Equivalent to DomainStrictNoDots|DomainStrictNonDomain.

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
Previous: 11.20.4 DefaultCookiePolicy Objects  Up: 11.20 cookielib  Next: 11.20.6 Examples
11.20.5 Cookie Objects

Cookie instances have Python attributes roughly corresponding to the standard cookie-attributes specified in the various cookie standards. The correspondence is not one-to-one, because there are complicated rules for assigning default values, and because the **max-age** and **expires** cookie-attributes contain equivalent information.

Assignment to these attributes should not be necessary other than in rare circumstances in a **CookiePolicy** method. The class does not enforce internal consistency, so you should know what you're doing if you do that.

**version**

Integer or **None**. Netscape cookies have version 0. RFC 2965 and RFC 2109 cookies have version 1.

**name**

Cookie name (a string).

**value**

Cookie value (a string), or **None**.

**port**

String representing a port or a set of ports (eg. '80', or '80,8080'), or **None**.

**path**

Cookie path (a string, eg. '/acme/rocket_launchers').

**secure**

True if cookie should only be returned over a secure connection.

**expires**

Integer expiry date in seconds since epoch, or **None**. See also the **is_expired()** method.

**discard**

True if this is a session cookie.
comment
String comment from the server explaining the function of this cookie, or None.

comment_url
URL linking to a comment from the server explaining the function of this cookie, or None.

port_specified
True if a port or set of ports was explicitly specified by the server (in the Set-Cookie: / Set-Cookie2: header).

domain_specified
True if a domain was explicitly specified by the server.

domain_initial_dot
True if the domain explicitly specified by the server began with a dot ('.').

Cookies may have additional non-standard cookie-attributes. These may be accessed using the following methods:

has_nonstandard_attr(name)
Return true if cookie has the named cookie-attribute.

get_nonstandard_attr(name, default=None)
If cookie has the named cookie-attribute, return its value. Otherwise, return default.

set_nonstandard_attr(name, value)
Set the value of the named cookie-attribute.

The Cookie class also defines the following method:

is_expired([now=None])
True if cookie has passed the time at which the server requested it should expire. If now is given (in seconds since the epoch), return whether the cookie has expired at the specified time.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.20.6 Examples

The first example shows the most common usage of cookielib:

```python
import cookielib, urllib2
cj = cookielib.CookieJar()
opener = urllib2.build_opener(urllib2.HTTPCookieProcessor(cj))
r = opener.open("http://example.com/")
```

This example illustrates how to open a URL using your Netscape, Mozilla, or Lynx cookies (assumes UNIX/Netscape convention for location of the cookies file):

```python
import os, cookielib, urllib2
cj = cookielib.MozillaCookieJar()
cj.load(os.path.join(os.environ["HOME"], ".netscape/cookies.txt"))
opener = urllib2.build_opener(urllib2.HTTPCookieProcessor(cj))
r = opener.open("http://example.com/")
```

The next example illustrates the use of DefaultCookiePolicy. Turn on RFC 2965 cookies, be more strict about domains when setting and returning Netscape cookies, and block some domains from setting cookies or having them returned:

```python
import urllib2
from cookielib import CookieJar, DefaultCookiePolicy
policy = DefaultCookiePolicy(  
    rfc2965=True, strict_ns_domain=Policy.DomainStrict,  
    blocked_domains=["ads.net", ".ads.net"])
cj = CookieJar(policy)
opener = urllib2.build_opener(urllib2.HTTPCookieProcessor(cj))
r = opener.open("http://example.com/")
```
11.21 Cookie -- HTTP state management

The Cookie module defines classes for abstracting the concept of cookies, an HTTP state management mechanism. It supports both simple string-only cookies, and provides an abstraction for having any serializable data-type as cookie value.

The module formerly strictly applied the parsing rules described in the RFC 2109 and RFC 2068 specifications. It has since been discovered that MSIE 3.0x doesn't follow the character rules outlined in those specs. As a result, the parsing rules used are a bit less strict.

**exception CookieError**

Exception failing because of RFC 2109 invalidity: incorrect attributes, incorrect Set-Cookie: header, etc.

**class BaseCookie** ([input])

This class is a dictionary-like object whose keys are strings and whose values are Morsel instances. Note that upon setting a key to a value, the value is first converted to a Morsel containing the key and the value.

If *input* is given, it is passed to the *load()* method.

**class SimpleCookie** ([input])

This class derives from BaseCookie and overrides *value_decode()* and *value_encode()* to be the identity and *str()* respectively.

**class SerialCookie** ([input])

This class derives from BaseCookie and overrides *value_decode()* and *value_encode()* to be the pickle.loads() and pickle.dumps() respectively.

*Deprecated since release 2.3.* Reading pickled values from untrusted cookie data is a huge security hole, as pickle strings can be crafted to cause
arbitrary code to execute on your server. It is supported for backwards compatibility only, and may eventually go away.

**class SmartCookie([input])**

This class derives from BaseCookie. It overrides `value_decode()` to be `pickle.loads()` if it is a valid pickle, and otherwise the value itself. It overrides `value_encode()` to be `pickle.dumps()` unless it is a string, in which case it returns the value itself.

*Deprecated since release 2.3.* The same security warning from SerialCookie applies here.

A further security note is warranted. For backwards compatibility, the Cookie module exports a class named Cookie which is just an alias for SmartCookie. This is probably a mistake and will likely be removed in a future version. You should not use the Cookie class in your applications, for the same reason why you should not use the SerialCookie class.

---

**See Also:**

Module **cookielib**: HTTP cookie handling for web clients. The cookielib and Cookie modules do not depend on each other.

**RFC 2109, HTTP State Management Mechanism**

This is the state management specification implemented by this module.

---

**Subsections**

- [11.21.1 Cookie Objects](#)
- [11.21.2 Morsel Objects](#)
- [11.21.3 Example](#)
11.21.1 Cookie Objects

**value_decode**( *val*)

Return a decoded value from a string representation. Return value can be any type. This method does nothing in BaseCookie -- it exists so it can be overridden.

**value_encode**( *val*)

Return an encoded value. *val* can be any type, but return value must be a string. This method does nothing in BaseCookie -- it exists so it can be overridden.

In general, it should be the case that **value_encode()** and **value_decode()** are inverses on the range of **value_decode**.

**output**([*attrs*, *header*, *sep]*)

Return a string representation suitable to be sent as HTTP headers. *attrs* and *header* are sent to each Morsel's **output()** method. *sep* is used to join the headers together, and is by default a newline.

**js_output**([*attrs]*)

Return an embeddable JavaScript snippet, which, if run on a browser which supports JavaScript, will act the same as if the HTTP headers was sent.

The meaning for *attrs* is the same as in **output()**.

**load**( *rawdata*)

If *rawdata* is a string, parse it as an HTTP_COOKIE and add the values found there as Morsels. If it is a dictionary, it is equivalent to:

```python
for k, v in rawdata.items():
    cookie[k] = v
```
Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
11.21.2 Morsel Objects

class Morsel():
    Abstract a key/value pair, which has some RFC 2109 attributes.

    Morsels are dictionary-like objects, whose set of keys is constant -- the valid RFC 2109 attributes, which are
    
    - expires
    - path
    - comment
    - domain
    - max-age
    - secure
    - version

    The keys are case-insensitive.

value
    The value of the cookie.

coded_value
    The encoded value of the cookie -- this is what should be sent.

key
    The name of the cookie.

set(key, value, coded_value)
    Set the key, value and coded_value members.

isReservedKey(K)
    Whether K is a member of the set of keys of a Morsel.

output([attrs, header])
    Return a string representation of the Morsel, suitable to be sent as an HTTP header. By default, all the attributes are included, unless attrs is given, in which case it should be a list of attributes to use. header is by default
"Set-Cookie:"

**js_output([attrs])**
Return an embeddable JavaScript snippet, which, if run on a browser which supports JavaScript, will act the same as if the HTTP header was sent.

The meaning for *attrs* is the same as in `output()`.

**OutputString([attrs])**
Return a string representing the Morsel, without any surrounding HTTP or JavaScript.

The meaning for *attrs* is the same as in `output()`.
11.21.3 Example

The following example demonstrates how to use the Cookie module.

```python
>>> import Cookie
>>> C = Cookie.SimpleCookie()
>>> C = Cookie.SerialCookie()
>>> C = Cookie.SmartCookie()
>>> C["fig"] = "newton"
>>> C["sugar"] = "wafer"
>>> print C # generate HTTP headers
Set-Cookie: sugar=wafer;
Set-Cookie: fig=newton;
>>> print C.output() # same thing
Set-Cookie: sugar=wafer;
Set-Cookie: fig=newton;
>>> C = Cookie.SmartCookie()
>>> C["rocky"] = "road"
>>> C["rocky"]['path'] = "/cookie"
>>> print C.output(header="Cookie:")
Cookie: rocky=road; Path=/cookie;
>>> print C.output(attrs=[], header="Cookie:")
Cookie: rocky=road;
>>> C = Cookie.SmartCookie()
>>> C.load("chips=ahoy; vienna=finger") # load from a string (HTTP h
>>> print C
Set-Cookie: vienna=finger;
Set-Cookie: chips=ahoy;
>>> C = Cookie.SmartCookie()
>>> C.load('keebler="E=everybody; L="Loves"; fudge=\012;";')
>>> print C
Set-Cookie: keebler="E=everybody; L="Loves"; fudge=\012;";
>>> C = Cookie.SmartCookie()
>>> C["oreo"] = "doublestuff"
>>> C["oreo"]['path'] = "/"
>>> print C
Set-Cookie: oreo=doublestuff; Path=/;
>>> C = Cookie.SmartCookie()
>>> C["twix"] = "none for you"
>>> C["twix"].value
'none for you'
>>> C = Cookie.SimpleCookie()
>>> C["number"] = 7 # equivalent to C["number"] = str(7)
>>> C["string"] = "seven"
>>> C["number"].value
'7'
>>> C["string"].value
'seven'
>>> print C
```
Set-Cookie: number=7;
Set-Cookie: string=seven;

>>> C = Cookie.SerialCookie()
>>> C["number"] = 7
>>> C["string"] = "seven"
>>> C["number"].value
7

>>> C["string"].value
'seven'

>>> print C
Set-Cookie: number="I7\012.";
Set-Cookie: string="S\'seven\\012p1\\012.";

>>> C = Cookie.SmartCookie()
>>> C["number"] = 7
>>> C["string"] = "seven"
>>> C["number"].value
7

>>> C["string"].value
'seven'

>>> print C
Set-Cookie: number="I7\012.";
Set-Cookie: string=seven;
11.22 xmlrpclib -- XML-RPC client access

New in version 2.2.

XML-RPC is a Remote Procedure Call method that uses XML passed via HTTP as a transport. With it, a client can call methods with parameters on a remote server (the server is named by a URI) and get back structured data. This module supports writing XML-RPC client code; it handles all the details of translating between conformable Python objects and XML on the wire.

```python
class ServerProxy( uri[, transport[, encoding[, verbose[, allow_none]]]])
```

A ServerProxy instance is an object that manages communication with a remote XML-RPC server. The required first argument is a URI (Uniform Resource Indicator), and will normally be the URL of the server. The optional second argument is a transport factory instance; by default it is an internal SafeTransport instance for https: URLs and an internal HTTP Transport instance otherwise. The optional third argument is an encoding, by default UTF-8. The optional fourth argument is a debugging flag. If allow_none is true, the Python constant None will be translated into XML; the default behaviour is for None to raise a TypeError. This is a commonly-used extension to the XML-RPC specification, but isn't supported by all clients and servers; see http://ontosys.com/xml-rpc/extensions.php for a description.

Both the HTTP and HTTPS transports support the URL syntax extension for HTTP Basic Authentication: http://user:pass@host:port/path. The user:pass portion will be base64-encoded as an HTTP `Authorization' header, and sent to the remote server as part of the connection process when invoking an XML-RPC method. You only need to use this if the remote server requires a Basic Authentication user and password.

The returned instance is a proxy object with methods that can be used to invoke corresponding RPC calls on the remote server. If the remote server
supports the introspection API, the proxy can also be used to query the remote server for the methods it supports (service discovery) and fetch other server-associated metadata.

ServerProxy instance methods take Python basic types and objects as arguments and return Python basic types and classes. Types that are conformable (e.g. that can be marshalled through XML), include the following (and except where noted, they are unmarshalled as the same Python type):

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>boolean</td>
<td>The True and False constants</td>
</tr>
<tr>
<td>integers</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>floating-point</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>point numbers</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>strings</td>
<td>Pass in directly</td>
</tr>
<tr>
<td>arrays</td>
<td>Any Python sequence type containing conformable elements. Arrays are returned as lists</td>
</tr>
<tr>
<td>structures</td>
<td>A Python dictionary. Keys must be strings, values may be any conformable type.</td>
</tr>
<tr>
<td>dates</td>
<td>in seconds since the epoch; pass in an instance of the DateTime wrapper class</td>
</tr>
<tr>
<td>binary data</td>
<td>pass in an instance of the Binary wrapper class</td>
</tr>
</tbody>
</table>

This is the full set of data types supported by XML-RPC. Method calls may also raise a special Fault instance, used to signal XML-RPC server errors, or ProtocolError used to signal an error in the HTTP/HTTPS transport layer. Both Fault and ProtocolError derive from a base class called Error. Note that even though starting with Python 2.2 you can subclass builtin types, the xmlrpclib module currently does not marshal instances of such subclasses.

When passing strings, characters special to XML such as "<", ">", and "&" will be automatically escaped. However, it's the caller's responsibility to ensure that the string is free of characters that aren't allowed in XML, such as the control characters with ASCII values between 0 and 31; failing to do
this will result in an XML-RPC request that isn't well-formed XML. If you have to pass arbitrary strings via XML-RPC, use the **Binary** wrapper class described below.

**Server** is retained as an alias for **ServerProxy** for backwards compatibility. New code should use **ServerProxy**.

**Python Library Reference**

Previous: 11.21.3 **Example**  
Up: 11. Internet Protocols and  
Next: 11.22.1 **ServerProxy** Objects

Release 2.4.4c1, documentation updated on 11 October 2006.  
See [About this document...](#) for information on suggesting changes.
11.22.1 ServerProxy Objects

A ServerProxy instance has a method corresponding to each remote procedure call accepted by the XML-RPC server. Calling the method performs an RPC, dispatched by both name and argument signature (e.g. the same method name can be overloaded with multiple argument signatures). The RPC finishes by returning a value, which may be either returned data in a conformant type or a Fault or ProtocolError object indicating an error.

Servers that support the XML introspection API support some common methods grouped under the reserved system member:

**system.listMethods()**
This method returns a list of strings, one for each (non-system) method supported by the XML-RPC server.

**system.methodSignature( name)**
This method takes one parameter, the name of a method implemented by the XML-RPC server. It returns an array of possible signatures for this method. A signature is an array of types. The first of these types is the return type of the method, the rest are parameters.

Because multiple signatures (ie. overloading) is permitted, this method returns a list of signatures rather than a singleton.

Signatures themselves are restricted to the top level parameters expected by a method. For instance if a method expects one array of structs as a parameter, and it returns a string, its signature is simply "string, array". If it expects three integers and returns a string, its signature is "string, int, int, int".

If no signature is defined for the method, a non-array value is returned. In Python this means that the type of the returned value will be something other that list.

**system.methodHelp( name)**
This method takes one parameter, the name of a method implemented by
the XML-RPC server. It returns a documentation string describing the use of that method. If no such string is available, an empty string is returned. The documentation string may contain HTML markup.

Introspection methods are currently supported by servers written in PHP, C and Microsoft .NET. Partial introspection support is included in recent updates to UserLand Frontier. Introspection support for Perl, Python and Java is available at the XML-RPC Hacks page.
11.22.2 Boolean Objects

This class may be initialized from any Python value; the instance returned depends only on its truth value. It supports various Python operators through `__cmp__()`, `__repr__()`, `__int__()`, and `__nonzero__()` methods, all implemented in the obvious ways.

It also has the following method, supported mainly for internal use by the unmarshalling code:

**encode(out)**

Write the XML-RPC encoding of this Boolean item to the out stream object.
11.22.3 DateTime Objects

This class may be initialized with seconds since the epoch, a time tuple, or an ISO 8601 time/date string. It has the following methods, supported mainly for internal use by the marshalling/unmarshalling code:

**decode**( string)
Accept a string as the instance's new time value.

**encode**( out)
Write the XML-RPC encoding of this DateTime item to the out stream object.

It also supports certain of Python's built-in operators through **cmp** and **repr** methods.
11.22.4 Binary Objects

This class may be initialized from string data (which may include NULs). The primary access to the content of a Binary object is provided by an attribute:

**data**

The binary data encapsulated by the Binary instance. The data is provided as an 8-bit string.

Binary objects have the following methods, supported mainly for internal use by the marshalling/unmarshalling code:

**decode**( string)

Accept a base64 string and decode it as the instance's new data.

**encode**( out)

Write the XML-RPC base 64 encoding of this binary item to the out stream object.

It also supports certain of Python's built-in operators through a `__cmp__()` method.
11.22.5 Fault Objects

A Fault object encapsulates the content of an XML-RPC fault tag. Fault objects have the following members:

**faultCode**
- A string indicating the fault type.

**faultString**
- A string containing a diagnostic message associated with the fault.
11.22.6 ProtocolError Objects

A ProtocolError object describes a protocol error in the underlying transport layer (such as a 404 `not found' error if the server named by the URI does not exist). It has the following members:

**url**

The URI or URL that triggered the error.

**errcode**

The error code.

**errmsg**

The error message or diagnostic string.

**headers**

A string containing the headers of the HTTP/HTTPS request that triggered the error.
11.22.7 MultiCall Objects

New in version 2.4.

In http://www.xmlrpc.com/discuss/msgReader%241208, an approach is presented to encapsulate multiple calls to a remote server into a single request.

class MultiCall(server)

Create an object used to boxcar method calls. server is the eventual target of the call. Calls can be made to the result object, but they will immediately return None, and only store the call name and parameters in the MultiCall object. Calling the object itself causes all stored calls to be transmitted as a single system.multicall request. The result of this call is a generator; iterating over this generator yields the individual results.

A usage example of this class is

    multicall = MultiCall(server_proxy)
    multicall.add(2,3)
    multicall.get_address("Guido")
    add_result, address = multicall()
11.22.8 Convenience Functions

**boolean**(value)

Convert any Python value to one of the XML-RPC Boolean constants, True or False.

**dumps**(params[, methodname[, methodresponse[, encoding[, allow_none]]]])

Convert params into an XML-RPC request. or into a response if methodresponse is true. params can be either a tuple of arguments or an instance of the Fault exception class. If methodresponse is true, only a single value can be returned, meaning that params must be of length 1. encoding, if supplied, is the encoding to use in the generated XML; the default is UTF-8. Python's None value cannot be used in standard XML-RPC; to allow using it via an extension, provide a true value for allow_none.

**loads**(data)

Convert an XML-RPC request or response into Python objects, a (params, methodname). params is a tuple of argument; methodname is a string, or None if no method name is present in the packet. If the XML-RPC packet represents a fault condition, this function will raise a Fault exception.
11.22.9 Example of Client Usage

```python
# simple test program (from the XML-RPC specification)
from xmlrpclib import ServerProxy, Error

# server = ServerProxy("http://localhost:8000") # local server
server = ServerProxy("http://betty.userland.com")

print server

try:
  print server.examples.getStateName(41)
except Error, v:
  print "ERROR", v
```

11.23 SimpleXMLRPCServer -- Basic XML-RPC server

The SimpleXMLRPCServer module provides a basic server framework for XML-RPC servers written in Python. Servers can either be free standing, using SimpleXMLRPCServer, or embedded in a CGI environment, using CGIXMLRPCRequestHandler.

```python
class SimpleXMLRPCServer(addr[, requestHandler[, logRequests]])
```

Create a new server instance. The requestHandler parameter should be a factory for request handler instances; it defaults to SimpleXMLRPCRequestHandler. The addr and requestHandler parameters are passed to the SocketServer.TCPServer constructor. If logRequests is true (the default), requests will be logged; setting this parameter to false will turn off logging. This class provides methods for registration of functions that can be called by the XML-RPC protocol.

```python
class CGIXMLRPCRequestHandler()
```

Create a new instance to handle XML-RPC requests in a CGI environment. New in version 2.3.

```python
class SimpleXMLRPCRequestHandler()
```

Create a new request handler instance. This request handler supports POST requests and modifies logging so that the logRequests parameter to the SimpleXMLRPCServer constructor parameter is honored.

---

Subsections

- [11.23.1 SimpleXMLRPCServer Objects](#)
- [11.23.2 CGIXMLRPCRequestHandler](#)
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.23.1 SimpleXMLRPCServer Objects

The SimpleXMLRPCServer class is based on SocketServer.TCPServer and provides a means of creating simple, stand alone XML-RPC servers.

register_function(function[, name])

Register a function that can respond to XML-RPC requests. If name is given, it will be the method name associated with function, otherwise function.__name__ will be used. name can be either a normal or Unicode string, and may contain characters not legal in Python identifiers, including the period character.

register_instance(instance[, allow_dotted_names])

Register an object which is used to expose method names which have not been registered using register_function(). If instance contains a _dispatch() method, it is called with the requested method name and the parameters from the request. Its API is def _dispatch(self, method, params) (note that params does not represent a variable argument list). If it calls an underlying function to perform its task, that function is called as func(*params), expanding the parameter list. The return value from _dispatch() is returned to the client as the result. If instance does not have a _dispatch() method, it is searched for an attribute matching the name of the requested method.

If the optional allow_dotted_names argument is true and the instance does not have a _dispatch() method, then if the requested method name contains periods, each component of the method name is searched for individually, with the effect that a simple hierarchical search is performed. The value found from this search is then called with the parameters from the request, and the return value is passed back to the client.

Warning: Enabling the allow_dotted_names option allows intruders to access your module's global variables and may allow intruders to execute arbitrary code on your
machine. Only use this option on a secure, closed network.

Changed in version 2.3.5, 2.4.1: allow_dotted_names was added to plug a security hole; prior versions are insecure.

register_introspection_functions()
Registers the XML-RPC introspection functions system.listMethods, system.methodHelp and system.methodSignature. New in version 2.3.

register_multicall_functions()
Registers the XML-RPC multicall function system.multicall.

Example:

class MyFuncs:
    def div(self, x, y) : return x // y

server = SimpleXMLRPCServer(("localhost", 8000))
server.register_function(pow)
server.register_function(lambda x,y: x+y, 'add')
server.register_introspection_functions()
server.register_introspection_functions()
server.register_func_ab
server.serve_forever()
The CGIXMLRPCRequestHandler class can be used to handle XML-RPC requests sent to Python CGI scripts.

**register_function** *(function[, name])*

Register a function that can respond to XML-RPC requests. If *name* is given, it will be the method name associated with function, otherwise *function.__name__* will be used. *name* can be either a normal or Unicode string, and may contain characters not legal in Python identifiers, including the period character.

**register_instance** *(instance)*

Register an object which is used to expose method names which have not been registered using `register_function()`. If instance contains a `_dispatch()` method, it is called with the requested method name and the parameters from the request; the return value is returned to the client as the result. If instance does not have a `_dispatch()` method, it is searched for an attribute matching the name of the requested method; if the requested method name contains periods, each component of the method name is searched for individually, with the effect that a simple hierarchical search is performed. The value found from this search is then called with the parameters from the request, and the return value is passed back to the client.

**register_introspection_functions** *

Register the XML-RPC introspection functions `system.listMethods`, `system.methodHelp` and `system.methodSignature`.

**register_multicall_functions** *

Register the XML-RPC multicall function `system.multicall`.

**handle_request** *(request_text = None)*

Handle a XML-RPC request. If *request_text* is given, it should be the POST data provided by the HTTP server, otherwise the contents of stdin will be used.
class MyFuncs:
    def div(self, x, y): return div(x,y)

handler = CGIXMLRPCRequestHandler()
handler.register_function(pow)
handler.register_function(lambda x,y: x+y, 'add')
handler.register_introspection_functions()

11.24 DocXMLRPCServer -- Self-documenting XML-RPC server

New in version 2.3.

The DocXMLRPCServer module extends the classes found in SimpleXMLRPCServer to serve HTML documentation in response to HTTP GET requests. Servers can either be free standing, using DocXMLRPCServer, or embedded in a CGI environment, using DocCGIXMLRPCRequestHandler.

```python
class DocXMLRPCServer(addr[, requestHandler[, logRequests]])
```

Create a new server instance. All parameters have the same meaning as for SimpleXMLRPCServer.SimpleXMLRPCServer; requestHandler defaults to DocXMLRPCRequestHandler.

```python
class DocCGIXMLRPCRequestHandler()
```

Create a new instance to handle XML-RPC requests in a CGI environment.

```python
class DocXMLRPCRequestHandler()
```

Create a new request handler instance. This request handler supports XML-RPC POST requests, documentation GET requests, and modifies logging so that the logRequests parameter to the DocXMLRPCServer constructor parameter is honored.

Subsections

- **11.24.1 DocXMLRPCServer Objects**
- **11.24.2 DocCGIXMLRPCRequestHandler**
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.24.1 DocXMLRPCServer Objects

The DocXMLRPCServer class is derived from SimpleXMLRPCServer.SimpleXMLRPCServer and provides a means of creating self-documenting, stand alone XML-RPC servers. HTTP POST requests are handled as XML-RPC method calls. HTTP GET requests are handled by generating pydoc-style HTML documentation. This allows a server to provide its own web-based documentation.

**set_server_title**(*server_title*)

Set the title used in the generated HTML documentation. This title will be used inside the HTML "title" element.

**set_server_name**(*server_name*)

Set the name used in the generated HTML documentation. This name will appear at the top of the generated documentation inside a "h1" element.

**set_server_documentation**(*server_documentation*)

Set the description used in the generated HTML documentation. This description will appear as a paragraph, below the server name, in the documentation.
11.24.2 DocCGIXMLRPCRequestHandler

The DocCGIXMLRPCRequestHandler class is derived from SimpleXMLRPCServer.CGIXMLRPCRequestHandler and provides a means of creating self-documenting, XML-RPC CGI scripts. HTTP POST requests are handled as XML-RPC method calls. HTTP GET requests are handled by generating pydoc-style HTML documentation. This allows a server to provide its own web-based documentation.

**set_server_title**(*server_title*)

Set the title used in the generated HTML documentation. This title will be used inside the HTML "title" element.

**set_server_name**(*server_name*)

Set the name used in the generated HTML documentation. This name will appear at the top of the generated documentation inside a "h1" element.

**set_server_documentation**(*server_documentation*)

Set the description used in the generated HTML documentation. This description will appear as a paragraph, below the server name, in the documentation.
11.25 asyncore -- Asynchronous socket handler

This module provides the basic infrastructure for writing asynchronous socket service clients and servers.

There are only two ways to have a program on a single processor do "more than one thing at a time." Multi-threaded programming is the simplest and most popular way to do it, but there is another very different technique, that lets you have nearly all the advantages of multi-threading, without actually using multiple threads. It's really only practical if your program is largely I/O bound. If your program is processor bound, then pre-emptive scheduled threads are probably what you really need. Network servers are rarely processor bound, however.

If your operating system supports the select() system call in its I/O library (and nearly all do), then you can use it to juggle multiple communication channels at once; doing other work while your I/O is taking place in the "background." Although this strategy can seem strange and complex, especially at first, it is in many ways easier to understand and control than multi-threaded programming. The asyncore module solves many of the difficult problems for you, making the task of building sophisticated high-performance network servers and clients a snap. For "conversational" applications and protocols the companion asynchat module is invaluable.

The basic idea behind both modules is to create one or more network channels, instances of class asyncore.dispatcher and asynchat.async_chat. Creating the channels adds them to a global map, used by the loop() function if you do not provide it with your own map.

Once the initial channel(s) is(are) created, calling the loop() function activates channel service, which continues until the last channel (including any that have been added to the map during asynchronous service) is closed.

```
loop( [timeout[, use_poll[, map[,count]]]])
```
Enter a polling loop that terminates after count passes or all open channels have been closed. All arguments are optional. The (count) parameter defaults to None, resulting in the loop terminating only when all channels have been closed. The timeout argument sets the timeout parameter for the appropriate select() or poll() call, measured in seconds; the default is 30 seconds. The use_poll parameter, if true, indicates that poll() should be used in preference to select() (the default is False). The map parameter is a dictionary whose items are the channels to watch. As channels are closed they are deleted from their map. If map is omitted, a global map is used (this map is updated by the default class __init__() - make sure you extend, rather than override, __init__() if you want to retain this behavior).

Channels (instances of asyncore.dispatcher, asyncchat.async_chat and subclasses thereof) can freely be mixed in the map.

**class dispatcher()**

The dispatcher class is a thin wrapper around a low-level socket object. To make it more useful, it has a few methods for event-handling which are called from the asynchronous loop. Otherwise, it can be treated as a normal non-blocking socket object.

Two class attributes can be modified, to improve performance, or possibly even to conserve memory.

**ac_in_buffer_size**

The asynchronous input buffer size (default 4096).

**ac_out_buffer_size**

The asynchronous output buffer size (default 4096).

The firing of low-level events at certain times or in certain connection states tells the asynchronous loop that certain higher-level events have taken place. For example, if we have asked for a socket to connect to another host, we know that the connection has been made when the socket becomes writable for the first time (at this point you know that you may write to it with the expectation of success). The implied higher-level events are:
<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>handle_connect()</td>
<td>Implied by the first write event</td>
</tr>
<tr>
<td>handle_close()</td>
<td>Implied by a read event with no data available</td>
</tr>
<tr>
<td>handle_accept()</td>
<td>Implied by a read event on a listening socket</td>
</tr>
</tbody>
</table>

During asynchronous processing, each mapped channel's `readable()` and `writable()` methods are used to determine whether the channel's socket should be added to the list of channels `select()`ed or `poll()`ed for read and write events.

Thus, the set of channel events is larger than the basic socket events. The full set of methods that can be overridden in your subclass follows:

**handle_read()**
Called when the asynchronous loop detects that a `read()` call on the channel's socket will succeed.

**handle_write()**
Called when the asynchronous loop detects that a writable socket can be written. Often this method will implement the necessary buffering for performance. For example:

```python
def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[sent:]
```

**handle_expt()**
Called when there is out of band (OOB) data for a socket connection. This will almost never happen, as OOB is tenuously supported and rarely used.

**handle_connect()**
Called when the active opener's socket actually makes a connection. Might send a "welcome" banner, or initiate a protocol negotiation with the remote endpoint, for example.

**handle_close()**
Called when the socket is closed.
**handle_error()**

Called when an exception is raised and not otherwise handled. The default version prints a condensed traceback.

**handle_accept()**

Called on listening channels (passive openers) when a connection can be established with a new remote endpoint that has issued a `connect()` call for the local endpoint.

**readable()**

Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which read events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in read events.

**writable()**

Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which write events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in write events.

In addition, each channel delegates or extends many of the socket methods. Most of these are nearly identical to their socket partners.

**create_socket**( family, type)

This is identical to the creation of a normal socket, and will use the same options for creation. Refer to the `socket` documentation for information on creating sockets.

**connect**( address)

As with the normal socket object, `address` is a tuple with the first element the host to connect to, and the second the port number.

**send**( data)

Send `data` to the remote end-point of the socket.

**recv**( buffer_size)
Read at most buffer_size bytes from the socket's remote end-point. An empty string implies that the channel has been closed from the other end.

**listen**(backlog)
Listen for connections made to the socket. The backlog argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

**bind**(address)
Bind the socket to address. The socket must not already be bound. (The format of address depends on the address family -- see above.)

**accept()**
Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair (conn, address) where conn is a new socket object usable to send and receive data on the connection, and address is the address bound to the socket on the other end of the connection.

**close()**
Close the socket. All future operations on the socket object will fail. The remote end-point will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

- 11.25.1 asyncore Example basic HTTP client

---

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
11.25.1 asyncore Example basic HTTP client

As a basic example, below is a very basic HTTP client that uses the dispatcher class to implement its socket handling:

```python
class http_client(asyncore.dispatcher):
    def __init__(self, host, path):
        asyncore.dispatcher.__init__(self)
        self.path = path
        self.create_socket(socket.AF_INET, socket.SOCK_STREAM)
        self.connect((host, 80))
        self.buffer = 'GET %s HTTP/1.0\r\n\r\n' % self.path

    def handle_connect(self):
        pass

    def handle_read(self):
        data = self.recv(8192)
        print(data)

    def writable(self):
        return (len(self.buffer) > 0)

    def handle_write(self):
        sent = self.send(self.buffer)
        self.buffer = self.buffer[:sent:]
```

Previous: 11.25 asyncore  Up: 11.25 asyncore  Next: 11.26 asynchat

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
11.26 asynchat -- Asynchronous socket command/response handler

This module builds on the asyncore infrastructure, simplifying asynchronous clients and servers and making it easier to handle protocols whose elements are terminated by arbitrary strings, or are of variable length. asynchat defines the abstract class async_chat that you subclass, providing implementations of the collect_incoming_data() and found_terminator() methods. It uses the same asynchronous loop as asyncore, and the two types of channel, asyncore.dispatcher and asynchat.async_chat, can freely be mixed in the channel map. Typically an asyncore.dispatcher server channel generates new asynchat.async_chat channel objects as it receives incoming connection requests.

class async_chat()

This class is an abstract subclass of asyncore.dispatcher. To make practical use of the code you must subclass async_chat, providing meaningful collect_incoming_data() and found_terminator() methods. The asyncore.dispatcher methods can be used, although not all make sense in a message/response context.

Like asyncore.dispatcher, async_chat defines a set of events that are generated by an analysis of socket conditions after a select() call. Once the polling loop has been started the async_chat object's methods are called by the event-processing framework with no action on the part of the programmer.

Unlike asyncore.dispatcher, async_chat allows you to define a first-in-first-out queue (fifo) of producers. A producer need have only one method, more(), which should return data to be transmitted on the channel. The producer indicates exhaustion (i.e. that it contains no more data) by having its more() method return the empty string. At this point the async_chat object removes the producer from the fifo and starts using the next producer, if any. When the producer fifo is empty the
handle_write() method does nothing. You use the channel object's set_terminator() method to describe how to recognize the end of, or an important breakpoint in, an incoming transmission from the remote endpoint.

To build a functioning async_chat subclass your input methods collect_incoming_data() and found_terminator() must handle the data that the channel receives asynchronously. The methods are described below.

**close_when_done()**
Pushes a None on to the producer fifo. When this producer is popped off the fifo it causes the channel to be closed.

**collect_incoming_data(data)**
Called with data holding an arbitrary amount of received data. The default method, which must be overridden, raises a NotImplementedError exception.

**discard_buffers()**
In emergencies this method will discard any data held in the input and/or output buffers and the producer fifo.

**found_terminator()**
Called when the incoming data stream matches the termination condition set by set_terminator. The default method, which must be overridden, raises a NotImplementedError exception. The buffered input data should be available via an instance attribute.

**get_terminator()**
Returns the current terminator for the channel.

**handle_close()**
Called when the channel is closed. The default method silently closes the channel's socket.

**handle_read()**
Called when a read event fires on the channel's socket in the asynchronous loop. The default method checks for the termination condition established by set_terminator(), which can be either the appearance of a particular string in the input stream or the receipt of a particular number of characters. When the terminator is found, handle_read calls the found_terminator() method after calling collect_incoming_data() with any data preceding the terminating condition.

handle_write()
Called when the application may write data to the channel. The default method calls the initiate_send() method, which in turn will call refill_buffer() to collect data from the producer fifo associated with the channel.

push(data)
Creates a simple_producer object (see below) containing the data and pushes it on to the channel's producer_fifo to ensure its transmission. This is all you need to do to have the channel write the data out to the network, although it is possible to use your own producers in more complex schemes to implement encryption and chunking, for example.

push_with_producer(producer)
Takes a producer object and adds it to the producer fifo associated with the channel. When all currently-pushed producers have been exhausted the channel will consume this producer's data by calling its more() method and send the data to the remote endpoint.

readable()
Should return True for the channel to be included in the set of channels tested by the select() loop for readability.

refill_buffer()
Refills the output buffer by calling the more() method of the producer at the head of the fifo. If it is exhausted then the producer is popped off the fifo and the next producer is activated. If the current producer is, or becomes, None then the channel is closed.
**set_terminator**(*term*)

Sets the terminating condition to be recognised on the channel. *term* may be any of three types of value, corresponding to three different ways to handle incoming protocol data.

<table>
<thead>
<tr>
<th><strong>term</strong></th>
<th><strong>Description</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>string</td>
<td>Will call <code>found_terminator()</code> when the string is found in the input stream</td>
</tr>
<tr>
<td>integer</td>
<td>Will call <code>found_terminator()</code> when the indicated number of characters have been received</td>
</tr>
<tr>
<td>None</td>
<td>The channel continues to collect data forever</td>
</tr>
</tbody>
</table>

Note that any data following the terminator will be available for reading by the channel after `found_terminator()` is called.

**writable()**

Should return `True` as long as items remain on the producer fifo, or the channel is connected and the channel's output buffer is non-empty.

---

**Subsections**

- [11.26.1 asynchat - Auxiliary Classes and Functions](#)
- [11.26.2 asynchat Example](#)
11.26.1 asynchat - Auxiliary Classes and Functions

class simple_producer(data[, buffer_size=512])
    A simple_producer takes a chunk of data and an optional buffer size. Repeated calls to its more() method yield successive chunks of the data no larger than buffer_size.

more()
    Produces the next chunk of information from the producer, or returns the empty string.

class fifo([list=None])
    Each channel maintains a fifo holding data which has been pushed by the application but not yet popped for writing to the channel. A fifo is a list used to hold data and/or producers until they are required. If the list argument is provided then it should contain producers or data items to be written to the channel.

is_empty()
    Returns True iff the fifo is empty.

first()
    Returns the least-recently push()ed item from the fifo.

push(data)
    Adds the given data (which may be a string or a producer object) to the producer fifo.

pop()
    If the fifo is not empty, returns True, first(), deleting the popped item. Returns False, None for an empty fifo.

The asynchat module also defines one utility function, which may be of use in network and textual analysis operations.
**find_prefix_at_end**(*haystack, needle*)

Returns `True` if string `haystack` ends with any non-empty prefix of string `needle`. 

---

*Python Library Reference*

11.26.2 asynchat Example

The following partial example shows how HTTP requests can be read with async_chat. A web server might create an http_request_handler object for each incoming client connection. Notice that initially the channel terminator is set to match the blank line at the end of the HTTP headers, and a flag indicates that the headers are being read.

Once the headers have been read, if the request is of type POST (indicating that further data are present in the input stream) then the Content-Length: header is used to set a numeric terminator to read the right amount of data from the channel.

The handle_request() method is called once all relevant input has been marshalled, after setting the channel terminator to None to ensure that any extraneous data sent by the web client are ignored.

```python
class http_request_handler(asyncchat.async_chat):
    def __init__(self, conn, addr, sessions, log):
        asyncchat.async_chat.__init__(self, conn=conn)
        self.addr = addr
        self.sessions = sessions
        self.ibuffer = []
        self.obuffer = ""
        self.set_terminator("\r\n\r\n")
        self.reading_headers = True
        self.handling = False
        self.cgi_data = None
        self.log = log

    def collect_incoming_data(self, data):
        """Buffer the data""
        self.ibuffer.append(data)

    def found_terminator(self):
        if self.reading_headers:
            self.reading_headers = False
            self.parse_headers("".join(self.ibuffer))
            self.ibuffer = []
            if self.op.upper() == "POST":
                clen = self.headers.getheader("content-length")
                self.set_terminator(int(clen))
            else:
                self.handling = True
```
self.set_terminator(None)
self.handle_request()

elif not self.handling:
    self.set_terminator(None)  # browsers sometimes over-send
    self.cgi_data = parse(self.headers, 
                          
                        

        self.handling = True
    self.ibuffer = []
self.handle_request()
12. Internet Data Handling

This chapter describes modules which support handling data formats commonly used on the Internet.

- **formatter**: Generic output formatter and device interface.
- **email**: Package supporting the parsing, manipulating, and generating email messages, including MIME documents.
- **email.Message**: The base class representing email messages.
- **email.Parser**: Parse flat text email messages to produce a message object structure.
- **email-generator**: Generate flat text email messages from a message structure.
- **email.Header**: Representing non-ASCII headers
- **email.Charset**: Character Sets
- **email.Encoders**: Encoders for email message payloads.
- **email.Errors**: The exception classes used by the email package.
- **email.Utils**: Miscellaneous email package utilities.
- **email.Iterators**: Iterate over a message object tree.
- **mailcap**: Mailcap file handling.
- **mailbox**: Read various mailbox formats.
- **mhlib**: Manipulate MH mailboxes from Python.
- **mimetools**: Tools for parsing MIME-style message bodies.
- **mimetypes**: Mapping of filename extensions to MIME types.
- **MimeWriter**: Generic MIME file writer.
- **mimify**: Mimification and unmimification of mail messages.
- **multifile**: Support for reading files which contain distinct parts, such as some MIME data.
- **rfc822**: Parse RFC 2822 style mail messages.
- **base64**: RFC 3548: Base16, Base32, Base64 Data Encodings
- **binascii**: Tools for converting between binary and various ASCII-encoded binary representations.
**binhex** Encode and decode files in binhex4 format.

**quopri** Encode and decode files using the MIME quoted-printable encoding.

**uu** Encode and decode files in uuencode format.

**xdrlib** Encoders and decoders for the External Data Representation (XDR).

**netrc** Loading of .netrc files.

**robotparser** Loads a robots.txt file and answers questions about fetchability of other URLs.

**csv** Write and read tabular data to and from delimited files.
12.1.1 The Formatter Interface
12.1 formatter -- Generic output formatting

This module supports two interface definitions, each with multiple implementations. The formatter interface is used by the HTMLParser class of the `httplib` module, and the writer interface is required by the formatter interface.

Formatter objects transform an abstract flow of formatting events into specific output events on writer objects. Formatters manage several stack structures to allow various properties of a writer object to be changed and restored; writers need not be able to handle relative changes nor any sort of ``change back'' operation. Specific writer properties which may be controlled via formatter objects are horizontal alignment, font, and left margin indentations. A mechanism is provided which supports providing arbitrary, non-exclusive style settings to a writer as well. Additional interfaces facilitate formatting events which are not reversible, such as paragraph separation.

Writer objects encapsulate device interfaces. Abstract devices, such as file formats, are supported as well as physical devices. The provided implementations all work with abstract devices. The interface makes available mechanisms for setting the properties which formatter objects manage and inserting data into the output.

Subsections

- 12.1.1 The Formatter Interface
- 12.1.2 Formatter Implementations
- 12.1.3 The Writer Interface
- 12.1.4 Writer Implementations
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.1.1 The Formatter Interface

Interfaces to create formatters are dependent on the specific formatter class being instantiated. The interfaces described below are the required interfaces which all formatters must support once initialized.

One data element is defined at the module level:

**AS_IS**

Value which can be used in the font specification passed to the `push_font()` method described below, or as the new value to any other `push_property()` method. Pushing the AS_IS value allows the corresponding `pop_property()` method to be called without having to track whether the property was changed.

The following attributes are defined for formatter instance objects:

**writer**

The writer instance with which the formatter interacts.

**end_paragraph( blanklines)**

Close any open paragraphs and insert at least `blanklines` before the next paragraph.

**add_line_break()**

Add a hard line break if one does not already exist. This does not break the logical paragraph.

**add_hor_rule( *args, **kw)**

Insert a horizontal rule in the output. A hard break is inserted if there is data in the current paragraph, but the logical paragraph is not broken. The arguments and keywords are passed on to the writer's `send_line_break()` method.

**add_flowing_data( data)**

Provide data which should be formatted with collapsed whitespace. Whitespace from preceding and successive calls to
add_flowing_data() is considered as well when the whitespace collapse is performed. The data which is passed to this method is expected to be word-wrapped by the output device. Note that any word-wrapping still must be performed by the writer object due to the need to rely on device and font information.

add_literal_data(data)

    Provide data which should be passed to the writer unchanged. Whitespace, including newline and tab characters, are considered legal in the value of data.

add_label_data(format, counter)

    Insert a label which should be placed to the left of the current left margin. This should be used for constructing bulleted or numbered lists. If the format value is a string, it is interpreted as a format specification for counter, which should be an integer. The result of this formatting becomes the value of the label; if format is not a string it is used as the label value directly. The label value is passed as the only argument to the writer's send_label_data() method. Interpretation of non-string label values is dependent on the associated writer.

    Format specifications are strings which, in combination with a counter value, are used to compute label values. Each character in the format string is copied to the label value, with some characters recognized to indicate a transform on the counter value. Specifically, the character "1" represents the counter value formatter as an Arabic number, the characters "A" and "a" represent alphabetic representations of the counter value in upper and lower case, respectively, and "I" and "i" represent the counter value in Roman numerals, in upper and lower case. Note that the alphabetic and roman transforms require that the counter value be greater than zero.

flush_softspace()

    Send any pending whitespace buffered from a previous call to add_flowing_data() to the associated writer object. This should be called before any direct manipulation of the writer object.

push_alignment(align)

    Push a new alignment setting onto the alignment stack. This may be AS_IS
if no change is desired. If the alignment value is changed from the previous
setting, the writer's new_alignment() method is called with the align
value.

pop_alignment()
    Restore the previous alignment.

push_font((size, italic, bold, teletype))
    Change some or all font properties of the writer object. Properties which are
not set to AS_IS are set to the values passed in while others are maintained
at their current settings. The writer's new_font() method is called with
the fully resolved font specification.

pop_font()
    Restore the previous font.

push_margin(margin)
    Increase the number of left margin indentations by one, associating the
logical tag margin with the new indentation. The initial margin level is 0.
Changed values of the logical tag must be true values; false values other
than AS_IS are not sufficient to change the margin.

pop_margin()
    Restore the previous margin.

push_style(*styles)
    Push any number of arbitrary style specifications. All styles are pushed onto
the styles stack in order. A tuple representing the entire stack, including
AS_IS values, is passed to the writer's new_styles() method.

pop_style([n = 1])
    Pop the last n style specifications passed to push_style(). A tuple
representing the revised stack, including AS_IS values, is passed to the
writer's new_styles() method.

set_spacing(spacing)
    Set the spacing style for the writer.
assert_line_data([flag = 1])

Inform the formatter that data has been added to the current paragraph out-of-band. This should be used when the writer has been manipulated directly. The optional flag argument can be set to false if the writer manipulations produced a hard line break at the end of the output.
12.1.2 Formatter Implementations

Two implementations of formatter objects are provided by this module. Most applications may use one of these classes without modification or subclassing.

class **NullFormatter**([*writer*])

A formatter which does nothing. If *writer* is omitted, a **NullWriter** instance is created. No methods of the writer are called by **NullFormatter** instances. Implementations should inherit from this class if implementing a writer interface but don't need to inherit any implementation.

class **AbstractFormatter**(*writer*)

The standard formatter. This implementation has demonstrated wide applicability to many writers, and may be used directly in most circumstances. It has been used to implement a full-featured World Wide Web browser.
12.1.3 The Writer Interface

Interfaces to create writers are dependent on the specific writer class being instantiated. The interfaces described below are the required interfaces which all writers must support once initialized. Note that while most applications can use the `AbstractFormatter` class as a formatter, the writer must typically be provided by the application.

`flush()`
Flush any buffered output or device control events.

`new_alignment(align)`
Set the alignment style. The `align` value can be any object, but by convention is a string or `None`, where `None` indicates that the writer's "preferred" alignment should be used. Conventional `align` values are 'left', 'center', 'right', and 'justify'.

`new_font(font)`
Set the font style. The value of `font` will be `None`, indicating that the device's default font should be used, or a tuple of the form `(size, italic, bold, teletype)`. Size will be a string indicating the size of font that should be used; specific strings and their interpretation must be defined by the application. The `italic`, `bold`, and `teletype` values are Boolean values specifying which of those font attributes should be used.

`new_margin(margin, level)`
Set the margin level to the integer `level` and the logical tag to `margin`. Interpretation of the logical tag is at the writer's discretion; the only restriction on the value of the logical tag is that it not be a false value for non-zero values of `level`.

`new_spacing(spacing)`
Set the spacing style to `spacing`.

`new_styles(styles)`
Set additional styles. The `styles` value is a tuple of arbitrary values; the
value AS_IS should be ignored. The styles tuple may be interpreted either as a set or as a stack depending on the requirements of the application and writer implementation.

**send_line_break()**
Break the current line.

**send_paragraph( blankline)**
Produce a paragraph separation of at least blankline blank lines, or the equivalent. The blankline value will be an integer. Note that the implementation will receive a call to send_line_break() before this call if a line break is needed; this method should not include ending the last line of the paragraph. It is only responsible for vertical spacing between paragraphs.

**send_hor_rule( *args, **kw)**
Display a horizontal rule on the output device. The arguments to this method are entirely application- and writer-specific, and should be interpreted with care. The method implementation may assume that a line break has already been issued via send_line_break().

**send_flowing_data( data)**
Output character data which may be word-wrapped and re-flowed as needed. Within any sequence of calls to this method, the writer may assume that spans of multiple whitespace characters have been collapsed to single space characters.

**send_literal_data( data)**
Output character data which has already been formatted for display. Generally, this should be interpreted to mean that line breaks indicated by newline characters should be preserved and no new line breaks should be introduced. The data may contain embedded newline and tab characters, unlike data provided to the send_formatted_data() interface.

**send_label_data( data)**
Set data to the left of the current left margin, if possible. The value of data is not restricted; treatment of non-string values is entirely application- and
writer-dependent. This method will only be called at the beginning of a line.
12.1.4 Writer Implementations

Three implementations of the writer object interface are provided as examples by this module. Most applications will need to derive new writer classes from the NullWriter class.

**class NullWriter()**

A writer which only provides the interface definition; no actions are taken on any methods. This should be the base class for all writers which do not need to inherit any implementation methods.

**class AbstractWriter()**

A writer which can be used in debugging formatters, but not much else. Each method simply announces itself by printing its name and arguments on standard output.

**class DumbWriter([file[, maxcol = 72]])**

Simple writer class which writes output on the file object passed in as file or, if file is omitted, on standard output. The output is simply word-wrapped to the number of columns specified by maxcol. This class is suitable for reflowing a sequence of paragraphs.
12.2 email -- An email and MIME handling package

New in version 2.2.

The email package is a library for managing email messages, including MIME and other RFC2822-based message documents. It subsumes most of the functionality in several older standard modules such as rfc822, mimetools, multifile, and other non-standard packages such as mimecntl. It is specifically not designed to do any sending of email messages to SMTP (RFC 2821) servers; that is the function of the smtplib module. The email package attempts to be as RFC-compliant as possible, supporting in addition to RFC 2822, such MIME-related RFCs as RFC 2045, RFC 2046, RFC 2047, and RFC 2231.

The primary distinguishing feature of the email package is that it splits the parsing and generating of email messages from the internal object model representation of email. Applications using the email package deal primarily with objects; you can add sub-objects to messages, remove sub-objects from messages, completely re-arrange the contents, etc. There is a separate parser and a separate generator which handles the transformation from flat text to the object model, and then back to flat text again. There are also handy subclasses for some common MIME object types, and a few miscellaneous utilities that help with such common tasks as extracting and parsing message field values, creating RFC-compliant dates, etc.

The following sections describe the functionality of the email package. The ordering follows a progression that should be common in applications: an email message is read as flat text from a file or other source, the text is parsed to produce the object structure of the email message, this structure is manipulated, and finally rendered back into flat text.

It is perfectly feasible to create the object structure out of whole cloth -- i.e. completely from scratch. From there, a similar progression can be taken as above.
Also included are detailed specifications of all the classes and modules that the email package provides, the exception classes you might encounter while using the email package, some auxiliary utilities, and a few examples. For users of the older mimelib package, or previous versions of the email package, a section on differences and porting is provided.

Previous: 12.1.4 Writer Implementations  Up: 12. Internet Data Handling  Next: 12.2.1 Representing an email
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.2.1 Representing an email message

The central class in the email package is the Message class; it is the base class for the email object model. Message provides the core functionality for setting and querying header fields, and for accessing message bodies.

Conceptually, a Message object consists of headers and payloads. Headers are RFC 2822 style field names and values where the field name and value are separated by a colon. The colon is not part of either the field name or the field value.

Headers are stored and returned in case-preserving form but are matched case-insensitively. There may also be a single envelope header, also known as the Unix-From header or the From_ header. The payload is either a string in the case of simple message objects or a list of Message objects for MIME container documents (e.g. multipart/* and message/rfc822).

Message objects provide a mapping style interface for accessing the message headers, and an explicit interface for accessing both the headers and the payload. It provides convenience methods for generating a flat text representation of the message object tree, for accessing commonly used header parameters, and for recursively walking over the object tree.

Here are the methods of the Message class:

```python
class Message()
    The constructor takes no arguments.

as_string([unixfrom])
    Return the entire message flatten as a string. When optional unixfrom is True, the envelope header is included in the returned string. unixfrom defaults to False.

    Note that this method is provided as a convenience and may not always format the message the way you want. For example, by default it mangles lines that begin with From. For more flexibility, instantiate a Generator instance and use its flatten() method directly.
```
example:

```python
from cStringIO import StringIO
from email.Generator import Generator
fp = StringIO()
g = Generator(fp, mangle_from_=False, maxheaderlen=60)
g.flatten(msg)
text = fp.getvalue()
```

`__str__()`
Equivalent to `as_string(unixfrom=True)`.

`is_multipart()`
Return `True` if the message's payload is a list of sub-`Message` objects, otherwise return `False`. When `is_multipart()` returns `False`, the payload should be a string object.

`set_unixfrom(unixfrom)`
Set the message's envelope header to `unixfrom`, which should be a string.

`get_unixfrom()`
Return the message's envelope header. Defaults to `None` if the envelope header was never set.

`attach(payload)`
Add the given `payload` to the current payload, which must be `None` or a list of `Message` objects before the call. After the call, the payload will always be a list of `Message` objects. If you want to set the payload to a scalar object (e.g. a string), use `set_payload()` instead.

`get_payload([i, decode])`
Return a reference the current payload, which will be a list of `Message` objects when `is_multipart()` is `True`, or a string when `is_multipart()` is `False`. If the payload is a list and you mutate the list object, you modify the message's payload in place.

With optional argument `i`, `get_payload()` will return the `i`-th element of the payload, counting from zero, if `is_multipart()` is `True`. An `IndexError` will be raised if `i` is less than 0 or greater than or equal to the
number of items in the payload. If the payload is a string (i.e. `is_multipart()` is `False`) and `i` is given, a `TypeError` is raised.

Optional `decode` is a flag indicating whether the payload should be decoded or not, according to the `Content-Transfer-Encoding:` header. When `True` and the message is not a multipart, the payload will be decoded if this header's value is "quoted-printable" or "base64". If some other encoding is used, or `Content-Transfer-Encoding:` header is missing, or if the payload has bogus base64 data, the payload is returned as-is (undecoded). If the message is a multipart and the `decode` flag is `True`, then `None` is returned. The default for `decode` is `False`.

**set_payload**(*payload[, charset]*)

Set the entire message object's payload to `payload`. It is the client's responsibility to ensure the payload invariants. Optional `charset` sets the message's default character set; see `set_charset()` for details.

Changed in version 2.2.2: `charset` argument added.

**set_charset**(*charset*)

Set the character set of the payload to `charset`, which can either be a `Charset` instance (see `email.Charset`), a string naming a character set, or `None`. If it is a string, it will be converted to a `Charset` instance. If `charset` is `None`, the `charset` parameter will be removed from the `Content-Type:` header. Anything else will generate a `TypeError`.

The message will be assumed to be of type `text/*` encoded with `charset.input_charset`. It will be converted to `charset.output_charset` and encoded properly, if needed, when generating the plain text representation of the message. MIME headers (MIME-Version:, Content-Type:, Content-Transfer-Encoding:) will be added as needed.

New in version 2.2.2.

**get_charset**()

Return the `Charset` instance associated with the message's payload. New in version 2.2.2.
The following methods implement a mapping-like interface for accessing the message's RFC 2822 headers. Note that there are some semantic differences between these methods and a normal mapping (i.e. dictionary) interface. For example, in a dictionary there are no duplicate keys, but here there may be duplicate message headers. Also, in dictionaries there is no guaranteed order to the keys returned by keys(), but in a Message object, headers are always returned in the order they appeared in the original message, or were added to the message later. Any header deleted and then re-added are always appended to the end of the header list.

These semantic differences are intentional and are biased toward maximal convenience.

Note that in all cases, any envelope header present in the message is not included in the mapping interface.

__len__()  
Return the total number of headers, including duplicates.

__contains__(name)  
Return true if the message object has a field named name. Matching is done case-insensitively and name should not include the trailing colon. Used for the in operator, e.g.:

```python
    if 'message-id' in myMessage:
        print 'Message-ID:', myMessage['message-id']
```

__getitem__(name)  
Return the value of the named header field. name should not include the colon field separator. If the header is missing, None is returned; a KeyError is never raised.

Note that if the named field appears more than once in the message's headers, exactly which of those field values will be returned is undefined. Use the get_all() method to get the values of all the extant named headers.

__setitem__(name, val)  
Add a header to the message with field name name and value val. The field
is appended to the end of the message's existing fields.

Note that this does not overwrite or delete any existing header with the same name. If you want to ensure that the new header is the only one present in the message with field name name, delete the field first, e.g.:

```python
del msg['subject']
msg['subject'] = 'Python roolz!'```

__delitem__(name)
Delete all occurrences of the field with name name from the message's headers. No exception is raised if the named field isn't present in the headers.

has_key(name)
Return true if the message contains a header field named name, otherwise return false.

keys()
Return a list of all the message's header field names.

values()
Return a list of all the message's field values.

items()
Return a list of 2-tuples containing all the message's field headers and values.

get(name[, failobj])
Return the value of the named header field. This is identical to __getitem__() except that optional failobj is returned if the named header is missing (defaults to None).

Here are some additional useful methods:

get_all(name[, failobj])
Return a list of all the values for the field named name. If there are no such named headers in the message, failobj is returned (defaults to None).
add_header(_name, _value, **_params)

Extended header setting. This method is similar to __setitem__() except that additional header parameters can be provided as keyword arguments. _name is the header field to add and _value is the primary value for the header.

For each item in the keyword argument dictionary _params, the key is taken as the parameter name, with underscores converted to dashes (since dashes are illegal in Python identifiers). Normally, the parameter will be added as key="value" unless the value is None, in which case only the key will be added.

Here's an example:

    msg.add_header('Content-Disposition', 'attachment', filename='bud.gif')

This will add a header that looks like

    Content-Disposition: attachment; filename="bud.gif"

replace_header(_name, _value)

Replace a header. Replace the first header found in the message that matches _name, retaining header order and field name case. If no matching header was found, a KeyError is raised.

New in version 2.2.2.

get_content_type()

Return the message's content type. The returned string is coerced to lower case of the form maintype/subtype. If there was no Content-Type: header in the message the default type as given by get_default_type() will be returned. Since according to RFC 2045, messages always have a default type, get_content_type() will always return a value.

RFC 2045 defines a message's default type to be text/plain unless it appears inside a multipart/digest container, in which case it would be message/rfc822. If the Content-Type: header has an invalid type specification, RFC 2045 mandates that the default type be text/plain.
New in version 2.2.2.

**get_content_maintype()**

Return the message's main content type. This is the maintype part of the string returned by `get_content_type()`.

New in version 2.2.2.

**get_content_subtype()**

Return the message's sub-content type. This is the subtype part of the string returned by `get_content_type()`.

New in version 2.2.2.

**get_default_type()**

Return the default content type. Most messages have a default content type of *text/plain*, except for messages that are subparts of *multipart/digest* containers. Such subparts have a default content type of *message/rfc822*.

New in version 2.2.2.

**set_default_type(ctype)**

Set the default content type. *ctype* should either be *text/plain* or *message/rfc822*, although this is not enforced. The default content type is not stored in the *Content-Type:* header.

New in version 2.2.2.

**get_params([failobj[, header[, unquote]]])**

Return the message's *Content-Type*: parameters, as a list. The elements of the returned list are 2-tuples of key/value pairs, as split on the "=" sign. The left hand side of the "=" is the key, while the right hand side is the value. If there is no "=" sign in the parameter the value is the empty string, otherwise the value is as described in `get_param()` and is unquoted if optional *unquote* is `True` (the default).

Optional *failobj* is the object to return if there is no *Content-Type*: header. Optional *header* is the header to search instead of *Content-Type*:.
Changed in version 2.2.2: *unquote* argument added.

**get_param( param[, failobj[, header[, unquote]]])**

Return the value of the Content-Type: header's parameter *param* as a string. If the message has no Content-Type: header or if there is no such parameter, then *failobj* is returned (defaults to `None`).

Optional *header* if given, specifies the message header to use instead of Content-Type:.

Parameter keys are always compared case insensitively. The return value can either be a string, or a 3-tuple if the parameter was [RFC 2231](https://tools.ietf.org/html/rfc2231) encoded. When it's a 3-tuple, the elements of the value are of the form `(CHARSET, LANGUAGE, VALUE)`. Note that both CHARSET and LANGUAGE can be `None`, in which case you should consider VALUE to be encoded in the us-ascii charset. You can usually ignore LANGUAGE.

If your application doesn't care whether the parameter was encoded as in [RFC 2231](https://tools.ietf.org/html/rfc2231), you can collapse the parameter value by calling `email.Utils.collapse_rfc2231_value()`, passing in the return value from `get_param()`. This will return a suitably decoded Unicode string when the value is a tuple, or the original string unquoted if it isn't. For example:

```python
rawparam = msg.get_param('foo')
param = email.Utils.collapse_rfc2231_value(rawparam)
```

In any case, the parameter value (either the returned string, or the VALUE item in the 3-tuple) is always unquoted, unless *unquote* is set to *False*.

Changed in version 2.2.2: *unquote* argument added, and 3-tuple return value possible.

**set_param( param, value[, header[, requote[, charset[, language]]]])**

Set a parameter in the Content-Type: header. If the parameter already exists in the header, its value will be replaced with *value*. If the Content-Type: header as not yet been defined for this message, it will be set to text/plain and the new parameter value will be appended as per [RFC 2045](https://tools.ietf.org/html/rfc2045).
Optional header specifies an alternative header to Content-Type:, and all parameters will be quoted as necessary unless optional requote is False (the default is True).

If optional charset is specified, the parameter will be encoded according to RFC 2231. Optional language specifies the RFC 2231 language, defaulting to the empty string. Both charset and language should be strings.

New in version 2.2.2.

def del_param(param[, header[, requote]])
    Remove the given parameter completely from the Content-Type: header. The header will be re-written in place without the parameter or its value. All values will be quoted as necessary unless requote is False (the default is True). Optional header specifies an alternative to Content-Type:.

    New in version 2.2.2.

def set_type(type[, header][, requote])
    Set the main type and subtype for the Content-Type: header. type must be a string in the form maintype/subtype, otherwise a ValueError is raised.

    This method replaces the Content-Type: header, keeping all the parameters in place. If requote is False, this leaves the existing header's quoting as is, otherwise the parameters will be quoted (the default).

    An alternative header can be specified in the header argument. When the Content-Type: header is set a MIME-Version: header is also added.

    New in version 2.2.2.

def get_filename([failobj])
    Return the value of the filename parameter of the Content-Disposion: header of the message. If the header does not have a filename parameter, this method falls back to looking for the name parameter. If neither is found, or the header is missing, then failobj is returned. The returned string will always be unquoted as per Utils.unquote().
get_boundary([failobj])

Return the value of the boundary parameter of the Content-Type: header of the message, or failobj if either the header is missing, or has no boundary parameter. The returned string will always be unquoted as per Utils.unquote().

set_boundary(boundary)

Set the boundary parameter of the Content-Type: header to boundary. set_boundary() will always quote boundary if necessary. A HeaderParseError is raised if the message object has no Content-Type: header.

Note that using this method is subtly different than deleting the old Content-Type: header and adding a new one with the new boundary via add_header(), because set_boundary() preserves the order of the Content-Type: header in the list of headers. However, it does not preserve any continuation lines which may have been present in the original Content-Type: header.

get_content_charset([failobj])

Return the charset parameter of the Content-Type: header, coerced to lower case. If there is no Content-Type: header, or if that header has no charset parameter, failobj is returned.

Note that this method differs from get_charset() which returns the Charset instance for the default encoding of the message body.

New in version 2.2.2.

get_charsets([failobj])

Return a list containing the character set names in the message. If the message is a multipart, then the list will contain one element for each subpart in the payload, otherwise, it will be a list of length 1.

Each item in the list will be a string which is the value of the charset parameter in the Content-Type: header for the represented subpart. However, if the subpart has no Content-Type: header, no charset
parameter, or is not of the text main MIME type, then that item in the returned list will be failobj.

walk()
The walk() method is an all-purpose generator which can be used to iterate over all the parts and subparts of a message object tree, in depth-first traversal order. You will typically use walk() as the iterator in a for loop; each iteration returns the next subpart.

Here's an example that prints the MIME type of every part of a multipart message structure:

```python
>>> for part in msg.walk():
...     print part.get_content_type()
multipart/report
text/plain
message/delivery-status
text/plain
text/plain
message/rfc822
```

Message objects can also optionally contain two instance attributes, which can be used when generating the plain text of a MIME message.

preamble
The format of a MIME document allows for some text between the blank line following the headers, and the first multipart boundary string. Normally, this text is never visible in a MIME-aware mail reader because it falls outside the standard MIME armor. However, when viewing the raw text of the message, or when viewing the message in a non-MIME aware reader, this text can become visible.

The preamble attribute contains this leading extra-armor text for MIME documents. When the Parser discovers some text after the headers but before the first boundary string, it assigns this text to the message's preamble attribute. When the Generator is writing out the plain text representation of a MIME message, and it finds the message has a preamble attribute, it will write this text in the area between the headers and the first boundary. See email.Parser and email.Generator for details.

Note that if the message object has no preamble, the preamble attribute will
be None.

epilogue
The epilogue attribute acts the same way as the preamble attribute, except that it contains text that appears between the last boundary and the end of the message.

One note: when generating the flat text for a multipart message that has no epilogue (using the standard Generator class), no newline is added after the closing boundary line. If the message object has an epilogue and its value does not start with a newline, a newline is printed after the closing boundary. This seems a little clumsy, but it makes the most practical sense. The upshot is that if you want to ensure that a newline get printed after your closing multipart boundary, set the epilogue to the empty string.

defects
The defects attribute contains a list of all the problems found when parsing this message. See email.Errors for a detailed description of the possible parsing defects.

New in version 2.4.

Subsections

- 12.2.1.1 Deprecated methods

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.2.2 Parsing email messages

Message object structures can be created in one of two ways: they can be created from whole cloth by instantiating `Message` objects and stringing them together via `attach()` and `set_payload()` calls, or they can be created by parsing a flat text representation of the email message.

The `email` package provides a standard parser that understands most email document structures, including MIME documents. You can pass the parser a string or a file object, and the parser will return to you the root `Message` instance of the object structure. For simple, non-MIME messages the payload of this root object will likely be a string containing the text of the message. For MIME messages, the root object will return `True` from its `is_multipart()` method, and the subparts can be accessed via the `get_payload()` and `walk()` methods.

There are actually two parser interfaces available for use, the classic `Parser` API and the incremental `FeedParser` API. The classic `Parser` API is fine if you have the entire text of the message in memory as a string, or if the entire message lives in a file on the file system. `FeedParser` is more appropriate for when you're reading the message from a stream which might block waiting for more input (e.g. reading an email message from a socket). The `FeedParser` can consume and parse the message incrementally, and only returns the root object when you close the parser\[12.1\].

Note that the parser can be extended in limited ways, and of course you can implement your own parser completely from scratch. There is no magical connection between the `email` package's bundled parser and the `Message` class, so your custom parser can create message object trees any way it finds necessary.

Footnotes

12.1 As of email package version 3.0, introduced in Python 2.4, the classic
Parser was re-implemented in terms of the FeedParser, so the semantics and results are identical between the two parsers.

Python Library Reference

Previous: 12.2.1.1 Deprecated methods Up: 12.2 email Next: 12.2.2.1
FeedParser API

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.2.3 Generating MIME documents

One of the most common tasks is to generate the flat text of the email message represented by a message object structure. You will need to do this if you want to send your message via the `smtplib` module or the `nntplib` module, or print the message on the console. Taking a message object structure and producing a flat text document is the job of the `Generator` class.

Again, as with the `email.Parser` module, you aren't limited to the functionality of the bundled generator; you could write one from scratch yourself. However the bundled generator knows how to generate most email in a standards-compliant way, should handle MIME and non-MIME email messages just fine, and is designed so that the transformation from flat text, to a message structure via the `Parser` class, and back to flat text, is idempotent (the input is identical to the output).

Here are the public methods of the `Generator` class:

```python
class Generator(outfp[, mangle_from_, maxheaderlen])
```

The constructor for the `Generator` class takes a file-like object called `outfp` for an argument. `outfp` must support the `write()` method and be usable as the output file in a Python extended print statement.

Optional `mangle_from_` is a flag that, when `True`, puts a "->" character in front of any line in the body that starts exactly as "From ", i.e. `From` followed by a space at the beginning of the line. This is the only guaranteed portable way to avoid having such lines be mistaken for a Unix mailbox format envelope header separator (see `WHY THE CONTENT-LENGTH FORMAT IS BAD` for details). `mangle_from_` defaults to `True`, but you might want to set this to `False` if you are not writing Unix mailbox format files.

Optional `maxheaderlen` specifies the longest length for a non-continued header. When a header line is longer than `maxheaderlen` (in characters, with tabs expanded to 8 spaces), the header will be split as defined in the `email.Header` class. Set to zero to disable header wrapping. The default is 78, as recommended (but not required) by `RFC 2822`. 

The other public Generator methods are:

**flatten**(msg[, unixfrom])

Print the textual representation of the message object structure rooted at msg to the output file specified when the Generator instance was created. Subparts are visited depth-first and the resulting text will be properly MIME encoded.

Optional unixfrom is a flag that forces the printing of the envelope header delimiter before the first RFC 2822 header of the root message object. If the root object has no envelope header, a standard one is crafted. By default, this is set to False to inhibit the printing of the envelope delimiter.

Note that for subparts, no envelope header is ever printed.

New in version 2.2.2.

**clone**(fp)

Return an independent clone of this Generator instance with the exact same options.

New in version 2.2.2.

**write**(s)

Write the string s to the underlying file object, i.e. outfp passed to Generator's constructor. This provides just enough file-like API for Generator instances to be used in extended print statements.

As a convenience, see the methods Message.as_string() and str(aMessage), a.k.a. Message.__str__(), which simplify the generation of a formatted string representation of a message object. For more detail, see email.Message.

The email.Generator module also provides a derived class, called DecodedGenerator which is like the Generator base class, except that non-text parts are substituted with a format string representing the part.

**class DecodedGenerator**(outfp[, mangle_from_[, maxheaderlen[, fmt]]])
This class, derived from `Generator` walks through all the subparts of a message. If the subpart is of main type `text`, then it prints the decoded payload of the subpart. Optional `_mangle_from_` and `maxheaderlen` are as with the `Generator` base class.

If the subpart is not of main type `text`, optional `fmt` is a format string that is used instead of the message payload. `fmt` is expanded with the following keywords, "%(keyword)s" format:

- `type` - Full MIME type of the non-text part
- `maintype` - Main MIME type of the non-text part
- `subtype` - Sub-MIME type of the non-text part
- `filename` - Filename of the non-text part
- `description` - Description associated with the non-text part
- `encoding` - Content transfer encoding of the non-text part

The default value for `fmt` is `None`, meaning

```
[Non-text (%(type)s) part of message omitted, filename %(filename)s]
```

New in version 2.2.2.
12.2.4 Creating email and MIME objects from scratch

Ordinarily, you get a message object structure by passing a file or some text to a parser, which parses the text and returns the root message object. However you can also build a complete message structure from scratch, or even individual Message objects by hand. In fact, you can also take an existing structure and add new Message objects, move them around, etc. This makes a very convenient interface for slicing-and-dicing MIME messages.

You can create a new object structure by creating Message instances, adding attachments and all the appropriate headers manually. For MIME messages though, the email package provides some convenient subclasses to make things easier. Each of these classes should be imported from a module with the same name as the class, from within the email package. E.g.:

```python
from email.MIMEText import MIMEText
```

Here are the classes:

**class MIMEBase(_maintype, _subtype, **_params)**

This is the base class for all the MIME-specific subclasses of Message. Ordinarily you won't create instances specifically of MIMEBase, although you could. MIMEBase is provided primarily as a convenient base class for more specific MIME-aware subclasses.

_maintype is the Content-Type: major type (e.g. text or image), and
_subtype is the Content-Type: minor type (e.g. plain or gif). _params is a parameter key/value dictionary and is passed directly to Message.add_header().

The MIMEBase class always adds a Content-Type: header (based on _maintype, _subtype, and _params), and a MIME-Version: header (always set to 1.0).

**class MIMENonMultipart()**

A subclass of MIMEBase, this is an intermediate base class for MIME
messages that are not multipart. The primary purpose of this class is to prevent the use of the attach() method, which only makes sense for multipart messages. If attach() is called, a MultipartConversionError exception is raised.

New in version 2.2.2.

class MIMEMultipart([subtype[, boundary[, _subparts[, _params]]]])

A subclass of MIMEBase, this is an intermediate base class for MIME messages that are multipart. Optional _subtype defaults to mixed, but can be used to specify the subtype of the message. A Content-Type: header of multipart/_subtype will be added to the message object. A MIME-Version: header will also be added.

Optional boundary is the multipart boundary string. When None (the default), the boundary is calculated when needed.

_subparts is a sequence of initial subparts for the payload. It must be possible to convert this sequence to a list. You can always attach new subparts to the message by using the Message.attach() method.

Additional parameters for the Content-Type: header are taken from the keyword arguments, or passed into the _params argument, which is a keyword dictionary.

New in version 2.2.2.

class MIMEAudio(_audiodata[, _subtype[, _encoder[, **_params]]])

A subclass of MIMENonMultipart, the MIMEAudio class is used to create MIME message objects of major type audio. _audiodata is a string containing the raw audio data. If this data can be decoded by the standard Python module sndhdr, then the subtype will be automatically included in the Content-Type: header. Otherwise you can explicitly specify the audio subtype via the _subtype parameter. If the minor type could not be guessed and _subtype was not given, then TypeError is raised.

Optional _encoder is a callable (i.e. function) which will perform the actual
encoding of the audio data for transport. This callable takes one argument, which is the MIMEAudio instance. It should use get_payload() and set_payload() to change the payload to encoded form. It should also add any Content-Transfer-Encoding: or other headers to the message object as necessary. The default encoding is base64. See the email.Encoders module for a list of the built-in encoders.

_params are passed straight through to the base class constructor.

class MIMEImage(_imagedata[, _subtype[, _encoder[, **_params]]]]

A subclass of MIMENonMultipart, the MIMEImage class is used to create MIME message objects of major type image. _imagedata is a string containing the raw image data. If this data can be decoded by the standard Python module imghdr, then the subtype will be automatically included in the Content-Type: header. Otherwise you can explicitly specify the image subtype via the _subtype parameter. If the minor type could not be guessed and _subtype was not given, then TypeError is raised.

Optional _encoder is a callable (i.e. function) which will perform the actual encoding of the image data for transport. This callable takes one argument, which is the MIMEImage instance. It should use get_payload() and set_payload() to change the payload to encoded form. It should also add any Content-Transfer-Encoding: or other headers to the message object as necessary. The default encoding is base64. See the email.Encoders module for a list of the built-in encoders.

_params are passed straight through to the MIMEBase constructor.

class MIMEMessage(_msg[, _subtype])

A subclass of MIMENonMultipart, the MIMEMessage class is used to create MIME objects of main type message. _msg is used as the payload, and must be an instance of class Message (or a subclass thereof), otherwise a TypeError is raised.

Optional _subtype sets the subtype of the message; it defaults to rfc822.

class MIMEText(_text[, _subtype[, _charset]])
A subclass of MIMENonMultipart, the MIMEText class is used to create MIME objects of major type text. _text is the string for the payload. _subtype is the minor type and defaults to plain. _charset is the character set of the text and is passed as a parameter to the MIMENonMultipart constructor; it defaults to us-ascii. No guessing or encoding is performed on the text data.

Changed in version 2.4: The previously deprecated _encoding argument has been removed. Encoding happens implicitly based on the _charset argument.
12.2.5 Internationalized headers
RFC 2822 is the base standard that describes the format of email messages. It
derives from the older RFC 822 standard which came into widespread use at a
time when most email was composed of ASCII characters only. RFC 2822 is a
specification written assuming email contains only 7-bit ASCII characters.
Of course, as email has been deployed worldwide, it has become
internationalized, such that language specific character sets can now be used in
email messages. The base standard still requires email messages to be transferred
using only 7-bit ASCII characters, so a slew of RFCs have been written
describing how to encode email containing non-ASCII characters into RFC
2822-compliant format. These RFCs include RFC 2045, RFC 2046, RFC 2047,
and RFC 2231. The email package supports these standards in its
email.Header and email.Charset modules.
If you want to include non-ASCII characters in your email headers, say in the
Subject: or To: fields, you should use the Header class and assign the field in
the Message object to an instance of Header instead of using a string for the
header value. For example:
>>> from email.Message import Message
>>> from email.Header import Header
>>> msg = Message()
>>> h = Header('p\xf6stal', 'iso-8859-1')
>>> msg['Subject'] = h
>>> print msg.as_string()
Subject: =?iso-8859-1?q?p=F6stal?=

Notice here how we wanted the Subject: field to contain a non-ASCII
character? We did this by creating a Header instance and passing in the
character set that the byte string was encoded in. When the subsequent
Message instance was flattened, the Subject: field was properly RFC 2047
encoded. MIME-aware mail readers would show this header using the embedded
ISO-8859-1 character.
New in version 2.2.2.
Here is the Header class description:


class Header([s[, charset[, maxlinelen[, header_name[, continuation_ws[, errors]]]]]])

Create a MIME-compliant header that can contain strings in different character sets.

Optional s is the initial header value. If None (the default), the initial header value is not set. You can later append to the header with append() method calls. s may be a byte string or a Unicode string, but see the append() documentation for semantics.

Optional charset serves two purposes: it has the same meaning as the charset argument to the append() method. It also sets the default character set for all subsequent append() calls that omit the charset argument. If charset is not provided in the constructor (the default), the us-ascii character set is used both as s's initial charset and as the default for subsequent append() calls.

The maximum line length can be specified explicit via maxlinelen. For splitting the first line to a shorter value (to account for the field header which isn't included in s, e.g. Subject:) pass in the name of the field in header_name. The default maxlinelen is 76, and the default value for header_name is None, meaning it is not taken into account for the first line of a long, split header.

Optional continuation_ws must be RFC 2822-compliant folding whitespace, and is usually either a space or a hard tab character. This character will be prepended to continuation lines.

Optional errors is passed straight through to the append() method.

append( s[, charset[, errors]])

Append the string s to the MIME header.

Optional charset, if given, should be a Charset instance (see email.charset) or the name of a character set, which will be converted to a Charset instance. A value of None (the default) means that the charset given in the constructor is used.
s may be a byte string or a Unicode string. If it is a byte string (i.e. \texttt{isinstance(s, str)} is true), then \texttt{charset} is the encoding of that byte string, and a \texttt{UnicodeError} will be raised if the string cannot be decoded with that character set.

If \textit{s} is a Unicode string, then \texttt{charset} is a hint specifying the character set of the characters in the string. In this case, when producing an \texttt{RFC 2822}-compliant header using \texttt{RFC 2047} rules, the Unicode string will be encoded using the following charsets in order: \texttt{us-ascii}, the \texttt{charset} hint, \texttt{utf-8}. The first character set to not provoke a \texttt{UnicodeError} is used.

Optional \texttt{errors} is passed through to any \texttt{unicode()} or \texttt{ustr.encode()} call, and defaults to ``strict''.

\texttt{encode([splicchars])}

Encode a message header into an RFC-compliant format, possibly wrapping long lines and encapsulating non-ASCII parts in base64 or quoted-printable encodings. Optional \texttt{splicchars} is a string containing characters to split long ASCII lines on, in rough support of \texttt{RFC 2822}'s highest level syntactic breaks. This doesn't affect \texttt{RFC 2047} encoded lines.

The \texttt{Header} class also provides a number of methods to support standard operators and built-in functions.

\texttt{__str__()}  
A synonym for \texttt{Header.encode()}. Useful for \texttt{str(aHeader)}.

\texttt{__unicode__()}  
A helper for the built-in \texttt{unicode()} function. Returns the header as a Unicode string.

\texttt{__eq__(other)}  
This method allows you to compare two \texttt{Header} instances for equality.

\texttt{__ne__(other)}  
This method allows you to compare two \texttt{Header} instances for inequality.

The \texttt{email.Header} module also provides the following convenient functions.
decode_header( header)
Decode a message header value without converting the character set. The
header value is in header.
This function returns a list of (decoded_string, charset) pairs
containing each of the decoded parts of the header. charset is None for
non-encoded parts of the header, otherwise a lower case string containing
the name of the character set specified in the encoded string.
Here's an example:
>>> from email.Header import decode_header
[('p\xf6stal', 'iso-8859-1')]

decoded_seq[, maxlinelen[, header_name[,
continuation_ws]]])
Create a Header instance from a sequence of pairs as returned by
decode_header().

make_header(

decode_header() takes a header value string and returns a sequence of
pairs of the format (decoded_string, charset) where charset is
the name of the character set.
This function takes one of those sequence of pairs and returns a Header
instance. Optional maxlinelen, header_name, and continuation_ws are as in
the Header constructor.

See About this document... for information on suggesting changes.


12.2.6 Representing character sets

This module provides a class `Charset` for representing character sets and character set conversions in email messages, as well as a character set registry and several convenience methods for manipulating this registry. Instances of `Charset` are used in several other modules within the `email` package.

New in version 2.2.2.

**class Charset([input_charset])**

Map character sets to their email properties.

This class provides information about the requirements imposed on email for a specific character set. It also provides convenience routines for converting between character sets, given the availability of the applicable codecs. Given a character set, it will do its best to provide information on how to use that character set in an email message in an RFC-compliant way.

Certain character sets must be encoded with quoted-printable or base64 when used in email headers or bodies. Certain character sets must be converted outright, and are not allowed in email.

Optional `input_charset` is as described below; it is always coerced to lower case. After being alias normalized it is also used as a lookup into the registry of character sets to find out the header encoding, body encoding, and output conversion codec to be used for the character set. For example, if `input_charset` is `iso-8859-1`, then headers and bodies will be encoded using quoted-printable and no output conversion codec is necessary. If `input_charset` is `euc-jp`, then headers will be encoded with base64, bodies will not be encoded, but output text will be converted from the `euc-jp` character set to the `iso-2022-jp` character set.

`Charset` instances have the following data attributes:

**input_charset**
The initial character set specified. Common aliases are converted to their official email names (e.g. `latin_1` is converted to `iso-8859-1`).
Defaults to 7-bit **us-ascii**.

**header_encoding**
If the character set must be encoded before it can be used in an email header, this attribute will be set to `Charset.QP` (for quoted-printable), `Charset.BASE64` (for base64 encoding), or `Charset.SHORTEST` for the shortest of QP or BASE64 encoding. Otherwise, it will be `None`.

**body_encoding**
Same as `header_encoding`, but describes the encoding for the mail message's body, which indeed may be different than the header encoding. `Charset.SHORTEST` is not allowed for `body_encoding`.

**output_charset**
Some character sets must be converted before they can be used in email headers or bodies. If the `input_charset` is one of them, this attribute will contain the name of the character set output will be converted to. Otherwise, it will be `None`.

**input_codec**
The name of the Python codec used to convert the `input_charset` to Unicode. If no conversion codec is necessary, this attribute will be `None`.

**output_codec**
The name of the Python codec used to convert Unicode to the `output_charset`. If no conversion codec is necessary, this attribute will have the same value as the `input_codec`.

`Charset` instances also have the following methods:

**get_body_encoding()**
Return the content transfer encoding used for body encoding.

This is either the string "**quoted-printable**" or "**base64**" depending on the encoding used, or it is a function, in which case you should call the function with a single argument, the Message object being encoded. The function should then set the `Content-Transfer-Encoding: header` itself to whatever is appropriate.
Returns the string "quoted-printable" if `body_encoding` is QP, returns the string "base64" if `body_encoding` is BASE64, and returns the string "7bit" otherwise.

`convert(s)`
Convert the string `s` from the `input_codec` to the `output_codec`.

`to_splittable(s)`
Convert a possibly multibyte string to a safely splittable format. `s` is the string to split.

Uses the `input_codec` to try and convert the string to Unicode, so it can be safely split on character boundaries (even for multibyte characters).

Returns the string as-is if it isn't known how to convert `s` to Unicode with the `input_charset`.

Characters that could not be converted to Unicode will be replaced with the Unicode replacement character "U+FFFD".

`from_splittable(ustr[, to_output])`
Convert a splittable string back into an encoded string. `ustr` is a Unicode string to \``unsplit``.

This method uses the proper codec to try and convert the string from Unicode back into an encoded format. Return the string as-is if it is not Unicode, or if it could not be converted from Unicode.

Characters that could not be converted from Unicode will be replaced with an appropriate character (usually "?").

If `to_output` is `True` (the default), uses `output_codec` to convert to an encoded format. If `to_output` is `False`, it uses `input_codec`.

`get_output_charset()`
Return the output character set.

This is the `output_charset` attribute if that is not `None`, otherwise it is
encoded_header_len()  
Return the length of the encoded header string, properly calculating for quoted-printable or base64 encoding.

header_encode(s[, convert])  
Header-encode the string s.

If convert is True, the string will be converted from the input charset to the output charset automatically. This is not useful for multibyte character sets, which have line length issues (multibyte characters must be split on a character, not a byte boundary); use the higher-level Header class to deal with these issues (see email.Header). convert defaults to False.

The type of encoding (base64 or quoted-printable) will be based on the header_encoding attribute.

body_encode(s[, convert])  
Body-encode the string s.

If convert is True (the default), the string will be converted from the input charset to output charset automatically. Unlike header_encode(), there are no issues with byte boundaries and multibyte charsets in email bodies, so this is usually pretty safe.

The type of encoding (base64 or quoted-printable) will be based on the body_encoding attribute.

The Charset class also provides a number of methods to support standard operations and built-in functions.

__str__()  
Returns input_charset as a string coerced to lower case. __repr__() is an alias for __str__().

eq(other)  
This method allows you to compare two Charset instances for equality.
This method allows you to compare two `Charset` instances for inequality.

The `email.Charset` module also provides the following functions for adding new entries to the global character set, alias, and codec registries:

**add_charset**(`charset`, `header_enc`, `body_enc`, `output_charset`)
Add character properties to the global registry.

`charset` is the input character set, and must be the canonical name of a character set.

Optional `header_enc` and `body_enc` is either `Charset.QP` for quoted-printable, `Charset.BASE64` for base64 encoding, `Charset.SHORTEST` for the shortest of quoted-printable or base64 encoding, or `None` for no encoding. `SHORTEST` is only valid for `header_enc`. The default is `None` for no encoding.

Optional `output_charset` is the character set that the output should be in. Conversions will proceed from input charset, to Unicode, to the output charset when the method `Charset.convert()` is called. The default is to output in the same character set as the input.

Both `input_charset` and `output_charset` must have Unicode codec entries in the module's character set-to-codec mapping; use `add_codec()` to add codecs the module does not know about. See the `codecs` module's documentation for more information.

The global character set registry is kept in the module global dictionary `CHARSETS`.

**add_alias**(`alias`, `canonical`)
Add a character set alias. `alias` is the alias name, e.g. `latin-1`. `canonical` is the character set's canonical name, e.g. `iso-8859-1`.

The global charset alias registry is kept in the module global dictionary `ALIASES`. 
add_codec( charset, codecname)

Add a codec that map characters in the given character set to and from Unicode.

charset is the canonical name of a character set. codecname is the name of a Python codec, as appropriate for the second argument to the unicode() built-in, or to the encode() method of a Unicode string.
12.2.7 Encoders

When creating Message objects from scratch, you often need to encode the payloads for transport through compliant mail servers. This is especially true for image/* and text/* type messages containing binary data.

The email package provides some convenient encodings in its Encoders module. These encoders are actually used by the MIMEAudio and MIMEImage class constructors to provide default encodings. All encoder functions take exactly one argument, the message object to encode. They usually extract the payload, encode it, and reset the payload to this newly encoded value. They should also set the Content-Transfer-Encoding: header as appropriate.

Here are the encoding functions provided:

**encode_quopri(msg)**
Encodes the payload into quoted-printable form and sets the Content-Transfer-Encoding: header to quoted-printable\(^\text{12.2}\). This is a good encoding to use when most of your payload is normal printable data, but contains a few unprintable characters.

**encode_base64(msg)**
Encodes the payload into base64 form and sets the Content-Transfer-Encoding: header to base64. This is a good encoding to use when most of your payload is unprintable data since it is a more compact form than quoted-printable. The drawback of base64 encoding is that it renders the text non-human readable.

**encode_7or8bit(msg)**
This doesn't actually modify the message's payload, but it does set the Content-Transfer-Encoding: header to either 7bit or 8bit as appropriate, based on the payload data.

**encode_noop(msg)**
This does nothing; it doesn't even set the Content-Transfer-Encoding: header.
Footnotes

...quoted-printable\textsuperscript{12.2}\.

Note that encoding with \texttt{encode_quopri()} also encodes all tabs and space characters in the data.
12.2.8 Exception and Defect classes

The following exception classes are defined in the email.Errors module:

**exception MessageError()**
This is the base class for all exceptions that the email package can raise. It is derived from the standard Exception class and defines no additional methods.

**exception MessageParseError()**
This is the base class for exceptions thrown by the Parser class. It is derived from MessageError.

**exception HeaderParseError()**
Raised under some error conditions when parsing the RFC 2822 headers of a message, this class is derived from MessageParseError. It can be raised from the Parser.parse() or Parser.parsestr() methods.

Situations where it can be raised include finding an envelope header after the first RFC 2822 header of the message, finding a continuation line before the first RFC 2822 header is found, or finding a line in the headers which is neither a header or a continuation line.

**exception BoundaryError()**
Raised under some error conditions when parsing the RFC 2822 headers of a message, this class is derived from MessageParseError. It can be raised from the Parser.parse() or Parser.parsestr() methods.

Situations where it can be raised include not being able to find the starting or terminating boundary in a multipart/* message when strict parsing is used.

**exception MultipartConversionError()**
Raised when a payload is added to a Message object using add_payload(), but the payload is already a scalar and the message's Content-Type: main type is not either multipart or missing.
MultipartConversionError multiply inherits from MessageError and the built-in TypeError.

Since Message.add_payload() is deprecated, this exception is rarely raised in practice. However the exception may also be raised if the attach() method is called on an instance of a class derived from MIMENonMultipart (e.g. MIMEImage).

Here's the list of the defects that the FeedParser can find while parsing messages. Note that the defects are added to the message where the problem was found, so for example, if a message nested inside a multipart/alternative had a malformed header, that nested message object would have a defect, but the containing messages would not.

All defect classes are subclassed from email.Errors.MessageDefect, but this class is not an exception!

New in version 2.4: All the defect classes were added.

- **NoBoundaryInMultipartDefect** - A message claimed to be a multipart, but had no boundary parameter.

- **StartBoundaryNotFoundDefect** - The start boundary claimed in the Content-Type: header was never found.

- **FirstHeaderLineIsContinuationDefect** - The message had a continuation line as its first header line.

- **MisplacedEnvelopeHeaderDefect** - A `Unix From" header was found in the middle of a header block.

- **MalformedHeaderDefect** - A header was found that was missing a colon, or was otherwise malformed.

- **MultipartInvariantViolationDefect** - A message claimed to be a multipart, but no subparts were found. Note that when a message has this defect, its is_multipart() method may return false even though its content type claims to be multipart.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.2.9 Miscellaneous utilities

There are several useful utilities provided in the email.Utils module:

quote\( (str) \)
Return a new string with backslashes in \( str \) replaced by two backslashes, and double quotes replaced by backslash-double quote.

unquote\( (str) \)
Return a new string which is an unquoted version of \( str \). If \( str \) ends and begins with double quotes, they are stripped off. Likewise if \( str \) ends and begins with angle brackets, they are stripped off.

parseaddr\( (address) \)
Parse address - which should be the value of some address-containing field such as \( To: \) or \( Cc: \) - into its constituent \( realname \) and \( email \ address \) parts. Returns a tuple of that information, unless the parse fails, in which case a 2-tuple of \( ('', '') \) is returned.

formataddr\( (pair) \)
The inverse of parseaddr(), this takes a 2-tuple of the form \( (realname, email\_address) \) and returns the string value suitable for a \( To: \) or \( Cc: \) header. If the first element of \( pair \) is false, then the second element is returned unmodified.

getaddresses\( (fieldvalues) \)
This method returns a list of 2-tuples of the form returned by parseaddr(). \( fieldvalues \) is a sequence of header field values as might be returned by Message.get_all(). Here's a simple example that gets all the recipients of a message:

```
from email.Utils import getaddresses

tos = msg.get_all('to', [])
ccs = msg.get_all('cc', [])
resent_tos = msg.get_all('resent-to', [])
resent_ccs = msg.get_all('resent-cc', [])
all_recipients = getaddresses(tos + ccs + resent_tos + resent_ccs)
```
parsedate( date)
Attempts to parse a date according to the rules in RFC 2822. However, some mailers don't follow that format as specified, so parsedate() tries to guess correctly in such cases. date is a string containing an RFC 2822 date, such as "Mon, 20 Nov 1995 19:12:08 -0500". If it succeeds in parsing the date, parsedate() returns a 9-tuple that can be passed directly to time.mktime(); otherwise None will be returned. Note that fields 6, 7, and 8 of the result tuple are not usable.

parsedate_tz( date)
Performs the same function as parsedate(), but returns either None or a 10-tuple; the first 9 elements make up a tuple that can be passed directly to time.mktime(), and the tenth is the offset of the date's timezone from UTC (which is the official term for Greenwich Mean Time). If the input string has no timezone, the last element of the tuple returned is None. Note that fields 6, 7, and 8 of the result tuple are not usable.

mktime_tz( tuple)
Turn a 10-tuple as returned by parsedate_tz() into a UTC timestamp. If the timezone item in the tuple is None, assume local time. Minor deficiency: mktime_tz() interprets the first 8 elements of tuple as a local time and then compensates for the timezone difference. This may yield a slight error around changes in daylight savings time, though not worth worrying about for common use.

formatdate([timeval[, localtime][, usegmt]])
Returns a date string as per RFC 2822, e.g.:

    Fri, 09 Nov 2001 01:08:47 -0000

Optional timeval if given is a floating point time value as accepted by time.gmtime() and time.localtime(), otherwise the current time is used.

Optional localtime is a flag that when True, interprets timeval, and returns a date relative to the local timezone instead of UTC, properly taking daylight savings time into account. The default is False meaning UTC is used.
Optional usegmt is a flag that when True, outputs a date string with the timezone as an ascii string GMT, rather than a numeric -0000. This is needed for some protocols (such as HTTP). This only applies when localtime is False. New in version 2.4.

**make_msgid([idstring])**

Returns a string suitable for an RFC 2822-compliant Message-ID: header. Optional idstring if given, is a string used to strengthen the uniqueness of the message id.

**decode_rfc2231(s)**

Decode the string s according to RFC 2231.

**encode_rfc2231(s[, charset[, language]])**

Encode the string s according to RFC 2231. Optional charset and language, if given is the character set name and language name to use. If neither is given, s is returned as-is. If charset is given but language is not, the string is encoded using the empty string for language.

**collapse_rfc2231_value(value[, errors[, fallback_charset]])**

When a header parameter is encoded in RFC 2231 format, Message.get_param() may return a 3-tuple containing the character set, language, and value. collapse_rfc2231_value() turns this into a unicode string. Optional errors is passed to the errors argument of the built-in unicode() function; it defaults to replace. Optional fallback_charset specifies the character set to use if the one in the RFC 2231 header is not known by Python; it defaults to us-ascii.

For convenience, if the value passed to collapse_rfc2231_value() is not a tuple, it should be a string and it is returned unquoted.

**decode_params(params)**

Decode parameters list according to RFC 2231. params is a sequence of 2-tuples containing elements of the form (content-type, string-value).

Changed in version 2.4: The dump_address_pair() function has been
removed; use `formataddr()` instead.

Changed in version 2.4: The `decode()` function has been removed; use the `Header.decode_header()` method instead.

Changed in version 2.4: The `encode()` function has been removed; use the `Header.encode()` method instead.

---

**Footnotes**

... Time)¹²³

Note that the sign of the timezone offset is the opposite of the sign of the `time.timezone` variable for the same timezone; the latter variable follows the POSIX standard while this module follows [RFC 2822](https://tools.ietf.org/html/rfc2822).

---

*Release 2.4.4c1, documentation updated on 11 October 2006.*

See [About this document...](https://docs.python.org/2/library) for information on suggesting changes.
12.2.10 Iterators

Iterating over a message object tree is fairly easy with the `Message.walk()` method. The `email.Iterators` module provides some useful higher level iterations over message object trees.

**body_line_iterator** *(msg[, decode])*  
This iterates over all the payloads in all the subparts of `msg`, returning the string payloads line-by-line. It skips over all the subpart headers, and it skips over any subpart with a payload that isn't a Python string. This is somewhat equivalent to reading the flat text representation of the message from a file using `readline()`, skipping over all the intervening headers.

Optional `decode` is passed through to `Message.get_payload()`.

**typed_subpart_iterator** *(msg[, maintype[, subtype]])*  
This iterates over all the subparts of `msg`, returning only those subparts that match the MIME type specified by `maintype` and `subtype`.

Note that `subtype` is optional; if omitted, then subpart MIME type matching is done only with the main type. `maintype` is optional too; it defaults to `text`.

Thus, by default `typed_subpart_iterator()` returns each subpart that has a MIME type of `text/*`.

The following function has been added as a useful debugging tool. It should not be considered part of the supported public interface for the package.

**_structure** *(msg[, fp[, level]])*  
Prints an indented representation of the content types of the message object structure. For example:

```python
>>> msg = email.message_from_file(somefile)
>>> _structure(msg)
multipart/mixed
    text/plain
    text/plain
    multipart/digest
```
Optional \textit{fp} is a file-like object to print the output to. It must be suitable for Python's extended print statement. \textit{level} is used internally.
12.2.11 Package History

Version 1 of the email package was bundled with Python releases up to Python 2.2.1. Version 2 was developed for the Python 2.3 release, and backported to Python 2.2.2. It was also available as a separate distutils-based package, and is compatible back to Python 2.1.

email version 3.0 was released with Python 2.4 and as a separate distutils-based package. It is compatible back to Python 2.3.

Here are the differences between email version 3 and version 2:

- The FeedParser class was introduced, and the Parser class was implemented in terms of the FeedParser. All parsing there for is non-strict, and parsing will make a best effort never to raise an exception. Problems found while parsing messages are stored in the message's defect attribute.

- All aspects of the API which raised DeprecationWarnings in version 2 have been removed. These include the _encoder argument to the MIMEText constructor, the Message.add_payload() method, the Utils.dump_address_pair() function, and the functions Utils.decode() and Utils.encode().

- New DeprecationWarnings have been added to: Generator.__call__(), Message.get_type(), Message.get_main_type(), Message.get_subtype(), and the strict argument to the Parser class. These are expected to be removed in email 3.1.

- Support for Pythons earlier than 2.3 has been removed.

Here are the differences between email version 2 and version 1:

- The email.Header and email.Charset modules have been added.

- The pickle format for Message instances has changed. Since this was never (and still isn't) formally defined, this isn't considered a backward
incompatibility. However if your application pickles and unpickles Message instances, be aware that in email version 2, Message instances now have private variables _charset and _default_type.

- Several methods in the Message class have been deprecated, or their signatures changed. Also, many new methods have been added. See the documentation for the Message class for details. The changes should be completely backward compatible.

- The object structure has changed in the face of message/rfc822 content types. In email version 1, such a type would be represented by a scalar payload, i.e. the container message's is_multipart() returned false, get_payload() was not a list object, but a single Message instance.

This structure was inconsistent with the rest of the package, so the object representation for message/rfc822 content types was changed. In email version 2, the container *does* return True from is_multipart(), and get_payload() returns a list containing a single Message item.

Note that this is one place that backward compatibility could not be completely maintained. However, if you're already testing the return type of get_payload(), you should be fine. You just need to make sure your code doesn't do a set_payload() with a Message instance on a container with a content type of message/rfc822.

- The Parser constructor's strict argument was added, and its parse() and parsestr() methods grew a headersonly argument. The strict flag was also added to functions email.message_from_file() and email.message_from_string().

- Generator.__call__() is deprecated; use Generator.flatten() instead. The Generator class has also grown the clone() method.

- The DecodedGenerator class in the email.Generator module was added.

- The intermediate base classes MIMENonMultipart and MIME_Multipart have been added, and interposed in the class hierarchy.
for most of the other MIME-related derived classes.

- The `_encoder` argument to the `MIMEText` constructor has been deprecated. Encoding now happens implicitly based on the `_charset` argument.

- The following functions in the `email.Utils` module have been deprecated: `dump_address_pairs()`, `decode()`, and `encode()`. The following functions have been added to the module: `make_msgid()`, `decode_rfc2231()`, `encode_rfc2231()`, and `decode_params()`.

- The non-public function `email.Iterators._structure()` was added.
12.2.12 Differences from mimelib

The email package was originally prototyped as a separate library called mimelib. Changes have been made so that method names are more consistent, and some methods or modules have either been added or removed. The semantics of some of the methods have also changed. For the most part, any functionality available in mimelib is still available in the email package, albeit often in a different way. Backward compatibility between the mimelib package and the email package was not a priority.

Here is a brief description of the differences between the mimelib and the email packages, along with hints on how to port your applications.

Of course, the most visible difference between the two packages is that the package name has been changed to email. In addition, the top-level package has the following differences:

- messageFromString() has been renamed to message_from_string().
- messageFromFile() has been renamed to message_from_file().

The Message class has the following differences:

- The method asString() was renamed to as_string().
- The method ismultipart() was renamed to is_multipart().
- The get_payload() method has grown a decode optional argument.
- The method getall() was renamed to get_all().
- The method addheader() was renamed to add_header().
- The method gettype() was renamed to get_type().
- The method getmaintype() was renamed to get_main_type().
The method `getsubtype()` was renamed to `get_subtype()`.

The method `getparams()` was renamed to `get_params()`. Also, whereas `getparams()` returned a list of strings, `get_params()` returns a list of 2-tuples, effectively the key/value pairs of the parameters, split on the "=" sign.

The method `getparam()` was renamed to `get_param()`.

The method `getcharsets()` was renamed to `get_charsets()`.

The method `getfilename()` was renamed to `get_filename()`.

The method `getboundary()` was renamed to `get_boundary()`.

The method `setboundary()` was renamed to `set_boundary()`.

The method `getdecodedpayload()` was removed. To get similar functionality, pass the value 1 to the `decode` flag of the `get_payload()` method.

The method `getpayloadastext()` was removed. Similar functionality is supported by the `DecodedGenerator` class in the `email.Generator` module.

The method `getbodyastext()` was removed. You can get similar functionality by creating an iterator with `typed_subpart_iterator()` in the `email.Iterators` module.

The `Parser` class has no differences in its public interface. It does have some additional smarts to recognize `message/delivery-status` type messages, which it represents as a `Message` instance containing separate `Message` subparts for each header block in the delivery status notification.

The `Generator` class has no differences in its public interface. There is a new class in the `email.Generator` module though, called `DecodedGenerator` which provides most of the functionality previously available in the `Message.getpayloadastext()` method.
The following modules and classes have been changed:

- The MIMEBase class constructor arguments _major and _minor have changed to _maintype and _subtype respectively.

- The Image class/module has been renamed to MIMEImage. The _minor argument has been renamed to _subtype.

- The Text class/module has been renamed to MIMEText. The _minor argument has been renamed to _subtype.

- The MessageRFC822 class/module has been renamed to MIMEMessage. Note that an earlier version of mimelib called this class/module RFC822, but that clashed with the Python standard library module rfc822 on some case-insensitive file systems.

Also, the MIMEMessage class now represents any kind of MIME message with main type message. It takes an optional argument _subtype which is used to set the MIME subtype. _subtype defaults to rfc822.

mimelib provided some utility functions in its address and date modules. All of these functions have been moved to the email.Utils module.

The MsgReader class/module has been removed. Its functionality is most closely supported in the body_line_iterator() function in the email.Iterators module.

---

**Footnotes**

... notification\(^{12,4}\)

Delivery Status Notifications (DSN) are defined in RFC 1894.
See About this document... for information on suggesting changes.
12.2.13 Examples

Here are a few examples of how to use the email package to read, write, and send simple email messages, as well as more complex MIME messages.

First, let's see how to create and send a simple text message:

```python
# Import smtplib for the actual sending function
import smtplib

# Import the email modules we'll need
from email.MIMEText import MIMEText

# Open a plain text file for reading.  For this example, assume that
# the text file contains only ASCII characters.
fp = open(textfile, 'rb')
# Create a text/plain message
msg = MIMEText(fp.read())
fp.close()

# me == the sender's email address
# you == the recipient's email address
msg['Subject'] = 'The contents of %s' % textfile
msg['From'] = me
msg['To'] = you

# Send the message via our own SMTP server, but don't include the
# envelope header.
s = smtplib.SMTP()
s.connect()
s.sendmail(me, [you], msg.as_string())
s.close()
```

Download as text (original file name: email-simple.py).

Here's an example of how to send a MIME message containing a bunch of family pictures that may be residing in a directory:

```python
# Import smtplib for the actual sending function
import smtplib

# Here are the email package modules we'll need
from email.MIMEImage import MIMEImage
from email.MIMEMultipart import MIMEMultipart

COMMASPACE = ', '
```
# Create the container (outer) email message.
msg = MIMEMultipart()
msg['Subject'] = 'Our family reunion'
# me == the sender's email address
# family = the list of all recipients' email addresses
msg['From'] = me
msg['To'] = COMMASPACE.join(family)
msg.preamble = 'Our family reunion'
# Guarantees the message ends in a newline
msg.epilogue = ''

# Assume we know that the image files are all in PNG format
for file in pngfiles:
    # Open the files in binary mode. Let the MIMEImage class automa
    # guess the specific image type.
    fp = open(file, 'rb')
    img = MIMEImage(fp.read())
    fp.close()
    msg.attach(img)

# Send the email via our own SMTP server.
s = smtplib.SMTP()
s.connect()
s.sendmail(me, family, msg.as_string())
s.close()

Download as text (original file name: email-mime.py).

Here's an example of how to send the entire contents of a directory as an email
message:

```
#!/usr/bin/env python

"""Send the contents of a directory as a MIME message.
Usage: dirmail [options] from to [to ...]*

Options:
    -h / --help
        Print this message and exit.

    -d directory
   --directory=directory
        Mail the contents of the specified directory, otherwise use
        current directory. Only the regular files in the directory
        and we don't recurse to subdirectories.

`from' is the email address of the sender of the message.

`to' is the email address of the recipient of the message, and multi
recipients may be given.
```
The email is sent by forwarding to your local SMTP server, which then does the normal delivery process. Your local machine must be running an SMTP server.

```python
import sys
import os
import getopt
import smtplib

# For guessing MIME type based on file name extension
import mimetypes

from email import Encoders
from email.Message import Message
from email.MIMEAudio import MIMEAudio
from email.MIMEBase import MIMEBase
from email.MIMEImage import MIMEImage
from email.MIMEText import MIMEText

COMMASPACE = ', '

def usage(code, msg=''):  # def usage( code, msg=''):  #
    print >> sys.stderr, __doc__
    if msg:
        print >> sys.stderr, msg
    sys.exit(code)

def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], 'hd:', ['help', 'directory='])
    except getopt.error, msg:
        usage(1, msg)

    dir = os.curdir
    for opt, arg in opts:
        if opt in ('-h', '--help'):
            usage(0)
        elif opt in ('-d', '--directory'):
            dir = arg

    if len(args) < 2:
        usage(1)

    sender = args[0]
    recips = args[1:]

    # Create the enclosing (outer) message
    outer = MIMEMultipart()
    outer['Subject'] = 'Contents of directory %s' % os.path.abspath(dir)
    outer['To'] = COMMASPACE.join(recips)
    outer['From'] = sender
```
for filename in os.listdir(dir):
    path = os.path.join(dir, filename)
    if not os.path.isfile(path):
        continue
    # Guess the content type based on the file's extension. Enc
    # will be ignored, although we should check for simple thing
    # gzip'd or compressed files.
    ctype, encoding = mimetypes.guess_type(path)
    if ctype is None or encoding is not None:
        # No guess could be made, or the file is encoded (compre
        # use a generic bag-of-bits type.
        ctype = 'application/octet-stream'
    maintype, subtype = ctype.split('/', 1)
    if maintype == 'text':
        fp = open(path)
        # Note: we should handle calculating the charset
        msg = MIMEText(fp.read(), _subtype=subtype)
        fp.close()
    elif maintype == 'image':
        fp = open(path, 'rb')
        msg = MIMEImage(fp.read(), _subtype=subtype)
        fp.close()
    elif maintype == 'audio':
        fp = open(path, 'rb')
        msg = MIMEAudio(fp.read(), _subtype=subtype)
        fp.close()
    else:
        fp = open(path, 'rb')
        msg = MIMEBase(maintype, subtype)
        msg.set_payload(fp.read())
        fp.close()
        # Encode the payload using Base64
        Encoders.encode_base64(msg)
        # Set the filename parameter
        msg.add_header('Content-Disposition', 'attachment', filename=filename)
        outer.attach(msg)

    # Now send the message
    s = smtplib.SMTP()
    s.connect()
    s.sendmail(sender, recips, outer.as_string())
    s.close()

if __name__ == '__main__':
    main()
And finally, here's an example of how to unpack a MIME message like the one above, into a directory of files:

```python
#!/usr/bin/env python

"""Unpack a MIME message into a directory of files.

Usage: unpackmail [options] msgfile

Options:
    -h / --help
        Print this message and exit.

    -d directory
    --directory=directory
        Unpack the MIME message into the named directory, which will be created if it doesn't already exist.

msgfile is the path to the file containing the MIME message.
"""

import sys
import os
import getopt
import errno
import mimetypes
import email
def usage(code, msg=''):  
    print >> sys.stderr, __doc__  
    if msg:  
        print >> sys.stderr, msg  
    sys.exit(code)
def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], 'hd:', ['help', 'directory='])
        except getopt.error, msg:
            usage(1, msg)

    dir = os.curdir
    for opt, arg in opts:
        if opt in ('-h', '--help'):
            usage(0)
        elif opt in ('-d', '--directory'):
            dir = arg

    try:
        msgfile = args[0]
        except IndexError:
            usage(1)```
try:
    os.mkdir(dir)
except OSError, e:
    # Ignore directory exists error
    if e.errno <> errno.EEXIST: raise

fp = open(msgfile)
msg = email.message_from_file(fp)
fp.close()

counter = 1
for part in msg.walk():
    # multipart/* are just containers
    if part.get_content_maintype() == 'multipart':
        continue
    # Applications should really sanitize the given filename so
    # email message can't be used to overwrite important files
    filename = part.get_filename()
    if not filename:
        ext = mimetypes.guess_extension(part.get_type())
        if not ext:
            # Use a generic bag-of-bits extension
            ext = '.bin'
        filename = 'part-%03d%s' % (counter, ext)
        counter += 1
    fp = open(os.path.join(dir, filename), 'wb')
    fp.write(part.get_payload(decode=1))
    fp.close()

if __name__ == '__main__':
    main()

Download as text (original file name: email-unpack.py).

Footnotes

... message:12.5

Thanks to Matthew Dixon Cowles for the original inspiration and examples.
12.3 mailcap -- Mailcap file handling.

Mailcap files are used to configure how MIME-aware applications such as mail readers and Web browsers react to files with different MIME types. (The name ``mailcap'' is derived from the phrase ``mail capability''.) For example, a mailcap file might contain a line like "video/mpeg; xmpeg %%s". Then, if the user encounters an email message or Web document with the MIME type video/mpeg, "%s" will be replaced by a filename (usually one belonging to a temporary file) and the xmpeg program can be automatically started to view the file.

The mailcap format is documented in RFC 1524, ``A User Agent Configuration Mechanism For Multimedia Mail Format Information," but is not an Internet standard. However, mailcap files are supported on most UNIX systems.

``findmatch( caps, MIMEtype[, key[, filename[, plist]]])``

Return a 2-tuple; the first element is a string containing the command line to be executed (which can be passed to os.system()), and the second element is the mailcap entry for a given MIME type. If no matching MIME type can be found, (None, None) is returned.

``key`` is the name of the field desired, which represents the type of activity to be performed; the default value is 'view', since in the most common case you simply want to view the body of the MIME-typed data. Other possible values might be 'compose' and 'edit', if you wanted to create a new body of the given MIME type or alter the existing body data. See RFC 1524 for a complete list of these fields.

``filename`` is the filename to be substituted for "%s" in the command line; the default value is '/dev/null' which is almost certainly not what you want, so usually you'll override it by specifying a filename.

``plist`` can be a list containing named parameters; the default value is simply an empty list. Each entry in the list must be a string containing the
parameter name, an equals sign ("="), and the parameter's value. Mailcap entries can contain named parameters like %{foo}, which will be replaced by the value of the parameter named 'foo'. For example, if the command line "showpartial %{id} %{number} %{total}" was in a mailcap file, and plist was set to ['id=1', 'number=2', 'total=3'], the resulting command line would be 'showpartial 1 2 3'.

In a mailcap file, the `test` field can optionally be specified to test some external condition (such as the machine architecture, or the window system in use) to determine whether or not the mailcap line applies. `findmatch()` will automatically check such conditions and skip the entry if the check fails.

**getcaps()**

Returns a dictionary mapping MIME types to a list of mailcap file entries. This dictionary must be passed to the `findmatch()` function. An entry is stored as a list of dictionaries, but it shouldn't be necessary to know the details of this representation.

The information is derived from all of the mailcap files found on the system. Settings in the user's mailcap file `$HOME/.mailcap` will override settings in the system mailcap files `/etc/mailcap`, `/usr/etc/mailcap`, and `/usr/local/etc/mailcap`.

An example usage:

```python
>>> import mailcap
>>> d=mailcap.getcaps()
>>> mailcap.findmatch(d, 'video/mpeg', filename='/tmp/tmp1223')
('xmpeg /tmp/tmp1223', {'view': 'xmpeg %s'})
```
12.4 mailbox -- Read various mailbox formats

This module defines a number of classes that allow easy and uniform access to mail messages in a (UNIX) mailbox.

**class UnixMailbox**(*fp*, *factory*)

Access to a classic UNIX-style mailbox, where all messages are contained in a single file and separated by "From "(a.k.a. "From_") lines. The file object *fp* points to the mailbox file. The optional *factory* parameter is a callable that should create new message objects. *factory* is called with one argument, *fp* by the next() method of the mailbox object. The default is the rfc822.Message class (see the [rfc822](#) module - and the note below).

**Note:** For reasons of this module's internal implementation, you will probably want to open the *fp* object in binary mode. This is especially important on Windows.

For maximum portability, messages in a UNIX-style mailbox are separated by any line that begins exactly with the string 'From ' (note the trailing space) if preceded by exactly two newlines. Because of the wide-range of variations in practice, nothing else on the From_ line should be considered. However, the current implementation doesn't check for the leading two newlines. This is usually fine for most applications.

The UnixMailbox class implements a more strict version of From_ line checking, using a regular expression that usually correctly matched From_ delimiters. It considers delimiter line to be separated by "From name time" lines. For maximum portability, use the PortableUnixMailbox class instead. This class is identical to UnixMailbox except that individual messages are separated by only "From " lines.
For more information, see _Configuring Netscape Mail on UNIX: Why the Content-Length Format is Bad_.

**class** PortableUnixMailbox**(fp[, factory])**

A less-strict version of UnixMailbox, which considers only the "From " at the beginning of the line separating messages. The ``name time" portion of the From line is ignored, to protect against some variations that are observed in practice. This works since lines in the message which begin with 'From ' are quoted by mail handling software at delivery-time.

**class** MmdfMailbox**(fp[, factory])**

Access an MMDF-style mailbox, where all messages are contained in a single file and separated by lines consisting of 4 control-A characters. The file object fp points to the mailbox file. Optional factory is as with the UnixMailbox class.

**class** MHMailbox**(dirname[, factory])**

Access an MH mailbox, a directory with each message in a separate file with a numeric name. The name of the mailbox directory is passed in dirname. factory is as with the UnixMailbox class.

**class** Maildir**(dirname[, factory])**

Access a Qmail mail directory. All new and current mail for the mailbox specified by dirname is made available. factory is as with the UnixMailbox class.

**class** BabylMailbox**(fp[, factory])**

Access a Babyl mailbox, which is similar to an MMDF mailbox. In Babyl format, each message has two sets of headers, the original headers and the visible headers. The original headers appear before a line containing only '*** EOOH ***' (End-Of-Original-Headers) and the visible headers appear after the EOOH line. Babyl-compliant mail readers will show you only the visible headers, and BabylMailbox objects will return messages containing only the visible headers. You'll have to do your own parsing of the mailbox file to get at the original headers. Mail messages start with the EOOH line and end with a line containing only '\037\014'. factory is as with the UnixMailbox class.
Note that because the `rfc822` module is deprecated, it is recommended that you use the `email` package to create message objects from a mailbox. (The default can't be changed for backwards compatibility reasons.) The safest way to do this is with bit of code:

```python
def msgfactory(fp):
    try:
        return email.message_from_file(fp)
    except email.Errors.MessageParseError:
        # Don't return None since that will # stop the mailbox iterator
        return ''

mbox = mailbox.UnixMailbox(fp, msgfactory)
```

The above wrapper is defensive against ill-formed MIME messages in the mailbox, but you have to be prepared to receive the empty string from the mailbox's `next()` method. On the other hand, if you know your mailbox contains only well-formed MIME messages, you can simplify this to:

```python
import email
import mailbox

mbox = mailbox.UnixMailbox(fp, email.message_from_file)
```

See Also:

- `mbox - file containing mail messages`
  Description of the traditional ``mbox'' mailbox format.

- `maildir - directory for incoming mail messages`
  Description of the ``maildir'' mailbox format.

  A description of problems with relying on the Content-Length: header for messages stored in mailbox files.
12.4.1 Mailbox Objects

All implementations of mailbox objects are iterable objects, and have one externally visible method. This method is used by iterators created from mailbox objects and may also be used directly.

next()

Return the next message in the mailbox, created with the optional *factory* argument passed into the mailbox object's constructor. By default this is an *rfc822.Message* object (see the *rfc822* module). Depending on the mailbox implementation the *fp* attribute of this object may be a true file object or a class instance simulating a file object, taking care of things like message boundaries if multiple mail messages are contained in a single file, etc. If no more messages are available, this method returns *None*. 

*Python Library Reference*

Release 2.4.4c1, documentation updated on 11 October 2006. 
See *About this document*... for information on suggesting changes.
12.5 mhlib -- Access to MH mailboxes

The mhlib module provides a Python interface to MH folders and their contents.

The module contains three basic classes, MH, which represents a particular collection of folders, Folder, which represents a single folder, and Message, which represents a single message.

```python
class MH([path[, profile]])
    MH represents a collection of MH folders.

class Folder(mh, name)
    The Folder class represents a single folder and its messages.

class Message(folder, number[, name])
    Message objects represent individual messages in a folder. The Message class is derived from mimetools.Message.
```

Subsections

- 12.5.1 MH Objects
- 12.5.2 Folder Objects
- 12.5.3 Message Objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.5.1 MH Objects

MH instances have the following methods:

**error**(*format[, ...]*)
Print an error message - can be overridden.

**getprofile**(*key*)
Return a profile entry (**None** if not set).

**getpath**()
Return the mailbox pathname.

**getcontext**()
Return the current folder name.

**setcontext**(*name*)
Set the current folder name.

**listfolders**()
Return a list of top-level folders.

**listallfolders**()
Return a list of all folders.

**listsubfolders**(*name*)
Return a list of direct subfolders of the given folder.

**listallsubfolders**(*name*)
Return a list of all subfolders of the given folder.

**makefolder**(*name*)
Create a new folder.

**deletefolder**(*name*)
Delete a folder - must have no subfolders.

```python
openfolder(name)
```

Return a new open folder object.
12.5.2 Folder Objects

Folder instances represent open folders and have the following methods:

error(format[, ...])
   Print an error message - can be overridden.

getfullname()
   Return the folder's full pathname.

getsequencesfilename()
   Return the full pathname of the folder's sequences file.

getmessagefilename(n)
   Return the full pathname of message n of the folder.

listmessages()
   Return a list of messages in the folder (as numbers).

gGetCurrent()
   Return the current message number.

setCurrent(n)
   Set the current message number to n.

parsesequence(seq)
   Parse msgs syntax into list of messages.

gGetLast()
   Get last message, or 0 if no messages are in the folder.

setlast(n)
   Set last message (internal use only).

getsequences()
Return dictionary of sequences in folder. The sequence names are used as keys, and the values are the lists of message numbers in the sequences.

\textbf{putsequences}(\textit{dict})

Return dictionary of sequences in folder name: list.

\textbf{removemessages}(\textit{list})

Remove messages in list from folder.

\textbf{refilemessages}(\textit{list, tofolder})

Move messages in list to other folder.

\textbf{movemessage}(\textit{n, tofolder, ton})

Move one message to a given destination in another folder.

\textbf{copymessage}(\textit{n, tofolder, ton})

Copy one message to a given destination in another folder.
12.5.3 Message Objects

The Message class adds one method to those of mimetools.Message:

`openmessage(n)`

Return a new open message object (costs a file descriptor).
12.6 mimetools -- Tools for parsing MIME messages

Deprecated since release 2.3. The email package should be used in preference to the mimetools module. This module is present only to maintain backward compatibility.

This module defines a subclass of the rfc822 module's Message class and a number of utility functions that are useful for the manipulation for MIME multipart or encoded message.

It defines the following items:

class Message(fp[, seekable])

Return a new instance of the Message class. This is a subclass of the rfc822.Message class, with some additional methods (see below). The seekable argument has the same meaning as for rfc822.Message.

choose_boundary()

Return a unique string that has a high likelihood of being usable as a part boundary. The string has the form 'hostipaddr.uid.pid.timestamp.random'.

decode(input, output, encoding)

Read data encoded using the allowed MIME encoding from open file object input and write the decoded data to open file object output. Valid values for encoding include 'base64', 'quoted-printable', 'uuencode', 'x-uuencode', 'uue', 'x-uue', '7bit', and '8bit'. Decoding messages encoded in '7bit' or '8bit' has no effect. The input is simply copied to the output.

encode(input, output, encoding)

Read data from open file object input and write it encoded using the allowed MIME encoding to open file object output. Valid values for
encoding are the same as for `decode()`.

**copyliteral**(`input`, `output`)
Read lines from open file `input` until EOF and write them to open file `output`.

**copybinary**(`input`, `output`)
Read blocks until EOF from open file `input` and write them to open file `output`. The block size is currently fixed at 8192.

---

**See Also:**

- [12.6.1 Additional Methods of Message Objects](#)

---

![Python Library Reference](#)
Release 2.4.4c1, documentation updated on 11 October 2006. 
See About this document... for information on suggesting changes.
12.6.1 Additional Methods of Message Objects

The Message class defines the following methods in addition to the rfc822.Message methods:

**getplist()**
Return the parameter list of the Content-Type: header. This is a list of strings. For parameters of the form "key=value", `key` is converted to lower case but `value` is not. For example, if the message contains the header "Content-type: text/html; spam=1; Spam=2; Spam" then getplist() will return the Python list `['spam=1', 'spam=2', 'Spam']`.

**getparam(name)**
Return the value of the first parameter (as returned by getplist()) of the form "name=value" for the given name. If `value` is surrounded by quotes of the form `'<...>'` or `""...""`, these are removed.

**getencoding()**
Return the encoding specified in the Content-Transfer-Encoding: message header. If no such header exists, return '7bit'. The encoding is converted to lower case.

**gettype()**
Return the message type (of the form "type/subtype") as specified in the Content-Type: header. If no such header exists, return 'text/plain'. The type is converted to lower case.

**getmaintype()**
Return the main type as specified in the Content-Type: header. If no such header exists, return 'text'. The main type is converted to lower case.

**getsubtype()**
Return the subtype as specified in the Content-Type: header. If no such header exists, return 'plain'. The subtype is converted to lower case.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.7 mimetypes -- Map filenames to MIME types

The mimetypes module converts between a filename or URL and the MIME type associated with the filename extension. Conversions are provided from filename to MIME type and from MIME type to filename extension; encodings are not supported for the latter conversion.

The module provides one class and a number of convenience functions. The functions are the normal interface to this module, but some applications may be interested in the class as well.

The functions described below provide the primary interface for this module. If the module has not been initialized, they will call init() if they rely on the information init() sets up.

**guess_type** *(filename[, strict]*)

Guess the type of a file based on its filename or URL, given by filename. The return value is a tuple *(type, encoding)* where type is None if the type can't be guessed (missing or unknown suffix) or a string of the form 'type/subtype', usable for a MIME content-type: header.

encoding is None for no encoding or the name of the program used to encode (e.g. compress or gzip). The encoding is suitable for use as a Content-Encoding: header, not as a Content-Transfer-Encoding: header. The mappings are table driven. Encoding suffixes are case sensitive; type suffixes are first tried case sensitively, then case insensitively.

Optional strict is a flag specifying whether the list of known MIME types is limited to only the official types registered with IANA are recognized. When strict is true (the default), only the IANA types are supported; when strict is false, some additional non-standard but commonly used MIME types are also recognized.

**guess_all_extensions** *(type[, strict]*)
Guess the extensions for a file based on its MIME type, given by `type`. The return value is a list of strings giving all possible filename extensions, including the leading dot ("."). The extensions are not guaranteed to have been associated with any particular data stream, but would be mapped to the MIME type `type` by `guess_type()`.

Optional `strict` has the same meaning as with the `guess_type()` function.

`guess_extension(type[, strict])`

Guess the extension for a file based on its MIME type, given by `type`. The return value is a string giving a filename extension, including the leading dot ("."). The extension is not guaranteed to have been associated with any particular data stream, but would be mapped to the MIME type `type` by `guess_type()`. If no extension can be guessed for `type`, `None` is returned.

Optional `strict` has the same meaning as with the `guess_type()` function.

Some additional functions and data items are available for controlling the behavior of the module.

`init([files])`

Initialize the internal data structures. If given, `files` must be a sequence of file names which should be used to augment the default type map. If omitted, the file names to use are taken from `knownfiles`. Each file named in `files` or `knownfiles` takes precedence over those named before it. Calling `init()` repeatedly is allowed.

`read_mime_types(filename)`

Load the type map given in the file `filename`, if it exists. The type map is returned as a dictionary mapping filename extensions, including the leading dot ("."), to strings of the form 'type/subtype'. If the file `filename` does not exist or cannot be read, `None` is returned.

`add_type(type, ext[, strict])`
Add a mapping from the mimetype *type* to the extension *ext*. When the extension is already known, the new type will replace the old one. When the type is already known the extension will be added to the list of known extensions.

When *strict* is the mapping will added to the official MIME types, otherwise to the non-standard ones.

**initialized**
Flag indicating whether or not the global data structures have been initialized. This is set to true by `init()`.

**knownfiles**
List of type map file names commonly installed. These files are typically named `mime.types` and are installed in different locations by different packages.

**suffix_map**
Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the `.tgz` extension is mapped to `.tar.gz` to allow the encoding and type to be recognized separately.

**encodings_map**
Dictionary mapping filename extensions to encoding types.

**types_map**
Dictionary mapping filename extensions to MIME types.

**common_types**
Dictionary mapping filename extensions to non-standard, but commonly found MIME types.

The `MimeType` class may be useful for applications which may want more than one MIME-type database:

```python
class MimeTypes([filenames])
```
This class represents a MIME-types database. By default, it provides access to the same database as the rest of this module. The initial database is a
copy of that provided by the module, and may be extended by loading additional `mime.types`-style files into the database using the `read()` or `readfp()` methods. The mapping dictionaries may also be cleared before loading additional data if the default data is not desired.

The optional `filenames` parameter can be used to cause additional files to be loaded ``on top'' of the default database.

New in version 2.2.
12.7.1 MimeTypes Objects

MimeTypes instances provide an interface which is very like that of the `mimetypes` module.

**suffix_map**
Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the `.tgz` extension is mapped to `.tar.gz` to allow the encoding and type to be recognized separately. This is initially a copy of the global `suffix_map` defined in the module.

**encodings_map**
Dictionary mapping filename extensions to encoding types. This is initially a copy of the global `encodings_map` defined in the module.

**types_map**
Dictionary mapping filename extensions to MIME types. This is initially a copy of the global `types_map` defined in the module.

**common_types**
Dictionary mapping filename extensions to non-standard, but commonly found MIME types. This is initially a copy of the global `common_types` defined in the module.

**guess_extension**(type[, strict])
Similar to the `guess_extension()` function, using the tables stored as part of the object.

**guess_type**(url[, strict])
Similar to the `guess_type()` function, using the tables stored as part of the object.

**read**(path)
Load MIME information from a file named `path`. This uses `readfp()` to parse the file.
readfp(file)

Load MIME type information from an open file. The file must have the format of the standard mime.types files.
12.8 MimeWriter -- Generic MIME file writer

Deprecated since release 2.3. The email package should be used in preference to the MimeWriter module. This module is present only to maintain backward compatibility.

This module defines the class MimeWriter. The MimeWriter class implements a basic formatter for creating MIME multi-part files. It doesn't seek around the output file nor does it use large amounts of buffer space. You must write the parts out in the order that they should occur in the final file. MimeWriter does buffer the headers you add, allowing you to rearrange their order.

```
class MimeWriter(fp)
    Return a new instance of the MimeWriter class. The only argument passed, fp, is a file object to be used for writing. Note that a StringIO object could also be used.
```

Subsections

- 12.8.1 MimeWriter Objects

Python Library Reference

Previous: 12.7.1 MimeTypes Objects  Up: 12. Internet Data Handling  Next: 12.8.1 MimeWriter Objects

Release 2.4.4c1, documentation updated on 11 October 2006. See About this document... for information on suggesting changes.
12.8.1 MimeWriter Objects

MimeWriter instances have the following methods:

**addheader**(*key*, *value*[, *prefix]*)

Add a header line to the MIME message. The *key* is the name of the header, where the *value* obviously provides the value of the header. The optional argument *prefix* determines where the header is inserted; "0" means append at the end, "1" is insert at the start. The default is to append.

**flushheaders()**

Causes all headers accumulated so far to be written out (and forgotten). This is useful if you don't need a body part at all, e.g. for a subpart of type message/rfc822 that's (mis)used to store some header-like information.

**startbody**(*ctype*[, *plist*[, *prefix*]])

Returns a file-like object which can be used to write to the body of the message. The content-type is set to the provided *ctype*, and the optional parameter *plist* provides additional parameters for the content-type declaration. *prefix* functions as in `addheader()` except that the default is to insert at the start.

**startmultipartbody**(*subtype*[, *boundary*[, *plist*[, *prefix*]])

Returns a file-like object which can be used to write to the body of the message. Additionally, this method initializes the multi-part code, where *subtype* provides the multipart subtype, *boundary* may provide a user-defined boundary specification, and *plist* provides optional parameters for the subtype. *prefix* functions as in `startbody()` except that the default is to insert at the start. Subparts should be created using `nextpart()`.

**nextpart()**

Returns a new instance of MimeWriter which represents an individual part in a multipart message. This may be used to write the part as well as used for creating recursively complex multipart messages. The message must first be initialized with `startmultipartbody()` before using
nextpart().

lastpart()

This is used to designate the last part of a multipart message, and should *always* be used when writing multipart messages.
12.9 mimify -- MIME processing of mail messages

Deprecated since release 2.3. The email package should be used in preference to the mimify module. This module is present only to maintain backward compatibility.

The mimify module defines two functions to convert mail messages to and from MIME format. The mail message can be either a simple message or a so-called multipart message. Each part is treated separately. Mimifying (a part of) a message entails encoding the message as quoted-printable if it contains any characters that cannot be represented using 7-bit ASCII. Unmimifying (a part of) a message entails undoing the quoted-printable encoding. Mimify and unmimify are especially useful when a message has to be edited before being sent. Typical use would be:

```
unmimify message
edit message
mimify message
send message
```

The modules defines the following user-callable functions and user-settable variables:

**mimify***(infile, outfile)***
Copy the message in *infile* to *outfile*, converting parts to quoted-printable and adding MIME mail headers when necessary. *infile* and *outfile* can be file objects (actually, any object that has a `readline()` method (for *infile*) or a `write()` method (for *outfile*)) or strings naming the files. If *infile* and *outfile* are both strings, they may have the same value.

**unmimify***(infile, outfile[, decode_base64])***
Copy the message in *infile* to *outfile*, decoding all quoted-printable parts. *infile* and *outfile* can be file objects (actually, any object that has a `readline()` method (for *infile*) or a `write()` method (for *outfile*)) or strings naming the files. If *infile* and *outfile* are both strings, they may have
the same value. If the `decode_base64` argument is provided and tests true, any parts that are coded in the base64 encoding are decoded as well.

**mime_decode_header** *(line)*
Return a decoded version of the encoded header line in `line`. This only supports the ISO 8859-1 charset (Latin-1).

**mime_encode_header** *(line)*
Return a MIME-encoded version of the header line in `line`.

**MAXLEN**
By default, a part will be encoded as quoted-printable when it contains any non-ASCII characters (characters with the 8th bit set), or if there are any lines longer than MAXLEN characters (default value 200).

**CHARSET**
When not specified in the mail headers, a character set must be filled in. The string used is stored in CHARSET, and the default value is ISO-8859-1 (also known as Latin1 (latin-one)).

This module can also be used from the command line. Usage is as follows:

```
mimify.py -e [-l length] [infile [outfile]]
mimify.py -d [-b] [infile [outfile]]
```

to encode (mimify) and decode (unmimify) respectively. `infile` defaults to standard input, `outfile` defaults to standard output. The same file can be specified for input and output.

If the `-l` option is given when encoding, if there are any lines longer than the specified `length`, the containing part will be encoded.

If the `-b` option is given when decoding, any base64 parts will be decoded as well.

**See Also:**

Module [quopri](#):
Encode and decode MIME quoted-printable files.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.10 multifile -- Support for files containing distinct parts

The MultiFile object enables you to treat sections of a text file as file-like input objects, with '' being returned by readline() when a given delimiter pattern is encountered. The defaults of this class are designed to make it useful for parsing MIME multipart messages, but by subclassing it and overriding methods it can be easily adapted for more general use.

**class MultiFile(fp[, seekable])**

Create a multi-file. You must instantiate this class with an input object argument for the MultiFile instance to get lines from, such as a file object returned by open().

MultiFile only ever looks at the input object's readline(), seek() and tell() methods, and the latter two are only needed if you want random access to the individual MIME parts. To use MultiFile on a non-seekable stream object, set the optional seekable argument to false; this will prevent using the input object's seek() and tell() methods.

It will be useful to know that in MultiFile's view of the world, text is composed of three kinds of lines: data, section-dividers, and end-markers. MultiFile is designed to support parsing of messages that may have multiple nested message parts, each with its own pattern for section-divider and end-marker lines.

**See Also:**

Module **email**: Comprehensive email handling package; supersedes the multifile module.
12.10.1 MultiFile Objects

A MultiFile instance has the following methods:

**readline**( *str*)
Read a line. If the line is data (not a section-divider or end-marker or real EOF) return it. If the line matches the most-recently-stacked boundary, return '' and set self.last to 1 or 0 according as the match is or is not an end-marker. If the line matches any other stacked boundary, raise an error. On encountering end-of-file on the underlying stream object, the method raises Error unless all boundaries have been popped.

**readlines**( *str*)
Return all lines remaining in this part as a list of strings.

**read**
Read all lines, up to the next section. Return them as a single (multiline) string. Note that this doesn't take a size argument!

**seek**( *pos[, whence]*)
Seek. Seek indices are relative to the start of the current section. The pos and whence arguments are interpreted as for a file seek.

**tell**
Return the file position relative to the start of the current section.

**next**
Skip lines to the next section (that is, read lines until a section-divider or end-marker has been consumed). Return true if there is such a section, false if an end-marker is seen. Re-enable the most-recently-pushed boundary.

**is_data**( *str*)
Return true if str is data and false if it might be a section boundary. As written, it tests for a prefix other than ' - - ' at start of line (which all MIME boundaries have) but it is declared so it can be overridden in derived classes.
Note that this test is used intended as a fast guard for the real boundary tests; if it always returns false it will merely slow processing, not cause it to fail.

**push**( *str*)

Push a boundary string. When a decorated version of this boundary is found as an input line, it will be interpreted as a section-divider or end-marker (depending on the decoration, see [RFC 2045](https://tools.ietf.org/html/rfc2045)). All subsequent reads will return the empty string to indicate end-of-file, until a call to **pop()** removes the boundary a or **next()** call reenables it.

It is possible to push more than one boundary. Encountering the most-recently-pushed boundary will return EOF; encountering any other boundary will raise an error.

**pop()**

Pop a section boundary. This boundary will no longer be interpreted as EOF.

**section_divider**( *str*)

Turn a boundary into a section-divider line. By default, this method prepends '---' (which MIME section boundaries have) but it is declared so it can be overridden in derived classes. This method need not append LF or CR-LF, as comparison with the result ignores trailing whitespace.

**end_marker**( *str*)

Turn a boundary string into an end-marker line. By default, this method prepends '---' and appends '---' (like a MIME-multipart end-of-message marker) but it is declared so it can be overridden in derived classes. This method need not append LF or CR-LF, as comparison with the result ignores trailing whitespace.

Finally, **MultiFile** instances have two public instance variables:

**level**

Nesting depth of the current part.

**last**
True if the last end-of-file was for an end-of-message marker.
import mimetools
import multifile
import StringIO

def extract_mime_part_matching(stream, mimetype):
    """Return the first element in a multipart MIME message on stream
    matching mimetype."""

    msg = mimetools.Message(stream)
    msgtype = msg.gettype()
    params = msg.getplist()

    data = StringIO.StringIO()
    if msgtype[:10] == "multipart/":
        file = multifile.MultiFile(stream)
        file.push(msg.getparam("boundary"))
        while file.next():
            submsg = mimetools.Message(file)
            try:
                data = StringIO.StringIO()
                mimetools.decode(file, data, submsg.getencoding())
            except ValueError:
                continue
            if submsg.gettype() == mimetype:
                break
        file.pop()
    return data.getvalue()
12.11 rfc822 -- Parse RFC 2822 mail headers

**Deprecated since release 2.3.** The `email` package should be used in preference to the `rfc822` module. This module is present only to maintain backward compatibility.

This module defines a class, `Message`, which represents an "email message" as defined by the Internet standard RFC 2822. Such messages consist of a collection of message headers, and a message body. This module also defines a helper class `AddressList` for parsing RFC 2822 addresses. Please refer to the RFC for information on the specific syntax of RFC 2822 messages.

The `mailbox` module provides classes to read mailboxes produced by various end-user mail programs.

```python
class Message(file[, seekable])
```

A `Message` instance is instantiated with an input object as parameter. Message relies only on the input object having a `readline()` method; in particular, ordinary file objects qualify. Instantiation reads headers from the input object up to a delimiter line (normally a blank line) and stores them in the instance. The message body, following the headers, is not consumed.

This class can work with any input object that supports a `readline()` method. If the input object has seek and tell capability, the `rewindbody()` method will work; also, illegal lines will be pushed back onto the input stream. If the input object lacks seek but has an `unread()` method that can push back a line of input, `Message` will use that to push back illegal lines. Thus this class can be used to parse messages coming from a buffered stream.

The optional `seekable` argument is provided as a workaround for certain stdio libraries in which `tell()` discards buffered data before discovering that the `lseek()` system call doesn't work. For maximum portability, you should set the seekable argument to zero to prevent that initial `tell()`
when passing in an unseekable object such as a file object created from a socket object.

Input lines as read from the file may either be terminated by CR-LF or by a single linefeed; a terminating CR-LF is replaced by a single linefeed before the line is stored.

All header matching is done independent of upper or lower case; e.g. $m[ 'From' ]$, $m[ 'from' ]$ and $m[ 'FROM' ]$ all yield the same result.

**class AddressList**( *field*)

You may instantiate the AddressList helper class using a single string parameter, a comma-separated list of RFC 2822 addresses to be parsed. (The parameter *None* yields an empty list.)

**quote**( *str*)

Return a new string with backslashes in *str* replaced by two backslashes and double quotes replaced by backslash-double quote.

**unquote**( *str*)

Return a new string which is an unquoted version of *str*. If *str* ends and begins with double quotes, they are stripped off. Likewise if *str* ends and begins with angle brackets, they are stripped off.

**parseaddr**( *address*)

Parse *address*, which should be the value of some address-containing field such as To: or Cc:, into its constituent ``realname'' and ``email address'' parts. Returns a tuple of that information, unless the parse fails, in which case a 2-tuple (None, None) is returned.

**dump_address_pair**( *pair*)

The inverse of parseaddr(), this takes a 2-tuple of the form (realname, email_address) and returns the string value suitable for a To: or Cc: header. If the first element of *pair* is false, then the second element is returned unmodified.

**parsedate**( *date*)

Attempts to parse a date according to the rules in RFC 2822, however, some
mailers don't follow that format as specified, so `parsedate()` tries to guess correctly in such cases. `date` is a string containing an RFC 2822 date, such as 'Mon, 20 Nov 1995 19:12:08 -0500'. If it succeeds in parsing the date, `parsedate()` returns a 9-tuple that can be passed directly to `time.mktime()`; otherwise `None` will be returned. Note that fields 6, 7, and 8 of the result tuple are not usable.

**parsedate_tz** *(date)*

Performs the same function as `parsedate()`, but returns either `None` or a 10-tuple; the first 9 elements make up a tuple that can be passed directly to `time.mktime()`, and the tenth is the offset of the date's timezone from UTC (which is the official term for Greenwich Mean Time). (Note that the sign of the timezone offset is the opposite of the sign of the `time.timezone` variable for the same timezone; the latter variable follows the POSIX standard while this module follows RFC 2822.) If the input string has no timezone, the last element of the tuple returned is `None`. Note that fields 6, 7, and 8 of the result tuple are not usable.

**mktime_tz** *(tuple)*

Turn a 10-tuple as returned by `parsedate_tz()` into a UTC timestamp. If the timezone item in the tuple is `None`, assume local time. Minor deficiency: this first interprets the first 8 elements as a local time and then compensates for the timezone difference; this may yield a slight error around daylight savings time switch dates. Not enough to worry about for common use.

---

**See Also:**

Module **email**: Comprehensive email handling package; supersedes the rfc822 module.

Module **mailbox**: Classes to read various mailbox formats produced by end-user mail programs.

Module **mimetypes**: 
Subclass of rfc822.Message that handles MIME encoded messages.

---

**Footnotes**

...2822. ¹²⁶

This module originally conformed to [RFC 822](https://www.rfc-editor.org/rfc/rfc822), hence the name. Since then, [RFC 2822](https://www.rfc-editor.org/rfc/rfc2822) has been released as an update to [RFC 822](https://www.rfc-editor.org/rfc/rfc822). This module should be considered [RFC 2822](https://www.rfc-editor.org/rfc/rfc2822)-conformant, especially in cases where the syntax or semantics have changed since [RFC 822](https://www.rfc-editor.org/rfc/rfc822).

12.11.1 Message Objects

A Message instance has the following methods:

**Message**

- **rewindbody()**
  Seek to the start of the message body. This only works if the file object is seekable.

- **isheader(line)**
  Returns a line's canonicalized fieldname (the dictionary key that will be used to index it) if the line is a legal RFC 2822 header; otherwise returns None (implying that parsing should stop here and the line be pushed back on the input stream). It is sometimes useful to override this method in a subclass.

- **islast(line)**
  Return true if the given line is a delimiter on which Message should stop. The delimiter line is consumed, and the file object's read location positioned immediately after it. By default this method just checks that the line is blank, but you can override it in a subclass.

- **iscomment(line)**
  Return True if the given line should be ignored entirely, just skipped. By default this is a stub that always returns False, but you can override it in a subclass.

- **getallmatchingheaders(name)**
  Return a list of lines consisting of all headers matching name, if any. Each physical line, whether it is a continuation line or not, is a separate list item. Return the empty list if no header matches name.

- **getfirstmatchingheader(name)**
  Return a list of lines comprising the first header matching name, and its continuation line(s), if any. Return None if there is no header matching name.
getrawheader( name)
Return a single string consisting of the text after the colon in the first header matching name. This includes leading whitespace, the trailing linefeed, and internal linefeeds and whitespace if there any continuation line(s) were present. Return None if there is no header matching name.

getheader( name[, default])
Like getrawheader( name), but strip leading and trailing whitespace. Internal whitespace is not stripped. The optional default argument can be used to specify a different default to be returned when there is no header matching name.

get( name[, default])
An alias for getheader(), to make the interface more compatible with regular dictionaries.

getaddr( name)
Return a pair (full name, email address) parsed from the string returned by getheader( name). If no header matching name exists, return (None, None); otherwise both the full name and the address are (possibly empty) strings.

Example: If m's first From: header contains the string 'jack@cwi.nl (Jack Jansen)', then m.getaddr('From') will yield the pair ('Jack Jansen', 'jack@cwi.nl'). If the header contained 'Jack Jansen <jack@cwi.nl>' instead, it would yield the exact same result.

getaddrlist( name)
This is similar to getaddr( list), but parses a header containing a list of email addresses (e.g. a To: header) and returns a list of (full name, email address) pairs (even if there was only one address in the header). If there is no header matching name, return an empty list.

If multiple headers exist that match the named header (e.g. if there are several Cc: headers), all are parsed for addresses. Any continuation lines the named headers contain are also parsed.
**getdate**( name )
Retrieve a header using getheader() and parse it into a 9-tuple compatible with time.mktime(); note that fields 6, 7, and 8 are not usable. If there is no header matching name, or it is unparsable, return None.

Date parsing appears to be a black art, and not all mailers adhere to the standard. While it has been tested and found correct on a large collection of email from many sources, it is still possible that this function may occasionally yield an incorrect result.

**getdate_tz**( name )
Retrieve a header using getheader() and parse it into a 10-tuple; the first 9 elements will make a tuple compatible with time.mktime(), and the 10th is a number giving the offset of the date's timezone from UTC. Note that fields 6, 7, and 8 are not usable. Similarly to getdate(), if there is no header matching name, or it is unparsable, return None.

Message instances also support a limited mapping interface. In particular: 
\( m[\text{name}] \) is like \( m\).getheader(name) but raises KeyError if there is no matching header; and \( \text{len}(m), m\).get(name[, default]), m.has_key(name), m.keys(), m.values() m.items(), and m.setdefault(name[, default]) act as expected, with the one difference that setdefault() uses an empty string as the default value. Message instances also support the mapping writable interface \( m[\text{name}] = \text{value} \) and \( \text{del } m[\text{name}] \). Message objects do not support the clear(), copy(), popitem(), or update() methods of the mapping interface. (Support for get() and setdefault() was only added in Python 2.2.)

Finally, Message instances have some public instance variables:

**headers**
A list containing the entire set of header lines, in the order in which they were read (except that setitem calls may disturb this order). Each line contains a trailing newline. The blank line terminating the headers is not contained in the list.
The file or file-like object passed at instantiation time. This can be used to read the message content.

**unixfrom**

The UNIX "From " line, if the message had one, or an empty string. This is needed to regenerate the message in some contexts, such as an mbox-style mailbox file.
12.11.2 AddressList Objects

An AddressList instance has the following methods:

___len__()  
Return the number of addresses in the address list.

___str__()  
Return a canonicalized string representation of the address list. Addresses are rendered in "name" <host@domain> form, comma-separated.

___add__(alist)  
Return a new AddressList instance that contains all addresses in both AddressList operands, with duplicates removed (set union).

___iadd__(alist)  
In-place version of ___add__(); turns this AddressList instance into the union of itself and the right-hand instance, alist.

___sub__(alist)  
Return a new AddressList instance that contains every address in the left-hand AddressList operand that is not present in the right-hand address operand (set difference).

___isub__(alist)  
In-place version of ___sub__(), removing addresses in this list which are also in alist.

Finally, AddressList instances have one public instance variable:

addresslist  
A list of tuple string pairs, one per address. In each member, the first is the canonicalized name part, the second is the actual route-address (@-separated username-host.domain pair).
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.12 base64 -- RFC 3548: Base16, Base32, Base64 Data Encodings

This module provides data encoding and decoding as specified in RFC 3548. This standard defines the Base16, Base32, and Base64 algorithms for encoding and decoding arbitrary binary strings into text strings that can be safely sent by email, used as parts of URLs, or included as part of an HTTP POST request. The encoding algorithm is not the same as the uuencode program.

There are two interfaces provided by this module. The modern interface supports encoding and decoding string objects using all three alphabets. The legacy interface provides for encoding and decoding to and from file-like objects as well as strings, but only using the Base64 standard alphabet.

The modern interface provides:

b64encode( s[, altchars])
   Encode a string use Base64.

   s is the string to encode. Optional altchars must be a string of at least length 2 (additional characters are ignored) which specifies an alternative alphabet for the + and / characters. This allows an application to e.g. generate URL or filesystem safe Base64 strings. The default is None, for which the standard Base64 alphabet is used.

   The encoded string is returned.

b64decode( s[, altchars])
   Decode a Base64 encoded string.

   s is the string to decode. Optional altchars must be a string of at least length 2 (additional characters are ignored) which specifies the alternative alphabet used instead of the + and / characters.

   The decoded string is returned. A TypeError is raised if s were incorrectly padded or if there are non-alphabet characters present in the
string.

**standard_b64encode( s)**
Encode string s using the standard Base64 alphabet.

**standard_b64decode( s)**
Decode string s using the standard Base64 alphabet.

**urlsafe_b64encode( s)**
Encode string s using a URL-safe alphabet, which substitutes - instead of +
and _ instead of / in the standard Base64 alphabet.

**urlsafe_b64decode( s)**
Decode string s using a URL-safe alphabet, which substitutes - instead of +
and _ instead of / in the standard Base64 alphabet.

**b32encode( s)**
Encode a string using Base32. s is the string to encode. The encoded string
is returned.

**b32decode( s[, casefold[, map01]])**
Decode a Base32 encoded string.

s is the string to decode. Optional casefold is a flag specifying whether a
lowercase alphabet is acceptable as input. For security purposes, the default
is False.

[RFC 3548] allows for optional mapping of the digit 0 (zero) to the letter O
(oh), and for optional mapping of the digit 1 (one) to either the letter I (eye)
or letter L (el). The optional argument map01 when not None, specifies
which letter the digit 1 should be mapped to (when map01 is not None, the
digit 0 is always mapped to the letter O). For security purposes the default
is None, so that 0 and 1 are not allowed in the input.

The decoded string is returned. A TypeError is raised if s were
incorrectly padded or if there are non-alphabet characters present in the
string.
**b16encode**(*s*)
Encode a string using Base16.

`s` is the string to encode. The encoded string is returned.

**b16decode**(*s*[,*casefold]*)
Decode a Base16 encoded string.

`s` is the string to decode. Optional *casefold* is a flag specifying whether a lowercase alphabet is acceptable as input. For security purposes, the default is *False*.

The decoded string is returned. A *TypeError* is raised if `s` were incorrectly padded or if there are non-alphabet characters present in the string.

The legacy interface:

**decode**(*input*, *output*)
Decode the contents of the *input* file and write the resulting binary data to the *output* file. *input* and *output* must either be file objects or objects that mimic the file object interface. *input* will be read until `input.read()` returns an empty string.

**decodestring**(*s*)
Decode the string `s`, which must contain one or more lines of base64 encoded data, and return a string containing the resulting binary data.

**encode**(*input*, *output*)
Encode the contents of the *input* file and write the resulting base64 encoded data to the *output* file. *input* and *output* must either be file objects or objects that mimic the file object interface. *input* will be read until `input.read()` returns an empty string. `encode()` returns the encoded data plus a trailing newline character (`'
'`).

**encodestring**(*s*)
Encode the string `s`, which can contain arbitrary binary data, and return a string containing one or more lines of base64-encoded data.
encodestring() returns a string containing one or more lines of base64-encoded data always including an extra trailing newline ("\n").

Section 5.2, "Base64 Content-Transfer-Encoding," provides the definition of the base64 encoding.
12.13 binascii -- Convert between binary and ASCII

The binascii module contains a number of methods to convert between binary and various ASCII-encoded binary representations. Normally, you will not use these functions directly but use wrapper modules like uu or binhex instead, this module solely exists because bit-manipulation of large amounts of data is slow in Python.

The binascii module defines the following functions:

**a2b_uu**( string)
Convert a single line of uuencoded data back to binary and return the binary data. Lines normally contain 45 (binary) bytes, except for the last line. Line data may be followed by whitespace.

**b2a_uu**( data)
Convert binary data to a line of ASCII characters, the return value is the converted line, including a newline char. The length of data should be at most 45.

**a2b_base64**( string)
Convert a block of base64 data back to binary and return the binary data. More than one line may be passed at a time.

**b2a_base64**( data)
Convert binary data to a line of ASCII characters in base64 coding. The return value is the converted line, including a newline char. The length of data should be at most 57 to adhere to the base64 standard.

**a2b_qp**( string[, header])
Convert a block of quoted-printable data back to binary and return the binary data. More than one line may be passed at a time. If the optional argument header is present and true, underscores will be decoded as spaces.
b2a_qp( data[, quotetabs, istext, header])
Convert binary data to a line(s) of ASCII characters in quoted-printable encoding. The return value is the converted line(s). If the optional argument quotetabs is present and true, all tabs and spaces will be encoded. If the optional argument istext is present and true, newlines are not encoded but trailing whitespace will be encoded. If the optional argument header is present and true, spaces will be encoded as underscores per RFC1522. If the optional argument header is present and false, newline characters will be encoded as well; otherwise linefeed conversion might corrupt the binary data stream.

a2b_hqx( string)
Convert binhex4 formatted ASCII data to binary, without doing RLE-decompression. The string should contain a complete number of binary bytes, or (in case of the last portion of the binhex4 data) have the remaining bits zero.

rledecode_hqx( data)
Perform RLE-decompression on the data, as per the binhex4 standard. The algorithm uses 0x90 after a byte as a repeat indicator, followed by a count. A count of 0 specifies a byte value of 0x90. The routine returns the decompressed data, unless data input data ends in an orphaned repeat indicator, in which case the Incomplete exception is raised.

rlecode_hqx( data)
Perform binhex4 style RLE-compression on data and return the result.

b2a_hqx( data)
Perform hexbin4 binary-to-ASCII translation and return the resulting string. The argument should already be RLE-coded, and have a length divisible by 3 (except possibly the last fragment).

crc_hqx( data, crc)
Compute the binhex4 crc value of data, starting with an initial crc and returning the result.

crc32( data[, crc])
Compute CRC-32, the 32-bit checksum of data, starting with an initial crc. This is consistent with the ZIP file checksum. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm. Use as follows:

```python
print binascii.crc32("hello world")
# Or, in two pieces:
crc = binascii.crc32("hello")
crc = binascii.crc32(" world", crc)
print crc
```

**b2a_hex** *(data)*

**hexlify** *(data)*

Return the hexadecimal representation of the binary *data*. Every byte of *data* is converted into the corresponding 2-digit hex representation. The resulting string is therefore twice as long as the length of *data*.

**a2b_hex** *(hexstr)*

**unhexlify** *(hexstr)*

Return the binary data represented by the hexadecimal string *hexstr*. This function is the inverse of *b2a_hex*(). *hexstr* must contain an even number of hexadecimal digits (which can be upper or lower case), otherwise a *TypeError* is raised.

**exception Error**

Exception raised on errors. These are usually programming errors.

**exception Incomplete**

Exception raised on incomplete data. These are usually not programming errors, but may be handled by reading a little more data and trying again.

Support for UU encoding used on UNIX.

Module **quopri**:  
Support for quoted-printable encoding used in MIME email messages.
12.14 binhex -- Encode and decode binhex4 files

This module encodes and decodes files in binhex4 format, a format allowing representation of Macintosh files in ASCII. On the Macintosh, both forks of a file and the finder information are encoded (or decoded), on other platforms only the data fork is handled.

The binhex module defines the following functions:

**binhex**( input, output)

Convert a binary file with filename input to binhex file output. The output parameter can either be a filename or a file-like object (any object supporting a write() and close() method).

**hexbin**( input[, output])

Decode a binhex file input. input may be a filename or a file-like object supporting read() and close() methods. The resulting file is written to a file named output, unless the argument is omitted in which case the output filename is read from the binhex file.

The following exception is also defined:

**exception Error**

Exception raised when something can't be encoded using the binhex format (for example, a filename is too long to fit in the filename field), or when input is not properly encoded binhex data.

---

**See Also:**

Module [binascii](#)

Support module containing ASCII-to-binary and binary-to-ASCII conversions.
Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.14.1 Notes

There is an alternative, more powerful interface to the coder and decoder, see the source for details.

If you code or decode textfiles on non-Macintosh platforms they will still use the Macintosh newline convention (carriage-return as end of line).

As of this writing, \texttt{hexbin()} appears to not work in all cases.
12.15 quopri -- Encode and decode MIME quoted-printable data

This module performs quoted-printable transport encoding and decoding, as defined in RFC 1521: "MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies". The quoted-printable encoding is designed for data where there are relatively few nonprintable characters; the base64 encoding scheme available via the base64 module is more compact if there are many such characters, as when sending a graphics file.

```
decode( input, output[,header])
```

Decode the contents of the input file and write the resulting decoded binary data to the output file. input and output must either be file objects or objects that mimic the file object interface. input will be read until input.readline() returns an empty string. If the optional argument header is present and true, underscore will be decoded as space. This is used to decode ``Q"-encoded headers as described in RFC 1522: "MIME (Multipurpose Internet Mail Extensions) Part Two: Message Header Extensions for Non-ASCII Text".

```
encode( input, output, quotetabs)
```

Encode the contents of the input file and write the resulting quoted-printable data to the output file. input and output must either be file objects or objects that mimic the file object interface. input will be read until input.readline() returns an empty string. quotetabs is a flag which controls whether to encode embedded spaces and tabs; when true it encodes such embedded whitespace, and when false it leaves them unencoded. Note that spaces and tabs appearing at the end of lines are always encoded, as per RFC 1521.

```
decodestring( s[,header])
```

Like decode(), except that it accepts a source string and returns the corresponding decoded string.
encodestring( s[, quotetabs])

Like encode(), except that it accepts a source string and returns the corresponding encoded string. quotetabs is optional (defaulting to 0), and is passed straight through to encode().

Module mimify:
    General utilities for processing of MIME messages.

Module base64:
    Encode and decode MIME base64 data.
12.16 uu -- Encode and decode uuencode files

This module encodes and decodes files in uuencode format, allowing arbitrary binary data to be transferred over ASCII-only connections. Wherever a file argument is expected, the methods accept a file-like object. For backwards compatibility, a string containing a pathname is also accepted, and the corresponding file will be opened for reading and writing; the pathname '-' is understood to mean the standard input or output. However, this interface is deprecated; it's better for the caller to open the file itself, and be sure that, when required, the mode is 'rb' or 'wb' on Windows.

This code was contributed by Lance Ellinghouse, and modified by Jack Jansen.

The uu module defines the following functions:

**encode**( in_file, out_file[, name[, mode]])

UUencode file in_file into file out_file. The uuencoded file will have the header specifying name and mode as the defaults for the results of decoding the file. The default defaults are taken from in_file, or '-' and 0666 respectively.

**decode**( in_file[, out_file[, mode[, quiet]]])

This call decodes uuencoded file in_file placing the result on file out_file. If out_file is a pathname, mode is used to set the permission bits if the file must be created. Defaults for out_file and mode are taken from the uuencode header. However, if the file specified in the header already exists, a uu.Error is raised.

decode() may print a warning to standard error if the input was produced by an incorrect uuencoder and Python could recover from that error. Setting quiet to a true value silences this warning.

**exception Error()**

Subclass of Exception, this can be raised by uu.decode() under
various situations, such as described above, but also including a badly formatted header, or truncated input file.

Module **binascii**: Support module containing ASCII-to-binary and binary-to-ASCII conversions.
12.17 xdrlib -- Encode and decode
XDR data

The xdrlib module supports the External Data Representation Standard as
described in RFC 1014, written by Sun Microsystems, Inc. June 1987. It
supports most of the data types described in the RFC.

The xdrlib module defines two classes, one for packing variables into XDR
representation, and another for unpacking from XDR representation. There are
also two exception classes.

class Packer()
Packer is the class for packing data into XDR representation. The
Packer class is instantiated with no arguments.

class Unpacker( data)
Unpacker is the complementary class which unpacks XDR data values
from a string buffer. The input buffer is given as data.

See Also:

RFC 1014, XDR: External Data Representation Standard
This RFC defined the encoding of data which was XDR at the time
this module was originally written. It has apparently been obsoleted by
RFC 1832.

RFC 1832, XDR: External Data Representation Standard
Newer RFC that provides a revised definition of XDR.

Subsections
- 12.17.1 Packer Objects
- 12.17.2 Unpacker Objects
• **12.17.3 Exceptions**

---

Release 2.4.4c1, documentation updated on 11 October 2006.  
See [About this document...](#) for information on suggesting changes.
12.17.1 Packer Objects

Packer instances have the following methods:

**get_buffer()**
Returns the current pack buffer as a string.

**reset()**
Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate `pack_type()` method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: `pack_uint()`, `pack_int()`, `pack_enum()`, `pack_bool()`, `pack_uhyper()`, and `pack_hyper()`.

**pack_float(value)**
Packs the single-precision floating point number `value`.

**pack_double(value)**
Packs the double-precision floating point number `value`.

The following methods support packing strings, bytes, and opaque data:

**pack_fstring(n, s)**
Packs a fixed length string, `s`. `n` is the length of the string but it is *not* packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.

**pack_fopaque(n, data)**
Packs a fixed length opaque data stream, similarly to `pack_fstring()`.

**pack_string(s)**
Packs a variable length string, `s`. The length of the string is first packed as an unsigned integer, then the string data is packed with `pack_fstring()`.
**pack_opaque**(*data*)

Packs a variable length opaque data string, similarly to **pack_string()**.

**pack_bytes**(*bytes*)

Packs a variable length byte stream, similarly to **pack_string()**.

The following methods support packing arrays and lists:

**pack_list**(*list, pack_item*)

Packs a *list* of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. **pack_item** is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```python
import xdrlib
p = xdrlib.Packer()
p.pack_list([1, 2, 3], p.pack_int)
```

**pack_farray**(*n, array, pack_item*)

Packs a fixed length list (*array*) of homogeneous items. *n* is the length of the list; it is *not* packed into the buffer, but a **ValueError** exception is raised if `len(array)` is not equal to *n*. As above, **pack_item** is the function used to pack each element.

**pack_array**(*list, pack_item*)

Packs a variable length *list* of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in **pack_farray()** above.
12.17.2 Unpacker Objects

The Unpacker class offers the following methods:

**reset**(data)
 Resets the string buffer with the given data.

**get_position()**
 Returns the current unpack position in the data buffer.

**set_position**(position)
 Sets the data buffer unpack position to position. You should be careful about using get_position() and set_position().

**get_buffer()**
 Returns the current unpack data buffer as a string.

**done()**
 Indicates unpack completion. Raises an Error exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a Packer, can be unpacked with an Unpacker. Unpacking methods are of the form unpack_type(), and take no arguments. They return the unpacked object.

**unpack_float()**
 Unpacks a single-precision floating point number.

**unpack_double()**
 Unpacks a double-precision floating point number, similarly to unpack_float().

In addition, the following methods unpack strings, bytes, and opaque data:

**unpack_fstring**(n)
 Unpacks and returns a fixed length string. n is the number of characters
expected. Padding with null bytes to guaranteed 4 byte alignment is
assumed.

**unpack_fopaque(n)**

Unpacks and returns a fixed length opaque data stream, similarly to
`unpack_fstring()`.

**unpack_string()**

Unpacks and returns a variable length string. The length of the string is first
unpacked as an unsigned integer, then the string data is unpacked with
`unpack_fstring()`.

**unpack_opaque()**

Unpacks and returns a variable length opaque data string, similarly to
`unpack_string()`.

**unpack_bytes()**

Unpacks and returns a variable length byte stream, similarly to
`unpack_string()`.

The following methods support unpacking arrays and lists:

**unpack_list(unpack_item)**

Unpacks and returns a list of homogeneous items. The list is unpacked one
element at a time by first unpacking an unsigned integer flag. If the flag is
1, then the item is unpacked and appended to the list. A flag of 0 indicates
the end of the list. `unpack_item` is the function that is called to unpack the
items.

**unpack_farray(n, unpack_item)**

Unpacks and returns (as a list) a fixed length array of homogeneous items. `n`
is number of list elements to expect in the buffer. As above, `unpack_item` is
the function used to unpack each element.

**unpack_array(unpack_item)**

Unpacks and returns a variable length `list` of homogeneous items. First, the
length of the list is unpacked as an unsigned integer, then each element is
unpacked as in `unpack_farray()` above.
12.17.3 Exceptions

Exceptions in this module are coded as class instances:

**exception Error**

The base exception class. **Error** has a single public data member **msg** containing the description of the error.

**exception ConversionError**

Class derived from **Error**. Contains no additional instance variables.

Here is an example of how you would catch one of these exceptions:

```python
import xdrlib
p = xdrlib.Packer()
try:
    p.pack_double(8.01)
except xdrlib.ConversionError, instance:
    print 'packing the double failed:', instance.msg
```

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
12.18 netrc -- netrc file processing

New in version 1.5.2.

The netrc class parses and encapsulates the netrc file format used by the UNIX ftp program and other FTP clients.

```python
class netrc([file])
```

A netrc instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file .netrc in the user's home directory will be read. Parse errors will raise NetrcParseError with diagnostic information including the file name, line number, and terminating token.

```python
exception NetrcParseError
```

Exception raised by the netrc class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: `msg` is a textual explanation of the error, `filename` is the name of the source file, and `lineno` gives the line number on which the error was found.

Subsections

- 12.18.1 netrc Objects

---

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
12.18.1 netrc Objects

A netrc instance has the following methods:

-authenticators( host)  
  Return a 3-tuple (login, account, password) of authenticators for host. If the netrc file did not contain an entry for the given host, return the tuple associated with the `default' entry. If neither matching host nor default entry is available, return None.

__repr__()  
  Dump the class data as a string in the format of a netrc file. (This discards comments and may reorder the entries.)

Instances of netrc have public instance variables:

hosts  
  Dictionary mapping host names to (login, account, password) tuples. The `default' entry, if any, is represented as a pseudo-host by that name.

macros  
  Dictionary mapping macro names to string lists.

Note: Passwords are limited to a subset of the ASCII character set. Versions of this module prior to 2.3 were extremely limited. Starting with 2.3, all ASCII punctuation is allowed in passwords. However, note that whitespace and non-printable characters are not allowed in passwords. This is a limitation of the way the .netrc file is parsed and may be removed in the future.
12.19 robotparser -- Parser for robots.txt

This module provides a single class, RobotFileParser, which answers questions about whether or not a particular user agent can fetch a URL on the Web site that published the robots.txt file. For more details on the structure of robots.txt files, see http://www.robotstxt.org/wc/norobots.html.

class RobotFileParser()

This class provides a set of methods to read, parse and answer questions about a single robots.txt file.

set_url( url)
Sets the URL referring to a robots.txt file.

read()
Reads the robots.txt URL and feeds it to the parser.

parse( lines)
Parses the lines argument.

can_fetch( useragent, url)
Returns True if the useragent is allowed to fetch the url according to the rules contained in the parsed robots.txt file.

mtime()
Returns the time the robots.txt file was last fetched. This is useful for long-running web spiders that need to check for new robots.txt files periodically.

modified()
Sets the time the robots.txt file was last fetched to the current time.
The following example demonstrates basic use of the RobotFileParser class.

```python
>>> import robotparser
>>> rp = robotparser.RobotFileParser()
>>> rp.set_url("http://www.musi-cal.com/robots.txt")
>>> rp.read()
>>> rp.can_fetch("*", "http://www.musi-cal.com/cgi-bin/search?city=San+Francisco")
False
>>> rp.can_fetch("*", "http://www.musi-cal.com/")
True
```
12.20 csv -- CSV File Reading and Writing

New in version 2.3.

The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. There is no "CSV standard", so the format is operationally defined by the many applications which read and write it. The lack of a standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The csv module implements classes to read and write tabular data in CSV format. It allows programmers to say, "write this data in the format preferred by Excel," or "read data from this file which was generated by Excel," without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The csv module's reader and writer objects read and write sequences. Programmers can also read and write data in dictionary form using the DictReader and DictWriter classes.

**Note:** This version of the csv module doesn't support Unicode input. Also, there are currently some issues regarding ASCII NUL characters. Accordingly, all input should generally be printable ASCII to be safe. These restrictions will be removed in the future.

See About this document... for information on suggesting changes.
12.20.1 Module Contents

The csv module defines the following functions:

**reader** *(csvfile[, dialect='excel'][, fmtparam])*

Return a reader object which will iterate over lines in the given csvfile. csvfile can be any object which supports the iterator protocol and returns a string each time its `next` method is called. If csvfile is a file object, it must be opened with the 'b' flag on platforms where that makes a difference. An optional dialect parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the Dialect class or one of the strings returned by the list_dialects function. The other optional fmtparam keyword arguments can be given to override individual formatting parameters in the current dialect. For more information about the dialect and formatting parameters, see section 12.20.2, "Dialects and Formatting Parameters" for details of these parameters.

All data read are returned as strings. No automatic data type conversion is performed.

**writer** *(csvfile[, dialect='excel'][, fmtparam])*

Return a writer object responsible for converting the user's data into delimited strings on the given file-like object. csvfile can be any object with a write method. If csvfile is a file object, it must be opened with the 'b' flag on platforms where that makes a difference. An optional dialect parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the Dialect class or one of the strings returned by the list_dialects function. The other optional fmtparam keyword arguments can be given to override individual formatting parameters in the current dialect. For more information about the dialect and formatting parameters, see section 12.20.2, "Dialects and Formatting Parameters" for details of these parameters. To make it as easy as possible to interface with modules which implement the DB API, the value None is written as the empty string. While this isn't a reversible transformation, it makes it easier to dump SQL
NULL data values to CSV files without preprocessing the data returned from a `cursor.fetch*()` call. All other non-string data are stringified with `str()` before being written.

`register_dialect(name, dialect)`

Associate `dialect` with `name`. `dialect` must be a subclass of `csv.Dialect`. `name` must be a string or Unicode object.

`unregister_dialect(name)`

Delete the dialect associated with `name` from the dialect registry. An `Error` is raised if `name` is not a registered dialect name.

`get_dialect(name)`

Return the dialect associated with `name`. An `Error` is raised if `name` is not a registered dialect name.

`list_dialects()`

Return the names of all registered dialects.

The `csv` module defines the following classes:

```python
csvfile[, fieldnames=\texttt{None},[, restkey=\texttt{None}[[, restval=\texttt{None}[[, dialect=('\texttt{excel}'[, *args, **kwds])]])]]]
```

Create an object which operates like a regular reader but maps the information read into a dict whose keys are given by the optional `fieldnames` parameter. If the `fieldnames` parameter is omitted, the values in the first row of the `csvfile` will be used as the fieldnames. If the row read has fewer fields than the fieldnames sequence, the value of `restval` will be used as the default value. If the row read has more fields than the fieldnames sequence, the remaining data is added as a sequence keyed by the value of `restkey`. If the row read has fewer fields than the fieldnames sequence, the remaining keys take the value of the optional `restval` parameter. Any other optional or keyword arguments are passed to the underlying `reader` instance.
class DictWriter(
    extrasaction='raise',
    dialect='excel',
    *args,
    **kwds)

Create an object which operates like a regular writer but maps dictionaries onto output rows. The fieldnames parameter identifies the order in which values in the dictionary passed to the writerow() method are written to the csvfile. The optional restval parameter specifies the value to be written if the dictionary is missing a key in fieldnames. If the dictionary passed to the writerow() method contains a key not found in fieldnames, the optional extrasaction parameter indicates what action to take. If it is set to 'raise' a ValueError is raised. If it is set to 'ignore', extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying writer instance.

Note that unlike the DictReader class, the fieldnames parameter of the DictWriter is not optional. Since Python's dict objects are not ordered, there is not enough information available to deduce the order in which the row should be written to the csvfile.

class Dialect
The Dialect class is a container class relied on primarily for its attributes, which are used to define the parameters for a specific reader or writer instance.

class Sniffer()

The Sniffer class is used to deduce the format of a CSV file.

The Sniffer class provides two methods:

sniff(sample[,delimiters=None])

Analyze the given sample and return a Dialect subclass reflecting the parameters found. If the optional delimiters parameter is given, it is interpreted as a string containing possible valid delimiter characters.

has_header(sample)

Analyze the sample text (presumed to be in CSV format) and return True if the first row appears to be a series of column headers.
The csv module defines the following constants:

**QUOTE_ALL**
Instructs writer objects to quote all fields.

**QUOTE_MINIMAL**
Instructs writer objects to only quote those fields which contain the current delimiter or begin with the current quotechar.

**QUOTE_NONNUMERIC**
Instructs writer objects to quote all non-numeric fields.

**QUOTE_NONE**
Instructs writer objects to never quote fields. When the current delimiter occurs in output data it is preceded by the current escapechar character. When QUOTE_NONE is in effect, it is an error not to have a single-character escapechar defined, even if no data to be written contains the delimiter character.

The csv module defines the following exception:

**exception Error**
Raised by any of the functions when an error is detected.
12.20.2 Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the Dialect class having a set of specific methods and a single validate() method. When creating reader or writer objects, the programmer can specify a string or a subclass of the Dialect class as the dialect parameter. In addition to, or instead of, the dialect parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the Dialect class.

Dialects support the following attributes:

**delimiter**
A one-character string used to separate fields. It defaults to ' , '.

**doublequote**
Controls how instances of quotechar appearing inside a field should be themselves be quoted. When True, the character is doubled. When False, the escapechar must be a one-character string which is used as a prefix to the quotechar. It defaults to True.

**escapechar**
A one-character string used to escape the delimiter if quoting is set to QUOTE_NONE. It defaults to None.

**lineterminator**
The string used to terminate lines in the CSV file. It defaults to ' \r\n '.

**quotechar**
A one-character string used to quote elements containing the delimiter or which start with the quotechar. It defaults to ' " '.

**quoting**
Controls when quotes should be generated by the writer. It can take on any of the QUOTE_* constants (see section 12.20.1) and defaults to QUOTE_MINIMAL.
skipinitialspace

When True, whitespace immediately following the delimiter is ignored. The default is False.
12.20.3 Reader Objects

Reader objects (DictReader instances and objects returned by the reader() function) have the following public methods:

next()

Return the next row of the reader's iterable object as a list, parsed according to the current dialect.
12.20.4 Writer Objects

Writer objects (DictWriter instances and objects returned by the writer() function) have the following public methods. A row must be a sequence of strings or numbers for Writer objects and a dictionary mapping fieldnames to strings or numbers (by passing them through str() first) for DictWriter objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

writerow(row)

Write the row parameter to the writer's file object, formatted according to the current dialect.

writerows(rows)

Write all the rows parameters (a list of row objects as described above) to the writer's file object, formatted according to the current dialect.
12.20.5 Examples

The "Hello, world" of csv reading is

```python
import csv
reader = csv.reader(open("some.csv", "rb"))
for row in reader:
    print row
```

To print just the first and last columns of each row try

```python
import csv
reader = csv.reader(open("some.csv", "rb"))
for row in reader:
    print row[0], row[-1]
```

The corresponding simplest possible writing example is

```python
import csv
writer = csv.writer(open("some.csv", "wb"))
for row in someiterable:
    writer.writerow(row)
```
13. Structured Markup Processing Tools

Python supports a variety of modules to work with various forms of structured data markup. This includes modules to work with the Standard Generalized Markup Language (SGML) and the Hypertext Markup Language (HTML), and several interfaces for working with the Extensible Markup Language (XML).

It is important to note that modules in the `xml` package require that there be at least one SAX-compliant XML parser available. Starting with Python 2.3, the Expat parser is included with Python, so the `xml.parsers.expat` module will always be available. You may still want to be aware of the PyXML add-on package; that package provides an extended set of XML libraries for Python.

The documentation for the `xml.dom` and `xml.sax` packages are the definition of the Python bindings for the DOM and SAX interfaces.

- **HTMLParser**: A simple parser that can handle HTML and XHTML.
- **sgmlib**: Only as much of an SGML parser as needed to parse HTML.
- **htmllib**: A parser for HTML documents.
- **htmlentitydefs**: Definitions of HTML general entities.
- **xml.parsers.expat**: An interface to the Expat non-validating XML parser.
- **xml.dom**: Document Object Model API for Python.
- **xml.dom.minidom**: Lightweight Document Object Model (DOM) implementation.
- **xml.dom.pulldom**: Support for building partial DOM trees from SAX events.
- **xml.sax**: Package containing SAX2 base classes and convenience functions.
- **xml.sax.handler**: Base classes for SAX event handlers.

Convenience functions and classes for use with...
xml.sax.saxutils  
SAX.

xml.sax.xmlreader  
Interface which SAX-compliant XML parsers must implement.

xmlLib  
A parser for XML documents.

13.1 HTMLParser -- Simple HTML and XHTML parser

New in version 2.2.

This module defines a class HTMLParser which serves as the basis for parsing text files formatted in HTML (HyperText Mark-up Language) and XHTML. Unlike the parser in htmllib, this parser is not based on the SGML parser in sgmllib.

class HTMLParser()

The HTMLParser class is instantiated without arguments.

An HTMLParser instance is fed HTML data and calls handler functions when tags begin and end. The HTMLParser class is meant to be overridden by the user to provide a desired behavior.

Unlike the parser in htmllib, this parser does not check that end tags match start tags or call the end-tag handler for elements which are closed implicitly by closing an outer element.

An exception is defined as well:

eexception HTMLParseError

Exception raised by the HTMLParser class when it encounters an error while parsing. This exception provides three attributes: msg is a brief message explaining the error, lineno is the number of the line on which the broken construct was detected, and offset is the number of characters into the line at which the construct starts.

HTMLParser instances have the following methods:

reset()

Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.
**feed**(*data*)

Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or **close**() is called.

**close**()

Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call the **HTMLParser** base class method **close**().

**getpos**()

Return current line number and offset.

**get_starttag_text**()

Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML ``as deployed'' or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

**handle_starttag**(*tag, attrs*)

This method is called to handle the start of a tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

The *tag* argument is the name of the tag converted to lower case. The *attrs* argument is a list of (*name*, *value*) pairs containing the attributes found inside the tag's <> brackets. The *name* will be translated to lower case and double quotes and backslashes in the *value* have been interpreted. For instance, for the tag `<A HREF="http://www.cwi.nl/">`, this method would be called as "**handle_starttag**('a', [('href', 'http://www.cwi.nl/')])."

**handle_startendtag**(*tag, attrs*)

Similar to **handle_starttag**(), but called when the parser encounters an XHTML-style empty tag (<a .../>). This method may be overridden by subclasses which require this particular lexical information; the default implementation simple calls **handle_starttag**() and
handle_endtag().

**handle_endtag**( *tag*)
This method is called to handle the end tag of an element. It is intended to be overridden by a derived class; the base class implementation does nothing. The *tag* argument is the name of the tag converted to lower case.

**handle_data**( *data*)
This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

**handle_charref**( *name*)
This method is called to process a character reference of the form "&#ref;". It is intended to be overridden by a derived class; the base class implementation does nothing.

**handle_entityref**( *name*)
This method is called to process a general entity reference of the form "&name;" where *name* is an general entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

**handle_comment**( *data*)
This method is called when a comment is encountered. The *comment* argument is a string containing the text between the "--" and "--" delimiters, but not the delimiters themselves. For example, the comment "<!--text-->" will cause this method to be called with the argument 'text'. It is intended to be overridden by a derived class; the base class implementation does nothing.

**handle_decl**( *decl*)
Method called when an SGML declaration is read by the parser. The *decl* parameter will be the entire contents of the declaration inside the <!...> markup. It is intended to be overridden by a derived class; the base class implementation does nothing.

**handle_pi**( *data*)
Method called when a processing instruction is encountered. The *data*
parameter will contain the entire processing instruction. For example, for
the processing instruction `<?proc color='red'>`, this method would
be called as `handle_pi("proc color='red'")`. It is intended to be
overridden by a derived class; the base class implementation does nothing.

**Note:** The `HTMLParser` class uses the SGML syntactic rules for
processing instructions. An XHTML processing instruction using the
trailing "?" will cause the "?" to be included in `data`.

toc m i

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.
13.1.1 Example HTML Parser Application

As a basic example, below is a very basic HTML parser that uses the HTMLParser class to print out tags as they are encountered:

```python
from HTMLParser import HTMLParser

class MyHTMLParser(HTMLParser):
    def handle_starttag(self, tag, attrs):
        print "Encountered the beginning of a %s tag" % tag

    def handle_endtag(self, tag):
        print "Encountered the end of a %s tag" % tag
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See About this document... for information on suggesting changes.
13.2 sgmllib -- Simple SGML parser

This module defines a class **SGMLParser** which serves as the basis for parsing text files formatted in SGML (Standard Generalized Mark-up Language). In fact, it does not provide a full SGML parser -- it only parses SGML insofar as it is used by HTML, and the module only exists as a base for the [httplib](https://docs.python.org/3/library/httplib.html) module. Another HTML parser which supports XHTML and offers a somewhat different interface is available in the [HTMLParser](https://docs.python.org/3/library/html.parser.html) module.

**class SGMLParser()**

The **SGMLParser** class is instantiated without arguments. The parser is hardcoded to recognize the following constructs:

- Opening and closing tags of the form "<tag attr="value" ...>" and "</tag>", respectively.

- Numeric character references of the form "&#name;".

- Entity references of the form "&name;".

- SGML comments of the form "<!-- text -->". Note that spaces, tabs, and newlines are allowed between the trailing "-->" and the immediately preceding "--".

A single exception is defined as well:

**exception SGMLParseError**

Exception raised by the **SGMLParser** class when it encounters an error while parsing. New in version 2.1.

**SGMLParser** instances have the following methods:

**reset()**

Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.
setnomoretags()
Stop processing tags. Treat all following input as literal input (CDATA).
(This is only provided so the HTML tag \texttt{<PLAINTEXT> can be implemented.)

setliteral()
Enter literal mode (CDATA mode).

feed( data)
Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or close() is called.

close()
Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call close().

get_starttag_text()
Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML ``as deployed'' or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

handle_starttag( tag, method, attributes)
This method is called to handle start tags for which either a start_tag() or do_tag() method has been defined. The tag argument is the name of the tag converted to lower case, and the method argument is the bound method which should be used to support semantic interpretation of the start tag. The attributes argument is a list of (name, value) pairs containing the attributes found inside the tag's <> brackets. The name has been translated to lower case and double quotes and backslashes in the value have been interpreted. For instance, for the tag \texttt{<A HREF="http://www.cwi.nl/">}, this method would be called as
\texttt{"unknown_starttag('a', [(['href', 'http://www.cwi.nl/'])])"}. The base implementation simply calls
method with attributes as the only argument.

**handle_endtag***(tag, method)***
This method is called to handle endtags for which an end_tag() method has been defined. The tag argument is the name of the tag converted to lower case, and the method argument is the bound method which should be used to support semantic interpretation of the end tag. If no end_tag() method is defined for the closing element, this handler is not called. The base implementation simply calls method.

**handle_data***(data)***
This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

**handle_charref***(ref)***
This method is called to process a character reference of the form 
"&#ref;". In the base implementation, ref must be a decimal number in the range 0-255. It translates the character to ASCII and calls the method handle_data() with the character as argument. If ref is invalid or out of range, the method unknown_charref(ref) is called to handle the error. A subclass must override this method to provide support for named character entities.

**handle_entityref***(ref)***
This method is called to process a general entity reference of the form "&ref;" where ref is an general entity reference. It looks for ref in the instance (or class) variable entitydefs which should be a mapping from entity names to corresponding translations. If a translation is found, it calls the method handle_data() with the translation; otherwise, it calls the method unknown_entityref(ref). The default entitydefs defines translations for &amp;, &apos, &gt;, &lt;, and &quot;.

**handle_comment***(comment)***
This method is called when a comment is encountered. The comment argument is a string containing the text between the "<!- -" and "--->" delimiters, but not the delimiters themselves. For example, the comment "<!- -text--->" will cause this method to be called with the argument
'text'. The default method does nothing.

**handle_decl**(data)
Method called when an SGML declaration is read by the parser. In practice, the DOCTYPE declaration is the only thing observed in HTML, but the parser does not discriminate among different (or broken) declarations. Internal subsets in a DOCTYPE declaration are not supported. The data parameter will be the entire contents of the declaration inside the < ! ... > markup. The default implementation does nothing.

**report_unbalanced**(tag)
This method is called when an end tag is found which does not correspond to any open element.

**unknown_starttag**(tag, attributes)
This method is called to process an unknown start tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

**unknown_endtag**(tag)
This method is called to process an unknown end tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

**unknown_charref**(ref)
This method is called to process unresolvable numeric character references. Refer to handle_charref() to determine what is handled by default. It is intended to be overridden by a derived class; the base class implementation does nothing.

**unknown_entityref**(ref)
This method is called to process an unknown entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

Apart from overriding or extending the methods listed above, derived classes may also define methods of the following form to define processing of specific tags. Tag names in the input stream are case independent; the tag occurring in method names must be in lower case:
**start_tag** *(attributes)*

This method is called to process an opening tag *tag*. It has preference over **do_tag**(). The *attributes* argument has the same meaning as described for **handle_starttag()** above.

**do_tag** *(attributes)*

This method is called to process an opening tag *tag* for which no **start_tag** method is defined. The *attributes* argument has the same meaning as described for **handle_starttag()** above.

**end_tag**

This method is called to process a closing tag *tag*.

Note that the parser maintains a stack of open elements for which no end tag has been found yet. Only tags processed by **start_tag**() are pushed on this stack. Definition of an **end_tag()** method is optional for these tags. For tags processed by **do_tag**() or by **unknown_tag()**, no **end_tag()** method must be defined; if defined, it will not be used. If both **start_tag()** and **do_tag**() methods exist for a tag, the **start_tag()** method takes precedence.
13.3 htmllib -- A parser for HTML documents

This module defines a class which can serve as a base for parsing text files formatted in the HyperText Mark-up Language (HTML). The class is not directly concerned with I/O -- it must be provided with input in string form via a method, and makes calls to methods of a `formatter` object in order to produce output. The `HTMLParser` class is designed to be used as a base class for other classes in order to add functionality, and allows most of its methods to be extended or overridden. In turn, this class is derived from and extends the `SGMLParser` class defined in module `sgmllib`. The `HTMLParser` implementation supports the HTML 2.0 language as described in RFC 1866. Two implementations of formatter objects are provided in the `formatter` module; refer to the documentation for that module for information on the formatter interface.

The following is a summary of the interface defined by `sgmllib.SGMLParser`:

- The interface to feed data to an instance is through the `feed()` method, which takes a string argument. This can be called with as little or as much text at a time as desired; "p.feed(a); p.feed(b)" has the same effect as "p.feed(a+b)". When the data contains complete HTML markup constructs, these are processed immediately; incomplete constructs are saved in a buffer. To force processing of all unprocessed data, call the `close()` method.

  For example, to parse the entire contents of a file, use:

  ```python
  parser.feed(open('myfile.html').read())
  parser.close()
  ```

- The interface to define semantics for HTML tags is very simple: derive a class and define methods called `start_tag()`, `end_tag()`, or `do_tag()`. The parser will call these at appropriate moments: `start_tag` or `do_tag()` is called when an opening tag of the form `<tag  ... >` is
encountered; \texttt{end\_tag( )} is called when a closing tag of the form \texttt{<tag>} is encountered. If an opening tag requires a corresponding closing tag, like \texttt{<H1> ... </H1>}, the class should define the \texttt{start\_tag( )} method; if a tag requires no closing tag, like \texttt{<P>}, the class should define the \texttt{do\_tag( )} method.

The module defines a parser class and an exception:

\textbf{class HTMLParser( formatter)}

This is the basic HTML parser class. It supports all entity names required by the XHTML 1.0 Recommendation (http://www.w3.org/TR/xhtml1). It also defines handlers for all HTML 2.0 and many HTML 3.0 and 3.2 elements.

\textbf{exception HTMLParseError}

Exception raised by the HTMLParser class when it encounters an error while parsing. New in version 2.4.

\textbf{See Also:}

Module \texttt{formatter}:  
Interface definition for transforming an abstract flow of formatting events into specific output events on writer objects.

Module \texttt{HTMLParser}:  
Alternate HTML parser that offers a slightly lower-level view of the input, but is designed to work with XHTML, and does not implement some of the SGML syntax not used in ``HTML as deployed'' and which isn't legal for XHTML.

Module \texttt{htmlentitydefs}:  
Definition of replacement text for XHTML 1.0 entities.

Module \texttt{sgmllib}:  
Base class for HTMLParser.
13.3.1 HTMLParser Objects

In addition to tag methods, the HTMLParser class provides some additional methods and instance variables for use within tag methods.

**formatter**

This is the formatter instance associated with the parser.

**nofill**

Boolean flag which should be true when whitespace should not be collapsed, or false when it should be. In general, this should only be true when character data is to be treated as "preformatted" text, as within a <PRE> element. The default value is false. This affects the operation of handle_data() and save_end().

**anchor_bgn( href, name, type)**

This method is called at the start of an anchor region. The arguments correspond to the attributes of the <A> tag with the same names. The default implementation maintains a list of hyperlinks (defined by the HREF attribute for <A> tags) within the document. The list of hyperlinks is available as the data attribute anchorlist.

**anchor_end()**

This method is called at the end of an anchor region. The default implementation adds a textual footnote marker using an index into the list of hyperlinks created by anchor_bgn().

**handle_image( source, alt[, ismap[, align[, width[, height]]]])**

This method is called to handle images. The default implementation simply passes the alt value to the handle_data() method.

**save_bgn()**

Begins saving character data in a buffer instead of sending it to the formatter object. Retrieve the stored data via save_end(). Use of the save_bgn() / save_end() pair may not be nested.
save_end()

Ends buffering character data and returns all data saved since the preceding call to `save_bgn()`. If the `nofill` flag is false, whitespace is collapsed to single spaces. A call to this method without a preceding call to `save_bgn()` will raise a `TypeError` exception.
13.4 htmlentitydefs -- Definitions of HTML general entities

This module defines three dictionaries, name2codepoint, codepoint2name, and entitydefs. entitydefs is used by the htmllib module to provide the entitydefs member of the HTMLParser class. The definition provided here contains all the entities defined by XHTML 1.0 that can be handled using simple textual substitution in the Latin-1 character set (ISO-8859-1).

**entitydefs**

A dictionary mapping XHTML 1.0 entity definitions to their replacement text in ISO Latin-1.

**name2codepoint**

A dictionary that maps HTML entity names to the Unicode codepoints. New in version 2.3.

**codepoint2name**

A dictionary that maps Unicode codepoints to HTML entity names. New in version 2.3.
13.5 xml.parsers.expat -- Fast XML parsing using Expat

New in version 2.0.

The `xml.parsers.expat` module is a Python interface to the Expat non-validating XML parser. The module provides a single extension type, `xmlparser`, that represents the current state of an XML parser. After an `xmlparser` object has been created, various attributes of the object can be set to handler functions. When an XML document is then fed to the parser, the handler functions are called for the character data and markup in the XML document.

This module uses the `pyexpat` module to provide access to the Expat parser. Direct use of the `pyexpat` module is deprecated.

This module provides one exception and one type object:

**exception ExpatError**

The exception raised when Expat reports an error. See section 13.5.2, "ExpatError Exceptions," for more information on interpreting Expat errors.

**exception error**

Alias for `ExpatError`.

**XMLParserType**

The type of the return values from the `ParserCreate()` function.

The `xml.parsers.expat` module contains two functions:

**ErrorString**(*errno*)

Returns an explanatory string for a given error number `errno`.

**ParserCreate**([`encoding`, `namespace_separator`])
Creates and returns a new `xmlparser` object. `encoding`, if specified, must be a string naming the encoding used by the XML data. Expat doesn't support as many encodings as Python does, and its repertoire of encodings can't be extended; it supports UTF-8, UTF-16, ISO-8859-1 (Latin1), and ASCII. If `encoding` is given it will override the implicit or explicit encoding of the document.

Expat can optionally do XML namespace processing for you, enabled by providing a value for `namespace_separator`. The value must be a one-character string; a `ValueError` will be raised if the string has an illegal length (None is considered the same as omission). When namespace processing is enabled, element type names and attribute names that belong to a namespace will be expanded. The element name passed to the element handlers `StartElementHandler` and `EndElementHandler` will be the concatenation of the namespace URI, the namespace separator character, and the local part of the name. If the namespace separator is a zero byte (`chr(0)`) then the namespace URI and the local part will be concatenated without any separator.

For example, if `namespace_separator` is set to a space character (" ") and the following document is parsed:

```xml
<?xml version="1.0"?>
<root xmlns:py="http://www.python.org/ns/">
    <py:elem1 />
    <elem2 xmlns="" />
</root>
```

`StartElementHandler` will receive the following strings for each element:

```
http://default-namespace.org/ root
http://www.python.org/ns/ elem1
elem2
```

13.5.1 XMLParser Objects

xmlparser objects have the following methods:

**Parse**(data[, isfinal])

Parses the contents of the string data, calling the appropriate handler functions to process the parsed data. isfinal must be true on the final call to this method. data can be the empty string at any time.

**ParseFile**(file)

Parse XML data reading from the object file. file only needs to provide the read(nbytes) method, returning the empty string when there's no more data.

**SetBase**(base)

Sets the base to be used for resolving relative URIs in system identifiers in declarations. Resolving relative identifiers is left to the application: this value will be passed through as the base argument to the ExternalEntityRefHandler, NotationDeclHandler, and UnparsedEntityDeclHandler functions.

**GetBase**( )

Returns a string containing the base set by a previous call to SetBase(), or None if SetBase() hasn't been called.

**GetInputContext**( )

Returns the input data that generated the current event as a string. The data is in the encoding of the entity which contains the text. When called while an event handler is not active, the return value is None. New in version 2.1.

**ExternalEntityParserCreate**(context[, encoding])

Create a `"child"` parser which can be used to parse an external parsed entity referred to by content parsed by the parent parser. The context parameter should be the string passed to the ExternalEntityRefHandler() handler function, described below. The child parser is created with the
unordered_attributes, returns_unicode and specified_attributes set to the values of this parser.

UseForeignDTD([flag])
Calling this with a true value for flag (the default) will cause Expat to call the ExternalEntityRefHandler with None for all arguments to allow an alternate DTD to be loaded. If the document does not contain a document type declaration, the ExternalEntityRefHandler will still be called, but the StartDoctypeDeclHandler and EndDoctypeDeclHandler will not be called.

Passing a false value for flag will cancel a previous call that passed a true value, but otherwise has no effect.

This method can only be called before the Parse() or ParseFile() methods are called; calling it after either of those have been called causes ExpatError to be raised with the code attribute set to errors.XML_ERROR_CANT_CHANGE_FEATURE_ONCE_PARSING.

New in version 2.3.

xmlparser objects have the following attributes:

buffer_size
The size of the buffer used when buffer_text is true. This value cannot be changed at this time. New in version 2.3.

buffer_text
Setting this to true causes the xmlparser object to buffer textual content returned by Expat to avoid multiple calls to the CharacterDataHandler() callback whenever possible. This can improve performance substantially since Expat normally breaks character data into chunks at every line ending. This attribute is false by default, and may be changed at any time. New in version 2.3.

buffer_used
If buffer_text is enabled, the number of bytes stored in the buffer. These bytes represent UTF-8 encoded text. This attribute has no meaningful interpretation when buffer_text is false. New in version 2.3.
ordered_attributes
   Setting this attribute to a non-zero integer causes the attributes to be
   reported as a list rather than a dictionary. The attributes are presented in the
   order found in the document text. For each attribute, two list entries are
   presented: the attribute name and the attribute value. (Older versions of this
   module also used this format.) By default, this attribute is false; it may be
   changed at any time. New in version 2.1.

returns_unicode
   If this attribute is set to a non-zero integer, the handler functions will be
   passed Unicode strings. If returns_unicode is 0, 8-bit strings
   containing UTF-8 encoded data will be passed to the handlers. Changed in
   version 1.6: Can be changed at any time to affect the result type.

specified_attributes
   If set to a non-zero integer, the parser will report only those attributes which
   were specified in the document instance and not those which were derived
   from attribute declarations. Applications which set this need to be
   especially careful to use what additional information is available from the
   declarations as needed to comply with the standards for the behavior of
   XML processors. By default, this attribute is false; it may be changed at any

The following attributes contain values relating to the most recent error
encountered by an xmlparser object, and will only have correct values once a
call to Parse() or ParseFile() has raised a
xml.parsers.expat.ExpatError exception.

ErrorByteIndex
   Byte index at which an error occurred.

ErrorCode
   Numeric code specifying the problem. This value can be passed to the
   ErrorString() function, or compared to one of the constants defined in
   the errors object.

ErrorColumnNumber
   Column number at which an error occurred.
**ErrorLineNumber**
Line number at which an error occurred.

The following attributes contain values relating to the current parse location in an `xmlparser` object. During a callback reporting a parse event they indicate the location of the first of the sequence of characters that generated the event. When called outside of a callback, the position indicated will be just past the last parse event (regardless of whether there was an associated callback). New in version 2.4.

**CurrentByteIndex**
Current byte index in the parser input.

**CurrentColumnNumber**
Current column number in the parser input.

**CurrentLineNumber**
Current line number in the parser input.

Here is the list of handlers that can be set. To set a handler on an `xmlparser` object `o`, use `o.handlername = func`. `handlername` must be taken from the following list, and `func` must be a callable object accepting the correct number of arguments. The arguments are all strings, unless otherwise stated.

**XmlDeclHandler** (*version, encoding, standalone*)
Called when the XML declaration is parsed. The XML declaration is the (optional) declaration of the applicable version of the XML recommendation, the encoding of the document text, and an optional `standalone` declaration. `version` and `encoding` will be strings of the type dictated by the `returns_unicode` attribute, and `standalone` will be 1 if the document is declared standalone, 0 if it is declared not to be standalone, or -1 if the standalone clause was omitted. This is only available with Expat version 1.95.0 or newer. New in version 2.1.

**StartDoctypeDeclHandler** (*doctypeName, systemId, publicId, has_internal_subset*)
Called when Expat begins parsing the document type declaration (`<!DOCTYPE ...`). The `doctypeName` is provided exactly as presented. The `systemId` and `publicId` parameters give the system and public identifiers
if specified, or None if omitted. has_internal_subset will be true if the
document contains and internal document declaration subset. This requires
Expat version 1.2 or newer.

EndDoctypeDeclHandler()
Called when Expat is done parsing the document type declaration. This
requires Expat version 1.2 or newer.

ElementDeclHandler( name, model)
Called once for each element type declaration. name is the name of the
element type, and model is a representation of the content model.

AttlistDeclHandler( elname, attname, type, default, required)
Called for each declared attribute for an element type. If an attribute list
declaration declares three attributes, this handler is called three times, once
for each attribute. elname is the name of the element to which the
declaration applies and attname is the name of the attribute declared. The
attribute type is a string passed as type; the possible values are 'CDATA',
'ID', 'IDREF', ... default gives the default value for the attribute used
when the attribute is not specified by the document instance, or None if
there is no default value (#IMPLIED values). If the attribute is required to
be given in the document instance, required will be true. This requires
Expat version 1.95.0 or newer.

StartElementHandler( name, attributes)
Called for the start of every element. name is a string containing the
element name, and attributes is a dictionary mapping attribute names to
their values.

EndElementHandler( name)
Called for the end of every element.

ProcessingInstructionHandler( target, data)
Called for every processing instruction.

CharacterDataHandler( data)
Called for character data. This will be called for normal character data,
CDATA marked content, and ignorable whitespace. Applications which must distinguish these cases can use the StartCdataSectionHandler, EndCdataSectionHandler, and ElementDeclHandler callbacks to collect the required information.

**UnparsedEntityDeclHandler**

\((entityName, base, systemId, publicId, notationName)\)

Called for unparsed (NDATA) entity declarations. This is only present for version 1.2 of the Expat library; for more recent versions, use EntityDeclHandler instead. (The underlying function in the Expat library has been declared obsolete.)

**EntityDeclHandler**

\((entityName, is_parameter_entity, value, base, systemId, publicId, notationName)\)

Called for all entity declarations. For parameter and internal entities, value will be a string giving the declared contents of the entity; this will be None for external entities. The notationName parameter will be None for parsed entities, and the name of the notation for unparsed entities. is_parameter_entity will be true if the entity is a parameter entity or false for general entities (most applications only need to be concerned with general entities). This is only available starting with version 1.95.0 of the Expat library. New in version 2.1.

**NotationDeclHandler**

\((notationName, base, systemId, publicId)\)

Called for notation declarations. notationName, base, and systemId, and publicId are strings if given. If the public identifier is omitted, publicId will be None.

**StartNamespaceDeclHandler**

\(\text{prefix, uri}\)

Called when an element contains a namespace declaration. Namespace declarations are processed before the StartElementHandler is called for the element on which declarations are placed.

**EndNamespaceDeclHandler**

\(\text{prefix}\)

Called when the closing tag is reached for an element that contained a namespace declaration. This is called once for each namespace declaration on the element in the reverse of the order for which the StartNamespaceDeclHandler was called to indicate the start of each
namespace declaration's scope. Calls to this handler are made after the corresponding EndElementHandler for the end of the element.

**CommentHandler**( data)
Called for comments. *data* is the text of the comment, excluding the leading `<!-` and trailing `-->`.

**StartCdataSectionHandler**( )
Called at the start of a CDATA section. This and EndCdataSectionHandler are needed to be able to identify the syntactical start and end for CDATA sections.

**EndCdataSectionHandler**( )
Called at the end of a CDATA section.

**DefaultHandler**( data)
