Initialize the internal data structures. If given, *files* must be a sequence of file names which should be used to augment the default type map. If omitted, the file names to use are taken from `knownfiles`. Each file named in *files* or `knownfiles` takes precedence over those named before it. Calling `init()` repeatedly is allowed.

read_mime_types(*filename*)

Load the type map given in the file *filename*, if it exists. The type map is returned as a dictionary mapping filename extensions, including the leading dot ("."), to strings of the form '*type/subtype*'. If the file *filename* does not exist or cannot be read, `None` is returned.

add_type(*type*, *ext*[, *strict*])

Add a mapping from the mimetype *type* to the extension *ext*. When the extension is already known, the new type will replace the old one. When the type is already known the extension will be added to the list of known extensions.

When *strict* is the mapping will added to the official MIME types, otherwise to the non-standard ones.

inited

Flag indicating whether or not the global data structures have been initialized. This is set to true by `init()`.

knownfiles

List of type map file names commonly installed. These files are typically named `mime.types` and are installed in different locations by different packages.

suffix_map

Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the `.tgz` extension is mapped to `.tar.gz` to allow the encoding and type to be recognized separately.

encodings_map

Dictionary mapping filename extensions to encoding types.

types_map

Dictionary mapping filename extensions to MIME types.

common_types

Dictionary mapping filename extensions to non-standard, but commonly found MIME types.

The `MimeTypes` class may be useful for applications which may want more than one MIME-type database:

class MimeTypes([filenames])

This class represents a MIME-types database. By default, it provides access to the same database as the rest of this module. The initial database is a

copy of that provided by the module, and may be extended by loading additional `mime.types`-style files into the database using the `read()` or `readfp()` methods. The mapping dictionaries may also be cleared before loading additional data if the default data is not desired.

The optional `filenames` parameter can be used to cause additional files to be loaded "on top" of the default database.

New in version 2.2.

12.7.1 MimeTypes Objects

MimeTypes instances provide an interface which is very like that of the [mimetypes](#) module.

suffix_map

Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the .tgz extension is mapped to .tar.gz to allow the encoding and type to be recognized separately. This is initially a copy of the global `suffix_map` defined in the module.

encodings_map

Dictionary mapping filename extensions to encoding types. This is initially a copy of the global `encodings_map` defined in the module.

types_map

Dictionary mapping filename extensions to MIME types. This is initially a copy of the global `types_map` defined in the module.

common_types

Dictionary mapping filename extensions to non-standard, but commonly found MIME types. This is initially a copy of the global `common_types` defined in the module.

guess_extension(*type*[, *strict*])

Similar to the `guess_extension()` function, using the tables stored as part of the object.

guess_type(*url*[, *strict*])

Similar to the `guess_type()` function, using the tables stored as part of the object.

read(*path*)

Load MIME information from a file named *path*. This uses `readfp()` to parse the file.

readfp(*file*)

Load MIME type information from an open file. The file must have the format of the standard `mime.types` files.

12.8 MimeWriter -- Generic MIME file writer

Deprecated since release 2.3. The [email](#) package should be used in preference to the `MimeWriter` module. This module is present only to maintain backward compatibility.

This module defines the class `MimeWriter`. The `MimeWriter` class implements a basic formatter for creating MIME multi-part files. It doesn't seek around the output file nor does it use large amounts of buffer space. You must write the parts out in the order that they should occur in the final file. `MimeWriter` does buffer the headers you add, allowing you to rearrange their order.

class `MimeWriter`(*fp*)

Return a new instance of the `MimeWriter` class. The only argument passed, *fp*, is a file object to be used for writing. Note that a `StringIO` object could also be used.

Subsections

- [12.8.1 MimeWriter Objects](#)

Previous: [12.7.1 MimeTypes Objects](#) Up: [12. Internet Data Handling](#) Next: [12.8.1 MimeWriter Objects](#)

Previous: [12.8 MimeWriter](#) Up: [12.8 MimeWriter](#) Next: [12.9 mimify](#)

12.8.1 MimeWriter Objects

`MimeWriter` instances have the following methods:

addheader(*key*, *value*[, *prefix*])

Add a header line to the MIME message. The *key* is the name of the header, where the *value* obviously provides the value of the header. The optional argument *prefix* determines where the header is inserted; "0" means append at the end, "1" is insert at the start. The default is to append.

flushheaders()

Causes all headers accumulated so far to be written out (and forgotten). This is useful if you don't need a body part at all, e.g. for a subpart of type `message/rfc822` that's (mis)used to store some header-like information.

startbody(*ctype*[, *plist*[, *prefix*]])

Returns a file-like object which can be used to write to the body of the message. The content-type is set to the provided *ctype*, and the optional parameter *plist* provides additional parameters for the content-type declaration. *prefix* functions as in `addheader ()` except that the default is to insert at the start.

startmultipartbody(*subtype*[, *boundary*[, *plist*[, *prefix*]]])

Returns a file-like object which can be used to write to the body of the message. Additionally, this method initializes the multi-part code, where *subtype* provides the multipart subtype, *boundary* may provide a user-defined boundary specification, and *plist* provides optional parameters for the subtype. *prefix* functions as in `startbody ()`. Subparts should be created using `nextpart ()`.

nextpart()

Returns a new instance of `MimeWriter` which represents an individual part in a multipart message. This may be used to write the part as well as used for creating recursively complex multipart messages. The message must first be initialized with `startmultipartbody ()` before using

`nextpart()`.

lastpart()

This is used to designate the last part of a multipart message, and should *always* be used when writing multipart messages.

12.9 `mimify` -- MIME processing of mail messages

Deprecated since release 2.3. The [email](#) package should be used in preference to the `mimify` module. This module is present only to maintain backward compatibility.

The `mimify` module defines two functions to convert mail messages to and from MIME format. The mail message can be either a simple message or a so-called multipart message. Each part is treated separately. Mimifying (a part of) a message entails encoding the message as quoted-printable if it contains any characters that cannot be represented using 7-bit ASCII. Unmimifying (a part of) a message entails undoing the quoted-printable encoding. Mimify and unmimify are especially useful when a message has to be edited before being sent. Typical use would be:

```
unmimify message
edit message
mimify message
send message
```

The module defines the following user-callable functions and user-settable variables:

`mimify`(*infile*, *outfile*)

Copy the message in *infile* to *outfile*, converting parts to quoted-printable and adding MIME mail headers when necessary. *infile* and *outfile* can be file objects (actually, any object that has a `readline()` method (for *infile*) or a `write()` method (for *outfile*)) or strings naming the files. If *infile* and *outfile* are both strings, they may have the same value.

`unmimify`(*infile*, *outfile*[, *decode_base64*])

Copy the message in *infile* to *outfile*, decoding all quoted-printable parts. *infile* and *outfile* can be file objects (actually, any object that has a `readline()` method (for *infile*) or a `write()` method (for *outfile*)) or strings naming the files. If *infile* and *outfile* are both strings, they may have

the same value. If the *decode_base64* argument is provided and tests true, any parts that are coded in the base64 encoding are decoded as well.

mime_decode_header(*line*)

Return a decoded version of the encoded header line in *line*. This only supports the ISO 8859-1 charset (Latin-1).

mime_encode_header(*line*)

Return a MIME-encoded version of the header line in *line*.

MAXLEN

By default, a part will be encoded as quoted-printable when it contains any non-ASCII characters (characters with the 8th bit set), or if there are any lines longer than MAXLEN characters (default value 200).

CHARSET

When not specified in the mail headers, a character set must be filled in. The string used is stored in CHARSET, and the default value is ISO-8859-1 (also known as Latin1 (latin-one)).

This module can also be used from the command line. Usage is as follows:

```
mimify.py -e [-l length] [infile [outfile]]
mimify.py -d [-b] [infile [outfile]]
```

to encode (mimify) and decode (unmimify) respectively. *infile* defaults to standard input, *outfile* defaults to standard output. The same file can be specified for input and output.

If the **-l** option is given when encoding, if there are any lines longer than the specified *length*, the containing part will be encoded.

If the **-b** option is given when decoding, any base64 parts will be decoded as well.

12.10 `multifile` -- Support for files containing distinct parts

The `MultiFile` object enables you to treat sections of a text file as file-like input objects, with `' '` being returned by `readline()` when a given delimiter pattern is encountered. The defaults of this class are designed to make it useful for parsing MIME multipart messages, but by subclassing it and overriding methods it can be easily adapted for more general use.

class `MultiFile`(*fp*[, *seekable*])

Create a multi-file. You must instantiate this class with an input object argument for the `MultiFile` instance to get lines from, such as a file object returned by `open()`.

`MultiFile` only ever looks at the input object's `readline()`, `seek()` and `tell()` methods, and the latter two are only needed if you want random access to the individual MIME parts. To use `MultiFile` on a non-seekable stream object, set the optional *seekable* argument to `false`; this will prevent using the input object's `seek()` and `tell()` methods.

It will be useful to know that in `MultiFile`'s view of the world, text is composed of three kinds of lines: data, section-dividers, and end-markers. `MultiFile` is designed to support parsing of messages that may have multiple nested message parts, each with its own pattern for section-divider and end-marker lines.

See Also:

Module [email](#):

Comprehensive email handling package; supersedes the `multifile` module.

Subsections

- [12.10.2 MultiFile Example](#)

Previous: [12.9 mimify](#) Up: [12. Internet Data Handling](#) Next: [12.10.1 MultiFile Objects](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.*

Previous: [12.10 multifile](#) Up: [12.10 multifile](#) Next: [12.10.2 MultiFile Example](#)

12.10.1 MultiFile Objects

A `MultiFile` instance has the following methods:

readline(*str*)

Read a line. If the line is data (not a section-divider or end-marker or real EOF) return it. If the line matches the most-recently-stacked boundary, return ' ' and set `self.last` to 1 or 0 according as the match is or is not an end-marker. If the line matches any other stacked boundary, raise an error. On encountering end-of-file on the underlying stream object, the method raises `Error` unless all boundaries have been popped.

readlines(*str*)

Return all lines remaining in this part as a list of strings.

read()

Read all lines, up to the next section. Return them as a single (multiline) string. Note that this doesn't take a size argument!

seek(*pos*[, *whence*])

Seek. Seek indices are relative to the start of the current section. The *pos* and *whence* arguments are interpreted as for a file seek.

tell()

Return the file position relative to the start of the current section.

next()

Skip lines to the next section (that is, read lines until a section-divider or end-marker has been consumed). Return true if there is such a section, false if an end-marker is seen. Re-enable the most-recently-pushed boundary.

is_data(*str*)

Return true if *str* is data and false if it might be a section boundary. As written, it tests for a prefix other than ' - - ' at start of line (which all MIME boundaries have) but it is declared so it can be overridden in derived classes.

Note that this test is used intended as a fast guard for the real boundary tests; if it always returns false it will merely slow processing, not cause it to fail.

push(*str*)

Push a boundary string. When a decorated version of this boundary is found as an input line, it will be interpreted as a section-divider or end-marker (depending on the decoration, see [RFC 2045](#)). All subsequent reads will return the empty string to indicate end-of-file, until a call to `pop()` removes the boundary a or `next()` call reenables it.

It is possible to push more than one boundary. Encountering the most-recently-pushed boundary will return EOF; encountering any other boundary will raise an error.

pop()

Pop a section boundary. This boundary will no longer be interpreted as EOF.

section_divider(*str*)

Turn a boundary into a section-divider line. By default, this method prepends ' - - ' (which MIME section boundaries have) but it is declared so it can be overridden in derived classes. This method need not append LF or CR-LF, as comparison with the result ignores trailing whitespace.

end_marker(*str*)

Turn a boundary string into an end-marker line. By default, this method prepends ' - - ' and appends ' - - ' (like a MIME-multipart end-of-message marker) but it is declared so it can be overridden in derived classes. This method need not append LF or CR-LF, as comparison with the result ignores trailing whitespace.

Finally, `MultiFile` instances have two public instance variables:

level

Nesting depth of the current part.

last

True if the last end-of-file was for an end-of-message marker.

[12.11.1 Message Objects](#)

12.11 rfc822 -- Parse RFC 2822 mail headers

Deprecated since release 2.3. The [email](#) package should be used in preference to the `rfc822` module. This module is present only to maintain backward compatibility.

This module defines a class, `Message`, which represents an "email message" as defined by the Internet standard [RFC 2822](#).^{12.6} Such messages consist of a collection of message headers, and a message body. This module also defines a helper class `AddressList` for parsing [RFC 2822](#) addresses. Please refer to the RFC for information on the specific syntax of [RFC 2822](#) messages.

The [mailbox](#) module provides classes to read mailboxes produced by various end-user mail programs.

class Message(*file*[, *seekable*])

A `Message` instance is instantiated with an input object as parameter. `Message` relies only on the input object having a `readline()` method; in particular, ordinary file objects qualify. Instantiation reads headers from the input object up to a delimiter line (normally a blank line) and stores them in the instance. The message body, following the headers, is not consumed.

This class can work with any input object that supports a `readline()` method. If the input object has `seek` and `tell` capability, the `rewindbody()` method will work; also, illegal lines will be pushed back onto the input stream. If the input object lacks `seek` but has an `unread()` method that can push back a line of input, `Message` will use that to push back illegal lines. Thus this class can be used to parse messages coming from a buffered stream.

The optional *seekable* argument is provided as a workaround for certain stdio libraries in which `tell()` discards buffered data before discovering that the `lseek()` system call doesn't work. For maximum portability, you should set the *seekable* argument to zero to prevent that initial `tell()`

when passing in an unseekable object such as a file object created from a socket object.

Input lines as read from the file may either be terminated by CR-LF or by a single linefeed; a terminating CR-LF is replaced by a single linefeed before the line is stored.

All header matching is done independent of upper or lower case; e.g. `m['From']`, `m['from']` and `m['FROM']` all yield the same result.

class AddressList(*field*)

You may instantiate the `AddressList` helper class using a single string parameter, a comma-separated list of [RFC 2822](#) addresses to be parsed. (The parameter `NONE` yields an empty list.)

quote(*str*)

Return a new string with backslashes in *str* replaced by two backslashes and double quotes replaced by backslash-double quote.

unquote(*str*)

Return a new string which is an *unquoted* version of *str*. If *str* ends and begins with double quotes, they are stripped off. Likewise if *str* ends and begins with angle brackets, they are stripped off.

parseaddr(*address*)

Parse *address*, which should be the value of some address-containing field such as `To:` or `Cc:`, into its constituent `"realname"` and `"email address"` parts. Returns a tuple of that information, unless the parse fails, in which case a 2-tuple `(None, None)` is returned.

dump_address_pair(*pair*)

The inverse of `parseaddr()`, this takes a 2-tuple of the form `(realname, email_address)` and returns the string value suitable for a `To:` or `Cc:` header. If the first element of *pair* is false, then the second element is returned unmodified.

parsedate(*date*)

Attempts to parse a date according to the rules in [RFC 2822](#). however, some

mailers don't follow that format as specified, so `parsedate()` tries to guess correctly in such cases. *date* is a string containing an [RFC 2822](#) date, such as `'Mon, 20 Nov 1995 19:12:08 -0500'`. If it succeeds in parsing the date, `parsedate()` returns a 9-tuple that can be passed directly to `time.mktime()`; otherwise `None` will be returned. Note that fields 6, 7, and 8 of the result tuple are not usable.

`parsedate_tz(date)`

Performs the same function as `parsedate()`, but returns either `None` or a 10-tuple; the first 9 elements make up a tuple that can be passed directly to `time.mktime()`, and the tenth is the offset of the date's timezone from UTC (which is the official term for Greenwich Mean Time). (Note that the sign of the timezone offset is the opposite of the sign of the `time.timezone` variable for the same timezone; the latter variable follows the POSIX standard while this module follows [RFC 2822](#).) If the input string has no timezone, the last element of the tuple returned is `None`. Note that fields 6, 7, and 8 of the result tuple are not usable.

`mktime_tz(tuple)`

Turn a 10-tuple as returned by `parsedate_tz()` into a UTC timestamp. If the timezone item in the tuple is `None`, assume local time. Minor deficiency: this first interprets the first 8 elements as a local time and then compensates for the timezone difference; this may yield a slight error around daylight savings time switch dates. Not enough to worry about for common use.

See Also:

Module [email](#):

Comprehensive email handling package; supersedes the `rfc822` module.

Module [mailbox](#):

Classes to read various mailbox formats produced by end-user mail programs.

Module [mimetools](#):

Subclass of `rfc822.Message` that handles MIME encoded messages.

Footnotes

...2822. [12.6](#)

This module originally conformed to [RFC 822](#), hence the name. Since then, [RFC 2822](#) has been released as an update to [RFC 822](#). This module should be considered [RFC 2822](#)-conformant, especially in cases where the syntax or semantics have changed since [RFC 822](#).

Previous: [12.11 rfc822](#) Up: [12.11 rfc822](#) Next: [12.11.2 AddressList Objects](#)

12.11.1 Message Objects

A Message instance has the following methods:

rewindbody()

Seek to the start of the message body. This only works if the file object is seekable.

isheader(*line*)

Returns a line's canonicalized fieldname (the dictionary key that will be used to index it) if the line is a legal [RFC 2822](#) header; otherwise returns `None` (implying that parsing should stop here and the line be pushed back on the input stream). It is sometimes useful to override this method in a subclass.

islast(*line*)

Return true if the given line is a delimiter on which Message should stop. The delimiter line is consumed, and the file object's read location positioned immediately after it. By default this method just checks that the line is blank, but you can override it in a subclass.

iscomment(*line*)

Return `True` if the given line should be ignored entirely, just skipped. By default this is a stub that always returns `False`, but you can override it in a subclass.

getallmatchingheaders(*name*)

Return a list of lines consisting of all headers matching *name*, if any. Each physical line, whether it is a continuation line or not, is a separate list item. Return the empty list if no header matches *name*.

getfirstmatchingheader(*name*)

Return a list of lines comprising the first header matching *name*, and its continuation line(s), if any. Return `None` if there is no header matching *name*.

getrawheader(*name*)

Return a single string consisting of the text after the colon in the first header matching *name*. This includes leading whitespace, the trailing linefeed, and internal linefeeds and whitespace if there any continuation line(s) were present. Return **NONE** if there is no header matching *name*.

getheader(*name*[, *default*])

Like `getrawheader (name)`, but strip leading and trailing whitespace. Internal whitespace is not stripped. The optional *default* argument can be used to specify a different default to be returned when there is no header matching *name*.

get(*name*[, *default*])

An alias for `getheader ()`, to make the interface more compatible with regular dictionaries.

getaddr(*name*)

Return a pair (*full name*, *email address*) parsed from the string returned by `getheader (name)`. If no header matching *name* exists, return (**None**, **None**); otherwise both the full name and the address are (possibly empty) strings.

Example: If *m*'s first **From:** header contains the string ' `jack@cwi.nl (Jack Jansen)` ', then `m.getaddr('From')` will yield the pair (' `Jack Jansen` ', ' `jack@cwi.nl` '). If the header contained ' `Jack Jansen <jack@cwi.nl>` ' instead, it would yield the exact same result.

getaddrlist(*name*)

This is similar to `getaddr (list)`, but parses a header containing a list of email addresses (e.g. a **To:** header) and returns a list of (*full name*, *email address*) pairs (even if there was only one address in the header). If there is no header matching *name*, return an empty list.

If multiple headers exist that match the named header (e.g. if there are several **Cc:** headers), all are parsed for addresses. Any continuation lines the named headers contain are also parsed.

getdate(*name*)

Retrieve a header using `getheader()` and parse it into a 9-tuple compatible with `time.mktime()`; note that fields 6, 7, and 8 are not usable. If there is no header matching *name*, or it is unparsable, return `None`.

Date parsing appears to be a black art, and not all mailers adhere to the standard. While it has been tested and found correct on a large collection of email from many sources, it is still possible that this function may occasionally yield an incorrect result.

getdate_tz(*name*)

Retrieve a header using `getheader()` and parse it into a 10-tuple; the first 9 elements will make a tuple compatible with `time.mktime()`, and the 10th is a number giving the offset of the date's timezone from UTC. Note that fields 6, 7, and 8 are not usable. Similarly to `getdate()`, if there is no header matching *name*, or it is unparsable, return `None`.

`Message` instances also support a limited mapping interface. In particular: `m[name]` is like `m.getheader(name)` but raises `KeyError` if there is no matching header; and `len(m)`, `m.get(name [, default])`, `m.has_key(name)`, `m.keys()`, `m.values()`, `m.items()`, and `m.setdefault(name [, default])` act as expected, with the one difference that `setdefault()` uses an empty string as the default value. `Message` instances also support the mapping writable interface `m[name] = value` and `del m[name]`. `Message` objects do not support the `clear()`, `copy()`, `popitem()`, or `update()` methods of the mapping interface. (Support for `get()` and `setdefault()` was only added in Python 2.2.)

Finally, `Message` instances have some public instance variables:

headers

A list containing the entire set of header lines, in the order in which they were read (except that `setitem` calls may disturb this order). Each line contains a trailing newline. The blank line terminating the headers is not contained in the list.

fp

The file or file-like object passed at instantiation time. This can be used to read the message content.

unixfrom

The UNIX "From " line, if the message had one, or an empty string. This is needed to regenerate the message in some contexts, such as an mbox-style mailbox file.

12.11.2 AddressList Objects

An `AddressList` instance has the following methods:

`__len__()`

Return the number of addresses in the address list.

`__str__()`

Return a canonicalized string representation of the address list. Addresses are rendered in "name" <host@domain> form, comma-separated.

`__add__(alist)`

Return a new `AddressList` instance that contains all addresses in both `AddressList` operands, with duplicates removed (set union).

`__iadd__(alist)`

In-place version of `__add__()`; turns this `AddressList` instance into the union of itself and the right-hand instance, *alist*.

`__sub__(alist)`

Return a new `AddressList` instance that contains every address in the left-hand `AddressList` operand that is not present in the right-hand address operand (set difference).

`__isub__(alist)`

In-place version of `__sub__()`, removing addresses in this list which are also in *alist*.

Finally, `AddressList` instances have one public instance variable:

addresslist

A list of tuple string pairs, one per address. In each member, the first is the canonicalized name part, the second is the actual route-address ("@"-separated username-host.domain pair).

[12.13 binascii](#)

12.12 base64 -- RFC 3548: Base16, Base32, Base64 Data Encodings

This module provides data encoding and decoding as specified in [RFC 3548](#). This standard defines the Base16, Base32, and Base64 algorithms for encoding and decoding arbitrary binary strings into text strings that can be safely sent by email, used as parts of URLs, or included as part of an HTTP POST request. The encoding algorithm is not the same as the **uuencode** program.

There are two interfaces provided by this module. The modern interface supports encoding and decoding string objects using all three alphabets. The legacy interface provides for encoding and decoding to and from file-like objects as well as strings, but only using the Base64 standard alphabet.

The modern interface provides:

b64encode(*s* [, *altchars*])

Encode a string use Base64.

s is the string to encode. Optional *altchars* must be a string of at least length 2 (additional characters are ignored) which specifies an alternative alphabet for the + and / characters. This allows an application to e.g. generate URL or filesystem safe Base64 strings. The default is `NONE`, for which the standard Base64 alphabet is used.

The encoded string is returned.

b64decode(*s* [, *altchars*])

Decode a Base64 encoded string.

s is the string to decode. Optional *altchars* must be a string of at least length 2 (additional characters are ignored) which specifies the alternative alphabet used instead of the + and / characters.

The decoded string is returned. A `TypeError` is raised if *s* were incorrectly padded or if there are non-alphabet characters present in the

string.

standard_b64encode(s)

Encode string *s* using the standard Base64 alphabet.

standard_b64decode(s)

Decode string *s* using the standard Base64 alphabet.

urlsafe_b64encode(s)

Encode string *s* using a URL-safe alphabet, which substitutes - instead of + and _ instead of / in the standard Base64 alphabet.

urlsafe_b64decode(s)

Decode string *s* using a URL-safe alphabet, which substitutes - instead of + and _ instead of / in the standard Base64 alphabet.

b32encode(s)

Encode a string using Base32. *s* is the string to encode. The encoded string is returned.

b32decode(s[, casefold[, map01]])

Decode a Base32 encoded string.

s is the string to decode. Optional *casefold* is a flag specifying whether a lowercase alphabet is acceptable as input. For security purposes, the default is `False`.

[RFC 3548](#) allows for optional mapping of the digit 0 (zero) to the letter O (oh), and for optional mapping of the digit 1 (one) to either the letter I (eye) or letter L (el). The optional argument *map01* when not `None`, specifies which letter the digit 1 should be mapped to (when *map01* is not `None`, the digit 0 is always mapped to the letter O). For security purposes the default is `None`, so that 0 and 1 are not allowed in the input.

The decoded string is returned. A `TypeError` is raised if *s* were incorrectly padded or if there are non-alphabet characters present in the string.

b16encode(s)

Encode a string using Base16.

s is the string to encode. The encoded string is returned.

b16decode(s[, casefold])

Decode a Base16 encoded string.

s is the string to decode. Optional *casefold* is a flag specifying whether a lowercase alphabet is acceptable as input. For security purposes, the default is `False`.

The decoded string is returned. A `TypeError` is raised if *s* were incorrectly padded or if there are non-alphabet characters present in the string.

The legacy interface:

decode(input, output)

Decode the contents of the *input* file and write the resulting binary data to the *output* file. *input* and *output* must either be file objects or objects that mimic the file object interface. *input* will be read until `input.read()` returns an empty string.

decodestring(s)

Decode the string *s*, which must contain one or more lines of base64 encoded data, and return a string containing the resulting binary data.

encode(input, output)

Encode the contents of the *input* file and write the resulting base64 encoded data to the *output* file. *input* and *output* must either be file objects or objects that mimic the file object interface. *input* will be read until `input.read()` returns an empty string. `encode()` returns the encoded data plus a trailing newline character (`'\n'`).

encodestring(s)

Encode the string *s*, which can contain arbitrary binary data, and return a string containing one or more lines of base64-encoded data.

`encodestring()` returns a string containing one or more lines of base64-encoded data always including an extra trailing newline (`'\n'`).

12.13 binascii -- Convert between binary and ASCII

The `binascii` module contains a number of methods to convert between binary and various ASCII-encoded binary representations. Normally, you will not use these functions directly but use wrapper modules like `uu` or `binhex` instead, this module solely exists because bit-manipulation of large amounts of data is slow in Python.

The `binascii` module defines the following functions:

a2b_uu(*string*)

Convert a single line of uuencoded data back to binary and return the binary data. Lines normally contain 45 (binary) bytes, except for the last line. Line data may be followed by whitespace.

b2a_uu(*data*)

Convert binary data to a line of ASCII characters, the return value is the converted line, including a newline char. The length of *data* should be at most 45.

a2b_base64(*string*)

Convert a block of base64 data back to binary and return the binary data. More than one line may be passed at a time.

b2a_base64(*data*)

Convert binary data to a line of ASCII characters in base64 coding. The return value is the converted line, including a newline char. The length of *data* should be at most 57 to adhere to the base64 standard.

a2b_qp(*string* [, *header*])

Convert a block of quoted-printable data back to binary and return the binary data. More than one line may be passed at a time. If the optional argument *header* is present and true, underscores will be decoded as spaces.

b2a_qp(*data*[, *quotetabs*, *istext*, *header*])

Convert binary data to a line(s) of ASCII characters in quoted-printable encoding. The return value is the converted line(s). If the optional argument *quotetabs* is present and true, all tabs and spaces will be encoded. If the optional argument *istext* is present and true, newlines are not encoded but trailing whitespace will be encoded. If the optional argument *header* is present and true, spaces will be encoded as underscores per RFC1522. If the optional argument *header* is present and false, newline characters will be encoded as well; otherwise linefeed conversion might corrupt the binary data stream.

a2b_hqx(*string*)

Convert binhex4 formatted ASCII data to binary, without doing RLE-decompression. The string should contain a complete number of binary bytes, or (in case of the last portion of the binhex4 data) have the remaining bits zero.

rledecode_hqx(*data*)

Perform RLE-decompression on the data, as per the binhex4 standard. The algorithm uses 0x90 after a byte as a repeat indicator, followed by a count. A count of 0 specifies a byte value of 0x90. The routine returns the decompressed data, unless data input data ends in an orphaned repeat indicator, in which case the `Incomplete` exception is raised.

rlecode_hqx(*data*)

Perform binhex4 style RLE-compression on *data* and return the result.

b2a_hqx(*data*)

Perform hexbin4 binary-to-ASCII translation and return the resulting string. The argument should already be RLE-coded, and have a length divisible by 3 (except possibly the last fragment).

crc_hqx(*data*, *crc*)

Compute the binhex4 crc value of *data*, starting with an initial *crc* and returning the result.

crc32(*data*[, *crc*])

Compute CRC-32, the 32-bit checksum of data, starting with an initial crc. This is consistent with the ZIP file checksum. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm. Use as follows:

```
print binascii.crc32("hello world")
# Or, in two pieces:
crc = binascii.crc32("hello")
crc = binascii.crc32(" world", crc)
print crc
```

b2a_hex(*data*)

hexlify(*data*)

Return the hexadecimal representation of the binary *data*. Every byte of *data* is converted into the corresponding 2-digit hex representation. The resulting string is therefore twice as long as the length of *data*.

a2b_hex(*hexstr*)

unhexlify(*hexstr*)

Return the binary data represented by the hexadecimal string *hexstr*. This function is the inverse of **b2a_hex**(). *hexstr* must contain an even number of hexadecimal digits (which can be upper or lower case), otherwise a `TypeError` is raised.

exception Error

Exception raised on errors. These are usually programming errors.

exception Incomplete

Exception raised on incomplete data. These are usually not programming errors, but may be handled by reading a little more data and trying again.

12.14 binhex -- Encode and decode binhex4 files

This module encodes and decodes files in binhex4 format, a format allowing representation of Macintosh files in ASCII. On the Macintosh, both forks of a file and the finder information are encoded (or decoded), on other platforms only the data fork is handled.

The `binhex` module defines the following functions:

binhex(*input*, *output*)

Convert a binary file with filename *input* to binhex file *output*. The *output* parameter can either be a filename or a file-like object (any object supporting a `write()` and `close()` method).

hexbin(*input*[, *output*])

Decode a binhex file *input*. *input* may be a filename or a file-like object supporting `read()` and `close()` methods. The resulting file is written to a file named *output*, unless the argument is omitted in which case the output filename is read from the binhex file.

The following exception is also defined:

exception Error

Exception raised when something can't be encoded using the binhex format (for example, a filename is too long to fit in the filename field), or when *input* is not properly encoded binhex data.

12.14.1 Notes

There is an alternative, more powerful interface to the coder and decoder, see the source for details.

If you code or decode textfiles on non-Macintosh platforms they will still use the Macintosh newline convention (carriage-return as end of line).

As of this writing, `hexbin()` appears to not work in all cases.

12.15 `quopri` -- Encode and decode MIME quoted-printable data

This module performs quoted-printable transport encoding and decoding, as defined in [RFC 1521](#): "MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies". The quoted-printable encoding is designed for data where there are relatively few nonprintable characters; the base64 encoding scheme available via the [base64](#) module is more compact if there are many such characters, as when sending a graphics file.

`decode`(*input*, *output*[,*header*])

Decode the contents of the *input* file and write the resulting decoded binary data to the *output* file. *input* and *output* must either be file objects or objects that mimic the file object interface. *input* will be read until *input.readline()* returns an empty string. If the optional argument *header* is present and true, underscore will be decoded as space. This is used to decode "Q"-encoded headers as described in [RFC 1522](#): "MIME (Multipurpose Internet Mail Extensions) Part Two: Message Header Extensions for Non-ASCII Text".

`encode`(*input*, *output*, *quotetabs*)

Encode the contents of the *input* file and write the resulting quoted-printable data to the *output* file. *input* and *output* must either be file objects or objects that mimic the file object interface. *input* will be read until *input.readline()* returns an empty string. *quotetabs* is a flag which controls whether to encode embedded spaces and tabs; when true it encodes such embedded whitespace, and when false it leaves them unencoded. Note that spaces and tabs appearing at the end of lines are always encoded, as per [RFC 1521](#).

`decodestring`(*s*[,*header*])

Like `decode()`, except that it accepts a source string and returns the corresponding decoded string.

encodestring(s[, quotetabs])

Like `encode()`, except that it accepts a source string and returns the corresponding encoded string. *quotetabs* is optional (defaulting to 0), and is passed straight through to `encode()`.

12.16 uu -- Encode and decode uuencode files

This module encodes and decodes files in uuencode format, allowing arbitrary binary data to be transferred over ASCII-only connections. Wherever a file argument is expected, the methods accept a file-like object. For backwards compatibility, a string containing a pathname is also accepted, and the corresponding file will be opened for reading and writing; the pathname ' - ' is understood to mean the standard input or output. However, this interface is deprecated; it's better for the caller to open the file itself, and be sure that, when required, the mode is 'rb' or 'wb' on Windows.

This code was contributed by Lance Ellinghouse, and modified by Jack Jansen.

The uu module defines the following functions:

encode(*in_file*, *out_file*[, *name*[, *mode*]])

Uuencode file *in_file* into file *out_file*. The uuencoded file will have the header specifying *name* and *mode* as the defaults for the results of decoding the file. The default defaults are taken from *in_file*, or ' - ' and 0666 respectively.

decode(*in_file*[, *out_file*[, *mode*[, *quiet*]])

This call decodes uuencoded file *in_file* placing the result on file *out_file*. If *out_file* is a pathname, *mode* is used to set the permission bits if the file must be created. Defaults for *out_file* and *mode* are taken from the uuencode header. However, if the file specified in the header already exists, a `uu.Error` is raised.

`decode()` may print a warning to standard error if the input was produced by an incorrect uuencoder and Python could recover from that error. Setting *quiet* to a true value silences this warning.

exception Error()

Subclass of `Exception`, this can be raised by `uu.decode()` under

various situations, such as described above, but also including a badly formatted header, or truncated input file.

12.17 xdrlib -- Encode and decode XDR data

The `xdrlib` module supports the External Data Representation Standard as described in [RFC 1014](#), written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The `xdrlib` module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

class Packer()

`Packer` is the class for packing data into XDR representation. The `Packer` class is instantiated with no arguments.

class Unpacker(data)

`Unpacker` is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as *data*.

See Also:

[RFC 1014, XDR: External Data Representation Standard](#)

This RFC defined the encoding of data which was XDR at the time this module was originally written. It has apparently been obsoleted by [RFC 1832](#).

[RFC 1832, XDR: External Data Representation Standard](#)

Newer RFC that provides a revised definition of XDR.

Previous: [12.17 xdrlib](#) Up: [12.17 xdrlib](#) Next: [12.17.2 Unpacker Objects](#)

12.17.1 Packer Objects

Packer instances have the following methods:

get_buffer()

Returns the current pack buffer as a string.

reset()

Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate `pack_type()` method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: `pack_uint()`, `pack_int()`, `pack_enum()`, `pack_bool()`, `pack_uhyper()`, and `pack_hyper()`.

pack_float(*value*)

Packs the single-precision floating point number *value*.

pack_double(*value*)

Packs the double-precision floating point number *value*.

The following methods support packing strings, bytes, and opaque data:

pack_fstring(*n*, *s*)

Packs a fixed length string, *s*. *n* is the length of the string but it is *not* packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.

pack_fopaque(*n*, *data*)

Packs a fixed length opaque data stream, similarly to `pack_fstring()`.

pack_string(*s*)

Packs a variable length string, *s*. The length of the string is first packed as an unsigned integer, then the string data is packed with `pack_fstring()`.

pack_opaque(*data*)

Packs a variable length opaque data string, similarly to `pack_string()`.

pack_bytes(*bytes*)

Packs a variable length byte stream, similarly to `pack_string()`.

The following methods support packing arrays and lists:

pack_list(*list*, *pack_item*)

Packs a *list* of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. *pack_item* is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```
import xdrlib
p = xdrlib.Packer()
p.pack_list([1, 2, 3], p.pack_int)
```

pack_farray(*n*, *array*, *pack_item*)

Packs a fixed length list (*array*) of homogeneous items. *n* is the length of the list; it is *not* packed into the buffer, but a `ValueError` exception is raised if `len(array)` is not equal to *n*. As above, *pack_item* is the function used to pack each element.

pack_array(*list*, *pack_item*)

Packs a variable length *list* of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in `pack_farray()` above.

Previous: [12.17.1 Packer Objects](#) Up: [12.17 xdrlib](#) Next: [12.17.3 Exceptions](#)

12.17.2 Unpacker Objects

The `Unpacker` class offers the following methods:

reset(*data*)

Resets the string buffer with the given *data*.

get_position()

Returns the current unpack position in the data buffer.

set_position(*position*)

Sets the data buffer unpack position to *position*. You should be careful about using `get_position()` and `set_position()`.

get_buffer()

Returns the current unpack data buffer as a string.

done()

Indicates unpack completion. Raises an `Error` exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a `Packer`, can be unpacked with an `Unpacker`. Unpacking methods are of the form `unpack_type()`, and take no arguments. They return the unpacked object.

unpack_float()

Unpacks a single-precision floating point number.

unpack_double()

Unpacks a double-precision floating point number, similarly to `unpack_float()`.

In addition, the following methods unpack strings, bytes, and opaque data:

unpack_fstring(*n*)

Unpacks and returns a fixed length string. *n* is the number of characters

expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

unpack_fopaque(*n*)

Unpacks and returns a fixed length opaque data stream, similarly to `unpack_fstring()`.

unpack_string()

Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with `unpack_fstring()`.

unpack_opaque()

Unpacks and returns a variable length opaque data string, similarly to `unpack_string()`.

unpack_bytes()

Unpacks and returns a variable length byte stream, similarly to `unpack_string()`.

The following methods support unpacking arrays and lists:

unpack_list(*unpack_item*)

Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list. *unpack_item* is the function that is called to unpack the items.

unpack_farray(*n*, *unpack_item*)

Unpacks and returns (as a list) a fixed length array of homogeneous items. *n* is number of list elements to expect in the buffer. As above, *unpack_item* is the function used to unpack each element.

unpack_array(*unpack_item*)

Unpacks and returns a variable length *list* of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is

unpacked as in `unpack_farray()` above.

12.17.3 Exceptions

Exceptions in this module are coded as class instances:

exception Error

The base exception class. `Error` has a single public data member `msg` containing the description of the error.

exception ConversionError

Class derived from `Error`. Contains no additional instance variables.

Here is an example of how you would catch one of these exceptions:

```
import xdrlib
p = xdrlib.Packer()
try:
    p.pack_double(8.01)
except xdrlib.ConversionError, instance:
    print 'packing the double failed:', instance.msg
```

Previous: [12.17.3 Exceptions](#) **Up:** [12. Internet Data Handling](#) **Next:** [12.18.1 netrc Objects](#)

12.18 netrc -- netrc file processing

New in version 1.5.2.

The `netrc` class parses and encapsulates the netrc file format used by the UNIX `ftp` program and other FTP clients.

class `netrc`([*file*])

A `netrc` instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file `.netrc` in the user's home directory will be read. Parse errors will raise `NetrcParseError` with diagnostic information including the file name, line number, and terminating token.

exception `NetrcParseError`

Exception raised by the `netrc` class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: `msg` is a textual explanation of the error, `filename` is the name of the source file, and `lineno` gives the line number on which the error was found.

Subsections

- [12.18.1 netrc Objects](#)

Previous: [12.18 netrc](#) Up: [12.18 netrc](#) Next: [12.19 robotparser](#)

12.18.1 netrc Objects

A `netrc` instance has the following methods:

authenticators(*host*)

Return a 3-tuple (*login*, *account*, *password*) of authenticators for *host*. If the `netrc` file did not contain an entry for the given host, return the tuple associated with the ``default'` entry. If neither matching host nor default entry is available, return `None`.

__repr__()

Dump the class data as a string in the format of a `netrc` file. (This discards comments and may reorder the entries.)

Instances of `netrc` have public instance variables:

hosts

Dictionary mapping host names to (*login*, *account*, *password*) tuples. The ``default'` entry, if any, is represented as a pseudo-host by that name.

macros

Dictionary mapping macro names to string lists.

Note: Passwords are limited to a subset of the ASCII character set. Versions of this module prior to 2.3 were extremely limited. Starting with 2.3, all ASCII punctuation is allowed in passwords. However, note that whitespace and non-printable characters are not allowed in passwords. This is a limitation of the way the `.netrc` file is parsed and may be removed in the future.

Previous: [12.18.1 netrc Objects](#) Up: [12. Internet Data Handling](#) Next: [12.20 CSV](#)

12.19 robotparser -- Parser for robots.txt

This module provides a single class, `RobotFileParser`, which answers questions about whether or not a particular user agent can fetch a URL on the Web site that published the `robots.txt` file. For more details on the structure of `robots.txt` files, see <http://www.robotstxt.org/wc/norobots.html>.

class RobotFileParser()

This class provides a set of methods to read, parse and answer questions about a single `robots.txt` file.

set_url(*url*)

Sets the URL referring to a `robots.txt` file.

read()

Reads the `robots.txt` URL and feeds it to the parser.

parse(*lines*)

Parses the *lines* argument.

can_fetch(*useragent*, *url*)

Returns `True` if the *useragent* is allowed to fetch the *url* according to the rules contained in the parsed `robots.txt` file.

mtime()

Returns the time the `robots.txt` file was last fetched. This is useful for long-running web spiders that need to check for new `robots.txt` files periodically.

modified()

Sets the time the `robots.txt` file was last fetched to the current time.

The following example demonstrates basic use of the RobotFileParser class.

```
>>> import robotparser
>>> rp = robotparser.RobotFileParser()
>>> rp.set_url("http://www.musi-cal.com/robots.txt")
>>> rp.read()
>>> rp.can_fetch("*", "http://www.musi-cal.com/cgi-bin/search?city=S
False
>>> rp.can_fetch("*", "http://www.musi-cal.com/")
True
```

12.20 csv -- CSV File Reading and Writing

New in version 2.3.

The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. There is no "CSV standard", so the format is operationally defined by the many applications which read and write it. The lack of a standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The `csv` module implements classes to read and write tabular data in CSV format. It allows programmers to say, "write this data in the format preferred by Excel," or "read data from this file which was generated by Excel," without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The `csv` module's `reader` and `writer` objects read and write sequences. Programmers can also read and write data in dictionary form using the `DictReader` and `DictWriter` classes.

Note: This version of the `csv` module doesn't support Unicode input. Also, there are currently some issues regarding ASCII NUL characters. Accordingly, all input should generally be printable ASCII to be safe. These restrictions will be removed in the future.

Previous: [12.20 csv](#) Up: [12.20 csv](#) Next: [12.20.2 Dialects and Formatting](#)

12.20.1 Module Contents

The CSV module defines the following functions:

reader(*csvfile*[, *dialect*= 'excel'[, *fmtparam*]])

Return a reader object which will iterate over lines in the given *csvfile*. *csvfile* can be any object which supports the iterator protocol and returns a string each time its `next` method is called. If *csvfile* is a file object, it must be opened with the 'b' flag on platforms where that makes a difference. An optional *dialect* parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects` function. The other optional *fmtparam* keyword arguments can be given to override individual formatting parameters in the current dialect. For more information about the dialect and formatting parameters, see section [12.20.2](#), "Dialects and Formatting Parameters" for details of these parameters.

All data read are returned as strings. No automatic data type conversion is performed.

writer(*csvfile*[, *dialect*= 'excel'[, *fmtparam*]])

Return a writer object responsible for converting the user's data into delimited strings on the given file-like object. *csvfile* can be any object with a `write` method. If *csvfile* is a file object, it must be opened with the 'b' flag on platforms where that makes a difference. An optional *dialect* parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects` function. The other optional *fmtparam* keyword arguments can be given to override individual formatting parameters in the current dialect. For more information about the dialect and formatting parameters, see section [12.20.2](#), "Dialects and Formatting Parameters" for details of these parameters. To make it as easy as possible to interface with modules which implement the DB API, the value `None` is written as the empty string. While this isn't a reversible transformation, it makes it easier to dump SQL

NULL data values to CSV files without preprocessing the data returned from a `cursor.fetch*()` call. All other non-string data are stringified with `str()` before being written.

register_dialect(*name*, *dialect*)

Associate *dialect* with *name*. *dialect* must be a subclass of `csv.Dialect`. *name* must be a string or Unicode object.

unregister_dialect(*name*)

Delete the dialect associated with *name* from the dialect registry. An `Error` is raised if *name* is not a registered dialect name.

get_dialect(*name*)

Return the dialect associated with *name*. An `Error` is raised if *name* is not a registered dialect name.

list_dialects()

Return the names of all registered dialects.

The `csv` module defines the following classes:

```
class DictReader(csvfile[, fieldnames=None[, restkey=None[,  
restval=None[, dialect='excel'[, *args,  
**kws]]]]])
```

Create an object which operates like a regular reader but maps the information read into a dict whose keys are given by the optional *fieldnames* parameter. If the *fieldnames* parameter is omitted, the values in the first row of the *csvfile* will be used as the fieldnames. If the row read has fewer fields than the fieldnames sequence, the value of *restval* will be used as the default value. If the row read has more fields than the fieldnames sequence, the remaining data is added as a sequence keyed by the value of *restkey*. If the row read has fewer fields than the fieldnames sequence, the remaining keys take the value of the optional *restval* parameter. Any other optional or keyword arguments are passed to the underlying `reader` instance.

```
csvfile, fieldnames[, restval=""[,
```

```
class DictWriter( extrasaction= 'raise'[, dialect= 'excel'[, *args,  
                    **kws]]])
```

Create an object which operates like a regular writer but maps dictionaries onto output rows. The *fieldnames* parameter identifies the order in which values in the dictionary passed to the `writerow()` method are written to the *csvfile*. The optional *restval* parameter specifies the value to be written if the dictionary is missing a key in *fieldnames*. If the dictionary passed to the `writerow()` method contains a key not found in *fieldnames*, the optional *extrasaction* parameter indicates what action to take. If it is set to 'raise' a `ValueError` is raised. If it is set to 'ignore', extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying `writer` instance.

Note that unlike the `DictReader` class, the *fieldnames* parameter of the `DictWriter` is not optional. Since Python's `dict` objects are not ordered, there is not enough information available to deduce the order in which the row should be written to the *csvfile*.

class Dialect

The `Dialect` class is a container class relied on primarily for its attributes, which are used to define the parameters for a specific `reader` or `writer` instance.

class Sniffer()

The `Sniffer` class is used to deduce the format of a CSV file.

The `Sniffer` class provides two methods:

sniff(*sample*[,*delimiters*=None])

Analyze the given *sample* and return a `Dialect` subclass reflecting the parameters found. If the optional *delimiters* parameter is given, it is interpreted as a string containing possible valid delimiter characters.

has_header(*sample*)

Analyze the sample text (presumed to be in CSV format) and return `True` if the first row appears to be a series of column headers.

The `csv` module defines the following constants:

QUOTE_ALL

Instructs `writer` objects to quote all fields.

QUOTE_MINIMAL

Instructs `writer` objects to only quote those fields which contain the current *delimiter* or begin with the current *quotechar*.

QUOTE_NONNUMERIC

Instructs `writer` objects to quote all non-numeric fields.

QUOTE_NONE

Instructs `writer` objects to never quote fields. When the current *delimiter* occurs in output data it is preceded by the current *escapechar* character. When `QUOTE_NONE` is in effect, it is an error not to have a single-character *escapechar* defined, even if no data to be written contains the *delimiter* character.

The `csv` module defines the following exception:

exception Error

Raised by any of the functions when an error is detected.

Previous: [12.20.1 Module Contents](#) Up: [12.20 csv](#) Next: [12.20.3 Reader Objects](#)

12.20.2 Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the `Dialect` class having a set of specific methods and a single `validate()` method. When creating `reader` or `writer` objects, the programmer can specify a string or a subclass of the `Dialect` class as the dialect parameter. In addition to, or instead of, the *dialect* parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the `Dialect` class.

Dialects support the following attributes:

delimiter

A one-character string used to separate fields. It defaults to `' , '`.

doublequote

Controls how instances of *quotechar* appearing inside a field should be themselves be quoted. When `True`, the character is doubled. When `False`, the *escapechar* must be a one-character string which is used as a prefix to the *quotechar*. It defaults to `True`.

escapechar

A one-character string used to escape the *delimiter* if *quoting* is set to `QUOTE_NONE`. It defaults to `None`.

lineterminator

The string used to terminate lines in the CSV file. It defaults to `'\r\n'`.

quotechar

A one-character string used to quote elements containing the *delimiter* or which start with the *quotechar*. It defaults to `'\"'`.

quoting

Controls when quotes should be generated by the writer. It can take on any of the `QUOTE_*` constants (see section [12.20.1](#)) and defaults to `QUOTE_MINIMAL`.

skipinitialspace

When `True`, whitespace immediately following the *delimiter* is ignored. The default is `False`.

12.20.3 Reader Objects

Reader objects (`DictReader` instances and objects returned by the `reader()` function) have the following public methods:

`next()`

Return the next row of the reader's iterable object as a list, parsed according to the current dialect.

Previous: [12.20.3 Reader Objects](#) Up: [12.20 csv](#) Next: [12.20.5 Examples](#)

12.20.4 Writer Objects

Writer objects (`DictWriter` instances and objects returned by the `writer()` function) have the following public methods. A *row* must be a sequence of strings or numbers for `Writer` objects and a dictionary mapping fieldnames to strings or numbers (by passing them through `str()` first) for `DictWriter` objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

`writerow(row)`

Write the *row* parameter to the writer's file object, formatted according to the current dialect.

`writerows(rows)`

Write all the *rows* parameters (a list of *row* objects as described above) to the writer's file object, formatted according to the current dialect.

Previous: [12.20.4 Writer Objects](#) Up: [12.20 csv](#) Next: [13. Structured Markup Processing](#)

12.20.5 Examples

The ``Hello, world" of csv reading is

```
import csv
reader = csv.reader(open("some.csv", "rb"))
for row in reader:
    print row
```

To print just the first and last columns of each row try

```
import csv
reader = csv.reader(open("some.csv", "rb"))
for row in reader:
    print row[0], row[-1]
```

The corresponding simplest possible writing example is

```
import csv
writer = csv.writer(open("some.csv", "wb"))
for row in someiterable:
    writer.writerow(row)
```

13. Structured Markup Processing Tools

Python supports a variety of modules to work with various forms of structured data markup. This includes modules to work with the Standard Generalized Markup Language (SGML) and the Hypertext Markup Language (HTML), and several interfaces for working with the Extensible Markup Language (XML).

It is important to note that modules in the `xml` package require that there be at least one SAX-compliant XML parser available. Starting with Python 2.3, the Expat parser is included with Python, so the [`xml.parsers.expat`](#) module will always be available. You may still want to be aware of the [PyXML add-on package](#); that package provides an extended set of XML libraries for Python.

The documentation for the `xml.dom` and `xml.sax` packages are the definition of the Python bindings for the DOM and SAX interfaces.

[HTMLParser](#)

A simple parser that can handle HTML and XHTML.

[sgmllib](#)

Only as much of an SGML parser as needed to parse HTML.

[htmllib](#)

A parser for HTML documents.

[htmlentitydefs](#)

Definitions of HTML general entities.

[xml.parsers.expat](#)

An interface to the Expat non-validating XML parser.

[xml.dom](#)

Document Object Model API for Python.

[xml.dom.minidom](#)

Lightweight Document Object Model (DOM) implementation.

[xml.dom.pulldom](#)

Support for building partial DOM trees from SAX events.

[xml.sax](#)

Package containing SAX2 base classes and convenience functions.

[xml.sax.handler](#)

Base classes for SAX event handlers.
Convenience functions and classes for use with

[xml.sax.saxutils](#) SAX.

[xml.sax.xmlreader](#) Interface which SAX-compliant XML parsers must implement.

[xmllib](#) A parser for XML documents.

Previous: [13. Structured Markup Processing](#) **Up:** [13. Structured Markup Processing](#) **Next:** [13.1.1 Example HTML Parser](#)

13.1 HTMLParser -- Simple HTML and XHTML parser

New in version 2.2.

This module defines a class `HTMLParser` which serves as the basis for parsing text files formatted in HTML (HyperText Mark-up Language) and XHTML. Unlike the parser in [htmllib](#), this parser is not based on the SGML parser in [sgmlib](#).

class HTMLParser()

The `HTMLParser` class is instantiated without arguments.

An `HTMLParser` instance is fed HTML data and calls handler functions when tags begin and end. The `HTMLParser` class is meant to be overridden by the user to provide a desired behavior.

Unlike the parser in [htmllib](#), this parser does not check that end tags match start tags or call the end-tag handler for elements which are closed implicitly by closing an outer element.

An exception is defined as well:

exception HTMLParseError

Exception raised by the `HTMLParser` class when it encounters an error while parsing. This exception provides three attributes: `msg` is a brief message explaining the error, `lineno` is the number of the line on which the broken construct was detected, and `offset` is the number of characters into the line at which the construct starts.

`HTMLParser` instances have the following methods:

reset()

Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.

feed(*data*)

Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or `close()` is called.

close()

Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call the `HTMLParser` base class method `close()`.

getpos()

Return current line number and offset.

get_starttag_text()

Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML "as deployed" or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

handle_starttag(*tag*, *attrs*)

This method is called to handle the start of a tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

The *tag* argument is the name of the tag converted to lower case. The *attrs* argument is a list of (*name*, *value*) pairs containing the attributes found inside the tag's <> brackets. The *name* will be translated to lower case and double quotes and backslashes in the *value* have been interpreted. For instance, for the tag ``, this method would be called as `"handle_starttag('a', [('href', 'http://www.cwi.nl/'])"`.

handle_startendtag(*tag*, *attrs*)

Similar to `handle_starttag()`, but called when the parser encounters an XHTML-style empty tag (`<a ... />`). This method may be overridden by subclasses which require this particular lexical information; the default implementation simply calls `handle_starttag()` and

`handle_endtag()`.

handle_endtag(*tag*)

This method is called to handle the end tag of an element. It is intended to be overridden by a derived class; the base class implementation does nothing. The *tag* argument is the name of the tag converted to lower case.

handle_data(*data*)

This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_charref(*name*)

This method is called to process a character reference of the form "&#ref;". It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_entityref(*name*)

This method is called to process a general entity reference of the form "&name;" where *name* is an general entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_comment(*data*)

This method is called when a comment is encountered. The *comment* argument is a string containing the text between the "--" and "--" delimiters, but not the delimiters themselves. For example, the comment "`<!-- text -->`" will cause this method to be called with the argument 'text'. It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_decl(*decl*)

Method called when an SGML declaration is read by the parser. The *decl* parameter will be the entire contents of the declaration inside the `<!-->` markup. It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_pi(*data*)

Method called when a processing instruction is encountered. The *data*

parameter will contain the entire processing instruction. For example, for the processing instruction `<?proc color='red'>`, this method would be called as `handle_pi("proc color='red'")`. It is intended to be overridden by a derived class; the base class implementation does nothing.

Note: The `HTMLParser` class uses the SGML syntactic rules for processing instructions. An XHTML processing instruction using the trailing `"?"` will cause the `"?"` to be included in *data*.

13.1.1 Example HTML Parser Application

As a basic example, below is a very basic HTML parser that uses the `HTMLParser` class to print out tags as they are encountered:

```
from HTMLParser import HTMLParser

class MyHTMLParser(HTMLParser):

    def handle_starttag(self, tag, attrs):
        print "Encountered the beginning of a %s tag" % tag

    def handle_endtag(self, tag):
        print "Encountered the end of a %s tag"
```

Previous: [13.1.1 Example HTML Parser Processing](#) **Up:** [13. Structured Markup](#)
Next: [13.3 htmllib](#)

13.2 sgmllib -- Simple SGML parser

This module defines a class `SGMLParser` which serves as the basis for parsing text files formatted in SGML (Standard Generalized Mark-up Language). In fact, it does not provide a full SGML parser -- it only parses SGML insofar as it is used by HTML, and the module only exists as a base for the [htmlib](#) module. Another HTML parser which supports XHTML and offers a somewhat different interface is available in the [HTMLParser](#) module.

class SGMLParser()

The `SGMLParser` class is instantiated without arguments. The parser is hardcoded to recognize the following constructs:

- Opening and closing tags of the form "`<tag attr="value" . . . >`" and "`</tag>`", respectively.
- Numeric character references of the form "`&#name;`".
- Entity references of the form "`&name;`".
- SGML comments of the form "`<! - -text- ->`". Note that spaces, tabs, and newlines are allowed between the trailing "`>`" and the immediately preceding "`- -`".

A single exception is defined as well:

exception SGMLParseError

Exception raised by the `SGMLParser` class when it encounters an error while parsing. New in version 2.1.

`SGMLParser` instances have the following methods:

reset()

Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.

setnomoretags()

Stop processing tags. Treat all following input as literal input (CDATA). (This is only provided so the HTML tag <PLAINTEXT> can be implemented.)

setliteral()

Enter literal mode (CDATA mode).

feed(*data*)

Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or `close()` is called.

close()

Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call `close()`.

get_starttag_text()

Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML ``as deployed" or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

handle_starttag(*tag, method, attributes*)

This method is called to handle start tags for which either a `start_tag()` or `do_tag()` method has been defined. The *tag* argument is the name of the tag converted to lower case, and the *method* argument is the bound method which should be used to support semantic interpretation of the start tag. The *attributes* argument is a list of (*name, value*) pairs containing the attributes found inside the tag's <> brackets. The *name* has been translated to lower case and double quotes and backslashes in the *value* have been interpreted. For instance, for the tag , this method would be called as "unknown_starttag('a', [('href', 'http://www.cwi.nl/'])]". The base implementation simply calls

method with *attributes* as the only argument.

handle_endtag(*tag*, *method*)

This method is called to handle endtags for which an `end_tag()` method has been defined. The *tag* argument is the name of the tag converted to lower case, and the *method* argument is the bound method which should be used to support semantic interpretation of the end tag. If no `end_tag()` method is defined for the closing element, this handler is not called. The base implementation simply calls *method*.

handle_data(*data*)

This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_charref(*ref*)

This method is called to process a character reference of the form "`&#ref;`". In the base implementation, *ref* must be a decimal number in the range 0-255. It translates the character to ASCII and calls the method `handle_data()` with the character as argument. If *ref* is invalid or out of range, the method `unknown_charref(ref)` is called to handle the error. A subclass must override this method to provide support for named character entities.

handle_entityref(*ref*)

This method is called to process a general entity reference of the form "`&ref;`" where *ref* is an general entity reference. It looks for *ref* in the instance (or class) variable `entitydefs` which should be a mapping from entity names to corresponding translations. If a translation is found, it calls the method `handle_data()` with the translation; otherwise, it calls the method `unknown_entityref(ref)`. The default `entitydefs` defines translations for `&`, `'`, `>`, `<`, and `"`;

handle_comment(*comment*)

This method is called when a comment is encountered. The *comment* argument is a string containing the text between the "`<!--`" and "`-->`" delimiters, but not the delimiters themselves. For example, the comment "`<!-- text -->`" will cause this method to be called with the argument

'text'. The default method does nothing.

handle_decl(*data*)

Method called when an SGML declaration is read by the parser. In practice, the DOCTYPE declaration is the only thing observed in HTML, but the parser does not discriminate among different (or broken) declarations. Internal subsets in a DOCTYPE declaration are not supported. The *data* parameter will be the entire contents of the declaration inside the <!...> markup. The default implementation does nothing.

report_unbalanced(*tag*)

This method is called when an end tag is found which does not correspond to any open element.

unknown_starttag(*tag*, *attributes*)

This method is called to process an unknown start tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

unknown_endtag(*tag*)

This method is called to process an unknown end tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

unknown_charref(*ref*)

This method is called to process unresolvable numeric character references. Refer to `handle_charref()` to determine what is handled by default. It is intended to be overridden by a derived class; the base class implementation does nothing.

unknown_entityref(*ref*)

This method is called to process an unknown entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

Apart from overriding or extending the methods listed above, derived classes may also define methods of the following form to define processing of specific tags. Tag names in the input stream are case independent; the *tag* occurring in method names must be in lower case:

start_tag(attributes)

This method is called to process an opening tag *tag*. It has preference over `do_tag()`. The *attributes* argument has the same meaning as described for `handle_starttag()` above.

do_tag(attributes)

This method is called to process an opening tag *tag* for which no `start_tag` method is defined. The *attributes* argument has the same meaning as described for `handle_starttag()` above.

end_tag()

This method is called to process a closing tag *tag*.

Note that the parser maintains a stack of open elements for which no end tag has been found yet. Only tags processed by `start_tag()` are pushed on this stack. Definition of an `end_tag()` method is optional for these tags. For tags processed by `do_tag()` or by `unknown_tag()`, no `end_tag()` method must be defined; if defined, it will not be used. If both `start_tag()` and `do_tag()` methods exist for a tag, the `start_tag()` method takes precedence.

Previous: [13.2 sgmlib](#) Up: [13. Structured Markup Processing](#) Next: [13.3.1 HTMLParser Objects](#)

13.3 `htmllib` -- A parser for HTML documents

This module defines a class which can serve as a base for parsing text files formatted in the HyperText Mark-up Language (HTML). The class is not directly concerned with I/O -- it must be provided with input in string form via a method, and makes calls to methods of a "formatter" object in order to produce output. The `HTMLParser` class is designed to be used as a base class for other classes in order to add functionality, and allows most of its methods to be extended or overridden. In turn, this class is derived from and extends the `SGMLParser` class defined in module [`sgmlib`](#). The `HTMLParser` implementation supports the HTML 2.0 language as described in [RFC 1866](#). Two implementations of formatter objects are provided in the [`formatter`](#) module; refer to the documentation for that module for information on the formatter interface.

The following is a summary of the interface defined by `sgmlib.SGMLParser`:

- The interface to feed data to an instance is through the `feed()` method, which takes a string argument. This can be called with as little or as much text at a time as desired; "`p.feed(a); p.feed(b)`" has the same effect as "`p.feed(a+b)`". When the data contains complete HTML markup constructs, these are processed immediately; incomplete constructs are saved in a buffer. To force processing of all unprocessed data, call the `close()` method.

For example, to parse the entire contents of a file, use:

```
parser.feed(open('myfile.html').read())
parser.close()
```

- The interface to define semantics for HTML tags is very simple: derive a class and define methods called `start_tag()`, `end_tag()`, or `do_tag()`. The parser will call these at appropriate moments: `start_tag` or `do_tag()` is called when an opening tag of the form `<tag . . .>` is

encountered; `end_tag()` is called when a closing tag of the form `<tag>` is encountered. If an opening tag requires a corresponding closing tag, like `<H1> ... </H1>`, the class should define the `start_tag()` method; if a tag requires no closing tag, like `<P>`, the class should define the `do_tag()` method.

The module defines a parser class and an exception:

class HTMLParser(*formatter*)

This is the basic HTML parser class. It supports all entity names required by the XHTML 1.0 Recommendation (<http://www.w3.org/TR/xhtml1>). It also defines handlers for all HTML 2.0 and many HTML 3.0 and 3.2 elements.

exception HTMLParseError

Exception raised by the `HTMLParser` class when it encounters an error while parsing. New in version 2.4.

See Also:

Module [formatter](#):

Interface definition for transforming an abstract flow of formatting events into specific output events on writer objects.

Module [HTMLParser](#):

Alternate HTML parser that offers a slightly lower-level view of the input, but is designed to work with XHTML, and does not implement some of the SGML syntax not used in "HTML as deployed" and which isn't legal for XHTML.

Module [htmlentitydefs](#):

Definition of replacement text for XHTML 1.0 entities.

Module [sgmlib](#):

Base class for `HTMLParser`.

13.3.1 HTMLParser Objects

In addition to tag methods, the `HTMLParser` class provides some additional methods and instance variables for use within tag methods.

formatter

This is the formatter instance associated with the parser.

nofill

Boolean flag which should be true when whitespace should not be collapsed, or false when it should be. In general, this should only be true when character data is to be treated as "preformatted" text, as within a `<PRE>` element. The default value is false. This affects the operation of `handle_data()` and `save_end()`.

anchor_bgn(*href, name, type*)

This method is called at the start of an anchor region. The arguments correspond to the attributes of the `<A>` tag with the same names. The default implementation maintains a list of hyperlinks (defined by the `HREF` attribute for `<A>` tags) within the document. The list of hyperlinks is available as the data attribute `anchorlist`.

anchor_end()

This method is called at the end of an anchor region. The default implementation adds a textual footnote marker using an index into the list of hyperlinks created by `anchor_bgn()`.

handle_image(*source, alt[, ismap[, align[, width[, height]]]])*)

This method is called to handle images. The default implementation simply passes the `alt` value to the `handle_data()` method.

save_bgn()

Begins saving character data in a buffer instead of sending it to the formatter object. Retrieve the stored data via `save_end()`. Use of the `save_bgn() / save_end()` pair may not be nested.

save_end()

Ends buffering character data and returns all data saved since the preceding call to `save_bgn()`. If the `nofill` flag is false, whitespace is collapsed to single spaces. A call to this method without a preceding call to `save_bgn()` will raise a `TypeError` exception.

13.4 `htmlentitydefs` -- Definitions of HTML general entities

This module defines three dictionaries, `name2codepoint`, `codepoint2name`, and `entitydefs`. `entitydefs` is used by the [htmllib](#) module to provide the `entitydefs` member of the `HTMLParser` class. The definition provided here contains all the entities defined by XHTML 1.0 that can be handled using simple textual substitution in the Latin-1 character set (ISO-8859-1).

`entitydefs`

A dictionary mapping XHTML 1.0 entity definitions to their replacement text in ISO Latin-1.

`name2codepoint`

A dictionary that maps HTML entity names to the Unicode codepoints. New in version 2.3.

`codepoint2name`

A dictionary that maps Unicode codepoints to HTML entity names. New in version 2.3.

Previous: [13.4 htmlentities](#) **Up:** [13. Structured Markup Processing](#) **Next:** [13.5.1 XMLParser Objects](#)

13.5 `xml.parsers.expat` -- Fast XML parsing using Expat

New in version 2.0.

The `xml.parsers.expat` module is a Python interface to the Expat non-validating XML parser. The module provides a single extension type, `xmlparser`, that represents the current state of an XML parser. After an `xmlparser` object has been created, various attributes of the object can be set to handler functions. When an XML document is then fed to the parser, the handler functions are called for the character data and markup in the XML document.

This module uses the `pyexpat` module to provide access to the Expat parser. Direct use of the `pyexpat` module is deprecated.

This module provides one exception and one type object:

exception `ExpatError`

The exception raised when Expat reports an error. See section [13.5.2](#), ``ExpatError Exceptions," for more information on interpreting Expat errors.

exception `error`

Alias for `ExpatError`.

`XMLParserType`

The type of the return values from the `ParserCreate()` function.

The `xml.parsers.expat` module contains two functions:

`ErrorString(errno)`

Returns an explanatory string for a given error number *errno*.

`ParserCreate([encoding[, namespace_separator]])`

Creates and returns a new `xmlparser` object. *encoding*, if specified, must be a string naming the encoding used by the XML data. Expat doesn't support as many encodings as Python does, and its repertoire of encodings can't be extended; it supports UTF-8, UTF-16, ISO-8859-1 (Latin1), and ASCII. If *encoding* is given it will override the implicit or explicit encoding of the document.

Expat can optionally do XML namespace processing for you, enabled by providing a value for *namespace_separator*. The value must be a one-character string; a `ValueError` will be raised if the string has an illegal length (`None` is considered the same as omission). When namespace processing is enabled, element type names and attribute names that belong to a namespace will be expanded. The element name passed to the element handlers `StartElementHandler` and `EndElementHandler` will be the concatenation of the namespace URI, the namespace separator character, and the local part of the name. If the namespace separator is a zero byte (`chr(0)`) then the namespace URI and the local part will be concatenated without any separator.

For example, if *namespace_separator* is set to a space character (" ") and the following document is parsed:

```
<?xml version="1.0"?>
<root xmlns      = "http://default-namespace.org/"
      xmlns:py   = "http://www.python.org/ns/">
  <py:elem1 />
  <elem2 xmlns="" />
</root>
```

`StartElementHandler` will receive the following strings for each element:

```
http://default-namespace.org/ root
http://www.python.org/ns/ elem1
elem2
```

13.5.1 XMLParser Objects

`xmlparser` objects have the following methods:

Parse(*data*[, *isfinal*])

Parses the contents of the string *data*, calling the appropriate handler functions to process the parsed data. *isfinal* must be true on the final call to this method. *data* can be the empty string at any time.

ParseFile(*file*)

Parse XML data reading from the object *file*. *file* only needs to provide the `read(nbytes)` method, returning the empty string when there's no more data.

SetBase(*base*)

Sets the base to be used for resolving relative URIs in system identifiers in declarations. Resolving relative identifiers is left to the application: this value will be passed through as the *base* argument to the `ExternalEntityRefHandler`, `NotationDeclHandler`, and `UnparsedEntityDeclHandler` functions.

GetBase()

Returns a string containing the base set by a previous call to `SetBase()`, or `None` if `SetBase()` hasn't been called.

GetInputContext()

Returns the input data that generated the current event as a string. The data is in the encoding of the entity which contains the text. When called while an event handler is not active, the return value is `None`. New in version 2.1.

ExternalEntityParserCreate(*context*[, *encoding*])

Create a "child" parser which can be used to parse an external parsed entity referred to by content parsed by the parent parser. The *context* parameter should be the string passed to the `ExternalEntityRefHandler()` handler function, described below. The child parser is created with the

`ordered_attributes`, `returns_unicode` and `specified_attributes` set to the values of this parser.

UseForeignDTD([*flag*])

Calling this with a true value for *flag* (the default) will cause Expat to call the `ExternalEntityRefHandler` with `None` for all arguments to allow an alternate DTD to be loaded. If the document does not contain a document type declaration, the `ExternalEntityRefHandler` will still be called, but the `StartDoctypeDeclHandler` and `EndDoctypeDeclHandler` will not be called.

Passing a false value for *flag* will cancel a previous call that passed a true value, but otherwise has no effect.

This method can only be called before the `Parse()` or `ParseFile()` methods are called; calling it after either of those have been called causes `ExpatriError` to be raised with the `code` attribute set to `errors.XML_ERROR_CANT_CHANGE_FEATURE_ONCE_PARSING`.

New in version 2.3.

`xmlparser` objects have the following attributes:

buffer_size

The size of the buffer used when `buffer_text` is true. This value cannot be changed at this time. New in version 2.3.

buffer_text

Setting this to true causes the `xmlparser` object to buffer textual content returned by Expat to avoid multiple calls to the `CharacterDataHandler()` callback whenever possible. This can improve performance substantially since Expat normally breaks character data into chunks at every line ending. This attribute is false by default, and may be changed at any time. New in version 2.3.

buffer_used

If `buffer_text` is enabled, the number of bytes stored in the buffer. These bytes represent UTF-8 encoded text. This attribute has no meaningful interpretation when `buffer_text` is false. New in version 2.3.

ordered_attributes

Setting this attribute to a non-zero integer causes the attributes to be reported as a list rather than a dictionary. The attributes are presented in the order found in the document text. For each attribute, two list entries are presented: the attribute name and the attribute value. (Older versions of this module also used this format.) By default, this attribute is false; it may be changed at any time. New in version 2.1.

returns_unicode

If this attribute is set to a non-zero integer, the handler functions will be passed Unicode strings. If `returns_unicode` is 0, 8-bit strings containing UTF-8 encoded data will be passed to the handlers. Changed in version 1.6: Can be changed at any time to affect the result type.

specified_attributes

If set to a non-zero integer, the parser will report only those attributes which were specified in the document instance and not those which were derived from attribute declarations. Applications which set this need to be especially careful to use what additional information is available from the declarations as needed to comply with the standards for the behavior of XML processors. By default, this attribute is false; it may be changed at any time. New in version 2.1.

The following attributes contain values relating to the most recent error encountered by an `xmlparser` object, and will only have correct values once a call to `Parse()` or `ParseFile()` has raised a `xml.parsers.expat.ExpatError` exception.

ErrorByteIndex

Byte index at which an error occurred.

ErrorCode

Numeric code specifying the problem. This value can be passed to the `ErrorString()` function, or compared to one of the constants defined in the `errors` object.

ErrorColumnNumber

Column number at which an error occurred.

ErrorLineNumber

Line number at which an error occurred.

The following attributes contain values relating to the current parse location in an `xmlparser` object. During a callback reporting a parse event they indicate the location of the first of the sequence of characters that generated the event. When called outside of a callback, the position indicated will be just past the last parse event (regardless of whether there was an associated callback). New in version 2.4.

CurrentByteIndex

Current byte index in the parser input.

CurrentColumnNumber

Current column number in the parser input.

CurrentLineNumber

Current line number in the parser input.

Here is the list of handlers that can be set. To set a handler on an `xmlparser` object *o*, use `o.handlername = func`. *handlername* must be taken from the following list, and *func* must be a callable object accepting the correct number of arguments. The arguments are all strings, unless otherwise stated.

XmlDeclHandler(*version*, *encoding*, *standalone*)

Called when the XML declaration is parsed. The XML declaration is the (optional) declaration of the applicable version of the XML recommendation, the encoding of the document text, and an optional "standalone" declaration. *version* and *encoding* will be strings of the type dictated by the `returns_unicode` attribute, and *standalone* will be `1` if the document is declared standalone, `0` if it is declared not to be standalone, or `-1` if the standalone clause was omitted. This is only available with Expat version 1.95.0 or newer. New in version 2.1.

StartDoctypeDeclHandler(*doctypeName*, *systemId*, *publicId*, *has_internal_subset*)

Called when Expat begins parsing the document type declaration (`<!DOCTYPE . . .`). The *doctypeName* is provided exactly as presented. The *systemId* and *publicId* parameters give the system and public identifiers

if specified, or `NONE` if omitted. *has_internal_subset* will be true if the document contains an internal document declaration subset. This requires Expat version 1.2 or newer.

EndDoctypeDeclHandler()

Called when Expat is done parsing the document type declaration. This requires Expat version 1.2 or newer.

ElementDeclHandler(*name*, *model*)

Called once for each element type declaration. *name* is the name of the element type, and *model* is a representation of the content model.

AttlistDeclHandler(*elname*, *attname*, *type*, *default*, *required*)

Called for each declared attribute for an element type. If an attribute list declaration declares three attributes, this handler is called three times, once for each attribute. *elname* is the name of the element to which the declaration applies and *attname* is the name of the attribute declared. The attribute type is a string passed as *type*; the possible values are 'CDATA', 'ID', 'IDREF', ... *default* gives the default value for the attribute used when the attribute is not specified by the document instance, or `NONE` if there is no default value (#IMPLIED values). If the attribute is required to be given in the document instance, *required* will be true. This requires Expat version 1.95.0 or newer.

StartElementHandler(*name*, *attributes*)

Called for the start of every element. *name* is a string containing the element name, and *attributes* is a dictionary mapping attribute names to their values.

EndElementHandler(*name*)

Called for the end of every element.

ProcessingInstructionHandler(*target*, *data*)

Called for every processing instruction.

CharacterDataHandler(*data*)

Called for character data. This will be called for normal character data,

CDATA marked content, and ignorable whitespace. Applications which must distinguish these cases can use the `StartCdataSectionHandler`, `EndCdataSectionHandler`, and `ElementDeclHandler` callbacks to collect the required information.

UnparsedEntityDeclHandler(*entityName*, *base*, *systemId*, *publicId*, *notationName*)

Called for unparsed (NDATA) entity declarations. This is only present for version 1.2 of the Expat library; for more recent versions, use `EntityDeclHandler` instead. (The underlying function in the Expat library has been declared obsolete.)

EntityDeclHandler(*entityName*, *is_parameter_entity*, *value*, *base*, *systemId*, *publicId*, *notationName*)

Called for all entity declarations. For parameter and internal entities, *value* will be a string giving the declared contents of the entity; this will be `None` for external entities. The *notationName* parameter will be `None` for parsed entities, and the name of the notation for unparsed entities.

is_parameter_entity will be true if the entity is a parameter entity or false for general entities (most applications only need to be concerned with general entities). This is only available starting with version 1.95.0 of the Expat library. New in version 2.1.

NotationDeclHandler(*notationName*, *base*, *systemId*, *publicId*)

Called for notation declarations. *notationName*, *base*, and *systemId*, and *publicId* are strings if given. If the public identifier is omitted, *publicId* will be `None`.

StartNamespaceDeclHandler(*prefix*, *uri*)

Called when an element contains a namespace declaration. Namespace declarations are processed before the `StartElementHandler` is called for the element on which declarations are placed.

EndNamespaceDeclHandler(*prefix*)

Called when the closing tag is reached for an element that contained a namespace declaration. This is called once for each namespace declaration on the element in the reverse of the order for which the `StartNamespaceDeclHandler` was called to indicate the start of each

namespace declaration's scope. Calls to this handler are made after the corresponding `EndElementHandler` for the end of the element.

CommentHandler(*data*)

Called for comments. *data* is the text of the comment, excluding the leading `<!--` and trailing `-->`.

StartCdataSectionHandler()

Called at the start of a CDATA section. This and `EndCdataSectionHandler` are needed to be able to identify the syntactical start and end for CDATA sections.

EndCdataSectionHandler()

Called at the end of a CDATA section.

DefaultHandler(*data*)

Called for any characters in the XML document for which no applicable handler has been specified. This means characters that are part of a construct which could be reported, but for which no handler has been supplied.

DefaultHandlerExpand(*data*)

This is the same as the `DefaultHandler`, but doesn't inhibit expansion of internal entities. The entity reference will not be passed to the default handler.

NotStandaloneHandler()

Called if the XML document hasn't been declared as being a standalone document. This happens when there is an external subset or a reference to a parameter entity, but the XML declaration does not set `standalone` to `yes` in an XML declaration. If this handler returns `0`, then the parser will throw an `XML_ERROR_NOT_STANDALONE` error. If this handler is not set, no exception is raised by the parser for this condition.

ExternalEntityRefHandler(*context, base, systemId, publicId*)

Called for references to external entities. *base* is the current base, as set by a previous call to `SetBase()`. The public and system identifiers, *systemId*

and *publicId*, are strings if given; if the public identifier is not given, *publicId* will be `None`. The *context* value is opaque and should only be used as described below.

For external entities to be parsed, this handler must be implemented. It is responsible for creating the sub-parser using `ExternalEntityParserCreate(context)`, initializing it with the appropriate callbacks, and parsing the entity. This handler should return an integer; if it returns `0`, the parser will throw an `XML_ERROR_EXTERNAL_ENTITY_HANDLING` error, otherwise parsing will continue.

If this handler is not provided, external entities are reported by the `DefaultHandler` callback, if provided.

13.5.2 ExpatError Exceptions

ExpatError exceptions have a number of interesting attributes:

code

Expat's internal error number for the specific error. This will match one of the constants defined in the `errors` object from this module. New in version 2.1.

lineno

Line number on which the error was detected. The first line is numbered 1. New in version 2.1.

offset

Character offset into the line where the error occurred. The first column is numbered 0. New in version 2.1.

Previous: [13.5.2 ExpatError Exceptions](#) **Up:** [13.5 xml.parsers.expat](#) **Next:**
[13.5.4 Content Model Descriptions](#)

13.5.3 Example

The following program defines three handlers that just print out their arguments.

```
import xml.parsers.expat

# 3 handler functions
def start_element(name, attrs):
    print 'Start element:', name, attrs
def end_element(name):
    print 'End element:', name
def char_data(data):
    print 'Character data:', repr(data)

p = xml.parsers.expat.ParserCreate()

p.StartElementHandler = start_element
p.EndElementHandler = end_element
p.CharacterDataHandler = char_data

p.Parse("""<?xml version="1.0"?>
<parent id="top"><child1 name="paul">Text goes here</child1>
<child2 name="fred">More text</child2>
</parent>""", 1)
```

The output from this program is:

```
Start element: parent {'id': 'top'}
Start element: child1 {'name': 'paul'}
Character data: 'Text goes here'
End element: child1
Character data: '\n'
Start element: child2 {'name': 'fred'}
Character data: 'More text'
End element: child2
Character data: '\n'
End element: parent
```

Previous: [13.5.3 Example constants](#) Up: [13.5 xml.parsers.expat](#) Next: [13.5.5 Expat error constants](#)

13.5.4 Content Model Descriptions

Content modules are described using nested tuples. Each tuple contains four values: the type, the quantifier, the name, and a tuple of children. Children are simply additional content module descriptions.

The values of the first two fields are constants defined in the `model` object of the `xml.parsers.expat` module. These constants can be collected in two groups: the model type group and the quantifier group.

The constants in the model type group are:

XML_CTYPE_ANY

The element named by the model name was declared to have a content model of ANY.

XML_CTYPE_CHOICE

The named element allows a choice from a number of options; this is used for content models such as (A | B | C).

XML_CTYPE_EMPTY

Elements which are declared to be EMPTY have this model type.

XML_CTYPE_MIXED

XML_CTYPE_NAME

XML_CTYPE_SEQ

Models which represent a series of models which follow one after the other are indicated with this model type. This is used for models such as (A, B, C).

The constants in the quantifier group are:

XML_CQUANT_NONE

No modifier is given, so it can appear exactly once, as for A.

XML_CQUANT_OPT

The model is optional: it can appear once or not at all, as for A?.

XML_CQUANT_PLUS

The model must occur one or more times (like A+).

XML_CQUANT_REP

The model must occur zero or more times, as for A*.

Previous: [13.5.4 Content Model Descriptions](#) **Up:** [13.5 xml.parsers.expat](#) **Next:** [13.6 xml.dom](#)

13.5.5 Expat error constants

The following constants are provided in the `errors` object of the [xml.parsers.expat](#) module. These constants are useful in interpreting some of the attributes of the `ExpatError` exception objects raised when an error has occurred.

The `errors` object has the following attributes:

XML_ERROR_ASYNC_ENTITY

XML_ERROR_ATTRIBUTE_EXTERNAL_ENTITY_REF

An entity reference in an attribute value referred to an external entity instead of an internal entity.

XML_ERROR_BAD_CHAR_REF

A character reference referred to a character which is illegal in XML (for example, character `0`, or `�`).

XML_ERROR_BINARY_ENTITY_REF

An entity reference referred to an entity which was declared with a notation, so cannot be parsed.

XML_ERROR_DUPLICATE_ATTRIBUTE

An attribute was used more than once in a start tag.

XML_ERROR_INCORRECT_ENCODING

XML_ERROR_INVALID_TOKEN

Raised when an input byte could not properly be assigned to a character; for example, a NUL byte (value `0`) in a UTF-8 input stream.

XML_ERROR_JUNK_AFTER_DOC_ELEMENT

Something other than whitespace occurred after the document element.

XML_ERROR_MISPLACED_XML_PI

An XML declaration was found somewhere other than the start of the input data.

XML_ERROR_NO_ELEMENTS

The document contains no elements (XML requires all documents to contain exactly one top-level element)..

XML_ERROR_NO_MEMORY

Expat was not able to allocate memory internally.

XML_ERROR_PARAM_ENTITY_REF

A parameter entity reference was found where it was not allowed.

XML_ERROR_PARTIAL_CHAR

An incomplete character was found in the input.

XML_ERROR_RECURSIVE_ENTITY_REF

An entity reference contained another reference to the same entity; possibly via a different name, and possibly indirectly.

XML_ERROR_SYNTAX

Some unspecified syntax error was encountered.

XML_ERROR_TAG_MISMATCH

An end tag did not match the innermost open start tag.

XML_ERROR_UNCLOSED_TOKEN

Some token (such as a start tag) was not closed before the end of the stream or the next token was encountered.

XML_ERROR_UNDEFINED_ENTITY

A reference was made to a entity which was not defined.

XML_ERROR_UNKNOWN_ENCODING

The document encoding is not supported by Expat.

XML_ERROR_UNCLOSED_CDATA_SECTION

A CDATA marked section was not closed.

XML_ERROR_EXTERNAL_ENTITY_HANDLING**XML_ERROR_NOT_STANDALONE**

The parser determined that the document was not ``standalone" though it

declared itself to be in the XML declaration, and the `NotStandaloneHandler` was set and returned 0.

XML_ERROR_UNEXPECTED_STATE

XML_ERROR_ENTITY_DECLARED_IN_PE

XML_ERROR_FEATURE_REQUIRES_XML_DTD

An operation was requested that requires DTD support to be compiled in, but Expat was configured without DTD support. This should never be reported by a standard build of the `xml.parsers.expat` module.

XML_ERROR_CANT_CHANGE_FEATURE_ONCE_PARSING

A behavioral change was requested after parsing started that can only be changed before parsing has started. This is (currently) only raised by `UseForeignDTD()`.

XML_ERROR_UNBOUND_PREFIX

An undeclared prefix was found when namespace processing was enabled.

XML_ERROR_UNDECLARING_PREFIX

The document attempted to remove the namespace declaration associated with a prefix.

XML_ERROR_INCOMPLETE_PE

A parameter entity contained incomplete markup.

XML_ERROR_XML_DECL

The document contained no document element at all.

XML_ERROR_TEXT_DECL

There was an error parsing a text declaration in an external entity.

XML_ERROR_PUBLICID

Characters were found in the public id that are not allowed.

XML_ERROR_SUSPENDED

The requested operation was made on a suspended parser, but isn't allowed. This includes attempts to provide additional input or to stop the parser.

XML_ERROR_NOT_SUSPENDED

An attempt to resume the parser was made when the parser had not been suspended.

XML_ERROR_ABORTED

This should not be reported to Python applications.

XML_ERROR_FINISHED

The requested operation was made on a parser which was finished parsing input, but isn't allowed. This includes attempts to provide additional input or to stop the parser.

XML_ERROR_SUSPEND_PE

Previous: [13.5.5 Expat error constants](#) **Up:** [13. Structured Markup Processing](#) **Next:** [13.6.1 Module Contents](#)

13.6 xml.dom -- The Document Object Model API

New in version 2.0.

The Document Object Model, or "DOM," is a cross-language API from the World Wide Web Consortium (W3C) for accessing and modifying XML documents. A DOM implementation presents an XML document as a tree structure, or allows client code to build such a structure from scratch. It then gives access to the structure through a set of objects which provided well-known interfaces.

The DOM is extremely useful for random-access applications. SAX only allows you a view of one bit of the document at a time. If you are looking at one SAX element, you have no access to another. If you are looking at a text node, you have no access to a containing element. When you write a SAX application, you need to keep track of your program's position in the document somewhere in your own code. SAX does not do it for you. Also, if you need to look ahead in the XML document, you are just out of luck.

Some applications are simply impossible in an event driven model with no access to a tree. Of course you could build some sort of tree yourself in SAX events, but the DOM allows you to avoid writing that code. The DOM is a standard tree representation for XML data.

The Document Object Model is being defined by the W3C in stages, or "levels" in their terminology. The Python mapping of the API is substantially based on the DOM Level 2 recommendation. The mapping of the Level 3 specification, currently only available in draft form, is being developed by the [Python XML Special Interest Group](#) as part of the [PyXML package](#). Refer to the documentation bundled with that package for information on the current state of DOM Level 3 support.

DOM applications typically start by parsing some XML into a DOM. How this is accomplished is not covered at all by DOM Level 1, and Level 2 provides only limited improvements: There is a `DOMImplementation` object class

which provides access to `Document` creation methods, but no way to access an XML reader/parser/Document builder in an implementation-independent way. There is also no well-defined way to access these methods without an existing `Document` object. In Python, each DOM implementation will provide a function `getDOMImplementation()`. DOM Level 3 adds a Load/Store specification, which defines an interface to the reader, but this is not yet available in the Python standard library.

Once you have a DOM document object, you can access the parts of your XML document through its properties and methods. These properties are defined in the DOM specification; this portion of the reference manual describes the interpretation of the specification in Python.

The specification provided by the W3C defines the DOM API for Java, ECMAScript, and OMG IDL. The Python mapping defined here is based in large part on the IDL version of the specification, but strict compliance is not required (though implementations are free to support the strict mapping from IDL). See section [13.6.3](#), "Conformance," for a detailed discussion of mapping requirements.

13.6.1 Module Contents

The `xml.dom` contains the following functions:

registerDOMImplementation(*name*, *factory*)

Register the *factory* function with the name *name*. The factory function should return an object which implements the `DOMImplementation` interface. The factory function can return the same object every time, or a new one for each call, as appropriate for the specific implementation (e.g. if that implementation supports some customization).

getDOMImplementation([*name*[, *features*]])

Return a suitable DOM implementation. The *name* is either well-known, the module name of a DOM implementation, or `None`. If it is not `None`, imports the corresponding module and returns a `DOMImplementation` object if the import succeeds. If no name is given, and if the environment variable `PYTHON_DOM` is set, this variable is used to find the implementation.

If name is not given, this examines the available implementations to find one with the required feature set. If no implementation can be found, raise an `ImportError`. The features list must be a sequence of (*feature*, *version*) pairs which are passed to the `hasFeature()` method on available `DOMImplementation` objects.

Some convenience constants are also provided:

EMPTY_NAMESPACE

The value used to indicate that no namespace is associated with a node in the DOM. This is typically found as the `namespaceURI` of a node, or used as the *namespaceURI* parameter to a namespaces-specific method. New in version 2.2.

XML_NAMESPACE

The namespace URI associated with the reserved prefix `xml`, as defined by [Namespaces in XML](#) (section 4). New in version 2.2.

XMLNS_NAMESPACE

The namespace URI for namespace declarations, as defined by [Document Object Model \(DOM\) Level 2 Core Specification](#) (section 1.1.8). New in version 2.2.

XHTML_NAMESPACE

The URI of the XHTML namespace as defined by [XHTML 1.0: The Extensible HyperText Markup Language](#) (section 3.1.1). New in version 2.2.

In addition, `xml.dom` contains a base `Node` class and the DOM exception classes. The `Node` class provided by this module does not implement any of the methods or attributes defined by the DOM specification; concrete DOM implementations must provide those. The `Node` class provided as part of this module does provide the constants used for the `nodeType` attribute on concrete `Node` objects; they are located within the class rather than at the module level to conform with the DOM specifications.

13.6.2 Objects in the DOM

The definitive documentation for the DOM is the DOM specification from the W3C.

Note that DOM attributes may also be manipulated as nodes instead of as simple strings. It is fairly rare that you must do this, however, so this usage is not yet documented.

Interface	Section	Purpose
DOMImplementation	13.6.2	Interface to the underlying implementation.
Node	13.6.2	Base interface for most objects in a document.
NodeList	13.6.2	Interface for a sequence of nodes.
DocumentType	13.6.2	Information about the declarations needed to process a document.
Document	13.6.2	Object which represents an entire document.
Element	13.6.2	Element nodes in the document hierarchy.
Attr	13.6.2	Attribute value nodes on element nodes.
Comment	13.6.2	Representation of comments in the source document.
Text	13.6.2	Nodes containing textual content from the document.
ProcessingInstruction	13.6.2	Processing instruction representation.

An additional section describes the exceptions defined for working with the DOM in Python.

13.7 xml.dom.minidom -- Lightweight DOM implementation

New in version 2.0.

`xml.dom.minidom` is a light-weight implementation of the Document Object Model interface. It is intended to be simpler than the full DOM and also significantly smaller.

DOM applications typically start by parsing some XML into a DOM. With `xml.dom.minidom`, this is done through the parse functions:

```
from xml.dom.minidom import parse, parseString

dom1 = parse('c:\\temp\\mydata.xml') # parse an XML file by name

datasource = open('c:\\temp\\mydata.xml')
dom2 = parse(datasource) # parse an open file

dom3 = parseString('<myxml>Some data<empty/> some more data</myxml>')
```

The `parse()` function can take either a filename or an open file object.

parse(*filename_or_file*, *parser*)

Return a `Document` from the given input. *filename_or_file* may be either a file name, or a file-like object. *parser*, if given, must be a SAX2 parser object. This function will change the document handler of the parser and activate namespace support; other parser configuration (like setting an entity resolver) must have been done in advance.

If you have XML in a string, you can use the `parseString()` function instead:

parseString(*string*[, *parser*])

Return a `Document` that represents the *string*. This method creates a `StringIO` object for the string and passes that on to `parse`.

Both functions return a `Document` object representing the content of the

document.

What the `parse()` and `parseString()` functions do is connect an XML parser with a "DOM builder" that can accept parse events from any SAX parser and convert them into a DOM tree. The name of the functions are perhaps misleading, but are easy to grasp when learning the interfaces. The parsing of the document will be completed before these functions return; it's simply that these functions do not provide a parser implementation themselves.

You can also create a `Document` by calling a method on a "DOM Implementation" object. You can get this object either by calling the `getDOMImplementation()` function in the `xml.dom` package or the `xml.dom.minidom` module. Using the implementation from the `xml.dom.minidom` module will always return a `Document` instance from the minidom implementation, while the version from `xml.dom` may provide an alternate implementation (this is likely if you have the `PyXML package` installed). Once you have a `Document`, you can add child nodes to it to populate the DOM:

```
from xml.dom.minidom import getDOMImplementation

impl = getDOMImplementation()

newdoc = impl.createDocument(None, "some_tag", None)
top_element = newdoc.documentElement
text = newdoc.createTextNode('Some textual content.')
top_element.appendChild(text)
```

Once you have a DOM document object, you can access the parts of your XML document through its properties and methods. These properties are defined in the DOM specification. The main property of the document object is the `documentElement` property. It gives you the main element in the XML document: the one that holds all others. Here is an example program:

```
dom3 = parseString("<myxml>Some data</myxml>")
assert dom3.documentElement.tagName == "myxml"
```

When you are finished with a DOM, you should clean it up. This is necessary because some versions of Python do not support garbage collection of objects that refer to each other in a cycle. Until this restriction is removed from all versions of Python, it is safest to write your code as if cycles would not be cleaned up.

The way to clean up a DOM is to call its `unlink()` method:

```
dom1.unlink()  
dom2.unlink()  
dom3.unlink()
```

`unlink()` is a `xml.dom.minidom`-specific extension to the DOM API. After calling `unlink()` on a node, the node and its descendants are essentially useless.

Previous: [13.7 xml.dom.minidom](#) Up: [13.7 xml.dom.minidom](#) Next: [13.7.2 DOM Example](#)

13.7.1 DOM Objects

The definition of the DOM API for Python is given as part of the [xml.dom](#) module documentation. This section lists the differences between the API and [xml.dom.minidom](#).

unlink()

Break internal references within the DOM so that it will be garbage collected on versions of Python without cyclic GC. Even when cyclic GC is available, using this can make large amounts of memory available sooner, so calling this on DOM objects as soon as they are no longer needed is good practice. This only needs to be called on the `Document` object, but may be called on child nodes to discard children of that node.

writexml(writer[,indent=""[,addindent=""[,newl=""]]])

Write XML to the writer object. The writer should have a `write()` method which matches that of the file object interface. The *indent* parameter is the indentation of the current node. The *addindent* parameter is the incremental indentation to use for subnodes of the current one. The *newl* parameter specifies the string to use to terminate newlines.

Changed in version 2.1: The optional keyword parameters *indent*, *addindent*, and *newl* were added to support pretty output.

Changed in version 2.3: For the `Document` node, an additional keyword argument *encoding* can be used to specify the encoding field of the XML header.

toxml([encoding])

Return the XML that the DOM represents as a string.

With no argument, the XML header does not specify an encoding, and the result is Unicode string if the default encoding cannot represent all characters in the document. Encoding this string in an encoding other than UTF-8 is likely incorrect, since UTF-8 is the default encoding of XML.

With an explicit *encoding* argument, the result is a byte string in the

specified encoding. It is recommended that this argument is always specified. To avoid UnicodeError exceptions in case of unrepresentable text data, the encoding argument should be specified as "utf-8".

Changed in version 2.3: the *encoding* argument was introduced.

toprettyxml([*indent*[, *newl*]])

Return a pretty-printed version of the document. *indent* specifies the indentation string and defaults to a tabulator; *newl* specifies the string emitted at the end of each line and defaults to `\n`.

New in version 2.1. Changed in version 2.3: the encoding argument; see `toxml()`.

The following standard DOM methods have special considerations with [xml.dom.minidom](#):

cloneNode(*deep*)

Although this method was present in the version of [xml.dom.minidom](#) packaged with Python 2.0, it was seriously broken. This has been corrected for subsequent releases.

13.7.2 DOM Example

This example program is a fairly realistic example of a simple program. In this particular case, we do not take much advantage of the flexibility of the DOM.

```
import xml.dom.minidom

document = """\
<slideshow>
<title>Demo slideshow</title>
<slide><title>Slide title</title>
<point>This is a demo</point>
<point>Of a program for processing slides</point>
</slide>

<slide><title>Another demo slide</title>
<point>It is important</point>
<point>To have more than</point>
<point>one slide</point>
</slide>
</slideshow>
"""

dom = xml.dom.minidom.parseString(document)

def getText(nodelist):
    rc = ""
    for node in nodelist:
        if node.nodeType == node.TEXT_NODE:
            rc = rc + node.data
    return rc

def handleSlideshow(slideshow):
    print "<html>"
    handleSlideshowTitle(slideshow.getElementsByTagName("title")[0])
    slides = slideshow.getElementsByTagName("slide")
    handleToc(slides)
    handleSlides(slides)
    print "</html>"

def handleSlides(slides):
    for slide in slides:
        handleSlide(slide)

def handleSlide(slide):
    handleSlideTitle(slide.getElementsByTagName("title")[0])
    handlePoints(slide.getElementsByTagName("point"))

def handleSlideshowTitle(title):
```

```
print "<title>%s</title>" % getText(title.childNodes)

def handleSlideTitle(title):
    print "<h2>%s</h2>" % getText(title.childNodes)

def handlePoints(points):
    print "<ul>"
    for point in points:
        handlePoint(point)
    print "</ul>"

def handlePoint(point):
    print "<li>%s</li>" % getText(point.childNodes)

def handleToc(slides):
    for slide in slides:
        title = slide.getElementsByTagName("title")[0]
        print "<p>%s</p>" % getText(title.childNodes)

handleSlideshow(dom)
```

13.7.3 minidom and the DOM standard

The `xml.dom.minidom` module is essentially a DOM 1.0-compatible DOM with some DOM 2 features (primarily namespace features).

Usage of the DOM interface in Python is straight-forward. The following mapping rules apply:

- Interfaces are accessed through instance objects. Applications should not instantiate the classes themselves; they should use the creator functions available on the `Document` object. Derived interfaces support all operations (and attributes) from the base interfaces, plus any new operations.
- Operations are used as methods. Since the DOM uses only `in` parameters, the arguments are passed in normal order (from left to right). There are no optional arguments. `void` operations return `None`.
- IDL attributes map to instance attributes. For compatibility with the OMG IDL language mapping for Python, an attribute `foo` can also be accessed through accessor methods `_get_foo()` and `_set_foo()`. `readonly` attributes must not be changed; this is not enforced at runtime.
- The types `short int`, `unsigned int`, `unsigned long long`, and `boolean` all map to Python integer objects.
- The type `DOMString` maps to Python strings. `xml.dom.minidom` supports either byte or Unicode strings, but will normally produce Unicode strings. Values of type `DOMString` may also be `None` where allowed to have the IDL `null` value by the DOM specification from the W3C.
- `const` declarations map to variables in their respective scope (e.g. `xml.dom.minidom.Node.PROCESSING_INSTRUCTION_NODE`); they must not be changed.
- `DOMException` is currently not supported in `xml.dom.minidom`. Instead, `xml.dom.minidom` uses standard Python exceptions such as

TypeError and AttributeError.

- NodeList objects are implemented using Python's built-in list type. Starting with Python 2.2, these objects provide the interface defined in the DOM specification, but with earlier versions of Python they do not support the official API. They are, however, much more ``Pythonic'' than the interface defined in the W3C recommendations.

The following interfaces have no implementation in [xml.dom.minidom](#):

- DOMTimeStamp
- DocumentType (added in Python 2.1)
- DOMImplementation (added in Python 2.1)
- CharacterData
- CDATASection
- Notation
- Entity
- EntityReference
- DocumentFragment

Most of these reflect information in the XML document that is not of general utility to most DOM users.

13.9 xml.sax -- Support for SAX2 parsers

New in version 2.0.

The `xml.sax` package provides a number of modules which implement the Simple API for XML (SAX) interface for Python. The package itself provides the SAX exceptions and the convenience functions which will be most used by users of the SAX API.

The convenience functions are:

make_parser([*parser_list*])

Create and return a SAX `XMLReader` object. The first parser found will be used. If *parser_list* is provided, it must be a sequence of strings which name modules that have a function named `create_parser()`. Modules listed in *parser_list* will be used before modules in the default list of parsers.

parse(*filename_or_stream*, *handler*[, *error_handler*])

Create a SAX parser and use it to parse a document. The document, passed in as *filename_or_stream*, can be a filename or a file object. The *handler* parameter needs to be a SAX `ContentHandler` instance. If *error_handler* is given, it must be a SAX `ErrorHandler` instance; if omitted, `SAXParseException` will be raised on all errors. There is no return value; all work must be done by the *handler* passed in.

parseString(*string*, *handler*[, *error_handler*])

Similar to `parse()`, but parses from a buffer *string* received as a parameter.

A typical SAX application uses three kinds of objects: readers, handlers and input sources. "Reader" in this context is another term for parser, i.e. some piece of code that reads the bytes or characters from the input source, and produces a sequence of events. The events then get distributed to the handler objects, i.e. the reader invokes a method on the handler. A SAX application must therefore

obtain a reader object, create or open the input sources, create the handlers, and connect these objects all together. As the final step of preparation, the reader is called to parse the input. During parsing, methods on the handler objects are called based on structural and syntactic events from the input data.

For these objects, only the interfaces are relevant; they are normally not instantiated by the application itself. Since Python does not have an explicit notion of interface, they are formally introduced as classes, but applications may use implementations which do not inherit from the provided classes. The `InputSource`, `Locator`, `Attributes`, `AttributesNS`, and `XMLReader` interfaces are defined in the module `xml.sax.xmlreader`. The handler interfaces are defined in `xml.sax.handler`. For convenience, `InputSource` (which is often instantiated directly) and the handler classes are also available from `xml.sax`. These interfaces are described below.

In addition to these classes, `xml.sax` provides the following exception classes.

exception SAXException(*msg*[, *exception*])

Encapsulate an XML error or warning. This class can contain basic error or warning information from either the XML parser or the application: it can be subclassed to provide additional functionality or to add localization. Note that although the handlers defined in the `ErrorHandler` interface receive instances of this exception, it is not required to actually raise the exception -- it is also useful as a container for information.

When instantiated, *msg* should be a human-readable description of the error. The optional *exception* parameter, if given, should be `None` or an exception that was caught by the parsing code and is being passed along as information.

This is the base class for the other SAX exception classes.

exception SAXParseException(*msg*, *exception*, *locator*)

Subclass of `SAXException` raised on parse errors. Instances of this class are passed to the methods of the `SAX ErrorHandler` interface to provide information about the parse error. This class supports the `SAX Locator` interface as well as the `SAXException` interface.

exception `SAXNotRecognizedException(msg[, exception])`

Subclass of `SAXException` raised when a `SAX XMLReader` is confronted with an unrecognized feature or property. `SAX` applications and extensions may use this class for similar purposes.

exception `SAXNotSupportedException(msg[, exception])`

Subclass of `SAXException` raised when a `SAX XMLReader` is asked to enable a feature that is not supported, or to set a property to a value that the implementation does not support. `SAX` applications and extensions may use this class for similar purposes.

13.10 `xml.sax.handler` -- Base classes for SAX handlers

New in version 2.0.

The SAX API defines four kinds of handlers: content handlers, DTD handlers, error handlers, and entity resolvers. Applications normally only need to implement those interfaces whose events they are interested in; they can implement the interfaces in a single object or in multiple objects. Handler implementations should inherit from the base classes provided in the module `xml.sax.handler`, so that all methods get default implementations.

class ContentHandler

This is the main callback interface in SAX, and the one most important to applications. The order of events in this interface mirrors the order of the information in the document.

class DTDHandler

Handle DTD events.

This interface specifies only those DTD events required for basic parsing (unparsed entities and attributes).

class EntityResolver

Basic interface for resolving entities. If you create an object implementing this interface, then register the object with your Parser, the parser will call the method in your object to resolve all external entities.

class ErrorHandler

Interface used by the parser to present error and warning messages to the application. The methods of this object control whether errors are immediately converted to exceptions or are handled in some other way.

In addition to these classes, `xml.sax.handler` provides symbolic constants for the feature and property names.

feature_namespaces

Value: "http://xml.org/sax/features/namespaces"

true: Perform Namespace processing.

false: Optionally do not perform Namespace processing (implies namespace-prefixes; default).

access: (parsing) read-only; (not parsing) read/write

feature_namespace_prefixes

Value: "http://xml.org/sax/features/namespace-prefixes"

true: Report the original prefixed names and attributes used for Namespace declarations.

false: Do not report attributes used for Namespace declarations, and optionally do not report original prefixed names (default).

access: (parsing) read-only; (not parsing) read/write

feature_string_interning

Value: "http://xml.org/sax/features/string-interning"

true: All element names, prefixes, attribute names, Namespace URIs, and local names are interned using the built-in intern function.

false: Names are not necessarily interned, although they may be (default).

access: (parsing) read-only; (not parsing) read/write

feature_validation

Value: "http://xml.org/sax/features/validation"

true: Report all validation errors (implies external-general-entities and external-parameter-entities).

false: Do not report validation errors.

access: (parsing) read-only; (not parsing) read/write

feature_external_ges

Value: "http://xml.org/sax/features/external-general-entities"

true: Include all external general (text) entities.

false: Do not include external general entities.

access: (parsing) read-only; (not parsing) read/write

feature_external_pes

Value: "http://xml.org/sax/features/external-

`parameter-entities"`

true: Include all external parameter entities, including the external DTD subset.

false: Do not include any external parameter entities, even the external DTD subset.

access: (parsing) read-only; (not parsing) read/write

all_features

List of all features.

property_lexical_handler

Value: `"http://xml.org/sax/properties/lexical-handler"`

data type: `xml.sax.sax2lib.LexicalHandler` (not supported in Python 2)

description: An optional extension handler for lexical events like comments.

access: read/write

property_declaration_handler

Value: `"http://xml.org/sax/properties/declaration-handler"`

data type: `xml.sax.sax2lib.DeclHandler` (not supported in Python 2)

description: An optional extension handler for DTD-related events other than notations and unparsed entities.

access: read/write

property_dom_node

Value: `"http://xml.org/sax/properties/dom-node"`

data type: `org.w3c.dom.Node` (not supported in Python 2)

description: When parsing, the current DOM node being visited if this is a DOM iterator; when not parsing, the root DOM node for iteration.

access: (parsing) read-only; (not parsing) read/write

property_xml_string

Value: `"http://xml.org/sax/properties/xml-string"`

data type: `String`

description: The literal string of characters that was the source for the current event.

access: read-only

all_properties

List of all known property names.

13.10.1 ContentHandler Objects

Users are expected to subclass `ContentHandler` to support their application. The following methods are called by the parser on the appropriate events in the input document:

setDocumentLocator(*locator*)

Called by the parser to give the application a locator for locating the origin of document events.

SAX parsers are strongly encouraged (though not absolutely required) to supply a locator: if it does so, it must supply the locator to the application by invoking this method before invoking any of the other methods in the `DocumentHandler` interface.

The locator allows the application to determine the end position of any document-related event, even if the parser is not reporting an error. Typically, the application will use this information for reporting its own errors (such as character content that does not match an application's business rules). The information returned by the locator is probably not sufficient for use with a search engine.

Note that the locator will return correct information only during the invocation of the events in this interface. The application should not attempt to use it at any other time.

startDocument()

Receive notification of the beginning of a document.

The SAX parser will invoke this method only once, before any other methods in this interface or in `DTDHandler` (except for `setDocumentLocator` ()).

endDocument()

Receive notification of the end of a document.

The SAX parser will invoke this method only once, and it will be the last

method invoked during the parse. The parser shall not invoke this method until it has either abandoned parsing (because of an unrecoverable error) or reached the end of input.

startPrefixMapping(*prefix*, *uri*)

Begin the scope of a prefix-URI Namespace mapping.

The information from this event is not necessary for normal Namespace processing: the SAX XML reader will automatically replace prefixes for element and attribute names when the `feature_namespaces` feature is enabled (the default).

There are cases, however, when applications need to use prefixes in character data or in attribute values, where they cannot safely be expanded automatically; the `startPrefixMapping()` and `endPrefixMapping()` events supply the information to the application to expand prefixes in those contexts itself, if necessary.

Note that `startPrefixMapping()` and `endPrefixMapping()` events are not guaranteed to be properly nested relative to each-other: all `startPrefixMapping()` events will occur before the corresponding `startElement()` event, and all `endPrefixMapping()` events will occur after the corresponding `endElement()` event, but their order is not guaranteed.

endPrefixMapping(*prefix*)

End the scope of a prefix-URI mapping.

See `startPrefixMapping()` for details. This event will always occur after the corresponding `endElement()` event, but the order of `endPrefixMapping()` events is not otherwise guaranteed.

startElement(*name*, *attrs*)

Signals the start of an element in non-namespace mode.

The *name* parameter contains the raw XML 1.0 name of the element type as a string and the *attrs* parameter holds an object of the [Attributes interface](#) containing the attributes of the element. The object passed as *attrs*

may be re-used by the parser; holding on to a reference to it is not a reliable way to keep a copy of the attributes. To keep a copy of the attributes, use the `copy()` method of the `attrs` object.

endElement(*name*)

Signals the end of an element in non-namespace mode.

The *name* parameter contains the name of the element type, just as with the `startElement()` event.

startElementNS(*name*, *qname*, *attrs*)

Signals the start of an element in namespace mode.

The *name* parameter contains the name of the element type as a (*uri*, *localname*) tuple, the *qname* parameter contains the raw XML 1.0 name used in the source document, and the *attrs* parameter holds an instance of the [AttributesNS interface](#) containing the attributes of the element. If no namespace is associated with the element, the *uri* component of *name* will be `None`. The object passed as *attrs* may be re-used by the parser; holding on to a reference to it is not a reliable way to keep a copy of the attributes. To keep a copy of the attributes, use the `copy()` method of the *attrs* object.

Parsers may set the *qname* parameter to `None`, unless the `feature_namespace_prefixes` feature is activated.

endElementNS(*name*, *qname*)

Signals the end of an element in namespace mode.

The *name* parameter contains the name of the element type, just as with the `startElementNS()` method, likewise the *qname* parameter.

characters(*content*)

Receive notification of character data.

The Parser will call this method to report each chunk of character data. SAX parsers may return all contiguous character data in a single chunk, or they may split it into several chunks; however, all of the characters in any

single event must come from the same external entity so that the Locator provides useful information.

content may be a Unicode string or a byte string; the `expat` reader module produces always Unicode strings.

Note: The earlier SAX 1 interface provided by the Python XML Special Interest Group used a more Java-like interface for this method. Since most parsers used from Python did not take advantage of the older interface, the simpler signature was chosen to replace it. To convert old code to the new interface, use *content* instead of slicing *content* with the old *offset* and *length* parameters.

ignorableWhitespace(*whitespace*)

Receive notification of ignorable whitespace in element content.

Validating Parsers must use this method to report each chunk of ignorable whitespace (see the W3C XML 1.0 recommendation, section 2.10): non-validating parsers may also use this method if they are capable of parsing and using content models.

SAX parsers may return all contiguous whitespace in a single chunk, or they may split it into several chunks; however, all of the characters in any single event must come from the same external entity, so that the Locator provides useful information.

processingInstruction(*target*, *data*)

Receive notification of a processing instruction.

The Parser will invoke this method once for each processing instruction found: note that processing instructions may occur before or after the main document element.

A SAX parser should never report an XML declaration (XML 1.0, section 2.8) or a text declaration (XML 1.0, section 4.3.1) using this method.

skippedEntity(*name*)

Receive notification of a skipped entity.

The Parser will invoke this method once for each entity skipped. Non-validating processors may skip entities if they have not seen the declarations (because, for example, the entity was declared in an external DTD subset). All processors may skip external entities, depending on the values of the `feature_external_ges` and the `feature_external_pes` properties.

13.10.3 EntityResolver Objects

resolveEntity(*publicId*, *systemId*)

Resolve the system identifier of an entity and return either the system identifier to read from as a string, or an `InputSource` to read from. The default implementation returns *systemId*.

[13.11 xml.sax.saxutils](#)

13.10.4 ErrorHandler Objects

Objects with this interface are used to receive error and warning information from the `XMLReader`. If you create an object that implements this interface, then register the object with your `XMLReader`, the parser will call the methods in your object to report all warnings and errors. There are three levels of errors available: warnings, (possibly) recoverable errors, and unrecoverable errors. All methods take a `SAXParseException` as the only parameter. Errors and warnings may be converted to an exception by raising the passed-in exception object.

error(*exception*)

Called when the parser encounters a recoverable error. If this method does not raise an exception, parsing may continue, but further document information should not be expected by the application. Allowing the parser to continue may allow additional errors to be discovered in the input document.

fatalError(*exception*)

Called when the parser encounters an error it cannot recover from; parsing is expected to terminate when this method returns.

warning(*exception*)

Called when the parser presents minor warning information to the application. Parsing is expected to continue when this method returns, and document information will continue to be passed to the application. Raising an exception in this method will cause parsing to end.

13.11 `xml.sax.saxutils` -- SAX Utilities

New in version 2.0.

The module `xml.sax.saxutils` contains a number of classes and functions that are commonly useful when creating SAX applications, either in direct use, or as base classes.

escape(*data* [, *entities*])

Escape "&", "<", and ">" in a string of data.

You can escape other strings of data by passing a dictionary as the optional *entities* parameter. The keys and values must all be strings; each key will be replaced with its corresponding value.

unescape(*data* [, *entities*])

Unescape "&"; "<"; and ">"; in a string of data.

You can unescape other strings of data by passing a dictionary as the optional *entities* parameter. The keys and values must all be strings; each key will be replaced with its corresponding value.

New in version 2.3.

quoteattr(*data* [, *entities*])

Similar to `escape()`, but also prepares *data* to be used as an attribute value. The return value is a quoted version of *data* with any additional required replacements. `quoteattr()` will select a quote character based on the content of *data*, attempting to avoid encoding any quote characters in the string. If both single- and double-quote characters are already in *data*, the double-quote characters will be encoded and *data* will be wrapped in double-quotes. The resulting string can be used directly as an attribute value:

```
>>> print "<element attr=%s>" % quoteattr("ab ' cd \" ef")
<element attr="ab ' cd &quot; ef">
```

This function is useful when generating attribute values for HTML or any SGML using the reference concrete syntax. New in version 2.2.

class XMLGenerator([out[, encoding]])

This class implements the `ContentHandler` interface by writing SAX events back into an XML document. In other words, using an `XMLGenerator` as the content handler will reproduce the original document being parsed. *out* should be a file-like object which will default to `sys.stdout`. *encoding* is the encoding of the output stream which defaults to `'iso-8859-1'`.

class XMLFilterBase(base)

This class is designed to sit between an `XMLReader` and the client application's event handlers. By default, it does nothing but pass requests up to the reader and events on to the handlers unmodified, but subclasses can override specific methods to modify the event stream or the configuration requests as they pass through.

prepare_input_source(source[, base])

This function takes an input source and an optional base URL and returns a fully resolved `InputSource` object ready for reading. The input source can be given as a string, a file-like object, or an `InputSource` object; parsers will use this function to implement the polymorphic *source* argument to their `parse()` method.

Previous: [13.11 xml.sax.saxutils](#) **Up:** [13. Structured Markup Processing](#) **Next:** [13.12.1 XMLReader Objects](#)

13.12 xml.sax.xmlreader -- Interface for XML parsers

New in version 2.0.

SAX parsers implement the XMLReader interface. They are implemented in a Python module, which must provide a function `create_parser()`. This function is invoked by `xml.sax.make_parser()` with no arguments to create a new parser object.

class XMLReader()

Base class which can be inherited by SAX parsers.

class IncrementalParser()

In some cases, it is desirable not to parse an input source at once, but to feed chunks of the document as they get available. Note that the reader will normally not read the entire file, but read it in chunks as well; still `parse()` won't return until the entire document is processed. So these interfaces should be used if the blocking behaviour of `parse()` is not desirable.

When the parser is instantiated it is ready to begin accepting data from the feed method immediately. After parsing has been finished with a call to close the reset method must be called to make the parser ready to accept new data, either from feed or using the parse method.

Note that these methods must *not* be called during parsing, that is, after parse has been called and before it returns.

By default, the class also implements the parse method of the XMLReader interface using the feed, close and reset methods of the IncrementalParser interface as a convenience to SAX 2.0 driver writers.

class Locator()

Interface for associating a SAX event with a document location. A locator

object will return valid results only during calls to `DocumentHandler` methods; at any other time, the results are unpredictable. If information is not available, methods may return `None`.

class `InputSource`([*systemId*])

Encapsulation of the information needed by the `XMLReader` to read entities.

This class may include information about the public identifier, system identifier, byte stream (possibly with character encoding information) and/or the character stream of an entity.

Applications will create objects of this class for use in the `XMLReader.parse()` method and for returning from `EntityResolver.resolveEntity`.

An `InputSource` belongs to the application, the `XMLReader` is not allowed to modify `InputSource` objects passed to it from the application, although it may make copies and modify those.

class `AttributesImpl`(*attrs*)

This is an implementation of the [Attributes interface](#) (see section [13.12.5](#)). This is a dictionary-like object which represents the element attributes in a `startElement()` call. In addition to the most useful dictionary operations, it supports a number of other methods as described by the interface. Objects of this class should be instantiated by readers; *attrs* must be a dictionary-like object containing a mapping from attribute names to attribute values.

class `AttributesNSImpl`(*attrs*, *qnames*)

Namespace-aware variant of `AttributesImpl`, which will be passed to `startElementNS()`. It is derived from `AttributesImpl`, but understands attribute names as two-tuples of *namespaceURI* and *localname*. In addition, it provides a number of methods expecting qualified names as they appear in the original document. This class implements the [AttributesNS interface](#) (see section [13.12.6](#)).

See [About this document...](#) for information on suggesting changes.

Previous: [13.12 xml.sax.xmlreader](#) Up: [13.12 xml.sax.xmlreader](#) Next: [13.12.2 IncrementalParser Objects](#)

13.12.1 XMLReader Objects

The XMLReader interface supports the following methods:

parse(*source*)

Process an input source, producing SAX events. The *source* object can be a system identifier (a string identifying the input source - typically a file name or an URL), a file-like object, or an `InputStream` object. When `parse()` returns, the input is completely processed, and the parser object can be discarded or reset. As a limitation, the current implementation only accepts byte streams; processing of character streams is for further study.

getContentHandler()

Return the current `ContentHandler`.

setContentHandler(*handler*)

Set the current `ContentHandler`. If no `ContentHandler` is set, content events will be discarded.

getDTDHandler()

Return the current `DTDHandler`.

setDTDHandler(*handler*)

Set the current `DTDHandler`. If no `DTDHandler` is set, DTD events will be discarded.

getEntityResolver()

Return the current `EntityResolver`.

setEntityResolver(*handler*)

Set the current `EntityResolver`. If no `EntityResolver` is set, attempts to resolve an external entity will result in opening the system identifier for the entity, and fail if it is not available.

getErrorHandler()

Return the current `ErrorHandler`.

setErrorHandler(*handler*)

Set the current error handler. If no `ErrorHandler` is set, errors will be raised as exceptions, and warnings will be printed.

setLocale(*locale*)

Allow an application to set the locale for errors and warnings.

SAX parsers are not required to provide localization for errors and warnings; if they cannot support the requested locale, however, they must throw a SAX exception. Applications may request a locale change in the middle of a parse.

getFeature(*featurename*)

Return the current setting for feature *featurename*. If the feature is not recognized, `SAXNotRecognizedException` is raised. The well-known featurenames are listed in the module `xml.sax.handler`.

setFeature(*featurename*, *value*)

Set the *featurename* to *value*. If the feature is not recognized, `SAXNotRecognizedException` is raised. If the feature or its setting is not supported by the parser, `SAXNotSupportedException` is raised.

getProperty(*propertyname*)

Return the current setting for property *propertyname*. If the property is not recognized, a `SAXNotRecognizedException` is raised. The well-known propertynames are listed in the module `xml.sax.handler`.

setProperty(*propertyname*, *value*)

Set the *propertyname* to *value*. If the property is not recognized, `SAXNotRecognizedException` is raised. If the property or its setting is not supported by the parser, `SAXNotSupportedException` is raised.

[IncrementalParser Objects](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.

[13.12.3 Locator Objects](#)

13.12.2 IncrementalParser Objects

Instances of `IncrementalParser` offer the following additional methods:

feed(*data*)

Process a chunk of *data*.

close()

Assume the end of the document. That will check well-formedness conditions that can be checked only at the end, invoke handlers, and may clean up resources allocated during parsing.

reset()

This method is called after `close` has been called to reset the parser so that it is ready to parse new documents. The results of calling `parse` or `feed` after `close` without calling `reset` are undefined.

Previous: [13.12.1 XMLReader Objects](#) Up: [13.12 xml.sax.xmlreader](#) Next: [13.12.3 Locator Objects](#)

Next: [13.12.4 InputSource Objects](#)

13.12.3 Locator Objects

Instances of `Locator` provide these methods:

`getColumnNumber()`

Return the column number where the current event ends.

`getLineNumber()`

Return the line number where the current event ends.

`getPublicId()`

Return the public identifier for the current event.

`getSystemId()`

Return the system identifier for the current event.

Next: [13.12.4 InputSource Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

Previous: [13.12.3 Locator Objects](#) **Up:** [13.12 xml.sax.xmlreader](#) **Next:** [13.12.5 The Attributes Interface](#)

13.12.4 InputSource Objects

setPublicId(*id*)

Sets the public identifier of this `InputSource`.

getPublicId()

Returns the public identifier of this `InputSource`.

setSystemId(*id*)

Sets the system identifier of this `InputSource`.

getSystemId()

Returns the system identifier of this `InputSource`.

setEncoding(*encoding*)

Sets the character encoding of this `InputSource`.

The encoding must be a string acceptable for an XML encoding declaration (see section 4.3.3 of the XML recommendation).

The encoding attribute of the `InputSource` is ignored if the `InputSource` also contains a character stream.

getEncoding()

Get the character encoding of this `InputSource`.

setByteStream(*bytefile*)

Set the byte stream (a Python file-like object which does not perform byte-to-character conversion) for this input source.

The SAX parser will ignore this if there is also a character stream specified, but it will use a byte stream in preference to opening a URI connection itself.

If the application knows the character encoding of the byte stream, it should set it with the `setEncoding` method.

getByteStream()

Get the byte stream for this input source.

The `getEncoding` method will return the character encoding for this byte stream, or `None` if unknown.

setCharacterStream(*charfile*)

Set the character stream for this input source. (The stream must be a Python 1.6 Unicode-wrapped file-like that performs conversion to Unicode strings.)

If there is a character stream specified, the SAX parser will ignore any byte stream and will not attempt to open a URI connection to the system identifier.

getCharacterStream()

Get the character stream for this input source.

Previous: [13.12.3 Locator Objects](#) Up: [13.12 xml.sax.xmlreader](#) Next: [13.12.5 The Attributes Interface](#)

[13.12.6 The AttributesNS Interface](#)

13.12.5 The Attributes Interface

`Attributes` objects implement a portion of the mapping protocol, including the methods `copy()`, `get()`, `has_key()`, `items()`, `keys()`, and `values()`. The following methods are also provided:

`getLength()`

Return the number of attributes.

`getNames()`

Return the names of the attributes.

`getType(name)`

Returns the type of the attribute *name*, which is normally 'CDATA'.

`getValue(name)`

Return the value of attribute *name*.

Previous: [13.12.5 The Attributes Interface](#) **Up:** [13.12 xml.sax.xmlreader](#) **Next:** [13.13 xmlilib](#)

13.12.6 The AttributesNS Interface

This interface is a subtype of the [Attributes interface](#) (see section [13.12.5](#)). All methods supported by that interface are also available on `AttributesNS` objects.

The following methods are also available:

getValueByQName(*name*)

Return the value for a qualified name.

getNameByQName(*name*)

Return the (*namespace*, *localname*) pair for a qualified name.

getQNameByName(*name*)

Return the qualified name for a (*namespace*, *localname*) pair.

getQNames()

Return the qualified names of all attributes.

Previous: [13.12.6 The AttributesNS Interface Processing](#) **Up:** [13. Structured Markup](#)
Next: [13.13.1 XML Namespaces](#)

13.13 xmlLib -- A parser for XML documents

Deprecated since release 2.0. Use [xml.sax](#) instead. The newer XML package includes full support for XML 1.0.

Changed in version 1.5.2: Added namespace support.

This module defines a class `XMLParser` which serves as the basis for parsing text files formatted in XML (Extensible Markup Language).

class XMLParser()

The `XMLParser` class must be instantiated without arguments. [13.1](#)

This class provides the following interface methods and instance variables:

attributes

A mapping of element names to mappings. The latter mapping maps attribute names that are valid for the element to the default value of the attribute, or if there is no default to `NONE`. The default value is the empty dictionary. This variable is meant to be overridden, not extended since the default is shared by all instances of `XMLParser`.

elements

A mapping of element names to tuples. The tuples contain a function for handling the start and end tag respectively of the element, or `NONE` if the method `unknown_starttag()` or `unknown_endtag()` is to be called. The default value is the empty dictionary. This variable is meant to be overridden, not extended since the default is shared by all instances of `XMLParser`.

entitydefs

A mapping of entitynames to their values. The default value contains definitions for `'lt'`, `'gt'`, `'amp'`, `'quot'`, and `'apos'`.

reset()

Reset the instance. Loses all unprocessed data. This is called implicitly at the instantiation time.

setnomoretags()

Stop processing tags. Treat all following input as literal input (CDATA).

setliteral()

Enter literal mode (CDATA mode). This mode is automatically exited when the close tag matching the last unclosed open tag is encountered.

feed(*data*)

Feed some text to the parser. It is processed insofar as it consists of complete tags; incomplete data is buffered until more data is fed or `close()` is called.

close()

Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call `close()`.

translate_references(*data*)

Translate all entity and character references in *data* and return the translated string.

getnamespace()

Return a mapping of namespace abbreviations to namespace URIs that are currently in effect.

handle_xml(*encoding, standalone*)

This method is called when the "`<?xml . . . ?>`" tag is processed. The arguments are the values of the encoding and standalone attributes in the tag. Both encoding and standalone are optional. The values passed to `handle_xml()` default to `NONE` and the string `'no'` respectively.

handle_doctype(*tag, pubid, syslit, data*)

This method is called when the "`<!DOCTYPE . . . >`" declaration is

processed. The arguments are the tag name of the root element, the Formal Public Identifier (or `NONE` if not specified), the system identifier, and the uninterpreted contents of the internal DTD subset as a string (or `NONE` if not present).

handle_starttag(*tag*, *method*, *attributes*)

This method is called to handle start tags for which a start tag handler is defined in the instance variable `elements`. The *tag* argument is the name of the tag, and the *method* argument is the function (method) which should be used to support semantic interpretation of the start tag. The *attributes* argument is a dictionary of attributes, the key being the *name* and the value being the *value* of the attribute found inside the tag's `<>` brackets. Character and entity references in the *value* have been interpreted. For instance, for the start tag ``, this method would be called as `handle_starttag('A', self.elements['A'][0], {'HREF': 'http://www.cwi.nl/'})`. The base implementation simply calls *method* with *attributes* as the only argument.

handle_endtag(*tag*, *method*)

This method is called to handle endtags for which an end tag handler is defined in the instance variable `elements`. The *tag* argument is the name of the tag, and the *method* argument is the function (method) which should be used to support semantic interpretation of the end tag. For instance, for the endtag ``, this method would be called as `handle_endtag('A', self.elements['A'][1])`. The base implementation simply calls *method*.

handle_data(*data*)

This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

handle_charref(*ref*)

This method is called to process a character reference of the form `"&#ref;"`. *ref* can either be a decimal number, or a hexadecimal number when preceded by an `"x"`. In the base implementation, *ref* must be a number in the range 0-255. It translates the character to ASCII and calls the method `handle_data()` with the character as argument. If *ref* is invalid or out of

range, the method `unknown_charref(ref)` is called to handle the error. A subclass must override this method to provide support for character references outside of the ASCII range.

handle_comment(*comment*)

This method is called when a comment is encountered. The *comment* argument is a string containing the text between the "`<!--`" and "`-->`" delimiters, but not the delimiters themselves. For example, the comment "`<!-- text -->`" will cause this method to be called with the argument `'text'`. The default method does nothing.

handle_cdata(*data*)

This method is called when a CDATA element is encountered. The *data* argument is a string containing the text between the "`<![CDATA["` and "`]]>`" delimiters, but not the delimiters themselves. For example, the entity "`<![CDATA[text]]>`" will cause this method to be called with the argument `'text'`. The default method does nothing, and is intended to be overridden.

handle_proc(*name*, *data*)

This method is called when a processing instruction (PI) is encountered. The *name* is the PI target, and the *data* argument is a string containing the text between the PI target and the closing delimiter, but not the delimiter itself. For example, the instruction "`<?XML text?>`" will cause this method to be called with the arguments `'XML'` and `'text'`. The default method does nothing. Note that if a document starts with "`<?xml . . ?>`", `handle_xml()` is called to handle it.

handle_special(*data*)

This method is called when a declaration is encountered. The *data* argument is a string containing the text between the "`<!`" and "`>`" delimiters, but not the delimiters themselves. For example, the entity declaration "`<!ENTITY text>`" will cause this method to be called with the argument `'ENTITY text'`. The default method does nothing. Note that "`<!DOCTYPE . . .>`" is handled separately if it is located at the start of the document.

syntax_error(*message*)

This method is called when a syntax error is encountered. The *message* is a description of what was wrong. The default method raises a `RuntimeError` exception. If this method is overridden, it is permissible for it to return. This method is only called when the error can be recovered from. Unrecoverable errors raise a `RuntimeError` without first calling `syntax_error()`.

unknown_starttag(*tag*, *attributes*)

This method is called to process an unknown start tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

unknown_endtag(*tag*)

This method is called to process an unknown end tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

unknown_charref(*ref*)

This method is called to process unresolvable numeric character references. It is intended to be overridden by a derived class; the base class implementation does nothing.

unknown_entityref(*ref*)

This method is called to process an unknown entity reference. It is intended to be overridden by a derived class; the base class implementation calls `syntax_error()` to signal an error.

13.13.1 XML Namespaces

This module has support for XML namespaces as defined in the XML Namespaces proposed recommendation.

Tag and attribute names that are defined in an XML namespace are handled as if the name of the tag or element consisted of the namespace (the URL that defines the namespace) followed by a space and the name of the tag or attribute. For instance, the tag `<html xmlns='http://www.w3.org/TR/REC-html40'>` is treated as if the tag name was `'http://www.w3.org/TR/REC-html40 html'`, and the tag `<html:a href='http://frob.com'>` inside the above mentioned element is treated as if the tag name were `'http://www.w3.org/TR/REC-html40 a'` and the attribute name as if it were `'http://www.w3.org/TR/REC-html40 href'`.

An older draft of the XML Namespaces proposal is also recognized, but triggers a warning.

14. Multimedia Services

The modules described in this chapter implement various algorithms or interfaces that are mainly useful for multimedia applications. They are available at the discretion of the installation. Here's an overview:

audioop	Manipulate raw audio data.
imageop	Manipulate raw image data.
aifc	Read and write audio files in AIFF or AIFC format.
sunau	Provide an interface to the Sun AU sound format.
wave	Provide an interface to the WAV sound format.
chunk	Module to read IFF chunks.
colorsys	Conversion functions between RGB and other color systems.
rgbimg	Read and write image files in ``SGI RGB" format (the module is <i>not</i> SGI specific though!).
imghdr	Determine the type of image contained in a file or byte stream.
sndhdr	Determine type of a sound file.
ossaudiodev	Access to OSS-compatible audio devices.

Previous: [14. Multimedia Services](#) Up: [14. Multimedia Services](#) Next: [14.2 imageop](#)

14.1 `audioop` -- Manipulate raw audio data

The `audioop` module contains some useful operations on sound fragments. It operates on sound fragments consisting of signed integer samples 8, 16 or 32 bits wide, stored in Python strings. This is the same format as used by the [`al`](#) and [`sunaudioev`](#) modules. All scalar items are integers, unless specified otherwise.

This module provides support for u-LAW and Intel/DVI ADPCM encodings.

A few of the more complicated operations only take 16-bit samples, otherwise the sample size (in bytes) is always a parameter of the operation.

The module defines the following variables and functions:

exception error

This exception is raised on all errors, such as unknown number of bytes per sample, etc.

`add(fragment1, fragment2, width)`

Return a fragment which is the addition of the two samples passed as parameters. *width* is the sample width in bytes, either 1, 2 or 4. Both fragments should have the same length.

`adpcm2lin(adpcmfragment, width, state)`

Decode an Intel/DVI ADPCM coded fragment to a linear fragment. See the description of `lin2adpcm()` for details on ADPCM coding. Return a tuple (*sample*, *newstate*) where the sample has the width specified in *width*.

`adpcm32lin(adpcmfragment, width, state)`

Decode an alternative 3-bit ADPCM code. See `lin2adpcm3()` for details.

avg(*fragment*, *width*)

Return the average over all samples in the fragment.

avgpp(*fragment*, *width*)

Return the average peak-peak value over all samples in the fragment. No filtering is done, so the usefulness of this routine is questionable.

bias(*fragment*, *width*, *bias*)

Return a fragment that is the original fragment with a bias added to each sample.

cross(*fragment*, *width*)

Return the number of zero crossings in the fragment passed as an argument.

findfactor(*fragment*, *reference*)

Return a factor F such that `rms(add(fragment, mul(reference, - F)))` is minimal, i.e., return the factor with which you should multiply *reference* to make it match as well as possible to *fragment*. The fragments should both contain 2-byte samples.

The time taken by this routine is proportional to `len(fragment)`.

findfit(*fragment*, *reference*)

Try to match *reference* as well as possible to a portion of *fragment* (which should be the longer fragment). This is (conceptually) done by taking slices out of *fragment*, using `findfactor()` to compute the best match, and minimizing the result. The fragments should both contain 2-byte samples. Return a tuple (*offset*, *factor*) where *offset* is the (integer) offset into *fragment* where the optimal match started and *factor* is the (floating-point) factor as per `findfactor()`.

findmax(*fragment*, *length*)

Search *fragment* for a slice of length *length* samples (not bytes!) with maximum energy, i.e., return i for which `rms(fragment[$i*2$: ($i+length$)*2])` is maximal. The fragments should both contain 2-byte samples.

The routine takes time proportional to `len(fragment)`.

getsample(*fragment*, *width*, *index*)

Return the value of sample *index* from the fragment.

lin2lin(*fragment*, *width*, *newwidth*)

Convert samples between 1-, 2- and 4-byte formats.

lin2adpcm(*fragment*, *width*, *state*)

Convert samples to 4 bit Intel/DVI ADPCM encoding. ADPCM coding is an adaptive coding scheme, whereby each 4 bit number is the difference between one sample and the next, divided by a (varying) step. The Intel/DVI ADPCM algorithm has been selected for use by the IMA, so it may well become a standard.

state is a tuple containing the state of the coder. The coder returns a tuple (*adpcmfrag*, *newstate*), and the *newstate* should be passed to the next call of `lin2adpcm()`. In the initial call, `None` can be passed as the state. *adpcmfrag* is the ADPCM coded fragment packed 2 4-bit values per byte.

lin2adpcm3(*fragment*, *width*, *state*)

This is an alternative ADPCM coder that uses only 3 bits per sample. It is not compatible with the Intel/DVI ADPCM coder and its output is not packed (due to laziness on the side of the author). Its use is discouraged.

lin2ulaw(*fragment*, *width*)

Convert samples in the audio fragment to u-LAW encoding and return this as a Python string. u-LAW is an audio encoding format whereby you get a dynamic range of about 14 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

minmax(*fragment*, *width*)

Return a tuple consisting of the minimum and maximum values of all samples in the sound fragment.

max(*fragment*, *width*)

Return the maximum of the *absolute value* of all samples in a fragment.

maxpp(*fragment*, *width*)

Return the maximum peak-peak value in the sound fragment.

mul(*fragment*, *width*, *factor*)

Return a fragment that has all samples in the original fragment multiplied by the floating-point value *factor*. Overflow is silently ignored.

ratecv(*fragment*, *width*, *nchannels*, *inrate*, *outrate*, *state*[, *weightA*[,
weightB]])

Convert the frame rate of the input fragment.

state is a tuple containing the state of the converter. The converter returns a tuple (*newfragment*, *newstate*), and *newstate* should be passed to the next call of `ratecv()`. The initial call should pass `None` as the state.

The *weightA* and *weightB* arguments are parameters for a simple digital filter and default to `1` and `0` respectively.

reverse(*fragment*, *width*)

Reverse the samples in a fragment and returns the modified fragment.

rms(*fragment*, *width*)

Return the root-mean-square of the fragment, i.e.

This is a measure of the power in an audio signal.

tomono(*fragment*, *width*, *lfactor*, *rfactor*)

Convert a stereo fragment to a mono fragment. The left channel is multiplied by *lfactor* and the right channel by *rfactor* before adding the two channels to give a mono signal.

tostereo(*fragment*, *width*, *lfactor*, *rfactor*)

Generate a stereo fragment from a mono fragment. Each pair of samples in the stereo fragment are computed from the mono sample, whereby left channel samples are multiplied by *lfactor* and right channel samples by

rfactor.

ulaw2lin(*fragment*, *width*)

Convert sound fragments in u-LAW encoding to linearly encoded sound fragments. u-LAW encoding always uses 8 bits samples, so *width* refers only to the sample width of the output fragment here.

Note that operations such as `mul()` or `max()` make no distinction between mono and stereo fragments, i.e. all samples are treated equal. If this is a problem the stereo fragment should be split into two mono fragments first and recombined later. Here is an example of how to do that:

```
def mul_stereo(sample, width, lfactor, rfactor):
    lsample = audioop.tomono(sample, width, 1, 0)
    rsample = audioop.tomono(sample, width, 0, 1)
    lsample = audioop.mul(sample, width, lfactor)
    rsample = audioop.mul(sample, width, rfactor)
    lsample = audioop.tostereo(lsample, width, 1, 0)
    rsample = audioop.tostereo(rsample, width, 0, 1)
    return audioop.add(lsample, rsample, width)
```

If you use the ADPCM coder to build network packets and you want your protocol to be stateless (i.e. to be able to tolerate packet loss) you should not only transmit the data but also the state. Note that you should send the *initial* state (the one you passed to `lin2adpcm()`) along to the decoder, not the final state (as returned by the coder). If you want to use `struct.struct()` to store the state in binary you can code the first element (the predicted value) in 16 bits and the second (the delta index) in 8.

The ADPCM coders have never been tried against other ADPCM coders, only against themselves. It could well be that I misinterpreted the standards in which case they will not be interoperable with the respective standards.

The `find*` routines might look a bit funny at first sight. They are primarily meant to do echo cancellation. A reasonably fast way to do this is to pick the most energetic piece of the output sample, locate that in the input sample and subtract the whole output sample from the input sample:

```
def echocancel(outputdata, inputdata):
    pos = audioop.findmax(outputdata, 800) # one tenth second
    out_test = outputdata[pos*2:]
    in_test = inputdata[pos*2:]
```

```
ipos, factor = audioop.findfit(in_test, out_test)
# Optional (for better cancellation):
# factor = audioop.findfactor(in_test[ipos*2:ipos*2+len(out_test
# out_test)
prefill = '\0'*(pos+ipos)*2
postfill = '\0'*(len(inputdata)-len(prefill)-len(outputdata))
outputdata = prefill + audioop.mul(outputdata,2,-factor) + postf
return audioop.add(inputdata, outputdata, 2)
```

14.2 `imageop` -- Manipulate raw image data

The `imageop` module contains some useful operations on images. It operates on images consisting of 8 or 32 bit pixels stored in Python strings. This is the same format as used by `gl.rectwrite()` and the [imgfile](#) module.

The module defines the following variables and functions:

exception error

This exception is raised on all errors, such as unknown number of bits per pixel, etc.

crop(*image*, *psize*, *width*, *height*, *x0*, *y0*, *x1*, *y1*)

Return the selected part of *image*, which should be *width* by *height* in size and consist of pixels of *psize* bytes. *x0*, *y0*, *x1* and *y1* are like the `gl.rectread()` parameters, i.e. the boundary is included in the new image. The new boundaries need not be inside the picture. Pixels that fall outside the old image will have their value set to zero. If *x0* is bigger than *x1* the new image is mirrored. The same holds for the *y* coordinates.

scale(*image*, *psize*, *width*, *height*, *newwidth*, *newheight*)

Return *image* scaled to size *newwidth* by *newheight*. No interpolation is done, scaling is done by simple-minded pixel duplication or removal. Therefore, computer-generated images or dithered images will not look nice after scaling.

tovideo(*image*, *psize*, *width*, *height*)

Run a vertical low-pass filter over an image. It does so by computing each destination pixel as the average of two vertically-aligned source pixels. The main use of this routine is to forestall excessive flicker if the image is displayed on a video device that uses interlacing, hence the name.

grey2mono(*image*, *width*, *height*, *threshold*)

Convert a 8-bit deep greyscale image to a 1-bit deep image by thresholding

all the pixels. The resulting image is tightly packed and is probably only useful as an argument to `mono2grey()`.

dither2mono(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 1-bit monochrome image using a (simple-minded) dithering algorithm.

mono2grey(*image*, *width*, *height*, *p0*, *p1*)

Convert a 1-bit monochrome image to an 8 bit greyscale or color image. All pixels that are zero-valued on input get value *p0* on output and all one-value input pixels get value *p1* on output. To convert a monochrome black-and-white image to greyscale pass the values 0 and 255 respectively.

grey2grey4(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 4-bit greyscale image without dithering.

grey2grey2(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 2-bit greyscale image without dithering.

dither2grey2(*image*, *width*, *height*)

Convert an 8-bit greyscale image to a 2-bit greyscale image with dithering. As for `dither2mono()`, the dithering algorithm is currently very simple.

grey42grey(*image*, *width*, *height*)

Convert a 4-bit greyscale image to an 8-bit greyscale image.

grey22grey(*image*, *width*, *height*)

Convert a 2-bit greyscale image to an 8-bit greyscale image.

backward_compatible

If set to 0, the functions in this module use a non-backward compatible way of representing multi-byte pixels on little-endian systems. The SGI for which this module was originally written is a big-endian system, so setting this variable will have no effect. However, the code wasn't originally intended to run on anything else, so it made assumptions about byte order

which are not universal. Setting this variable to 0 will cause the byte order to be reversed on little-endian systems, so that it then is the same as on big-endian systems.

14.3 `aifc` -- Read and write AIFF and AIFC files

This module provides support for reading and writing AIFF and AIFF-C files. AIFF is Audio Interchange File Format, a format for storing digital audio samples in a file. AIFF-C is a newer version of the format that includes the ability to compress the audio data.

Caveat: Some operations may only work under IRIX; these will raise `ImportError` when attempting to import the `c1` module, which is only available on IRIX.

Audio files have a number of parameters that describe the audio data. The sampling rate or frame rate is the number of times per second the sound is sampled. The number of channels indicate if the audio is mono, stereo, or quadro. Each frame consists of one sample per channel. The sample size is the size in bytes of each sample. Thus a frame consists of $nchannels * samplesize$ bytes, and a second's worth of audio consists of $nchannels * samplesize * framerate$ bytes.

For example, CD quality audio has a sample size of two bytes (16 bits), uses two channels (stereo) and has a frame rate of 44,100 frames/second. This gives a frame size of 4 bytes ($2 * 2$), and a second's worth occupies $2 * 2 * 44100$ bytes (176,400 bytes).

Module `aifc` defines the following function:

`open(file[, mode]`)

Open an AIFF or AIFF-C file and return an object instance with methods that are described below. The argument *file* is either a string naming a file or a file object. *mode* must be `'r'` or `'rb'` when the file must be opened for reading, or `'w'` or `'wb'` when the file must be opened for writing. If omitted, *file . mode* is used if it exists, otherwise `'rb'` is used. When used for writing, the file object should be seekable, unless you know ahead of time how many samples you are going to write in total and use

`writewframesraw()` and `setnframes()`.

Objects returned by `open()` when a file is opened for reading have the following methods:

`getnchannels()`

Return the number of audio channels (1 for mono, 2 for stereo).

`getsampwidth()`

Return the size in bytes of individual samples.

`getframerate()`

Return the sampling rate (number of audio frames per second).

`getnframes()`

Return the number of audio frames in the file.

`getcomptype()`

Return a four-character string describing the type of compression used in the audio file. For AIFF files, the returned value is 'NONE'.

`getcompname()`

Return a human-readable description of the type of compression used in the audio file. For AIFF files, the returned value is 'not compressed'.

`getparams()`

Return a tuple consisting of all of the above values in the above order.

`getmarkers()`

Return a list of markers in the audio file. A marker consists of a tuple of three elements. The first is the mark ID (an integer), the second is the mark position in frames from the beginning of the data (an integer), the third is the name of the mark (a string).

`getmark(id)`

Return the tuple as described in `getmarkers()` for the mark with the given *id*.

readframes(*nframes*)

Read and return the next *nframes* frames from the audio file. The returned data is a string containing for each frame the uncompressed samples of all channels.

rewind()

Rewind the read pointer. The next `readframes()` will start from the beginning.

setpos(*pos*)

Seek to the specified frame number.

tell()

Return the current frame number.

close()

Close the AIFF file. After calling this method, the object can no longer be used.

Objects returned by `open()` when a file is opened for writing have all the above methods, except for `readframes()` and `setpos()`. In addition the following methods exist. The `get*()` methods can only be called after the corresponding `set*()` methods have been called. Before the first `writeframes()` or `writeframesraw()`, all parameters except for the number of frames must be filled in.

aiff()

Create an AIFF file. The default is that an AIFF-C file is created, unless the name of the file ends in `'.aiff'` in which case the default is an AIFF file.

aifc()

Create an AIFF-C file. The default is that an AIFF-C file is created, unless the name of the file ends in `'.aiff'` in which case the default is an AIFF file.

setnchannels(*nchannels*)

Specify the number of channels in the audio file.

setsampwidth(*width*)

Specify the size in bytes of audio samples.

setframerate(*rate*)

Specify the sampling frequency in frames per second.

setnframes(*nframes*)

Specify the number of frames that are to be written to the audio file. If this parameter is not set, or not set correctly, the file needs to support seeking.

setcomptype(*type, name*)

Specify the compression type. If not specified, the audio data will not be compressed. In AIFF files, compression is not possible. The name parameter should be a human-readable description of the compression type, the type parameter should be a four-character string. Currently the following compression types are supported: NONE, ULAW, ALAW, G722.

setparams(*nchannels, sampwidth, framerate, comptype, compname*)

Set all the above parameters at once. The argument is a tuple consisting of the various parameters. This means that it is possible to use the result of a `getparams()` call as argument to `setparams()`.

setmark(*id, pos, name*)

Add a mark with the given id (larger than 0), and the given name at the given position. This method can be called at any time before `close()`.

tell()

Return the current write position in the output file. Useful in combination with `setmark()`.

writeframes(*data*)

Write data to the output file. This method can only be called after the audio file parameters have been set.

writeframesraw(*data*)

Like `writeframes()`, except that the header of the audio file is not updated.

close()

Close the AIFF file. The header of the file is updated to reflect the actual size of the audio data. After calling this method, the object can no longer be used.

14.4 sunau -- Read and write Sun AU files

The `sunau` module provides a convenient interface to the Sun AU sound format. Note that this module is interface-compatible with the modules [aifc](#) and [wave](#).

An audio file consists of a header followed by the data. The fields of the header are:

Field	Contents
magic word	The four bytes ".snd".
header size	Size of the header, including info, in bytes.
data size	Physical size of the data, in bytes.
encoding	Indicates how the audio samples are encoded.
sample rate	The sampling rate.
# of channels	The number of channels in the samples.
info	ASCII string giving a description of the audio file (padded with null bytes).

Apart from the `info` field, all header fields are 4 bytes in size. They are all 32-bit unsigned integers encoded in big-endian byte order.

The `sunau` module defines the following functions:

open(*file*, *mode*)

If *file* is a string, open the file by that name, otherwise treat it as a seekable file-like object. *mode* can be any of

'r'

Read only mode.

'w'

Write only mode.

Note that it does not allow read/write files.

A *mode* of 'r' returns a `AU_read` object, while a *mode* of 'w' or 'wb' returns a `AU_write` object.

openfp(*file, mode*)

A synonym for `open`, maintained for backwards compatibility.

The `sunau` module defines the following exception:

exception Error

An error raised when something is impossible because of Sun AU specs or implementation deficiency.

The `sunau` module defines the following data items:

AUDIO_FILE_MAGIC

An integer every valid Sun AU file begins with, stored in big-endian form. This is the string ".snd" interpreted as an integer.

AUDIO_FILE_ENCODING_MULAW_8

AUDIO_FILE_ENCODING_LINEAR_8

AUDIO_FILE_ENCODING_LINEAR_16

AUDIO_FILE_ENCODING_LINEAR_24

AUDIO_FILE_ENCODING_LINEAR_32

AUDIO_FILE_ENCODING_ALAW_8

Values of the encoding field from the AU header which are supported by this module.

AUDIO_FILE_ENCODING_FLOAT

AUDIO_FILE_ENCODING_DOUBLE

AUDIO_FILE_ENCODING_ADPCM_G721

AUDIO_FILE_ENCODING_ADPCM_G722

AUDIO_FILE_ENCODING_ADPCM_G723_3

AUDIO_FILE_ENCODING_ADPCM_G723_5

Additional known values of the encoding field from the AU header, but which are not supported by this module.

14.4.1 AU_read Objects

AU_read objects, as returned by `open()` above, have the following methods:

close()

Close the stream, and make the instance unusable. (This is called automatically on deletion.)

getnchannels()

Returns number of audio channels (1 for mono, 2 for stereo).

getsampwidth()

Returns sample width in bytes.

getframerate()

Returns sampling frequency.

getnframes()

Returns number of audio frames.

getcomptype()

Returns compression type. Supported compression types are 'ULAW', 'ALAW' and 'NONE'.

getcompname()

Human-readable version of `getcomptype()`. The supported types have the respective names 'CCITT G.711 u-law', 'CCITT G.711 A-law' and 'not compressed'.

getparams()

Returns a tuple (*nchannels*, *sampwidth*, *framerate*, *nframes*, *comptype*, *compname*), equivalent to output of the `get*()` methods.

readframes(*n*)

Reads and returns at most *n* frames of audio, as a string of bytes. The data

will be returned in linear format. If the original data is in u-LAW format, it will be converted.

rewind()

Rewind the file pointer to the beginning of the audio stream.

The following two methods define a term "position" which is compatible between them, and is otherwise implementation dependent.

setpos(*pos*)

Set the file pointer to the specified position. Only values returned from `tell()` should be used for *pos*.

tell()

Return current file pointer position. Note that the returned value has nothing to do with the actual position in the file.

The following two functions are defined for compatibility with the [aifc](#), and don't do anything interesting.

getmarkers()

Returns None.

getmark(*id*)

Raise an error.

Previous: [14.4.1 AU_read Objects](#) Up: [14.4 sunau](#) Next: [14.5 wave](#)

14.4.2 AU_write Objects

AU_write objects, as returned by `open()` above, have the following methods:

setnchannels(*n*)

Set the number of channels.

setsampwidth(*n*)

Set the sample width (in bytes.)

setframerate(*n*)

Set the frame rate.

setnframes(*n*)

Set the number of frames. This can be later changed, when and if more frames are written.

setcomptype(*type, name*)

Set the compression type and description. Only 'NONE' and 'ULAW' are supported on output.

setparams(*tuple*)

The *tuple* should be (*nchannels*, *sampwidth*, *framerate*, *nframes*, *comptype*, *compname*), with values valid for the `set*()` methods. Set all parameters.

tell()

Return current position in the file, with the same disclaimer for the `AU_read.tell()` and `AU_read.setpos()` methods.

writeframesraw(*data*)

Write audio frames, without correcting *nframes*.

writeframes(*data*)

Write audio frames and make sure *nframes* is correct.

close()

Make sure *nframes* is correct, and close the file.

This method is called upon deletion.

Note that it is invalid to set any parameters after calling `writeframes()` or `writeframesraw()`.

14.5 wave -- Read and write WAV files

The `wave` module provides a convenient interface to the WAV sound format. It does not support compression/decompression, but it does support mono/stereo.

The `wave` module defines the following function and exception:

open(*file* [, *mode*])

If *file* is a string, open the file by that name, other treat it as a seekable file-like object. *mode* can be any of

'r', 'rb'

Read only mode.

'w', 'wb'

Write only mode.

Note that it does not allow read/write WAV files.

A *mode* of 'r' or 'rb' returns a `Wave_read` object, while a *mode* of 'w' or 'wb' returns a `Wave_write` object. If *mode* is omitted and a file-like object is passed as *file*, *file.mode* is used as the default value for *mode* (the "b" flag is still added if necessary).

openfp(*file*, *mode*)

A synonym for `open()`, maintained for backwards compatibility.

exception Error

An error raised when something is impossible because it violates the WAV specification or hits an implementation deficiency.

14.5.1 Wave_read Objects

Wave_read objects, as returned by `open()`, have the following methods:

close()

Close the stream, and make the instance unusable. This is called automatically on object collection.

getnchannels()

Returns number of audio channels (1 for mono, 2 for stereo).

getsampwidth()

Returns sample width in bytes.

getframerate()

Returns sampling frequency.

getnframes()

Returns number of audio frames.

getcomptype()

Returns compression type ('NONE' is the only supported type).

getcompname()

Human-readable version of `getcomptype()`. Usually 'not compressed' parallels 'NONE'.

getparams()

Returns a tuple (*nchannels*, *sampwidth*, *framerate*, *nframes*, *comptype*, *compname*), equivalent to output of the `get*()` methods.

readframes(*n*)

Reads and returns at most *n* frames of audio, as a string of bytes.

rewind()

Rewind the file pointer to the beginning of the audio stream.

The following two methods are defined for compatibility with the [aifc](#) module, and don't do anything interesting.

getmarkers()

Returns None.

getmark(*id*)

Raise an error.

The following two methods define a term "position" which is compatible between them, and is otherwise implementation dependent.

setpos(*pos*)

Set the file pointer to the specified position.

tell()

Return current file pointer position.

14.5.2 Wave_write Objects

Wave_write objects, as returned by `open()`, have the following methods:

close()

Make sure *nframes* is correct, and close the file. This method is called upon deletion.

setnchannels(*n*)

Set the number of channels.

setsampwidth(*n*)

Set the sample width to *n* bytes.

setframerate(*n*)

Set the frame rate to *n*.

setnframes(*n*)

Set the number of frames to *n*. This will be changed later if more frames are written.

setcomptype(*type*, *name*)

Set the compression type and description.

setparams(*tuple*)

The *tuple* should be (*nchannels*, *sampwidth*, *framerate*, *nframes*, *comptype*, *compname*), with values valid for the `set*()` methods. Sets all parameters.

tell()

Return current position in the file, with the same disclaimer for the `wave_read.tell()` and `wave_read.setpos()` methods.

writeframesraw(*data*)

Write audio frames, without correcting *nframes*.

`writeframes(data)`

Write audio frames and make sure *nframes* is correct.

Note that it is invalid to set any parameters after calling `writeframes()` or `writeframesraw()`, and any attempt to do so will raise `wave.Error`.

14.6 chunk -- Read IFF chunked data

This module provides an interface for reading files that use EA IFF 85 chunks. [14.1](#) This format is used in at least the Audio Interchange File Format (AIFF/AIFF-C) and the Real Media File Format (RMFF). The WAVE audio file format is closely related and can also be read using this module.

A chunk has the following structure:

Offset	Length	Contents
0	4	Chunk ID
4	4	Size of chunk in big-endian byte order, not including the header
8	n	Data bytes, where n is the size given in the preceding field
$8 + n$	0 or 1	Pad byte needed if n is odd and chunk alignment is used

The ID is a 4-byte string which identifies the type of chunk.

The size field (a 32-bit value, encoded using big-endian byte order) gives the size of the chunk data, not including the 8-byte header.

Usually an IFF-type file consists of one or more chunks. The proposed usage of the `Chunk` class defined here is to instantiate an instance at the start of each chunk and read from the instance until it reaches the end, after which a new instance can be instantiated. At the end of the file, creating a new instance will fail with a `EOFError` exception.

class `Chunk`(*file*[, *align*, *bigendian*, *inclheader*])

Class which represents a chunk. The *file* argument is expected to be a file-like object. An instance of this class is specifically allowed. The only method that is needed is `read()`. If the methods `seek()` and `tell()` are present and don't raise an exception, they are also used. If these methods are present and raise an exception, they are expected to not have altered the object. If the optional argument *align* is true, chunks are assumed to be aligned on 2-byte boundaries. If *align* is false, no alignment is assumed. The default value is true. If the optional argument *bigendian* is false, the

chunk size is assumed to be in little-endian order. This is needed for WAVE audio files. The default value is true. If the optional argument *inclheader* is true, the size given in the chunk header includes the size of the header. The default value is false.

A `Chunk` object supports the following methods:

getname()

Returns the name (ID) of the chunk. This is the first 4 bytes of the chunk.

getsize()

Returns the size of the chunk.

close()

Close and skip to the end of the chunk. This does not close the underlying file.

The remaining methods will raise `IOError` if called after the `close()` method has been called.

isatty()

Returns `False`.

seek(*pos* [, *whence*])

Set the chunk's current position. The *whence* argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file's end). There is no return value. If the underlying file does not allow seek, only forward seeks are allowed.

tell()

Return the current position into the chunk.

read([*size*])

Read at most *size* bytes from the chunk (less if the read hits the end of the chunk before obtaining *size* bytes). If the *size* argument is negative or omitted, read all data until the end of the chunk. The bytes are returned as a

string object. An empty string is returned when the end of the chunk is encountered immediately.

skip()

Skip to the end of the chunk. All further calls to `read()` for the chunk will return `''`. If you are not interested in the contents of the chunk, this method should be called so that the file points to the start of the next chunk.

Footnotes

... chunks. [14.1](#)

14.7 colorsys -- Conversions between color systems

The `colorsys` module defines bidirectional conversions of color values between colors expressed in the RGB (Red Green Blue) color space used in computer monitors and three other coordinate systems: YIQ, HLS (Hue Lightness Saturation) and HSV (Hue Saturation Value). Coordinates in all of these color spaces are floating point values. In the YIQ space, the Y coordinate is between 0 and 1, but the I and Q coordinates can be positive or negative. In all other spaces, the coordinates are all between 0 and 1.

More information about color spaces can be found at <http://www.poynton.com/ColorFAQ.html>.

The `colorsys` module defines the following functions:

rgb_to_yiq(*r, g, b*)

Convert the color from RGB coordinates to YIQ coordinates.

yi_q_to_rgb(*y, i, q*)

Convert the color from YIQ coordinates to RGB coordinates.

rgb_to_hls(*r, g, b*)

Convert the color from RGB coordinates to HLS coordinates.

hls_to_rgb(*h, l, s*)

Convert the color from HLS coordinates to RGB coordinates.

rgb_to_hsv(*r, g, b*)

Convert the color from RGB coordinates to HSV coordinates.

hsv_to_rgb(*h, s, v*)

Convert the color from HSV coordinates to RGB coordinates.

Example:

```
>>> import colorsys
>>> colorsys.rgb_to_hsv(.3, .4, .2)
(0.25, 0.5, 0.4)
>>> colorsys.hsv_to_rgb(0.25, 0.5, 0.4)
(0.3, 0.4, 0.2)
```

14.8 `rgbimg` -- Read and write ``SGI RGB'' files

The `rgbimg` module allows Python programs to access SGI `imglib` image files (also known as `.rgb` files). The module is far from complete, but is provided anyway since the functionality that there is enough in some cases. Currently, colormap files are not supported.

Note: This module is only built by default for 32-bit platforms; it is not expected to work properly on other systems.

The module defines the following variables and functions:

exception error

This exception is raised on all errors, such as unsupported file type, etc.

sizeofimage(*file*)

This function returns a tuple (x, y) where x and y are the size of the image in pixels. Only 4 byte RGBA pixels, 3 byte RGB pixels, and 1 byte greyscale pixels are currently supported.

longimagedata(*file*)

This function reads and decodes the image on the specified file, and returns it as a Python string. The string has 4 byte RGBA pixels. The bottom left pixel is the first in the string. This format is suitable to pass to `gl.glRectwrite()`, for instance.

longstoimage(*data*, *x*, *y*, *z*, *file*)

This function writes the RGBA data in *data* to image file *file*. *x* and *y* give the size of the image. *z* is 1 if the saved image should be 1 byte greyscale, 3 if the saved image should be 3 byte RGB data, or 4 if the saved images should be 4 byte RGBA data. The input data always contains 4 bytes per pixel. These are the formats returned by `gl.glRectread()`.

ttob(*flag*)

This function sets a global flag which defines whether the scan lines of the image are read or written from bottom to top (flag is zero, compatible with SGI GL) or from top to bottom(flag is one, compatible with X). The default is zero.

14.9 `imghdr` -- Determine the type of an image

The `imghdr` module determines the type of image contained in a file or byte stream.

The `imghdr` module defines the following function:

what(*filename*[, *h*])

Tests the image data contained in the file named by *filename*, and returns a string describing the image type. If optional *h* is provided, the *filename* is ignored and *h* is assumed to contain the byte stream to test.

The following image types are recognized, as listed below with the return value from `what()`:

Value	Image format
'rgb'	SGI ImgLib Files
'gif'	GIF 87a and 89a Files
'pbm'	Portable Bitmap Files
'pgm'	Portable Graymap Files
'ppm'	Portable Pixmap Files
'tiff'	TIFF Files
'rast'	Sun Raster Files
'xbm'	X Bitmap Files
'jpeg'	JPEG data in JFIF format
'bmp'	BMP files
'png'	Portable Network Graphics

You can extend the list of file types `imghdr` can recognize by appending to this variable:

tests

A list of functions performing the individual tests. Each function takes two

arguments: the byte-stream and an open file-like object. When `what ()` is called with a byte-stream, the file-like object will be `None`.

The test function should return a string describing the image type if the test succeeded, or `None` if it failed.

Example:

```
>>> import imghdr
>>> imghdr.what('/tmp/bass.gif')
'gif'
```

14.10 sndhdr -- Determine type of sound file

The `sndhdr` provides utility functions which attempt to determine the type of sound data which is in a file. When these functions are able to determine what type of sound data is stored in a file, they return a tuple (*type*, *sampling_rate*, *channels*, *frames*, *bits_per_sample*). The value for *type* indicates the data type and will be one of the strings 'aifc', 'aiff', 'au', 'hcom', 'sndr', 'sndt', 'voc', 'wav', '8svx', 'sb', 'ub', or 'ul'. The *sampling_rate* will be either the actual value or 0 if unknown or difficult to decode. Similarly, *channels* will be either the number of channels or 0 if it cannot be determined or if the value is difficult to decode. The value for *frames* will be either the number of frames or -1. The last item in the tuple, *bits_per_sample*, will either be the sample size in bits or 'A' for A-LAW or 'U' for u-LAW.

what(*filename*)

Determines the type of sound data stored in the file *filename* using `whathdr()`. If it succeeds, returns a tuple as described above, otherwise `None` is returned.

whathdr(*filename*)

Determines the type of sound data stored in a file based on the file header. The name of the file is given by *filename*. This function returns a tuple as described above on success, or `None`.

Previous: [14.10 sndhdr](#) Up: [14. Multimedia Services](#) Next: [14.11.1 Audio Device Objects](#)

14.11 ossaudiodev -- Access to OSS-compatible audio devices

Availability: **Linux, FreeBSD.**

New in version 2.3.

This module allows you to access the OSS (Open Sound System) audio interface. OSS is available for a wide range of open-source and commercial Unices, and is the standard audio interface for Linux and recent versions of FreeBSD.

See Also:

[Open Sound System Programmer's Guide](#)

the official documentation for the OSS C API

The module defines a large number of constants supplied by the OSS device driver; see `<sys/soundcard.h>` on either Linux or FreeBSD for a listing .

`ossaudiodev` defines the following variables and functions:

exception `OSSAudioError`

This exception is raised on certain errors. The argument is a string describing what went wrong.

(If `ossaudiodev` receives an error from a system call such as `open()`, `write()`, or `ioctl()`, it raises `IOError`. Errors detected directly by `ossaudiodev` result in `OSSAudioError`.)

(For backwards compatibility, the exception class is also available as `ossaudiodev.error`.)

open([*device*,]*mode*)

Open an audio device and return an OSS audio device object. This object supports many file-like methods, such as `read()`, `write()`, and `fileno()` (although there are subtle differences between conventional Unix read/write semantics and those of OSS audio devices). It also supports a number of audio-specific methods; see below for the complete list of methods.

device is the audio device filename to use. If it is not specified, this module first looks in the environment variable `AUDIODEV` for a device to use. If not found, it falls back to `/dev/dsp`.

mode is one of 'r' for read-only (record) access, 'w' for write-only (playback) access and 'rw' for both. Since many sound cards only allow one process to have the recorder or player open at a time, it is a good idea to open the device only for the activity needed. Further, some sound cards are half-duplex: they can be opened for reading or writing, but not both at once.

Note the unusual calling syntax: the *first* argument is optional, and the second is required. This is a historical artifact for compatibility with the older `linuxaudiodev` module which `ossaudiodev` supersedes.

openmixer([*device*])

Open a mixer device and return an OSS mixer device object. *device* is the mixer device filename to use. If it is not specified, this module first looks in the environment variable `MIXERDEV` for a device to use. If not found, it falls back to `/dev/mixer`.

Previous: [14.11 ossaudiodev](#) **Up:** [14.11 ossaudiodev](#) **Next:** [14.11.2 Mixer](#)
[Device Objects](#)

14.11.1 Audio Device Objects

Before you can write to or read from an audio device, you must call three methods in the correct order:

1. `setfmt()` to set the output format
2. `channels()` to set the number of channels
3. `speed()` to set the sample rate

Alternately, you can use the `setparameters()` method to set all three audio parameters at once. This is more convenient, but may not be as flexible in all cases.

The audio device objects returned by `open()` define the following methods:

close()

Explicitly close the audio device. When you are done writing to or reading from an audio device, you should explicitly close it. A closed device cannot be used again.

fileno()

Return the file descriptor associated with the device.

read(*size*)

Read *size* bytes from the audio input and return them as a Python string. Unlike most UNIX device drivers, OSS audio devices in blocking mode (the default) will block `read()` until the entire requested amount of data is available.

write(*data*)

Write the Python string *data* to the audio device and return the number of bytes written. If the audio device is in blocking mode (the default), the entire string is always written (again, this is different from usual UNIX device semantics). If the device is in non-blocking mode, some data may not be written--see `writeall()`.

data)

writeall()

Write the entire Python string *data* to the audio device: waits until the audio device is able to accept data, writes as much data as it will accept, and repeats until *data* has been completely written. If the device is in blocking mode (the default), this has the same effect as `write()`; `writeall()` is only useful in non-blocking mode. Has no return value, since the amount of data written is always equal to the amount of data supplied.

The following methods each map to exactly one `ioctl()` system call. The correspondence is obvious: for example, `setfmt()` corresponds to the `SNDCTL_DSP_SETFMT` `ioctl`, and `sync()` to `SNDCTL_DSP_SYNC` (this can be useful when consulting the OSS documentation). If the underlying `ioctl()` fails, they all raise `IOError`.

nonblock()

Put the device into non-blocking mode. Once in non-blocking mode, there is no way to return it to blocking mode.

getfmts()

Return a bitmask of the audio output formats supported by the soundcard. Some of the formats supported by OSS are:

Format	Description
<code>AFMT_MU_LAW</code>	a logarithmic encoding (used by Sun <code>.au</code> files and <code>/dev/audio</code>)
<code>AFMT_A_LAW</code>	a logarithmic encoding
<code>AFMT_IMA_ADPCM</code>	a 4:1 compressed format defined by the Interactive Multimedia Association
<code>AFMT_U8</code>	Unsigned, 8-bit audio
<code>AFMT_S16_LE</code>	Signed, 16-bit audio, little-endian byte order (as used by Intel processors)
<code>AFMT_S16_BE</code>	Signed, 16-bit audio, big-endian byte order (as used by 68k, PowerPC, Sparc)
<code>AFMT_S8</code>	Signed, 8 bit audio
<code>AFMT_U16_LE</code>	Unsigned, 16-bit little-endian audio
<code>AFMT_U16_BE</code>	Unsigned, 16-bit big-endian audio

Consult the OSS documentation for a full list of audio formats, and note

that most devices support only a subset of these formats. Some older devices only support AFMT_U8; the most common format used today is AFMT_S16_LE.

setfmt(*format*)

Try to set the current audio format to *format*--see `getfmts()` for a list. Returns the audio format that the device was set to, which may not be the requested format. May also be used to return the current audio format--do this by passing an "audio format" of AFMT_QUERY.

channels(*nchannels*)

Set the number of output channels to *nchannels*. A value of 1 indicates monophonic sound, 2 stereophonic. Some devices may have more than 2 channels, and some high-end devices may not support mono. Returns the number of channels the device was set to.

speed(*samplerate*)

Try to set the audio sampling rate to *samplerate* samples per second. Returns the rate actually set. Most sound devices don't support arbitrary sampling rates. Common rates are:

Rate	Description
8000	default rate for /dev/audio
11025	speech recording
22050	
44100	CD quality audio (at 16 bits/sample and 2 channels)
96000	DVD quality audio (at 24 bits/sample)

sync()

Wait until the sound device has played every byte in its buffer. (This happens implicitly when the device is closed.) The OSS documentation recommends closing and re-opening the device rather than using `sync()`.

reset()

Immediately stop playing or recording and return the device to a state where it can accept commands. The OSS documentation recommends closing and re-opening the device after calling `reset()`.

post()

Tell the driver that there is likely to be a pause in the output, making it possible for the device to handle the pause more intelligently. You might use this after playing a spot sound effect, before waiting for user input, or before doing disk I/O.

The following convenience methods combine several ioctls, or one ioctl and some simple calculations.

setparameters(*format*, *nchannels*, *samplerate* [, *strict=False*])

Set the key audio sampling parameters--sample format, number of channels, and sampling rate--in one method call. *format*, *nchannels*, and *samplerate* should be as specified in the `setfmt()`, `channels()`, and `speed()` methods. If *strict* is true, `setparameters()` checks to see if each parameter was actually set to the requested value, and raises `OSSAudioError` if not. Returns a tuple (*format*, *nchannels*, *samplerate*) indicating the parameter values that were actually set by the device driver (i.e., the same as the return values of `setfmt()`, `channels()`, and `speed()`).

For example,

```
(fmt, channels, rate) = dsp.setparameters(fmt, channels, rate)
```

is equivalent to

```
fmt = dsp.setfmt(fmt)
channels = dsp.channels(channels)
rate = dsp.rate(channels)
```

bufsize()

Returns the size of the hardware buffer, in samples.

obufcount()

Returns the number of samples that are in the hardware buffer yet to be played.

obuffree()

Returns the number of samples that could be queued into the hardware

buffer to be played without blocking.

14.11.2 Mixer Device Objects

The mixer object provides two file-like methods:

close()

This method closes the open mixer device file. Any further attempts to use the mixer after this file is closed will raise an IOError.

fileno()

Returns the file handle number of the open mixer device file.

The remaining methods are specific to audio mixing:

controls()

This method returns a bitmask specifying the available mixer controls ("Control" being a specific mixable "channel", such as SOUND_MIXER_PCM or SOUND_MIXER_SYNTH). This bitmask indicates a subset of all available mixer controls--the SOUND_MIXER_* constants defined at module level. To determine if, for example, the current mixer object supports a PCM mixer, use the following Python code:

```
mixer=ossaudiodev.openmixer()
if mixer.controls() & (1 << ossaudiodev.SOUND_MIXER_PCM):
    # PCM is supported
    ... code ...
```

For most purposes, the SOUND_MIXER_VOLUME (master volume) and SOUND_MIXER_PCM controls should suffice--but code that uses the mixer should be flexible when it comes to choosing mixer controls. On the Gravis Ultrasound, for example, SOUND_MIXER_VOLUME does not exist.

stereocontrols()

Returns a bitmask indicating stereo mixer controls. If a bit is set, the corresponding control is stereo; if it is unset, the control is either monophonic or not supported by the mixer (use in combination with controls() to determine which).

See the code example for the controls() function for an example of

getting data from a bitmask.

reccontrols()

Returns a bitmask specifying the mixer controls that may be used to record. See the code example for `controls()` for an example of reading from a bitmask.

get(*control*)

Returns the volume of a given mixer control. The returned volume is a 2-tuple (`left_volume`, `right_volume`). Volumes are specified as numbers from 0 (silent) to 100 (full volume). If the control is monophonic, a 2-tuple is still returned, but both volumes are the same.

Raises `OSSAudioError` if an invalid control was is specified, or `IOError` if an unsupported control is specified.

set(*control*, (*left*, *right*))

Sets the volume for a given mixer control to (`left`, `right`). `left` and `right` must be ints and between 0 (silent) and 100 (full volume). On success, the new volume is returned as a 2-tuple. Note that this may not be exactly the same as the volume specified, because of the limited resolution of some soundcard's mixers.

Raises `OSSAudioError` if an invalid mixer control was specified, or if the specified volumes were out-of-range.

get_recsrc()

This method returns a bitmask indicating which control(s) are currently being used as a recording source.

set_recsrc(*bitmask*)

Call this function to specify a recording source. Returns a bitmask indicating the new recording source (or sources) if successful; raises `IOError` if an invalid source was specified. To set the current recording source to the microphone input:

```
mixer.setrecsrc (1 << ossaudiodev.SOUND_MIXER_MIC)
```

Previous: [14.11.2 Mixer Device Objects](#) **Up:** [Python Library Reference](#) **Next:** [15.1 hmac](#)

15. Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. Here's an overview:

- [hmac](#) Keyed-Hashing for Message Authentication (HMAC) implementation for Python.
- [md5](#) RSA's MD5 message digest algorithm.
- [sha](#) NIST's secure hash algorithm, SHA.

Hardcore cypherpunks will probably find the cryptographic modules written by A.M. Kuchling of further interest; the package adds built-in modules for DES and IDEA encryption, provides a Python module for reading and decrypting PGP files, and then some. These modules are not distributed with Python but available separately. See the URL <http://www.amk.ca/python/code/crypto.html> for more information.

Previous: [15. Cryptographic Services](#) Up: [15. Cryptographic Services](#) Next:
[15.2 md5](#)

15.1 hmac -- Keyed-Hashing for Message Authentication

New in version 2.2.

This module implements the HMAC algorithm as described by [RFC 2104](#).

new(*key*[, *msg*[, *digestmod*]])

Return a new hmac object. If *msg* is present, the method call `update(msg)` is made. *digestmod* is the digest module for the HMAC object to use. It defaults to the [md5](#) module.

An HMAC object has the following methods:

update(*msg*)

Update the hmac object with the string *msg*. Repeated calls are equivalent to a single call with the concatenation of all the arguments:
`m.update(a); m.update(b)` is equivalent to `m.update(a + b)`.

digest()

Return the digest of the strings passed to the `update()` method so far. This is a 16-byte string (for [md5](#)) or a 20-byte string (for [sha](#)) which may contain non-ASCII characters, including NUL bytes.

hexdigest()

Like `digest()` except the digest is returned as a string of length 32 for [md5](#) (40 for [sha](#)), containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

copy()

Return a copy ("clone") of the hmac object. This can be used to efficiently compute the digests of strings that share a common initial substring.

15.2 md5 -- MD5 message digest algorithm

This module implements the interface to RSA's MD5 message digest algorithm (see also Internet [RFC 1321](#)). Its use is quite straightforward: use `new()` to create an `md5` object. You can now feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the *digest* (a strong kind of 128-bit checksum, a.k.a. ``fingerprint'') of the concatenation of the strings fed to it so far using the `digest()` method.

For example, to obtain the digest of the string 'Nobody inspects the spammish repetition':

```
>>> import md5
>>> m = md5.new()
>>> m.update("Nobody inspects")
>>> m.update(" the spammish repetition")
>>> m.digest()
'\xbbd\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
```

More condensed:

```
>>> md5.new("Nobody inspects the spammish repetition").digest()
'\xbbd\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
```

The following values are provided as constants in the module and as attributes of the `md5` objects returned by `new()`:

digest_size

The size of the resulting digest in bytes. This is always 16.

The `md5` module provides the following functions:

new([arg])

Return a new `md5` object. If `arg` is present, the method call `update(arg)` is made.

md5([arg])

For backward compatibility reasons, this is an alternative name for the `new()` function.

An md5 object has the following methods:

update(*arg*)

Update the md5 object with the string *arg*. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a)`; `m.update(b)` is equivalent to `m.update(a+b)`.

digest()

Return the digest of the strings passed to the `update()` method so far. This is a 16-byte string which may contain non-ASCII characters, including null bytes.

hexdigest()

Like `digest()` except the digest is returned as a string of length 32, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

copy()

Return a copy ("clone") of the md5 object. This can be used to efficiently compute the digests of strings that share a common initial substring.

See Also:

Module [sha](#):

Similar module implementing the Secure Hash Algorithm (SHA). The SHA algorithm is considered a more secure hash.

Previous: [15.2 md5](#) Up: [15. Cryptographic Services](#) Next: [16. Graphical User Interfaces](#)

15.3 sha -- SHA-1 message digest algorithm

This module implements the interface to NIST's secure hash algorithm, known as SHA-1. SHA-1 is an improved version of the original SHA hash algorithm. It is used in the same way as the [md5](#) module: use `new()` to create an sha object, then feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the *digest* of the concatenation of the strings fed to it so far. SHA-1 digests are 160 bits instead of MD5's 128 bits.

`new([string])`

Return a new sha object. If *string* is present, the method call `update(string)` is made.

The following values are provided as constants in the module and as attributes of the sha objects returned by `new()`:

blocksize

Size of the blocks fed into the hash function; this is always 1. This size is used to allow an arbitrary string to be hashed.

digest_size

The size of the resulting digest in bytes. This is always 20.

An sha object has the same methods as md5 objects:

update(*arg*)

Update the sha object with the string *arg*. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a)`; `m.update(b)` is equivalent to `m.update(a+b)`.

digest()

Return the digest of the strings passed to the `update()` method so far. This is a 20-byte string which may contain non-ASCII characters, including null bytes.

hexdigest()

Like `digest()` except the digest is returned as a string of length 40, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

copy()

Return a copy ("clone") of the sha object. This can be used to efficiently compute the digests of strings that share a common initial substring.

16. Graphical User Interfaces with Tk

Tk/Tcl has long been an integral part of Python. It provides a robust and platform independent windowing toolkit, that is available to Python programmers using the [Tkinter](#) module, and its extension, the [Tix](#) module.

The [Tkinter](#) module is a thin object-oriented layer on top of Tcl/Tk. To use [Tkinter](#), you don't need to write Tcl code, but you will need to consult the Tk documentation, and occasionally the Tcl documentation. [Tkinter](#) is a set of wrappers that implement the Tk widgets as Python classes. In addition, the internal module `_tkinter` provides a threadsafe mechanism which allows Python and Tcl to interact.

Tk is not the only GUI for Python, but is however the most commonly used one; see section , ``Other User Interface Modules and Packages," for more information on other GUI toolkits for Python.

Tkinter	Interface to Tcl/Tk for graphical user interfaces

16.1 Tkinter -- Python interface to Tcl/Tk

The `Tkinter` module ("Tk interface") is the standard Python interface to the Tk GUI toolkit. Both Tk and `Tkinter` are available on most UNIX platforms, as well as on Windows and Macintosh systems. (Tk itself is not part of Python; it is maintained at ActiveState.)

16.1.1 Tkinter Modules

Most of the time, the `Tkinter` module is all you really need, but a number of additional modules are available as well. The Tk interface is located in a binary module named `_tkinter`. This module contains the low-level interface to Tk, and should never be used directly by application programmers. It is usually a shared library (or DLL), but might in some cases be statically linked with the Python interpreter.

In addition to the Tk interface module, `Tkinter` includes a number of Python modules. The two most important modules are the `Tkinter` module itself, and a module called `Tkconstants`. The former automatically imports the latter, so to use Tkinter, all you need to do is to import one module:

```
import Tkinter
```

Or, more often:

```
from Tkinter import *
```

class Tk(*screenName=None, baseName=None, className='Tk', useTk=1*)

The Tk class is instantiated without arguments. This creates a toplevel widget of Tk which usually is the main window of an application. Each instance has its own associated Tcl interpreter. Changed in version 2.4: The *useTk* parameter was added.

Tcl(*screenName=None, baseName=None, className='Tk', useTk=0*)

The Tcl function is a factory function which creates an object much like that created by the Tk class, except that it does not initialize the Tk subsystem. This is most often useful when driving the Tcl interpreter in an environment where one doesn't want to create extraneous toplevel windows, or where one cannot (i.e. Unix/Linux systems without an X server). An object created by the Tcl object can have a Toplevel window created (and the Tk subsystem initialized) by calling its `loadtk` method. New in version 2.4.

Other modules that provide Tk support include:

[ScrolledText](#)

Text widget with a vertical scroll bar built in.

tkColorChooser

Dialog to let the user choose a color.

tkCommonDialog

Base class for the dialogs defined in the other modules listed here.

tkFileDialog

Common dialogs to allow the user to specify a file to open or save.

tkFont

Utilities to help work with fonts.

tkMessageBox

Access to standard Tk dialog boxes.

tkSimpleDialog

Basic dialogs and convenience functions.

Tkdnd

Drag-and-drop support for [Tkinter](#). This is experimental and should become deprecated when it is replaced with the Tk DND.

[turtle](#)

Turtle graphics in a Tk window.

16.1.2 Tkinter Life Preserver

This section is not designed to be an exhaustive tutorial on either Tk or Tkinter. Rather, it is intended as a stop gap, providing some introductory orientation on the system.

Credits:

- Tkinter was written by Steen Lumholt and Guido van Rossum.
- Tk was written by John Ousterhout while at Berkeley.
- This Life Preserver was written by Matt Conway at the University of Virginia.
- The html rendering, and some liberal editing, was produced from a FrameMaker version by Ken Manheimer.
- Fredrik Lundh elaborated and revised the class interface descriptions, to get them current with Tk 4.2.
- Mike Clarkson converted the documentation to LaTeX, and compiled the User Interface chapter of the reference manual.

Previous: [16.1.2.2 A Simple Hello](#) Up: [16.1 Tkinter](#) Next: [16.1.4 Mapping Basic Tk](#)

16.1.3 A (Very) Quick Look at Tcl/Tk

The class hierarchy looks complicated, but in actual practice, application programmers almost always refer to the classes at the very bottom of the hierarchy.

Notes:

- These classes are provided for the purposes of organizing certain functions under one namespace. They aren't meant to be instantiated independently.
- The Tk class is meant to be instantiated only once in an application. Application programmers need not instantiate one explicitly, the system creates one whenever any of the other classes are instantiated.
- The `Widget` class is not meant to be instantiated, it is meant only for subclassing to make "real" widgets (in C++, this is called an "abstract class").

To make use of this reference material, there will be times when you will need to know how to read short passages of Tk and how to identify the various parts of a Tk command. (See section [16.1.4](#) for the [Tkinter](#) equivalents of what's below.)

Tk scripts are Tcl programs. Like all Tcl programs, Tk scripts are just lists of tokens separated by spaces. A Tk widget is just its *class*, the *options* that help configure it, and the *actions* that make it do useful things.

To make a widget in Tk, the command is always of the form:

```
classCommand newPathname options
```

classCommand

denotes which kind of widget to make (a button, a label, a menu...)

newPathname

is the new name for this widget. All names in Tk must be unique. To help enforce this, widgets in Tk are named with *pathnames*, just like files in a file system. The top level widget, the *root*, is called `.` (period) and children

are delimited by more periods. For example, `.myApp.controlPanel.okButton` might be the name of a widget.

options

configure the widget's appearance and in some cases, its behavior. The options come in the form of a list of flags and values. Flags are preceded by a ``-`, like unix shell command flags, and values are put in quotes if they are more than one word.

For example:

```
button    .fred    -fg red -text "hi there"
  ^         ^          \_____/
  |         |          |
class    new widget  options
command widget (-opt val -opt val ...)
```

Once created, the pathname to the widget becomes a new command. This new *widget command* is the programmer's handle for getting the new widget to perform some *action*. In C, you'd express this as `someAction(fred, someOptions)`, in C++, you would express this as `fred.someAction(someOptions)`, and in Tk, you say:

```
.fred someAction someOptions
```

Note that the object name, `.fred`, starts with a dot.

As you'd expect, the legal values for *someAction* will depend on the widget's class: `.fred disable` works if `fred` is a button (`fred` gets greyed out), but does not work if `fred` is a label (disabling of labels is not supported in Tk).

The legal values of *someOptions* is action dependent. Some actions, like `disable`, require no arguments, others, like a text-entry box's `delete` command, would need arguments to specify what range of text to delete.

Previous: [16.1.3 A \(Very\) Quick](#) Up: [16.1 Tkinter](#) Next: [16.1.5 How Tk and](#)

16.1.4 Mapping Basic Tk into Tkinter

Class commands in Tk correspond to class constructors in Tkinter.

```
button .fred          =====> fred = Button()
```

The master of an object is implicit in the new name given to it at creation time. In Tkinter, masters are specified explicitly.

```
button .panel.fred    =====> fred = Button(panel)
```

The configuration options in Tk are given in lists of hyphenated tags followed by values. In Tkinter, options are specified as keyword-arguments in the instance constructor, and keyword-args for configure calls or as instance indices, in dictionary style, for established instances. See section [16.1.6](#) on setting options.

```
button .fred -fg red    =====> fred = Button(panel, fg = "r"  
.fred configure -fg red  =====> fred["fg"] = red  
OR ==> fred.config(fg = "red")
```

In Tk, to perform an action on a widget, use the widget name as a command, and follow it with an action name, possibly with arguments (options). In Tkinter, you call methods on the class instance to invoke actions on the widget. The actions (methods) that a given widget can perform are listed in the Tkinter.py module.

```
.fred invoke          =====> fred.invoke()
```

To give a widget to the packer (geometry manager), you call pack with optional arguments. In Tkinter, the Pack class holds all this functionality, and the various forms of the pack command are implemented as methods. All widgets in [Tkinter](#) are subclassed from the Packer, and so inherit all the packing methods. See the [Tix](#) module documentation for additional information on the Form geometry manager.

```
pack .fred -side left  =====> fred.pack(side = "left")
```

Release 2.4.4c1, documentation updated on 11 October 2006.

16.1.5 How Tk and Tkinter are Related

Note: This was derived from a graphical image; the image will be used more directly in a subsequent version of this document.

From the top down:

Your App Here (Python)

A Python application makes a [Tkinter](#) call.

Tkinter (Python Module)

This call (say, for example, creating a button widget), is implemented in the *Tkinter* module, which is written in Python. This Python function will parse the commands and the arguments and convert them into a form that makes them look as if they had come from a Tk script instead of a Python script.

tkinter (C)

These commands and their arguments will be passed to a C function in the *tkinter* - note the lowercase - extension module.

Tk Widgets (C and Tcl)

This C function is able to make calls into other C modules, including the C functions that make up the Tk library. Tk is implemented in C and some Tcl. The Tcl part of the Tk widgets is used to bind certain default behaviors to widgets, and is executed once at the point where the Python [Tkinter](#) module is imported. (The user never sees this stage).

Tk (C)

The Tk part of the Tk Widgets implement the final mapping to ...

Xlib (C)

the Xlib library to draw graphics on the screen.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

16.2 Tix -- Extension widgets for Tk

The Tix (Tk Interface Extension) module provides an additional rich set of widgets. Although the standard Tk library has many useful widgets, they are far from complete. The Tix library provides most of the commonly needed widgets that are missing from standard Tk: HList, ComboBox, Control (a.k.a. SpinBox) and an assortment of scrollable widgets. Tix also includes many more widgets that are generally useful in a wide range of applications: Notebook, FileEntry, PanedWindow, etc; there are more than 40 of them.

With all these new widgets, you can introduce new interaction techniques into applications, creating more useful and more intuitive user interfaces. You can design your application by choosing the most appropriate widgets to match the special needs of your application and users.

Previous: [16.2 Tix](#) Up: [16.2 Tix](#) Next: [16.2.2 Tix Widgets](#)

16.2.1 Using Tix

class Tix(*screenName*[, *baseName*[, *className*]])

Toplevel widget of Tix which represents mostly the main window of an application. It has an associated Tcl interpreter.

Classes in the [Tix](#) module subclasses the classes in the [Tkinter](#) module. The former imports the latter, so to use [Tix](#) with Tkinter, all you need to do is to import one module. In general, you can just import [Tix](#), and replace the toplevel call to `Tkinter.Tk` with `Tix.Tk`:

```
import Tix
from Tkconstants import *
root = Tix.Tk()
```

To use [Tix](#), you must have the [Tix](#) widgets installed, usually alongside your installation of the Tk widgets. To test your installation, try the following:

```
import Tix
root = Tix.Tk()
root.tk.eval('package require Tix')
```

If this fails, you have a Tk installation problem which must be resolved before proceeding. Use the environment variable `TIX_LIBRARY` to point to the installed [Tix](#) library directory, and make sure you have the dynamic object library (`tix8183.dll` or `libtix8183.so`) in the same directory that contains your Tk dynamic object library (`tk8183.dll` or `libtk8183.so`). The directory with the dynamic object library should also have a file called `pkgIndex.tcl` (case sensitive), which contains the line:

```
package ifneeded Tix 8.1 [list load "[file join $dir tix8183.dll]" T
```

Previous: [16.2.1 Using Tix](#) Up: [16.2 Tix](#) Next: [16.2.2.1 Basic Widgets](#)

16.2.2 Tix Widgets

[Tix](#) introduces over 40 widget classes to the [Tkinter](#) repertoire. There is a demo of all the [Tix](#) widgets in the `Demo/tix` directory of the standard distribution.

16.2.3 Tix Commands

class `tixCommand()`

The `tix commands` provide access to miscellaneous elements of `Tix`'s internal state and the `Tix` application context. Most of the information manipulated by these methods pertains to the application as a whole, or to a screen or display, rather than to a particular window.

To view the current settings, the common usage is:

```
import Tix
root = Tix.Tk()
print root.tix_configure()
```

tix_configure() (*cnf,* ***kw*)

Query or modify the configuration options of the Tix application context. If no option is specified, returns a dictionary all of the available options. If option is specified with no value, then the method returns a list describing the one named option (this list will be identical to the corresponding sublist of the value returned if no option is specified). If one or more option-value pairs are specified, then the method modifies the given option(s) to have the given value(s); in this case the method returns an empty string. Option may be any of the configuration options.

tix_cget() (*option*)

Returns the current value of the configuration option given by *option*. Option may be any of the configuration options.

tix_getbitmap() (*name*)

Locates a bitmap file of the name *name*.xpm or *name* in one of the bitmap directories (see the `tix_addbitmapdir()` method). By using `tix_getbitmap()`, you can avoid hard coding the pathnames of the bitmap files in your application. When successful, it returns the complete pathname of the bitmap file, prefixed with the character "@". The returned value can be used to configure the `bitmap` option of the Tk and Tix widgets.

tix_addbitmapdir(*directory*)

Tix maintains a list of directories under which the `tix_getimage()` and `tix_getbitmap()` methods will search for image files. The standard bitmap directory is `$TIX_LIBRARY/bitmaps`. The `tix_addbitmapdir()` method adds *directory* into this list. By using this method, the image files of an applications can also be located using the `tix_getimage()` or `tix_getbitmap()` method.

tix_filedialog([*dlgclass*])

Returns the file selection dialog that may be shared among different calls from this application. This method will create a file selection dialog widget when it is called the first time. This dialog will be returned by all subsequent calls to `tix_filedialog()`. An optional *dlgclass* parameter can be passed as a string to specified what type of file selection dialog widget is desired. Possible options are `tix`, `FileSelectDialog` or `tixExFileSelectDialog`.

tix_getimage(*self*, *name*)

Locates an image file of the name *name*.xpm, *name*.xbm or *name*.ppm in one of the bitmap directories (see the `tix_addbitmapdir()` method above). If more than one file with the same name (but different extensions) exist, then the image type is chosen according to the depth of the X display: xbm images are chosen on monochrome displays and color images are chosen on color displays. By using `tix_getimage()`, you can avoid hard coding the pathnames of the image files in your application. When successful, this method returns the name of the newly created image, which can be used to configure the `image` option of the Tk and Tix widgets.

tix_option_get(*name*)

Gets the options maintained by the Tix scheme mechanism.

tix_resetoptions(*newScheme*, *newFontSet*[, *newScmPrio*])

Resets the scheme and fontset of the Tix application to *newScheme* and *newFontSet*, respectively. This affects only those widgets created after this call. Therefore, it is best to call the `resetoptions` method before the creation of any widgets in a Tix application.

The optional parameter *newScmPrio* can be given to reset the priority level of the Tk options set by the Tix schemes.

Because of the way Tk handles the X option database, after Tix has been imported and inited, it is not possible to reset the color schemes and font sets using the `tix_config()` method. Instead, the `tix_resetoptions()` method must be used.

16.3 ScrolledText -- Scrolled Text Widget

Availability: **Tk**.

The `ScrolledText` module provides a class of the same name which implements a basic text widget which has a vertical scroll bar configured to do the "right thing." Using the `ScrolledText` class is a lot easier than setting up a text widget and scroll bar directly. The constructor is the same as that of the `Tkinter.Text` class.

The text widget and scrollbar are packed together in a `Frame`, and the methods of the `Grid` and `Pack` geometry managers are acquired from the `Frame` object. This allows the `ScrolledText` widget to be used directly to achieve most normal geometry management behavior.

Should more specific control be necessary, the following attributes are available:

frame

The frame which surrounds the text and scroll bar widgets.

vbar

The scroll bar widget.

16.4 turtle -- Turtle graphics for Tk

Availability: **Tk**.

The `turtle` module provides turtle graphics primitives, in both an object-oriented and procedure-oriented ways. Because it uses `Tkinter` for the underlying graphics, it needs a version of python installed with Tk support.

The procedural interface uses a pen and a canvas which are automatically created when any of the functions are called.

The `turtle` module defines the following functions:

degrees()

Set angle measurement units to degrees.

radians()

Set angle measurement units to radians.

reset()

Clear the screen, re-center the pen, and set variables to the default values.

clear()

Clear the screen.

tracer(*flag*)

Set tracing on/off (according to whether *flag* is true or not). Tracing means line are drawn more slowly, with an animation of an arrow along the line.

forward(*distance*)

Go forward *distance* steps.

backward(*distance*)

Go backward *distance* steps.

left(*angle*)

Turn left *angle* units. Units are by default degrees, but can be set via the `degrees()` and `radians()` functions.

right(*angle*)

Turn right *angle* units. Units are by default degrees, but can be set via the `degrees()` and `radians()` functions.

up()

Move the pen up -- stop drawing.

down()

Move the pen down -- draw when moving.

width(*width*)

Set the line width to *width*.

color(*s*)**color((*r*, *g*, *b*))****color(*r*, *g*, *b*)**

Set the pen color. In the first form, the color is specified as a Tk color specification as a string. The second form specifies the color as a tuple of the RGB values, each in the range [0..1]. For the third form, the color is specified giving the RGB values as three separate parameters (each in the range [0..1]).

write(*text*[, *move*])

Write *text* at the current pen position. If *move* is true, the pen is moved to the bottom-right corner of the text. By default, *move* is false.

fill(*flag*)

The complete specifications are rather complex, but the recommended usage is: call `fill(1)` before drawing a path you want to fill, and call `fill(0)` when you finish to draw the path.

circle(*radius*[, *extent*])

Draw a circle with radius *radius* whose center-point is *radius* units left of the turtle. *extent* determines which part of a circle is drawn: if not given it defaults to a full circle.

If *extent* is not a full circle, one endpoint of the arc is the current pen position. The arc is drawn in a counter clockwise direction if *radius* is positive, otherwise in a clockwise direction. In the process, the direction of the turtle is changed by the amount of the *extent*.

goto(*x*, *y*)

goto((*x*, *y*))

Go to co-ordinates *x*, *y*. The co-ordinates may be specified either as two separate arguments or as a 2-tuple.

This module also does `from math import *`, so see the documentation for the [math](#) module for additional constants and functions useful for turtle graphics.

demo()

Exercise the module a bit.

exception Error

Exception raised on any error caught by this module.

For examples, see the code of the `demo()` function.

This module defines the following classes:

class Pen()

Define a pen. All above functions can be called as a methods on the given pen. The constructor automatically creates a canvas do be drawn on.

class RawPen(*canvas*)

Define a pen which draws on a canvas *canvas*. This is useful if you want to use the module to create graphics in a ``real" program.

16.4.1 Pen and RawPen Objects

Pen and RawPen objects have all the global functions described above, except for `demo()` as methods, which manipulate the given pen.

The only method which is more powerful as a method is `degrees()`.

degrees([*fullcircle*])

fullcircle is by default 360. This can cause the pen to have any angular units whatever: give *fullcircle* 2* for radians, or 400 for gradians.

16.5 Idle

Idle is the Python IDE built with the [Tkinter](#) GUI toolkit.

IDLE has the following features:

- coded in 100% pure Python, using the [Tkinter](#) GUI toolkit
- cross-platform: works on Windows and UNIX (on Mac OS, there are currently problems with Tcl/Tk)
- multi-window text editor with multiple undo, Python colorizing and many other features, e.g. smart indent and call tips
- Python shell window (a.k.a. interactive interpreter)
- debugger (not complete, but you can set breakpoints, view and step)

16.6 Other Graphical User Interface Packages

There are an number of extension widget sets to [Tkinter](#).

[Python megawidgets](#)

is a toolkit for building high-level compound widgets in Python using the [Tkinter](#) module. It consists of a set of base classes and a library of flexible and extensible megawidgets built on this foundation. These megawidgets include notebooks, comboboxes, selection widgets, paned widgets, scrolled widgets, dialog windows, etc. Also, with the Pmw.Blt interface to BLT, the busy, graph, stripchart, tabset and vector commands are be available.

The initial ideas for Pmw were taken from the Tk `itcl` extensions [`incr Tk`] by Michael McLennan and [`incr widgets`] by Mark Ulferts. Several of the megawidgets are direct translations from the `itcl` to Python. It offers most of the range of widgets that [`incr widgets`] does, and is almost as complete as Tix, lacking however Tix's fast `HList` widget for drawing trees.

[Tkinter3000 Widget Construction Kit \(WCK\)](#)

is a library that allows you to write new Tkinter widgets in pure Python. The WCK framework gives you full control over widget creation, configuration, screen appearance, and event handling. WCK widgets can be very fast and light-weight, since they can operate directly on Python data structures, without having to transfer data through the Tk/Tcl layer.

Tk is not the only GUI for Python, but is however the most commonly used one.

[wxWindows](#)

is a GUI toolkit that combines the most attractive attributes of Qt, Tk, Motif, and GTK+ in one powerful and efficient package. It is implemented in C++. wxWindows supports two flavors of UNIX implementation: GTK+ and Motif, and under Windows, it has a standard Microsoft Foundation Classes (MFC) appearance, because it uses Win32 widgets. There is a

Python class wrapper, independent of Tkinter.

wxWindows is much richer in widgets than [Tkinter](#), with its help system, sophisticated HTML and image viewers, and other specialized widgets, extensive documentation, and printing capabilities.

PyQt

PyQt is a **sip**-wrapped binding to the Qt toolkit. Qt is an extensive C++ GUI toolkit that is available for UNIX, Windows and Mac OS X. **sip** is a tool for generating bindings for C++ libraries as Python classes, and is specifically designed for Python. An online manual is available at <http://www.opendocspublishing.com/pyqt/> (errata are located at <http://www.valdyas.org/python/book.html>).

[PyKDE](#)

PyKDE is a **sip**-wrapped interface to the KDE desktop libraries. KDE is a desktop environment for UNIX computers; the graphical components are based on Qt.

[FXPy](#)

is a Python extension module which provides an interface to the [FOX](#) GUI. FOX is a C++ based Toolkit for developing Graphical User Interfaces easily and effectively. It offers a wide, and growing, collection of Controls, and provides state of the art facilities such as drag and drop, selection, as well as OpenGL widgets for 3D graphical manipulation. FOX also implements icons, images, and user-convenience features such as status line help, and tooltips.

Even though FOX offers a large collection of controls already, FOX leverages C++ to allow programmers to easily build additional Controls and GUI elements, simply by taking existing controls, and creating a derived class which simply adds or redefines the desired behavior.

[PyGTK](#)

is a set of bindings for the [GTK](#) widget set. It provides an object oriented interface that is slightly higher level than the C one. It automatically does all the type casting and reference counting that you would have to do normally with the C API. There are also [bindings](#) to [GNOME](#), and a [tutorial](#) is available.

Next: [17. Restricted Execution](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

Previous: [16.6 Other Graphical User](#) Up: [Python Library Reference](#) Next: [17.1 rexec](#)

17. Restricted Execution

Warning: In Python 2.3 these modules have been disabled due to various known and not readily fixable security holes. The modules are still documented here to help in reading old code that uses the `rexec` and `Bastion` modules.

Restricted execution is the basic framework in Python that allows for the segregation of trusted and untrusted code. The framework is based on the notion that trusted Python code (a *supervisor*) can create a ``padded cell' (or environment) with limited permissions, and run the untrusted code within this cell. The untrusted code cannot break out of its cell, and can only interact with sensitive system resources through interfaces defined and managed by the trusted code. The term ``restricted execution" is favored over ``safe-Python" since true safety is hard to define, and is determined by the way the restricted environment is created. Note that the restricted environments can be nested, with inner cells creating subcells of lesser, but never greater, privilege.

An interesting aspect of Python's restricted execution model is that the interfaces presented to untrusted code usually have the same names as those presented to trusted code. Therefore no special interfaces need to be learned to write code designed to run in a restricted environment. And because the exact nature of the padded cell is determined by the supervisor, different restrictions can be imposed, depending on the application. For example, it might be deemed ``safe" for untrusted code to read any file within a specified directory, but never to write a file. In this case, the supervisor may redefine the built-in `open()` function so that it raises an exception whenever the *mode* parameter is `'w'`. It might also perform a `chroot()`-like operation on the *filename* parameter, such that root is always relative to some safe ``sandbox" area of the filesystem. In this case, the untrusted code would still see an built-in `open()` function in its environment, with the same calling interface. The semantics would be identical too, with `IOErrors` being raised when the supervisor determined that an unallowable parameter is being used.

The Python run-time determines whether a particular code block is executing in

restricted execution mode based on the identity of the `__builtins__` object in its global variables: if this is (the dictionary of) the standard [builtin](#) module, the code is deemed to be unrestricted, else it is deemed to be restricted.

Python code executing in restricted mode faces a number of limitations that are designed to prevent it from escaping from the padded cell. For instance, the function object attribute `func_globals` and the class and instance object attribute `__dict__` are unavailable.

Two modules provide the framework for setting up restricted execution environments:

[rexec](#) Basic restricted execution framework.

[Bastion](#) Providing restricted access to objects.

See Also:

[Grail Home Page](#)

Grail, an Internet browser written in Python, uses these modules to support Python applets. More information on the use of Python's restricted execution mode in Grail is available on the Web site.

Previous: [17. Restricted Execution](#) Up: [17. Restricted Execution](#) Next: [17.1.1 RExec Objects](#)

17.1 rexec -- Restricted execution framework

Changed in version 2.3: Disabled module.

Warning: The documentation has been left in place to help in reading old code that uses the module.

This module contains the `RExec` class, which supports `r_eval()`, `r_execfile()`, `r_exec()`, and `r_import()` methods, which are restricted versions of the standard Python functions `eval()`, `execfile()` and the `exec` and `import` statements. Code executed in this restricted environment will only have access to modules and functions that are deemed safe; you can subclass `RExec` to add or remove capabilities as desired.

Warning: While the `rexec` module is designed to perform as described below, it does have a few known vulnerabilities which could be exploited by carefully written code. Thus it should not be relied upon in situations requiring "production ready" security. In such situations, execution via sub-processes or very careful "cleansing" of both code and data to be processed may be necessary. Alternatively, help in patching known `rexec` vulnerabilities would be welcomed.

Note: The `RExec` class can prevent code from performing unsafe operations like reading or writing disk files, or using TCP/IP sockets. However, it does not protect against code using extremely large amounts of memory or processor time.

```
class RExec( [hooks[, verbose]])
```

Returns an instance of the `RExec` class.

`hooks` is an instance of the `RHooks` class or a subclass of it. If it is omitted or `None`, the default `RHooks` class is instantiated. Whenever the `rexec` module searches for a module (even a built-in one) or reads a module's code, it doesn't actually go out to the file system itself. Rather, it calls methods of an `RHooks` instance that was passed to or created by its constructor. (Actually, the `RExec` object doesn't make these calls -- they are made by a module loader object that's part of the `RExec` object. This allows another level of flexibility, which can be useful when changing the mechanics of `import` within the restricted environment.)

By providing an alternate `RHooks` object, we can control the file system accesses made to import a module, without changing the actual algorithm that controls the order in which those accesses are made. For instance, we could substitute an `RHooks` object that passes all filesystem requests to a file server elsewhere, via some RPC mechanism such as ILU. Grail's applet loader uses this to support importing applets from a URL for a directory.

If `verbose` is true, additional debugging output may be sent to standard output.

It is important to be aware that code running in a restricted environment can still call the `sys.exit()` function. To disallow restricted code from exiting the interpreter, always protect calls that cause restricted code to run with a `try/except` statement that catches the `SystemExit` exception. Removing the `sys.exit()` function from the restricted environment is not sufficient -- the restricted code could still use `raise SystemExit`. Removing `SystemExit` is not a reasonable option; some library code makes use of this and would break were it not available.

See Also:

[Grail Home Page](#)

Grail is a Web browser written entirely in Python. It uses the `rexec` module as a foundation for supporting Python applets, and can be used as an example usage of this module.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [17.1 rexec](#) Up: [17.1 rexec](#) Next: [17.1.2 Defining restricted environments](#)

17.1.1 RExec Objects

RExec instances support the following methods:

r_eval(*code*)

code must either be a string containing a Python expression, or a compiled code object, which will be evaluated in the restricted environment's `__main__` module. The value of the expression or code object will be returned.

r_exec(*code*)

code must either be a string containing one or more lines of Python code, or a compiled code object, which will be executed in the restricted environment's `__main__` module.

r_execfile(*filename*)

Execute the Python code contained in the file *filename* in the restricted environment's `__main__` module.

Methods whose names begin with "s_" are similar to the functions beginning with "r_", but the code will be granted access to restricted versions of the standard I/O streams `sys.stdin`, `sys.stderr`, and `sys.stdout`.

s_eval(*code*)

code must be a string containing a Python expression, which will be evaluated in the restricted environment.

s_exec(*code*)

code must be a string containing one or more lines of Python code, which will be executed in the restricted environment.

s_execfile(*code*)

Execute the Python code contained in the file *filename* in the restricted environment.

RExec objects must also support various methods which will be implicitly

called by code executing in the restricted environment. Overriding these methods in a subclass is used to change the policies enforced by a restricted environment.

r_import(*modulename*[, *globals*[, *locals*[, *fromlist*]]])

Import the module *modulename*, raising an `ImportError` exception if the module is considered unsafe.

r_open(*filename*[, *mode*[, *bufsize*]])

Method called when `open()` is called in the restricted environment. The arguments are identical to those of `open()`, and a file object (or a class instance compatible with file objects) should be returned. `RExec`'s default behaviour is allow opening any file for reading, but forbidding any attempt to write a file. See the example below for an implementation of a less restrictive `r_open()`.

r_reload(*module*)

Reload the module object *module*, re-parsing and re-initializing it.

r_unload(*module*)

Unload the module object *module* (remove it from the restricted environment's `sys.modules` dictionary).

And their equivalents with access to restricted standard I/O streams:

s_import(*modulename*[, *globals*[, *locals*[, *fromlist*]]])

Import the module *modulename*, raising an `ImportError` exception if the module is considered unsafe.

s_reload(*module*)

Reload the module object *module*, re-parsing and re-initializing it.

s_unload(*module*)

Unload the module object *module*.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [17.1.1 RExec Objects](#) Up: [17.1 rexec](#) Next: [17.1.3 An example](#)

17.1.2 Defining restricted environments

The `RExec` class has the following class attributes, which are used by the `__init__()` method. Changing them on an existing instance won't have any effect; instead, create a subclass of `RExec` and assign them new values in the class definition. Instances of the new class will then use those new values. All these attributes are tuples of strings.

`nok_builtin_names`

Contains the names of built-in functions which will *not* be available to programs running in the restricted environment. The value for `RExec` is `('open', 'reload', '__import__')`. (This gives the exceptions, because by far the majority of built-in functions are harmless. A subclass that wants to override this variable should probably start with the value from the base class and concatenate additional forbidden functions -- when new dangerous built-in functions are added to Python, they will also be added to this module.)

`ok_builtin_modules`

Contains the names of built-in modules which can be safely imported. The value for `RExec` is `('audioop', 'array', 'binascii', 'cmath', 'errno', 'imageop', 'marshal', 'math', 'md5', 'operator', 'parser', 'regex', 'select', 'sha', '_sre', 'strop', 'struct', 'time')`. A similar remark about overriding this variable applies -- use the value from the base class as a starting point.

`ok_path`

Contains the directories which will be searched when an `import` is performed in the restricted environment. The value for `RExec` is the same as `sys.path` (at the time the module is loaded) for unrestricted code.

`ok_posix_names`

Contains the names of the functions in the `os` module which will be available to programs running in the restricted environment. The value for `RExec` is `('error', 'fstat', 'listdir', 'lstat', 'readlink', 'stat', 'times', 'uname', 'getpid',`

```
'getppid', 'getcwd', 'getuid', 'getgid',  
'geteuid', 'getegid').
```

ok_sys_names

Contains the names of the functions and variables in the [sys](#) module which will be available to programs running in the restricted environment. The value for RExec is ('ps1', 'ps2', 'copyright', 'version', 'platform', 'exit', 'maxint').

ok_file_types

Contains the file types from which modules are allowed to be loaded. Each file type is an integer constant defined in the [imp](#) module. The meaningful values are PY_SOURCE, PY_COMPILED, and C_EXTENSION. The value for RExec is (C_EXTENSION, PY_SOURCE). Adding PY_COMPILED in subclasses is not recommended; an attacker could exit the restricted execution mode by putting a forged byte-compiled file (.pyc) anywhere in your file system, for example by writing it to /tmp or uploading it to the /incoming directory of your public FTP server.

Previous: [17.1.2 Defining restricted environments](#) Up: [17.1 rexec](#) Next: [17.2 Bastion](#)

17.1.3 An example

Let us say that we want a slightly more relaxed policy than the standard `RExec` class. For example, if we're willing to allow files in `/tmp` to be written, we can subclass the `RExec` class:

```
class TmpWriterRExec(rexec.RExec):
    def r_open(self, file, mode='r', buf=-1):
        if mode in ('r', 'rb'):
            pass
        elif mode in ('w', 'wb', 'a', 'ab'):
            # check filename : must begin with /tmp/
            if file[:5] != '/tmp/':
                raise IOError, "can't write outside /tmp"
            elif (string.find(file, '/../') >= 0 or
                  file[:3] == '../' or file[-3:] == '/../'):
                raise IOError, "'..' in filename forbidden"
            else: raise IOError, "Illegal open() mode"
        return open(file, mode, buf)
```

Notice that the above code will occasionally forbid a perfectly valid filename; for example, code in the restricted environment won't be able to open a file called `/tmp/foo/../bar`. To fix this, the `r_open()` method would have to simplify the filename to `/tmp/bar`, which would require splitting apart the filename and performing various operations on it. In cases where security is at stake, it may be preferable to write simple code which is sometimes overly restrictive, instead of more general code that is also more complex and may harbor a subtle security hole.

17.2 Bastion -- Restricting access to objects

Changed in version 2.3: Disabled module.

Warning: The documentation has been left in place to help in reading old code that uses the module.

According to the dictionary, a bastion is ``a fortified area or position", or ``something that is considered a stronghold." It's a suitable name for this module, which provides a way to forbid access to certain attributes of an object. It must always be used with the [rexec](#) module, in order to allow restricted-mode programs access to certain safe attributes of an object, while denying access to other, unsafe attributes.

Bastion(*object*[, *filter*[, *name*[, *class*]]])

Protect the object *object*, returning a bastion for the object. Any attempt to access one of the object's attributes will have to be approved by the *filter* function; if the access is denied an `AttributeError` exception will be raised.

If present, *filter* must be a function that accepts a string containing an attribute name, and returns true if access to that attribute will be permitted; if *filter* returns false, the access is denied. The default filter denies access to any function beginning with an underscore ("`_`"). The bastion's string representation will be "`<Bastion for name>`" if a value for *name* is provided; otherwise, "`repr(object)`" will be used.

class, if present, should be a subclass of `BastionClass`; see the code in `bastion.py` for the details. Overriding the default `BastionClass` will rarely be required.

class BastionClass(*getfunc*, *name*)

Class which actually implements bastion objects. This is the default class used by `Bastion()`. The `getfunc` parameter is a function which returns the value of an attribute which should be exposed to the restricted execution environment when called with the name of the attribute as the only parameter. `name` is used to construct the `repr()` of the `BastionClass` instance.

18. Python Language Services

Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

parser	Access parse trees for Python source code.
symbol	Constants representing internal nodes of the parse tree.
token	Constants representing terminal nodes of the parse tree.
keyword	Test whether a string is a keyword in Python.
tokenize	Lexical scanner for Python source code.
tabnanny	Tool for detecting white space related problems in Python source files in a directory tree.
pyclbr	Supports information extraction for a Python class browser.
py_compile	Compile Python source files to byte-code files.
compileall	Tools for byte-compiling all Python source files in a directory tree.
dis	Disassembler for Python byte code.
pickletools	Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful functions.
distutils	Support for building and installing Python modules into an existing Python installation.

Next: [18.1.1 Creating AST Objects](#)

18.1 parser -- Access Python parse trees

The `parser` module provides an interface to Python's internal parser and byte-code compiler. The primary purpose for this interface is to allow Python code to edit the parse tree of a Python expression and create executable code from this. This is better than trying to parse and modify an arbitrary Python code fragment as a string because parsing is performed in a manner identical to the code forming the application. It is also faster.

There are a few things to note about this module which are important to making use of the data structures created. This is not a tutorial on editing the parse trees for Python code, but some examples of using the `parser` module are presented.

Most importantly, a good understanding of the Python grammar processed by the internal parser is required. For full information on the language syntax, refer to the [Python Language Reference](#). The parser itself is created from a grammar specification defined in the file `Grammar/Grammar` in the standard Python distribution. The parse trees stored in the AST objects created by this module are the actual output from the internal parser when created by the `expr()` or `suite()` functions, described below. The AST objects created by `sequence2ast()` faithfully simulate those structures. Be aware that the values of the sequences which are considered "correct" will vary from one version of Python to another as the formal grammar for the language is revised. However, transporting code from one Python version to another as source text will always allow correct parse trees to be created in the target version, with the only restriction being that migrating to an older version of the interpreter will not support more recent language constructs. The parse trees are not typically compatible from one version to another, whereas source code has always been forward-compatible.

Each element of the sequences returned by `ast2list()` or `ast2tuple()` has a simple form. Sequences representing non-terminal elements in the grammar always have a length greater than one. The first element is an integer which identifies a production in the grammar. These integers are given symbolic names in the C header file `Include/graminit.h` and the Python module [symbol](#).

Each additional element of the sequence represents a component of the production as recognized in the input string: these are always sequences which have the same form as the parent. An important aspect of this structure which should be noted is that keywords used to identify the parent node type, such as the keyword `if` in an `if_stmt`, are included in the node tree without any special treatment. For example, the `if` keyword is represented by the tuple `(1, 'if')`, where `1` is the numeric value associated with all `NAME` tokens, including variable and function names defined by the user. In an alternate form returned when line number information is requested, the same token might be represented as `(1, 'if', 12)`, where the `12` represents the line number at which the terminal symbol was found.

Terminal elements are represented in much the same way, but without any child elements and the addition of the source text which was identified. The example of the `if` keyword above is representative. The various types of terminal symbols are defined in the C header file `Include/token.h` and the Python module [token](#).

The `AST` objects are not required to support the functionality of this module, but are provided for three purposes: to allow an application to amortize the cost of processing complex parse trees, to provide a parse tree representation which conserves memory space when compared to the Python list or tuple representation, and to ease the creation of additional modules in C which manipulate parse trees. A simple ```wrapper``` class may be created in Python to hide the use of `AST` objects.

The `parser` module defines functions for a few distinct purposes. The most important purposes are to create `AST` objects and to convert `AST` objects to other representations such as parse trees and compiled code objects, but there are also functions which serve to query the type of parse tree represented by an `AST` object.

Previous: [18.1 parser](#) Up: [18.1 parser](#) Next: [18.1.2 Converting AST Objects](#)

18.1.1 Creating AST Objects

AST objects may be created from source code or from a parse tree. When creating an AST object from source, different functions are used to create the 'eval' and 'exec' forms.

expr(*source*)

The `expr()` function parses the parameter *source* as if it were an input to "`compile(source, 'file.py', 'eval')`". If the parse succeeds, an AST object is created to hold the internal parse tree representation, otherwise an appropriate exception is thrown.

suite(*source*)

The `suite()` function parses the parameter *source* as if it were an input to "`compile(source, 'file.py', 'exec')`". If the parse succeeds, an AST object is created to hold the internal parse tree representation, otherwise an appropriate exception is thrown.

sequence2ast(*sequence*)

This function accepts a parse tree represented as a sequence and builds an internal representation if possible. If it can validate that the tree conforms to the Python grammar and all nodes are valid node types in the host version of Python, an AST object is created from the internal representation and returned to the caller. If there is a problem creating the internal representation, or if the tree cannot be validated, a `ParserError` exception is thrown. An AST object created this way should not be assumed to compile correctly; normal exceptions thrown by compilation may still be initiated when the AST object is passed to `compileast()`. This may indicate problems not related to syntax (such as a `MemoryError` exception), but may also be due to constructs such as the result of parsing `del f(0)`, which escapes the Python parser but is checked by the bytecode compiler.

Sequences representing terminal tokens may be represented as either two-element lists of the form `(1, 'name')` or as three-element lists of the form `(1, 'name', 56)`. If the third element is present, it is assumed to

be a valid line number. The line number may be specified for any subset of the terminal symbols in the input tree.

tuple2ast(*sequence*)

This is the same function as `sequence2ast ()`. This entry point is maintained for backward compatibility.

Previous: [18.1.1 Creating AST Objects](#) Up: [18.1 parser](#) Next: [18.1.3 Queries on AST](#)

18.1.2 Converting AST Objects

AST objects, regardless of the input used to create them, may be converted to parse trees represented as list- or tuple- trees, or may be compiled into executable code objects. Parse trees may be extracted with or without line numbering information.

ast2list(*ast*[, *line_info*])

This function accepts an AST object from the caller in *ast* and returns a Python list representing the equivalent parse tree. The resulting list representation can be used for inspection or the creation of a new parse tree in list form. This function does not fail so long as memory is available to build the list representation. If the parse tree will only be used for inspection, `ast2tuple()` should be used instead to reduce memory consumption and fragmentation. When the list representation is required, this function is significantly faster than retrieving a tuple representation and converting that to nested lists.

If *line_info* is true, line number information will be included for all terminal tokens as a third element of the list representing the token. Note that the line number provided specifies the line on which the token *ends*. This information is omitted if the flag is false or omitted.

ast2tuple(*ast*[, *line_info*])

This function accepts an AST object from the caller in *ast* and returns a Python tuple representing the equivalent parse tree. Other than returning a tuple instead of a list, this function is identical to `ast2list()`.

If *line_info* is true, line number information will be included for all terminal tokens as a third element of the list representing the token. This information is omitted if the flag is false or omitted.

compileast(*ast*[, *filename* = '<ast>'])

The Python byte compiler can be invoked on an AST object to produce code objects which can be used as part of an `EXEC` statement or a call to the built-in `eval()` function. This function provides the interface to the

compiler, passing the internal parse tree from *ast* to the parser, using the source file name specified by the *filename* parameter. The default value supplied for *filename* indicates that the source was an AST object.

Compiling an AST object may result in exceptions related to compilation; an example would be a `SyntaxError` caused by the parse tree for `del f(0)`: this statement is considered legal within the formal grammar for Python but is not a legal language construct. The `SyntaxError` raised for this condition is actually generated by the Python byte-compiler normally, which is why it can be raised at this point by the `parser` module. Most causes of compilation failure can be diagnosed programmatically by inspection of the parse tree.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [18.1.2 Converting AST Objects](#) **Up:** [18.1 parser](#) **Next:** [18.1.4 Exceptions and Error](#)

18.1.3 Queries on AST Objects

Two functions are provided which allow an application to determine if an AST was created as an expression or a suite. Neither of these functions can be used to determine if an AST was created from source code via `expr()` or `suite()` or from a parse tree via `sequence2ast()`.

`isexpr(ast)`

When `ast` represents an 'eval' form, this function returns true, otherwise it returns false. This is useful, since code objects normally cannot be queried for this information using existing built-in functions. Note that the code objects created by `compileast()` cannot be queried like this either, and are identical to those created by the built-in `compile()` function.

`issuite(ast)`

This function mirrors `isexpr()` in that it reports whether an AST object represents an 'exec' form, commonly known as a "suite." It is not safe to assume that this function is equivalent to "not `isexpr(ast)`", as additional syntactic fragments may be supported in the future.

Previous: [18.1.3 Queries on AST](#) Up: [18.1 parser](#) Next: [18.1.5 AST Objects](#)

18.1.4 Exceptions and Error Handling

The parser module defines a single exception, but may also pass other built-in exceptions from other portions of the Python runtime environment. See each function for information about the exceptions it can raise.

exception `ParserError`

Exception raised when a failure occurs within the parser module. This is generally produced for validation failures rather than the built in `SyntaxError` thrown during normal parsing. The exception argument is either a string describing the reason of the failure or a tuple containing a sequence causing the failure from a parse tree passed to `sequence2ast()` and an explanatory string. Calls to `sequence2ast()` need to be able to handle either type of exception, while calls to other functions in the module will only need to be aware of the simple string values.

Note that the functions `compileast()`, `expr()`, and `suite()` may throw exceptions which are normally thrown by the parsing and compilation process. These include the built in exceptions `MemoryError`, `OverflowError`, `SyntaxError`, and `SystemError`. In these cases, these exceptions carry all the meaning normally associated with them. Refer to the descriptions of each function for detailed information.

Previous: [18.1.4 Exceptions and Error](#) **Up:** [18.1 parser](#) **Next:** [18.1.6 Examples](#)

18.1.5 AST Objects

Ordered and equality comparisons are supported between AST objects. Pickling of AST objects (using the [pickle](#) module) is also supported.

ASTType

The type of the objects returned by `expr()`, `suite()` and `sequence2ast()`.

AST objects have the following methods:

compile([*filename*])

Same as `compileast(ast, filename)`.

isexpr()

Same as `isexpr(ast)`.

issuite()

Same as `issuite(ast)`.

tolist([*line_info*])

Same as `ast2list(ast, line_info)`.

totuple([*line_info*])

Same as `ast2tuple(ast, line_info)`.

Previous: [18.1.5 AST Objects](#) Up: [18.1 parser](#) Next: [18.1.6.1 Emulation of compile\(\)](#)

18.1.6 Examples

The parser modules allows operations to be performed on the parse tree of Python source code before the bytecode is generated, and provides for inspection of the parse tree for information gathering purposes. Two examples are presented. The simple example demonstrates emulation of the `compile()` built-in function and the complex example shows the use of a parse tree for information discovery.

18.2 `symbol` -- Constants used with Python parse trees

This module provides constants which represent the numeric values of internal nodes of the parse tree. Unlike most Python constants, these use lower-case names. Refer to the file `Grammar/Grammar` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one additional data object:

`sym_name`

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

See Also:

Module [`parser`](#):

The second example for the [`parser`](#) module shows how to use the `symbol` module.

Previous: [18.2 symbol](#) Up: [18. Python Language Services](#) Next: [18.4 keyword](#)

18.3 token -- Constants used with Python parse trees

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file `Grammar/Grammar` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one data object and some functions. The functions mirror definitions in the Python C header files.

tok_name

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

ISTERMINAL(*x*)

Return true for terminal token values.

ISNONTERMINAL(*x*)

Return true for non-terminal token values.

ISEOF(*x*)

Return true if *x* is the marker indicating the end of input.

See Also:

Module [parser](#):

The second example for the [parser](#) module shows how to use the `symbol` module.

18.4 keyword -- Testing for Python keywords

This module allows a Python program to determine if a string is a keyword.

iskeyword(s)

Return true if s is a Python keyword.

kwlist

Sequence containing all the keywords defined for the interpreter. If any keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.

Previous: [18.4 keyword](#) Up: [18. Python Language Services](#) Next: [18.6 tabnanny](#)

18.5 tokenize -- Tokenizer for Python source

The `tokenize` module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing "pretty-printers," including colorizers for on-screen displays.

The primary entry point is a generator:

generate_tokens(*readline*)

The `generate_tokens()` generator requires one argument, *readline*, which must be a callable object which provides the same interface as the `readline()` method of built-in file objects (see section [2.3.9](#)). Each call to the function should return one line of input as a string.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple (*srow*, *scol*) of ints specifying the row and column where the token begins in the source; a 2-tuple (*erow*, *ecol*) of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed is the *logical* line; continuation lines are included. New in version 2.2.

An older entry point is retained for backward compatibility:

tokenize(*readline*[, *tokeneater*])

The `tokenize()` function accepts two parameters: one representing the input stream, and one providing an output mechanism for `tokenize()`.

The first parameter, *readline*, must be a callable object which provides the same interface as the `readline()` method of built-in file objects (see section [2.3.9](#)). Each call to the function should return one line of input as a string.

The second parameter, *tokeneater*, must also be a callable object. It is called

once for each token, with five arguments, corresponding to the tuples generated by `generate_tokens()`.

All constants from the `token` module are also exported from `tokenize`, as are two additional token type values that might be passed to the `tokeneer` function by `tokenize()`:

COMMENT

Token value used to indicate a comment.

NL

Token value used to indicate a non-terminating newline. The `NEWLINE` token indicates the end of a logical line of Python code; `NL` tokens are generated when a logical line of code is continued over multiple physical lines.

Previous: [18.5 tokenize](#) Up: [18. Python Language Services](#) Next: [18.7 pylbr](#)

18.6 tabnanny -- Detection of ambiguous indentation

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function `check()` described below.

Warning: The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

check(*file_or_dir*)

If *file_or_dir* is a directory and not a symbolic link, then recursively descend the directory tree named by *file_or_dir*, checking all `.py` files along the way. If *file_or_dir* is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the `print` statement.

verbose

Flag indicating whether to print verbose messages. This is incremented by the `-v` option if called as a script.

filename_only

Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the `-q` option if called as a script.

exception NannyNag

Raised by `token eater()` if detecting an ambiguous indent. Captured and handled in `check()`.

token eater(*type, token, start, end, line*)

This function is used by `check()` as a callback parameter to the function `tokenize.tokenize()`.

18.7 pyc1br -- Python class browser support

The `pyc1br` can be used to determine some limited information about the classes, methods and top-level functions defined in a module. The information provided is sufficient to implement a traditional three-pane class browser. The information is extracted from the source code rather than by importing the module, so this module is safe to use with untrusted source code. This restriction makes it impossible to use this module with modules not implemented in Python, including many standard and optional extension modules.

readmodule(*module*[, *path*])

Read a module and return a dictionary mapping class names to class descriptor objects. The parameter *module* should be the name of a module as a string; it may be the name of a module within a package. The *path* parameter should be a sequence, and is used to augment the value of `sys.path`, which is used to locate module source code.

readmodule_ex(*module*[, *path*])

Like `readmodule()`, but the returned dictionary, in addition to mapping class names to class descriptor objects, also maps top-level function names to function descriptor objects. Moreover, if the module being read is a package, the key `'__path__'` in the returned dictionary has as its value a list which contains the package search path.

18.7.1 Class Descriptor Objects

The class descriptor objects used as values in the dictionary returned by `readmodule()` and `readmodule_ex()` provide the following data members:

module

The name of the module defining the class described by the class descriptor.

name

The name of the class.

super

A list of class descriptors which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by `readmodule()` are listed as a string with the class name instead of class descriptors.

methods

A dictionary mapping method names to line numbers.

file

Name of the file containing the `class` statement defining the class.

lineno

The line number of the `class` statement within the file named by `file`.

Previous: [18.7.1 Class Descriptor Objects](#) Up: [18.7 pycldr](#) Next: [18.8 py_compile](#)

18.7.2 Function Descriptor Objects

The function descriptor objects used as values in the dictionary returned by `readmodule_ex()` provide the following data members:

module

The name of the module defining the function described by the function descriptor.

name

The name of the function.

file

Name of the file containing the `def` statement defining the function.

lineno

The line number of the `def` statement within the file named by `file`.

18.8 py_compile -- Compile Python source files

The `py_compile` module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

exception `PyCompileError`

Exception raised when an error occurs while attempting to compile the file.

`compile(file[, cfile[, dfile[, doraise]])`

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file name *file*. The byte-code is written to *cfile*, which defaults to *file* + 'c' ('o' if optimization is enabled in the current interpreter). If *dfile* is specified, it is used as the name of the source file in error messages instead of *file*. If *doraise* = True, a `PyCompileError` is raised when an error is encountered while compiling *file*. If *doraise* = False (the default), an error string is written to `sys.stderr`, but no exception is raised.

`main([args])`

Compile several source files. The files named in *args* (or on the command line, if *args* is not specified) are compiled and the resulting bytecode is cached in the normal manner. This function does not search a directory structure to locate source files; it only compiles files named explicitly.

When this module is run as a script, the `main()` is used to compile all the files named on the command line.

18.9 compileall -- Byte-compile Python libraries

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree, allowing users without permission to write to the libraries to take advantage of cached byte-code files.

The source file for this module may also be used as a script to compile Python sources in directories named on the command line or in `sys.path`.

compile_dir(*dir*[, *maxlevels*[, *ddir*[, *force*[, *rx*[, *quiet*]]]]])

Recursively descend the directory tree named by *dir*, compiling all `.py` files along the way. The *maxlevels* parameter is used to limit the depth of the recursion; it defaults to `10`. If *ddir* is given, it is used as the base path from which the filenames used in error messages will be generated. If *force* is true, modules are re-compiled even if the timestamps are up to date.

If *rx* is given, it specifies a regular expression of file names to exclude from the search; that expression is searched for in the full path.

If *quiet* is true, nothing is printed to the standard output in normal operation.

compile_path([*skip_curdir*[, *maxlevels*[, *force*]]])

Byte-compile all the `.py` files found along `sys.path`. If *skip_curdir* is true (the default), the current directory is not included in the search. The *maxlevels* and *force* parameters default to `0` and are passed to the `compile_dir()` function.

18.10 `dis` -- Disassembler for Python byte code

The `dis` module supports the analysis of Python byte code by disassembling it. Since there is no Python assembler, this module defines the Python assembly language. The Python byte code which this module takes as an input is defined in the file `Include/opcode.h` and used by the compiler and the interpreter.

Example: Given the function `myfunc`:

```
def myfunc(alist):
    return len(alist)
```

the following command can be used to get the disassembly of `myfunc()`:

```
>>> dis.dis(myfunc)
 2          0 LOAD_GLOBAL          0 (len)
          3 LOAD_FAST            0 (alist)
          6 CALL_FUNCTION         1
          9 RETURN_VALUE
        10 LOAD_CONST           0 (None)
        13 RETURN_VALUE
```

(The ``2" is a line number).

The `dis` module defines the following functions and constants:

`dis`([*bytesource*])

Disassemble the *bytesource* object. *bytesource* can denote either a module, a class, a method, a function, or a code object. For a module, it disassembles all functions. For a class, it disassembles all methods. For a single code sequence, it prints one line per byte code instruction. If no object is provided, it disassembles the last traceback.

`distb`([*tb*])

Disassembles the top-of-stack function of a traceback, using the last traceback if none was passed. The instruction causing the exception is indicated.

disassemble(*code*[, *lasti*])

Disassembles a code object, indicating the last instruction if *lasti* was provided. The output is divided in the following columns:

1. the line number, for the first instruction of each line
2. the current instruction, indicated as "- ->",
3. a labelled instruction, indicated with ">>",
4. the address of the instruction,
5. the operation code name,
6. operation parameters, and
7. interpretation of the parameters in parentheses.

The parameter interpretation recognizes local and global variable names, constant values, branch targets, and compare operators.

disco(*code*[, *lasti*])

A synonym for `disassemble`. It is more convenient to type, and kept for compatibility with earlier Python releases.

opname

Sequence of operation names, indexable using the byte code.

cmp_op

Sequence of all compare operation names.

hasconst

Sequence of byte codes that have a constant parameter.

hasfree

Sequence of byte codes that access a free variable.

hasname

Sequence of byte codes that access an attribute by name.

hasjrel

Sequence of byte codes that have a relative jump target.

hasjabs

Sequence of byte codes that have an absolute jump target.

haslocal

Sequence of byte codes that access a local variable.

hascompare

Sequence of byte codes of Boolean operations.

18.10.1 Python Byte Code Instructions

The Python compiler currently generates the following byte code instructions.

STOP_CODE

Indicates end-of-code to the compiler, not used by the interpreter.

NOP

Do nothing code. Used as a placeholder by the bytecode optimizer.

POP_TOP

Removes the top-of-stack (TOS) item.

ROT_TWO

Swaps the two top-most stack items.

ROT_THREE

Lifts second and third stack item one position up, moves top down to position three.

ROT_FOUR

Lifts second, third and fourth stack item one position up, moves top down to position four.

DUP_TOP

Duplicates the reference on top of the stack.

Unary Operations take the top of the stack, apply the operation, and push the result back on the stack.

UNARY_POSITIVE

Implements $TOS = +TOS$.

UNARY_NEGATIVE

Implements $TOS = -TOS$.

UNARY_NOT

Implements $TOS = \text{not } TOS$.

UNARY_CONVERT

Implements $TOS = \text{`TOS`}$.

UNARY_INVERT

Implements $TOS = \sim TOS$.

GET_ITER

Implements $TOS = \text{iter}(TOS)$.

Binary operations remove the top of the stack (TOS) and the second top-most stack item (TOS1) from the stack. They perform the operation, and put the result back on the stack.

BINARY_POWER

Implements $TOS = TOS1 ** TOS$.

BINARY_MULTIPLY

Implements $TOS = TOS1 * TOS$.

BINARY_DIVIDE

Implements $TOS = TOS1 / TOS$ when from `__future__ import division` is not in effect.

BINARY_FLOOR_DIVIDE

Implements $TOS = TOS1 // TOS$.

BINARY_TRUE_DIVIDE

Implements $TOS = TOS1 / TOS$ when from `__future__ import division` is in effect.

BINARY_MODULO

Implements $TOS = TOS1 \% TOS$.

BINARY_ADD

Implements $TOS = TOS1 + TOS$.

BINARY_SUBTRACT

Implements $TOS = TOS1 - TOS$.

BINARY_SUBSCR

Implements $TOS = TOS1[TOS]$.

BINARY_LSHIFT

Implements $TOS = TOS1 \ll TOS$.

BINARY_RSHIFT

Implements $TOS = TOS1 \gg TOS$.

BINARY_AND

Implements $TOS = TOS1 \& TOS$.

BINARY_XOR

Implements $TOS = TOS1 \wedge TOS$.

BINARY_OR

Implements $TOS = TOS1 | TOS$.

In-place operations are like binary operations, in that they remove TOS and TOS1, and push the result back on the stack, but the operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.

INPLACE_POWER

Implements in-place $TOS = TOS1 ** TOS$.

INPLACE_MULTIPLY

Implements in-place $TOS = TOS1 * TOS$.

INPLACE_DIVIDE

Implements in-place $TOS = TOS1 / TOS$ when from `__future__ import division` is not in effect.

INPLACE_FLOOR_DIVIDE

Implements in-place $TOS = TOS1 // TOS$.

INPLACE_TRUE_DIVIDE

Implements in-place $TOS = TOS1 / TOS$ when from `__future__ import division` is in effect.

INPLACE_MODULO

Implements in-place $TOS = TOS1 \% TOS$.

INPLACE_ADD

Implements in-place $TOS = TOS1 + TOS$.

INPLACE_SUBTRACT

Implements in-place $TOS = TOS1 - TOS$.

INPLACE_LSHIFT

Implements in-place $TOS = TOS1 \ll TOS$.

INPLACE_RSHIFT

Implements in-place $TOS = TOS1 \gg TOS$.

INPLACE_AND

Implements in-place $TOS = TOS1 \& TOS$.

INPLACE_XOR

Implements in-place $TOS = TOS1 \wedge TOS$.

INPLACE_OR

Implements in-place $TOS = TOS1 | TOS$.

The slice opcodes take up to three parameters.

SLICE+0

Implements $TOS = TOS[:]$.

SLICE+1

Implements $TOS = TOS1[TOS:]$.

SLICE+2

Implements $TOS = TOS1[:TOS]$.

SLICE+3

Implements $TOS = TOS2[TOS1:TOS]$.

Slice assignment needs even an additional parameter. As any statement, they put nothing on the stack.

STORE_SLICE+0

Implements `TOS[:]` = TOS1.

STORE_SLICE+1

Implements `TOS1[TOS:]` = TOS2.

STORE_SLICE+2

Implements `TOS1[:TOS]` = TOS2.

STORE_SLICE+3

Implements `TOS2[TOS1:TOS]` = TOS3.

DELETE_SLICE+0

Implements `del TOS[:]`.

DELETE_SLICE+1

Implements `del TOS1[TOS:]`.

DELETE_SLICE+2

Implements `del TOS1[:TOS]`.

DELETE_SLICE+3

Implements `del TOS2[TOS1:TOS]`.

STORE_SUBSCR

Implements `TOS1[TOS]` = TOS2.

DELETE_SUBSCR

Implements `del TOS1[TOS]`.

Miscellaneous opcodes.

PRINT_EXPR

Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with `POP_STACK`.

PRINT_ITEM

Prints TOS to the file-like object bound to `sys.stdout`. There is one such instruction for each item in the `print` statement.

PRINT_ITEM_TO

Like `PRINT_ITEM`, but prints the item second from TOS to the file-like object at TOS. This is used by the extended print statement.

PRINT_NEWLINE

Prints a new line on `sys.stdout`. This is generated as the last operation of a `print` statement, unless the statement ends with a comma.

PRINT_NEWLINE_TO

Like `PRINT_NEWLINE`, but prints the new line on the file-like object on the TOS. This is used by the extended print statement.

BREAK_LOOP

Terminates a loop due to a `break` statement.

CONTINUE_LOOP *target*

Continues a loop due to a `continue` statement. *target* is the address to jump to (which should be a `FOR_ITER` instruction).

LIST_APPEND

Calls `list.append(TOS1, TOS)`. Used to implement list comprehensions.

LOAD_LOCALS

Pushes a reference to the locals of the current scope on the stack. This is used in the code for a class definition: After the class body is evaluated, the locals are passed to the class definition.

RETURN_VALUE

Returns with TOS to the caller of the function.

YIELD_VALUE

Pops TOS and yields it from a generator.

IMPORT_STAR

Loads all symbols not starting with `"_"` directly from the module TOS to the local namespace. The module is popped after loading all names. This opcode implements `from module import *`.

EXEC_STMT

Implements `exec TOS2, TOS1, TOS`. The compiler fills missing optional parameters with `None`.

POP_BLOCK

Removes one block from the block stack. Per frame, there is a stack of blocks, denoting nested loops, try statements, and such.

END_FINALLY

Terminates a `finally` clause. The interpreter recalls whether the exception has to be re-raised, or whether the function returns, and continues with the outer-next block.

BUILD_CLASS

Creates a new class object. `TOS` is the methods dictionary, `TOS1` the tuple of the names of the base classes, and `TOS2` the class name.

All of the following opcodes expect arguments. An argument is two bytes, with the more significant byte last.

STORE_NAME *namei*

Implements `name = TOS`. *namei* is the index of *name* in the attribute `co_names` of the code object. The compiler tries to use `STORE_LOCAL` or `STORE_GLOBAL` if possible.

DELETE_NAME *namei*

Implements `del name`, where *namei* is the index into `co_names` attribute of the code object.

UNPACK_SEQUENCE *count*

Unpacks `TOS` into *count* individual values, which are put onto the stack right-to-left.

DUP_TOPX *count*

Duplicate *count* items, keeping them in the same order. Due to implementation limits, *count* should be between 1 and 5 inclusive.

STORE_ATTR *namei*

Implements `TOS.name = TOS1`, where *namei* is the index of *name* in

co_names.

DELETE_ATTR *namei*

Implements `del TOS.name`, using *namei* as index into `co_names`.

STORE_GLOBAL *namei*

Works as `STORE_NAME`, but stores the name as a global.

DELETE_GLOBAL *namei*

Works as `DELETE_NAME`, but deletes a global name.

LOAD_CONST *consti*

Pushes `"co_consts[consti]"` onto the stack.

LOAD_NAME *namei*

Pushes the value associated with `"co_names[namei]"` onto the stack.

BUILD_TUPLE *count*

Creates a tuple consuming *count* items from the stack, and pushes the resulting tuple onto the stack.

BUILD_LIST *count*

Works as `BUILD_TUPLE`, but creates a list.

BUILD_MAP *zero*

Pushes a new empty dictionary object onto the stack. The argument is ignored and set to zero by the compiler.

LOAD_ATTR *namei*

Replaces TOS with `getattr(TOS, co_names[namei])`.

COMPARE_OP *opname*

Performs a Boolean operation. The operation name can be found in `cmp_op[opname]`.

IMPORT_NAME *namei*

Imports the module `co_names[namei]`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent `STORE_FAST` instruction modifies the namespace.

IMPORT_FROM *namei*

Loads the attribute `co_names[namei]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a `STORE_FAST` instruction.

JUMP_FORWARD *delta*

Increments byte code counter by *delta*.

JUMP_IF_TRUE *delta*

If TOS is true, increment the byte code counter by *delta*. TOS is left on the stack.

JUMP_IF_FALSE *delta*

If TOS is false, increment the byte code counter by *delta*. TOS is not changed.

JUMP_ABSOLUTE *target*

Set byte code counter to *target*.

FOR_ITER *delta*

TOS is an iterator. Call its `next()` method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted TOS is popped, and the byte code counter is incremented by *delta*.

LOAD_GLOBAL *namei*

Loads the global named `co_names[namei]` onto the stack.

SETUP_LOOP *delta*

Pushes a block for a loop onto the block stack. The block spans from the current instruction with a size of *delta* bytes.

SETUP_EXCEPT *delta*

Pushes a try block from a try-except clause onto the block stack. *delta* points to the first except block.

SETUP_FINALLY *delta*

Pushes a try block from a try-except clause onto the block stack. *delta* points to the finally block.

LOAD_FAST *var_num*

Pushes a reference to the local `co_varnames[var_num]` onto the stack.

STORE_FAST *var_num*

Stores TOS into the local `co_varnames[var_num]`.

DELETE_FAST *var_num*

Deletes local `co_varnames[var_num]`.

LOAD_CLOSURE *i*

Pushes a reference to the cell contained in slot *i* of the cell and free variable storage. The name of the variable is `co_cellvars[i]` if *i* is less than the length of `co_cellvars`. Otherwise it is `co_freevars[i - len(co_cellvars)]`.

LOAD_DEREF *i*

Loads the cell contained in slot *i* of the cell and free variable storage. Pushes a reference to the object the cell contains on the stack.

STORE_DEREF *i*

Stores TOS into the cell contained in slot *i* of the cell and free variable storage.

SET_LINENO *lineno*

This opcode is obsolete.

RAISE_VARARGS *argc*

Raises an exception. *argc* indicates the number of parameters to the raise statement, ranging from 0 to 3. The handler will find the traceback as TOS2, the parameter as TOS1, and the exception as TOS.

CALL_FUNCTION *argc*

Calls a function. The low byte of *argc* indicates the number of positional parameters, the high byte the number of keyword parameters. On the stack, the opcode finds the keyword parameters first. For each keyword argument, the value is on top of the key. Below the keyword parameters, the positional parameters are on the stack, with the right-most parameter on top. Below the parameters, the function object to call is on the stack.

MAKE_FUNCTION *argc*

Pushes a new function object on the stack. TOS is the code associated with the function. The function object is defined to have *argc* default parameters, which are found below TOS.

MAKE_CLOSURE *argc*

Creates a new function object, sets its *func_closure* slot, and pushes it on the stack. TOS is the code associated with the function. If the code object has N free variables, the next N items on the stack are the cells for these variables. The function also has *argc* default parameters, where are found before the cells.

BUILD_SLICE *argc*

Pushes a slice object on the stack. *argc* must be 2 or 3. If it is 2, `slice(TOS1, TOS)` is pushed; if it is 3, `slice(TOS2, TOS1, TOS)` is pushed. See the `slice()` built-in function for more information.

EXTENDED_ARG *ext*

Prefixes any opcode which has an argument too big to fit into the default two bytes. *ext* holds two additional bytes which, taken together with the subsequent opcode's argument, comprise a four-byte argument, *ext* being the two most-significant bytes.

CALL_FUNCTION_VAR *argc*

Calls a function. *argc* is interpreted as in `CALL_FUNCTION`. The top element on the stack contains the variable argument list, followed by keyword and positional arguments.

CALL_FUNCTION_KW *argc*

Calls a function. *argc* is interpreted as in `CALL_FUNCTION`. The top element on the stack contains the keyword arguments dictionary, followed by explicit keyword and positional arguments.

CALL_FUNCTION_VAR_KW *argc*

Calls a function. *argc* is interpreted as in `CALL_FUNCTION`. The top element on the stack contains the keyword arguments dictionary, followed by the variable-arguments tuple, followed by explicit keyword and positional arguments.

18.11 `pickletools` -- Tools for pickle developers.

This module contains various constants relating to the intimate details of the `pickle` module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the `pickle` and `cPickle` implementations; ordinary users of the `pickle` module probably won't find the `pickletools` module relevant.

`dis`(*pickle*[, *out*=None, *memo*=None, *indentlevel*=4])

Outputs a symbolic disassembly of the pickle to the file-like object *out*, defaulting to `sys.stdout`. *pickle* can be a string or a file-like object. *memo* can be a Python dictionary that will be used as the pickle's memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by MARK opcodes in the stream, are indented by *indentlevel* spaces.

`genops`(*pickle*)

Provides an iterator over all of the opcodes in a pickle, returning a sequence of (*opcode*, *arg*, *pos*) triples. *opcode* is an instance of an `OpcodeInfo` class; *arg* is the decoded value, as a Python object, of the opcode's argument; *pos* is the position at which this opcode is located. *pickle* can be a string or a file-like object.

18.12 distutils -- Building and installing Python modules

The `distutils` package provides support for building and installing additional modules into a Python installation. The new modules may be either 100%-pure Python, or may be extension modules written in C, or may be collections of Python packages which include modules coded in both Python and C.

This package is discussed in two separate documents which are included in the Python documentation package. To learn about distributing new modules using the `distutils` facilities, read [Distributing Python Modules](#); this includes documentation needed to extend `distutils`. To learn about installing Python modules, whether or not the author made use of the `distutils` package, read [Installing Python Modules](#).

See Also:

[Distributing Python Modules](#)

The manual for developers and packagers of Python modules. This describes how to prepare `distutils`-based packages so that they may be easily installed into an existing Python installation.

[Installing Python Modules](#)

An "administrators" manual which includes information on installing modules into an existing Python installation. You do not need to be a Python programmer to read this manual.

See [About this document..](#) for information on suggesting changes.

19. Python compiler package

The Python compiler package is a tool for analyzing Python source code and generating Python bytecode. The compiler contains libraries to generate an abstract syntax tree from Python source code and to generate Python bytecode from the tree.

The [compiler](#) package is a Python source to bytecode translator written in Python. It uses the built-in parser and standard [parser](#) module to generate a concrete syntax tree. This tree is used to generate an abstract syntax tree (AST) and then Python bytecode.

The full functionality of the package duplicates the builtin compiler provided with the Python interpreter. It is intended to match its behavior almost exactly. Why implement another compiler that does the same thing? The package is useful for a variety of purposes. It can be modified more easily than the builtin compiler. The AST it generates is useful for analyzing Python source code.

This chapter explains how the various components of the [compiler](#) package work. It blends reference material with a tutorial.

The following modules are part of the [compiler](#) package:

[compiler](#)

[compiler.ast](#)

[compiler.visitor](#)

Previous: [19. Python compiler package](#) **Up:** [19. Python compiler package](#)
Next: [19.2 Limitations](#)

19.1 The basic interface

The top-level of the package defines four functions. If you import `compiler`, you will get these functions and a collection of modules contained in the package.

parse(*buf*)

Returns an abstract syntax tree for the Python source code in *buf*. The function raises `SyntaxError` if there is an error in the source code. The return value is a `compiler.ast.Module` instance that contains the tree.

parseFile(*path*)

Return an abstract syntax tree for the Python source code in the file specified by *path*. It is equivalent to `parse(open(path).read())`.

walk(*ast*, *visitor*[, *verbose*])

Do a pre-order walk over the abstract syntax tree *ast*. Call the appropriate method on the *visitor* instance for each node encountered.

compile(*source*, *filename*, *mode*, *flags=None*, *dont_inherit=None*)

Compile the string *source*, a Python module, statement or expression, into a code object that can be executed by the `exec` statement or `eval()`. This function is a replacement for the built-in `compile()` function.

The *filename* will be used for run-time error messages.

The *mode* must be 'exec' to compile a module, 'single' to compile a single (interactive) statement, or 'eval' to compile an expression.

The *flags* and *dont_inherit* arguments affect future-related statements, but are not supported yet.

compileFile(*source*)

Compiles the file *source* and generates a .pyc file.

The `compiler` package contains the following modules: [ast](#), `consts`,

future, misc, pyassem, pycodegen, symbols, transformer, and [visitor](#).

Previous: [19.1 The basic interface](#) **Up:** [19. Python compiler package](#) **Next:**
[19.3 Python Abstract Syntax](#)

19.2 Limitations

There are some problems with the error checking of the compiler package. The interpreter detects syntax errors in two distinct phases. One set of errors is detected by the interpreter's parser, the other set by the compiler. The compiler package relies on the interpreter's parser, so it get the first phases of error checking for free. It implements the second phase itself, and that implementation is incomplete. For example, the compiler package does not raise an error if a name appears more than once in an argument list: `def f(x, x): ...`

A future version of the compiler should fix these problems.

Previous: [19.2 Limitations](#) **Up:** [19. Python compiler package](#) **Next:** [19.3.1 AST Nodes](#)

19.3 Python Abstract Syntax

The `compiler.ast` module defines an abstract syntax for Python. In the abstract syntax tree, each node represents a syntactic construct. The root of the tree is `Module` object.

The abstract syntax offers a higher level interface to parsed Python source code. The [parser](#) module and the compiler written in C for the Python interpreter use a concrete syntax tree. The concrete syntax is tied closely to the grammar description used for the Python parser. Instead of a single node for a construct, there are often several levels of nested nodes that are introduced by Python's precedence rules.

The abstract syntax tree is created by the `compiler.transformer` module. The transformer relies on the builtin Python parser to generate a concrete syntax tree. It generates an abstract syntax tree from the concrete tree.

The `transformer` module was created by Greg Stein and Bill Tutt for an experimental Python-to-C compiler. The current version contains a number of modifications and improvements, but the basic form of the abstract syntax and of the transformer are due to Stein and Tutt.

19.3.1 AST Nodes

The `compiler.ast` module is generated from a text file that describes each node type and its elements. Each node type is represented as a class that inherits from the abstract base class `compiler.ast.Node` and defines a set of named attributes for child nodes.

class Node()

The `Node` instances are created automatically by the parser generator. The recommended interface for specific `Node` instances is to use the public attributes to access child nodes. A public attribute may be bound to a single node or to a sequence of nodes, depending on the `Node` type. For example, the `bases` attribute of the `Class` node, is bound to a list of base class nodes, and the `doc` attribute is bound to a single node.

Each `Node` instance has a `lineno` attribute which may be `None`. XXX
Not sure what the rules are for which nodes will have a useful `lineno`.

All `Node` objects offer the following methods:

getChildren()

Returns a flattened list of the child nodes and objects in the order they occur. Specifically, the order of the nodes is the order in which they appear in the Python grammar. Not all of the children are `Node` instances. The names of functions and classes, for example, are plain strings.

getChildNodes()

Returns a flattened list of the child nodes in the order they occur. This method is like `getChildren()`, except that it only returns those children that are `Node` instances.

Two examples illustrate the general structure of `Node` classes. The `while` statement is defined by the following grammar production:

```
while_stmt:    "while" expression ":" suite
              ["else" ":" suite]
```

The `While` node has three attributes: `test`, `body`, and `else_`. (If the natural name for an attribute is also a Python reserved word, it can't be used as an attribute name. An underscore is appended to the word to make it a legal identifier, hence `else_` instead of `else`.)

The `if` statement is more complicated because it can include several tests.

```
if_stmt: 'if' test ':' suite ('elif' test ':' suite)* ['else' ':' su
```

The `If` node only defines two attributes: `tests` and `else_`. The `tests` attribute is a sequence of test expression, consequent body pairs. There is one pair for each `if/elif` clause. The first element of the pair is the test expression. The second elements is a `Stmt` node that contains the code to execute if the test is true.

The `getChildren()` method of `If` returns a flat list of child nodes. If there are three `if/elif` clauses and no `else` clause, then `getChildren()` will return a list of six elements: the first test expression, the first `Stmt`, the second text expression, etc.

The following table lists each of the `Node` subclasses defined in `compiler.ast` and each of the public attributes available on their instances. The values of most of the attributes are themselves `Node` instances or sequences of instances. When the value is something other than an instance, the type is noted in the comment. The attributes are listed in the order in which they are returned by `getChildren()` and `getChildNodes()`.

Node type	Attribute	Value
Add	<code>left</code>	left operand
	<code>right</code>	right operand
And	<code>nodes</code>	list of operands
AssAttr		<i>attribute as target of assignment</i>
	<code>expr</code>	expression on the left-hand side of the dot

19.3.2 Assignment nodes

There is a collection of nodes used to represent assignments. Each assignment statement in the source code becomes a single `Assign` node in the AST. The `nodes` attribute is a list that contains a node for each assignment target. This is necessary because assignment can be chained, e.g. `a = b = 2`. Each Node in the list will be one of the following classes: `ASSAttr`, `ASSList`, `ASSName`, or `ASSTuple`.

Each target assignment node will describe the kind of object being assigned to: `ASSName` for a simple name, e.g. `a = 1`. `ASSAttr` for an attribute assigned, e.g. `a.x = 1`. `ASSList` and `ASSTuple` for list and tuple expansion respectively, e.g. `a, b, c = a_tuple`.

The target assignment nodes also have a `flags` attribute that indicates whether the node is being used for assignment or in a delete statement. The `ASSName` is also used to represent a delete statement, e.g. `del x`.

When an expression contains several attribute references, an assignment or delete statement will contain only one `ASSAttr` node - for the final attribute reference. The other attribute references will be represented as `GetAttr` nodes in the `expr` attribute of the `ASSAttr` instance.

19.3.3 Examples

This section shows several simple examples of ASTs for Python source code. The examples demonstrate how to use the `parse()` function, what the repr of an AST looks like, and how to access attributes of an AST node.

The first module defines a single function. Assume it is stored in `/tmp/doublelib.py`.

```
"""This is an example module.

This is the docstring.
"""

def double(x):
    "Return twice the argument"
    return x * 2
```

In the interactive interpreter session below, I have reformatted the long AST reprs for readability. The AST reprs use unqualified class names. If you want to create an instance from a repr, you must import the class names from the `compiler.ast` module.

```
>>> import compiler
>>> mod = compiler.parseFile("/tmp/doublelib.py")
>>> mod
Module('This is an example module.\n\nThis is the docstring.\n',
      Stmt([Function(None, 'double', ['x'], [], 0,
                    'Return twice the argument',
                    Stmt([Return(Mul((Name('x'), Const(2))))]))]))
>>> from compiler.ast import *
>>> Module('This is an example module.\n\nThis is the docstring.\n',
...       Stmt([Function(None, 'double', ['x'], [], 0,
...                     'Return twice the argument',
...                     Stmt([Return(Mul((Name('x'), Const(2))))]))]))
Module('This is an example module.\n\nThis is the docstring.\n',
      Stmt([Function(None, 'double', ['x'], [], 0,
                    'Return twice the argument',
                    Stmt([Return(Mul((Name('x'), Const(2))))]))]))
>>> mod.doc
'This is an example module.\n\nThis is the docstring.\n'
>>> for node in mod.node.nodes:
...     print node
...
Function(None, 'double', ['x'], [], 0, 'Return twice the argument',
        Stmt([Return(Mul((Name('x'), Const(2))))]))
```

```
>>> func = mod.node.nodes[0]
>>> func.code
Stmt([Return(Mul((Name('x'), Const(2))))])
```

19.4 Using Visitors to Walk ASTs

The visitor pattern is ... The `compiler` package uses a variant on the visitor pattern that takes advantage of Python's introspection features to eliminate the need for much of the visitor's infrastructure.

The classes being visited do not need to be programmed to accept visitors. The visitor need only define visit methods for classes it is specifically interested in; a default visit method can handle the rest.

XXX The magic `visit()` method for visitors.

walk(*tree*, *visitor*[, *verbose*])

class ASTVisitor()

The `ASTVisitor` is responsible for walking over the tree in the correct order. A walk begins with a call to `preorder()`. For each node, it checks the *visitor* argument to `preorder()` for a method named `visitNodeType`, where `NodeType` is the name of the node's class, e.g. for a `While` node a `visitWhile()` would be called. If the method exists, it is called with the node as its first argument.

The visitor method for a particular node type can control how child nodes are visited during the walk. The `ASTVisitor` modifies the visitor argument by adding a visit method to the visitor; this method can be used to visit a particular child node. If no visitor is found for a particular node type, the `default()` method is called.

`ASTVisitor` objects have the following methods:

XXX describe extra arguments

default(*node*[, ...])

dispatch(*node*[, ...])

`preorder(tree, visitor)`

19.5 Bytecode Generation

The code generator is a visitor that emits bytecodes. Each visit method can call the `emit ()` method to emit a new bytecode. The basic code generator is specialized for modules, classes, and functions. An assembler converts that emitted instructions to the low-level bytecode format. It handles things like generator of constant lists of code objects and calculation of jump offsets.

20. SGI IRIX Specific Services

The modules described in this chapter provide interfaces to features that are unique to SGI's IRIX operating system (versions 4 and 5).

a1	Audio functions on the SGI.
AL	Constants used with the a1 module.
cd	Interface to the CD-ROM on Silicon Graphics systems.
f1	FORMS library for applications with graphical user interfaces.
FL	Constants used with the f1 module.
flp	Functions for loading stored FORMS designs.
fm	<i>Font Manager</i> interface for SGI workstations.
gl	Functions from the Silicon Graphics <i>Graphics Library</i> .
DEVICE	Constants used with the gl module.
GL	Constants used with the gl module.
imgfile	Support for SGI <i>imglib</i> files.
jpeg	Read and write image files in compressed JPEG format.

Previous: [20. SGI IRIX Specific](#) **Up:** [20. SGI IRIX Specific](#) **Next:** [20.1.1 Configuration Objects](#)

20.1 a1 -- Audio functions on the SGI

Availability: **IRIX**.

This module provides access to the audio facilities of the SGI Indy and Indigo workstations. See section 3A of the IRIX man pages for details. You'll need to read those man pages to understand what these functions do! Some of the functions are not available in IRIX releases before 4.0.5. Again, see the manual to check whether a specific function is available on your platform.

All functions and methods defined in this module are equivalent to the C functions with "AL" prefixed to their name.

Symbolic constants from the C header file `<audio.h>` are defined in the standard module [AL](#), see below.

Warning: The current version of the audio library may dump core when bad argument values are passed rather than returning an error status. Unfortunately, since the precise circumstances under which this may happen are undocumented and hard to check, the Python interface can provide no protection against this kind of problems. (One example is specifying an excessive queue size -- there is no documented upper limit.)

The module defines the following functions:

openport(*name*, *direction*[, *config*])

The name and direction arguments are strings. The optional *config* argument is a configuration object as returned by `newconfig()`. The return value is an *audio port object*; methods of audio port objects are described below.

newconfig()

The return value is a new *audio configuration object*; methods of audio configuration objects are described below.

queryparams(*device*)

The *device* argument is an integer. The return value is a list of integers containing the data returned by `ALqueryparams()`.

getparams(*device*, *list*)

The *device* argument is an integer. The *list* argument is a list such as returned by `queryparams()`; it is modified in place (!).

setparams(*device*, *list*)

The *device* argument is an integer. The *list* argument is a list such as returned by `queryparams()`.

20.1.2 Port Objects

Port objects, as returned by `openport ()`, have the following methods:

closeport()

Close the port.

getfd()

Return the file descriptor as an int.

getfilled()

Return the number of filled samples.

getfillable()

Return the number of fillable samples.

readsamps(*nsamples*)

Read a number of samples from the queue, blocking if necessary. Return the data as a string containing the raw data, (e.g., 2 bytes per sample in big-endian byte order (high byte, low byte) if you have set the sample width to 2 bytes).

writesamps(*samples*)

Write samples into the queue, blocking if necessary. The samples are encoded as described for the `readsamps ()` return value.

getfillpoint()

Return the `fill point'.

setfillpoint(*fillpoint*)

Set the `fill point'.

getconfig()

Return a configuration object containing the current configuration of the port.

setconfig(*config*)

Set the configuration from the argument, a configuration object.

getstatus(*list*)

Get status information on last error.

20.3 cd -- CD-ROM access on SGI systems

Availability: **IRIX**.

This module provides an interface to the Silicon Graphics CD library. It is available only on Silicon Graphics systems.

The way the library works is as follows. A program opens the CD-ROM device with `open()` and creates a parser to parse the data from the CD with `createparser()`. The object returned by `open()` can be used to read data from the CD, but also to get status information for the CD-ROM device, and to get information about the CD, such as the table of contents. Data from the CD is passed to the parser, which parses the frames, and calls any callback functions that have previously been added.

An audio CD is divided into *tracks* or *programs* (the terms are used interchangeably). Tracks can be subdivided into *indices*. An audio CD contains a *table of contents* which gives the starts of the tracks on the CD. Index 0 is usually the pause before the start of a track. The start of the track as given by the table of contents is normally the start of index 1.

Positions on a CD can be represented in two ways. Either a frame number or a tuple of three values, minutes, seconds and frames. Most functions use the latter representation. Positions can be both relative to the beginning of the CD, and to the beginning of the track.

Module `cd` defines the following functions and constants:

createparser()

Create and return an opaque parser object. The methods of the parser object are described below.

msftoframe(*minutes, seconds, frames*)

Converts a (*minutes, seconds, frames*) triple representing time in absolute time code into the corresponding CD frame number.

open([*device*[, *mode*]])

Open the CD-ROM device. The return value is an opaque player object; methods of the player object are described below. The device is the name of the SCSI device file, e.g. `'/dev/scsi/sc0d410 '`, or `None`. If omitted or `None`, the hardware inventory is consulted to locate a CD-ROM drive. The *mode*, if not omitted, should be the string `'r '` .

The module defines the following variables:

exception error

Exception raised on various errors.

DATASIZE

The size of one frame's worth of audio data. This is the size of the audio data as passed to the callback of type `audio`.

BLOCKSIZE

The size of one uninterpreted frame of audio data.

The following variables are states as returned by `getstatus()`:

READY

The drive is ready for operation loaded with an audio CD.

NODISC

The drive does not have a CD loaded.

CDROM

The drive is loaded with a CD-ROM. Subsequent play or read operations will return I/O errors.

ERROR

An error occurred while trying to read the disc or its table of contents.

PLAYING

The drive is in CD player mode playing an audio CD through its audio jacks.

PAUSED

The drive is in CD layer mode with play paused.

STILL

The equivalent of PAUSED on older (non 3301) model Toshiba CD-ROM drives. Such drives have never been shipped by SGI.

audio

pnum

Previous: [20.3 cd](#) Up: [20.3 cd](#) Next: [20.3.2 Parser Objects](#)

20.3.1 Player Objects

Player objects (returned by `open()`) have the following methods:

allowremoval()

Unlocks the eject button on the CD-ROM drive permitting the user to eject the caddy if desired.

bestreadsize()

Returns the best value to use for the *num_frames* parameter of the `readdata()` method. Best is defined as the value that permits a continuous flow of data from the CD-ROM drive.

close()

Frees the resources associated with the player object. After calling `close()`, the methods of the object should no longer be used.

eject()

Ejects the caddy from the CD-ROM drive.

getstatus()

Returns information pertaining to the current state of the CD-ROM drive. The returned information is a tuple with the following values: *state*, *track*, *rtime*, *atime*, *ttime*, *first*, *last*, *scsi_audio*, *cur_block*. *rtime* is the time relative to the start of the current track; *atime* is the time relative to the beginning of the disc; *ttime* is the total time on the disc. For more information on the meaning of the values, see the man page `CDgetstatus(3dm)`. The value of *state* is one of the following: **ERROR**, **NODISC**, **READY**, **PLAYING**, **PAUSED**, **STILL**, or **CDROM**.

gettrackinfo(track)

Returns information about the specified track. The returned information is a tuple consisting of two elements, the start time of the track and the duration of the track.

msftoblock(min, sec, frame)

Converts a minutes, seconds, frames triple representing a time in absolute time code into the corresponding logical block number for the given CD-ROM drive. You should use `msftoframe()` rather than `msftoblock()` for comparing times. The logical block number differs from the frame number by an offset required by certain CD-ROM drives.

play(*start*, *play*)

Starts playback of an audio CD in the CD-ROM drive at the specified track. The audio output appears on the CD-ROM drive's headphone and audio jacks (if fitted). Play stops at the end of the disc. *start* is the number of the track at which to start playing the CD; if *play* is 0, the CD will be set to an initial paused state. The method `togglepause()` can then be used to commence play.

playabs(*minutes*, *seconds*, *frames*, *play*)

Like `play()`, except that the start is given in minutes, seconds, and frames instead of a track number.

playtrack(*start*, *play*)

Like `play()`, except that playing stops at the end of the track.

playtrackabs(*track*, *minutes*, *seconds*, *frames*, *play*)

Like `play()`, except that playing begins at the specified absolute time and ends at the end of the specified track.

preventremoval()

Locks the eject button on the CD-ROM drive thus preventing the user from arbitrarily ejecting the caddy.

readda(*num_frames*)

Reads the specified number of frames from an audio CD mounted in the CD-ROM drive. The return value is a string representing the audio frames. This string can be passed unaltered to the `parseframe()` method of the parser object.

seek(*minutes*, *seconds*, *frames*)

Sets the pointer that indicates the starting point of the next read of digital

audio data from a CD-ROM. The pointer is set to an absolute time code location specified in *minutes*, *seconds*, and *frames*. The return value is the logical block number to which the pointer has been set.

seekblock(*block*)

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to the specified logical block number. The return value is the logical block number to which the pointer has been set.

seektrack(*track*)

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to the specified track. The return value is the logical block number to which the pointer has been set.

stop()

Stops the current playing operation.

togglepause()

Pauses the CD if it is playing, and makes it play if it is paused.

Previous: [20.3.1 Player Objects](#) Up: [20.3 cd](#) Next: [20.4 fl](#)

20.3.2 Parser Objects

Parser objects (returned by `createparser()`) have the following methods:

addcallback(*type*, *func*, *arg*)

Adds a callback for the parser. The parser has callbacks for eight different types of data in the digital audio data stream. Constants for these types are defined at the `cd` module level (see above). The callback is called as follows: `func(arg, type, data)`, where *arg* is the user supplied argument, *type* is the particular type of callback, and *data* is the data returned for this *type* of callback. The type of the data depends on the *type* of callback as follows:

Type	Value
<code>audio</code>	String which can be passed unmodified to <code>al.writesamps()</code> .
<code>pnum</code>	Integer giving the program (track) number.
<code>index</code>	Integer giving the index number.
<code>ptime</code>	Tuple consisting of the program time in minutes, seconds, and frames.
<code>atime</code>	Tuple consisting of the absolute time in minutes, seconds, and frames.
<code>catalog</code>	String of 13 characters, giving the catalog number of the CD.
<code>ident</code>	String of 12 characters, giving the ISRC identification number of the recording. The string consists of two characters country code, three characters owner code, two characters giving the year, and five characters giving a serial number.
<code>control</code>	Integer giving the control bits from the CD subcode data

deleteparser()

Deletes the parser and frees the memory it was using. The object should not be used after this call. This call is done automatically when the last reference to the object is removed.

parseframe(*frame*)

Parses one or more frames of digital audio data from a CD such as returned by `readdata()`. It determines which subcodes are present in the data. If these subcodes have changed since the last frame, then `parseframe()` executes a callback of the appropriate type passing to it the subcode data found in the frame. Unlike the `C` function, more than one frame of digital audio data can be passed to this method.

removecallback(*type*)

Removes the callback for the given *type*.

resetparser()

Resets the fields of the parser used for tracking subcodes to an initial state. `resetparser()` should be called after the disc has been changed.

20.4 fl -- FORMS library for graphical user interfaces

Availability: **IRIX**.

This module provides an interface to the FORMS Library by Mark Overmars. The source for the library can be retrieved by anonymous ftp from host "ftp.cs.ruu.nl", directory SGI/FORMS. It was last tested with version 2.0b.

Most functions are literal translations of their C equivalents, dropping the initial "fl_" from their name. Constants used by the library are defined in module [FL](#) described below.

The creation of objects is a little different in Python than in C: instead of the 'current form' maintained by the library to which new FORMS objects are added, all functions that add a FORMS object to a form are methods of the Python object representing the form. Consequently, there are no Python equivalents for the C functions `fl_addto_form()` and `fl_end_form()`, and the equivalent of `fl_bgn_form()` is called `fl.make_form()`.

Watch out for the somewhat confusing terminology: FORMS uses the word *object* for the buttons, sliders etc. that you can place in a form. In Python, 'object' means any value. The Python interface to FORMS introduces two new Python object types: form objects (representing an entire form) and FORMS objects (representing one button, slider etc.). Hopefully this isn't too confusing.

There are no 'free objects' in the Python interface to FORMS, nor is there an easy way to add object classes written in Python. The FORMS interface to GL event handling is available, though, so you can mix FORMS with pure GL windows.

Please note: importing `fl` implies a call to the GL function `foreground()` and to the FORMS routine `fl_init()`.

20.4.1 Functions Defined in Module `f1`

Module `f1` defines the following functions. For more information about what they do, see the description of the equivalent C function in the FORMS documentation:

`make_form()` (*type, width, height*)

Create a form with given type, width and height. This returns a *form* object, whose methods are described below.

`do_forms()`

The standard FORMS main loop. Returns a Python object representing the FORMS object needing interaction, or the special value `FL.EVENT`.

`check_forms()`

Check for FORMS events. Returns what `do_forms()` above returns, or `None` if there is no event that immediately needs interaction.

`set_event_callback()` (*function*)

Set the event callback function.

`set_graphics_mode()` (*rgbmode, doublebuffering*)

Set the graphics modes.

`get_rgbmode()`

Return the current rgb mode. This is the value of the C global variable `f1_rgbmode`.

`show_message()` (*str1, str2, str3*)

Show a dialog box with a three-line message and an OK button.

`show_question()` (*str1, str2, str3*)

Show a dialog box with a three-line message and YES and NO buttons. It returns `1` if the user pressed YES, `0` if NO.

show_choice(*str1*, *str2*, *str3*, *but1*[, *but2*[, *but3*]])

Show a dialog box with a three-line message and up to three buttons. It returns the number of the button clicked by the user (1, 2 or 3).

show_input(*prompt*, *default*)

Show a dialog box with a one-line prompt message and text field in which the user can enter a string. The second argument is the default input string. It returns the string value as edited by the user.

show_file_selector(*message*, *directory*, *pattern*, *default*)

Show a dialog box in which the user can select a file. It returns the absolute filename selected by the user, or `NONE` if the user presses Cancel.

get_directory()

get_pattern()

get_filename()

These functions return the directory, pattern and filename (the tail part only) selected by the user in the last `show_file_selector()` call.

qdevice(*dev*)

unqdevice(*dev*)

isqueued(*dev*)

qtest()

qread()

qreset()

qenter(*dev*, *val*)

get_mouse()

tie(*button*, *valuator1*, *valuator2*)

These functions are the FORMS interfaces to the corresponding GL functions. Use these if you want to handle some GL events yourself when using `fl.do_events()`. When a GL event is detected that FORMS cannot handle, `fl.do_forms()` returns the special value `FL.EVENT` and you should call `fl.qread()` to read the event from the queue. Don't use the equivalent GL functions!

color()

mapcolor()

getmcolor()

See the description in the FORMS documentation of `fl_color()`,
`fl_mapcolor()` and `fl_getmcolor()`.

Previous: [20.4.1 Functions Defined in](#) **Up:** [20.4 fl](#) **Next:** [20.4.3 FORMS Objects](#)

20.4.2 Form Objects

Form objects (returned by `make_form()` above) have the following methods. Each method corresponds to a C function whose name is prefixed with "fl_"; and whose first argument is a form pointer; please refer to the official FORMS documentation for descriptions.

All the `add_*` methods return a Python object representing the FORMS object. Methods of FORMS objects are described below. Most kinds of FORMS object also have some methods specific to that kind; these methods are listed here.

show_form(*placement, bordertype, name*)

Show the form.

hide_form()

Hide the form.

redraw_form()

Redraw the form.

set_form_position(*x, y*)

Set the form's position.

freeze_form()

Freeze the form.

unfreeze_form()

Unfreeze the form.

activate_form()

Activate the form.

deactivate_form()

Deactivate the form.

bgn_group()

Begin a new group of objects; return a group object.

end_group()

End the current group of objects.

find_first()

Find the first object in the form.

find_last()

Find the last object in the form.

add_box(*type, x, y, w, h, name*)

Add a box object to the form. No extra methods.

add_text(*type, x, y, w, h, name*)

Add a text object to the form. No extra methods.

add_clock(*type, x, y, w, h, name*)

Add a clock object to the form.

Method: `get_clock()`.

add_button(*type, x, y, w, h, name*)

Add a button object to the form.

Methods: `get_button()`, `set_button()`.

add_lightbutton(*type, x, y, w, h, name*)

Add a lightbutton object to the form.

Methods: `get_button()`, `set_button()`.

add_roundbutton(*type, x, y, w, h, name*)

Add a roundbutton object to the form.

Methods: `get_button()`, `set_button()`.

add_slider(*type, x, y, w, h, name*)

Add a slider object to the form.

Methods: `set_slider_value()`, `get_slider_value()`,

set_slider_bounds(), get_slider_bounds(),
set_slider_return(), set_slider_size(),
set_slider_precision(), set_slider_step().

add_valslider(*type, x, y, w, h, name*)

Add a valslider object to the form.

Methods: set_slider_value(), get_slider_value(),
set_slider_bounds(), get_slider_bounds(),
set_slider_return(), set_slider_size(),
set_slider_precision(), set_slider_step().

add_dial(*type, x, y, w, h, name*)

Add a dial object to the form.

Methods: set_dial_value(), get_dial_value(),
set_dial_bounds(), get_dial_bounds().

add_positioner(*type, x, y, w, h, name*)

Add a positioner object to the form.

Methods: set_positioner_xvalue(),
set_positioner_yvalue(), set_positioner_xbounds(),
set_positioner_ybounds(), get_positioner_xvalue(),
get_positioner_yvalue(), get_positioner_xbounds(),
get_positioner_ybounds().

add_counter(*type, x, y, w, h, name*)

Add a counter object to the form.

Methods: set_counter_value(), get_counter_value(),
set_counter_bounds(), set_counter_step(),
set_counter_precision(), set_counter_return().

add_input(*type, x, y, w, h, name*)

Add a input object to the form.

Methods: set_input(), get_input(), set_input_color(),
set_input_return().

add_menu(*type, x, y, w, h, name*)

Add a menu object to the form.

Methods: `set_menu()`, `get_menu()`, `addto_menu()`.

add_choice(*type, x, y, w, h, name*)

Add a choice object to the form.

Methods: `set_choice()`, `get_choice()`, `clear_choice()`, `addto_choice()`, `replace_choice()`, `delete_choice()`, `get_choice_text()`, `set_choice_fontsize()`, `set_choice_fontstyle()`.

add_browser(*type, x, y, w, h, name*)

Add a browser object to the form.

Methods: `set_browser_topline()`, `clear_browser()`, `add_browser_line()`, `addto_browser()`, `insert_browser_line()`, `delete_browser_line()`, `replace_browser_line()`, `get_browser_line()`, `load_browser()`, `get_browser_maxline()`, `select_browser_line()`, `deselect_browser_line()`, `deselect_browser()`, `isselected_browser_line()`, `get_browser()`, `set_browser_fontsize()`, `set_browser_fontstyle()`, `set_browser_specialkey()`.

add_timer(*type, x, y, w, h, name*)

Add a timer object to the form.

Methods: `set_timer()`, `get_timer()`.

Form objects have the following data attributes; see the FORMS documentation:

Name	C Type	Meaning
window	int (read-only)	GL window id
w	float	form width
h	float	form height
x	float	form x origin
y	float	form y origin
deactivated	int	nonzero if form is deactivated
visible	int	nonzero if form is visible
frozen	int	nonzero if form is frozen

doublebuf | int | nonzero if double buffering on

20.4.3 FORMS Objects

Besides methods specific to particular kinds of FORMS objects, all FORMS objects also have the following methods:

set_callback(*function, argument*)

Set the object's callback function and argument. When the object needs interaction, the callback function will be called with two arguments: the object, and the callback argument. (FORMS objects without a callback function are returned by `f1.do_forms()` or `f1.check_forms()` when they need interaction.) Call this method without arguments to remove the callback function.

delete_object()

Delete the object.

show_object()

Show the object.

hide_object()

Hide the object.

redraw_object()

Redraw the object.

freeze_object()

Freeze the object.

unfreeze_object()

Unfreeze the object.

FORMS objects have these data attributes; see the FORMS documentation:

Name	C Type	Meaning
<code>objclass</code>	int (read-only)	object class
<code>type</code>	int (read-only)	object type

boxtype	int	box type
x	float	x origin
y	float	y origin
w	float	width
h	float	height
col1	int	primary color
col2	int	secondary color
align	int	alignment
lcol	int	label color
lsize	float	label font size
label	string	label string
lstyle	int	label style
pushed	int (read-only)	(see FORMS docs)
focus	int (read-only)	(see FORMS docs)
belowmouse	int (read-only)	(see FORMS docs)
frozen	int (read-only)	(see FORMS docs)
active	int (read-only)	(see FORMS docs)
input	int (read-only)	(see FORMS docs)
visible	int (read-only)	(see FORMS docs)
radio	int (read-only)	(see FORMS docs)
automatic	int (read-only)	(see FORMS docs)

20.5 FL -- Constants used with the fl module

Availability: **IRIX**.

This module defines symbolic constants needed to use the built-in module [fl](#) (see above); they are equivalent to those defined in the C header file `<forms.h>` except that the name prefix "FL_" is omitted. Read the module source for a complete list of the defined names. Suggested use:

```
import fl
from FL import *
```

20.7 fm -- *Font Manager* interface

Availability: **IRIX**.

This module provides access to the IRIS *Font Manager* library. It is available only on Silicon Graphics machines. See also: *4Sight User's Guide*, section 1, chapter 5: ``Using the IRIS Font Manager."

This is not yet a full interface to the IRIS Font Manager. Among the unsupported features are: matrix operations; cache operations; character operations (use string operations instead); some details of font info; individual glyph metrics; and printer matching.

It supports the following operations:

init()

Initialization function. Calls `fminit()`. It is normally not necessary to call this function, since it is called automatically the first time the `fm` module is imported.

findfont(*fontname*)

Return a font handle object. Calls `fmfindfont(fontname)`.

enumerate()

Returns a list of available font names. This is an interface to `fmenumerate()`.

prstr(*string*)

Render a string using the current font (see the `setFont()` font handle method below). Calls `fmprstr(string)`.

setpath(*string*)

Sets the font search path. Calls `fmsetpath(string)`. (XXX Does not work!?!)

fontpath()

Returns the current font search path.

Font handle objects support the following operations:

scalefont(*factor*)

Returns a handle for a scaled version of this font. Calls `fmscalefont(fh, factor)`.

setfont()

Makes this font the current font. Note: the effect is undone silently when the font handle object is deleted. Calls `fmsetfont(fh)`.

getfontname()

Returns this font's name. Calls `fmgetfontname(fh)`.

getcomment()

Returns the comment string associated with this font. Raises an exception if there is none. Calls `fmgetcomment(fh)`.

getfontinfo()

Returns a tuple giving some pertinent data about this font. This is an interface to `fmgetfontinfo()`. The returned tuple contains the following numbers: (*printermatched*, *fixed_width*, *xorig*, *yorig*, *xsize*, *ysize*, *height*, *nglyphs*).

getstrwidth(*string*)

Returns the width, in pixels, of *string* when drawn in this font. Calls `fmgetstrwidth(fh, string)`.

Previous: [20.7 fm](#) Up: [20. SGI IRIX Specific](#) Next: [20.9 DEVICE](#)

20.8 gl -- *Graphics Library* interface

Availability: **IRIX**.

This module provides access to the Silicon Graphics *Graphics Library*. It is available only on Silicon Graphics machines.

Warning: Some illegal calls to the GL library cause the Python interpreter to dump core. In particular, the use of most GL calls is unsafe before the first window is opened.

The module is too large to document here in its entirety, but the following should help you to get started. The parameter conventions for the C functions are translated to Python as follows:

- All (short, long, unsigned) int values are represented by Python integers.
- All float and double values are represented by Python floating point numbers. In most cases, Python integers are also allowed.
- All arrays are represented by one-dimensional Python lists. In most cases, tuples are also allowed.
- All string and character arguments are represented by Python strings, for instance, `winopen('Hi There!')` and `rotate(900, 'z')`.
- All (short, long, unsigned) integer arguments or return values that are only used to specify the length of an array argument are omitted. For example, the C call

```
lndef(deftype, index, np, props)
```

is translated to Python as

```
lndef(deftype, index, props)
```

- Output arguments are omitted from the argument list; they are transmitted as function return values instead. If more than one value must be returned, the return value is a tuple. If the C function has both a regular return value (that is not omitted because of the previous rule) and an output argument, the return value comes first in the tuple. Examples: the C call

```
getmcolor(i, &red, &green, &blue)
```

is translated to Python as

```
red, green, blue = getmcolor(i)
```

The following functions are non-standard or have special argument conventions:

varray(*argument*)

Equivalent to but faster than a number of `v3d()` calls. The *argument* is a list (or tuple) of points. Each point must be a tuple of coordinates (x, y, z) or (x, y) . The points may be 2- or 3-dimensional but must all have the same dimension. Float and int values may be mixed however. The points are always converted to 3D double precision points by assuming $z = 0.0$ if necessary (as indicated in the man page), and for each point `v3d()` is called.

nvarray()

Equivalent to but faster than a number of `n3f` and `v3f` calls. The argument is an array (list or tuple) of pairs of normals and points. Each pair is a tuple of a point and a normal for that point. Each point or normal must be a tuple of coordinates (x, y, z) . Three coordinates must be given. Float and int values may be mixed. For each pair, `n3f()` is called for the normal, and then `v3f()` is called for the point.

vnarray()

Similar to `nvarray()` but the pairs have the point first and the normal second.

nurbssurface(*s_k, t_k, ctl, s_ord, t_ord, type*)

Defines a nurbs surface. The dimensions of `ctl[][]` are computed as follows: `[len(s_k) - s_ord], [len(t_k) - t_ord]`.

nurbscurve(*knots, ctlpoints, order, type*)

Defines a nurbs curve. The length of `ctlpoints` is `len(knots) - order`.

pw1curve(*points, type*)

Defines a piecewise-linear curve. *points* is a list of points. *type* must be

N_ST.

pick(*n*)

select(*n*)

The only argument to these functions specifies the desired size of the pick or select buffer.

endpick()

endselect()

These functions have no arguments. They return a list of integers representing the used part of the pick/select buffer. No method is provided to detect buffer overrun.

Here is a tiny but complete example GL program in Python:

```
import gl, GL, time

def main():
    gl.foreground()
    gl.perspective(500, 900, 500, 900)
    w = gl.winopen('CrissCross')
    gl.ortho2(0.0, 400.0, 0.0, 400.0)
    gl.color(GL.WHITE)
    gl.clear()
    gl.color(GL.RED)
    gl.bgnline()
    gl.v2f(0.0, 0.0)
    gl.v2f(400.0, 400.0)
    gl.endline()
    gl.bgnline()
    gl.v2f(400.0, 0.0)
    gl.v2f(0.0, 400.0)
    gl.endline()
    time.sleep(5)

main()
```

See Also:

[PyOpenGL: The Python OpenGL Binding](#)

An interface to OpenGL is also available; see information about the **PyOpenGL** project online at <http://pyopengl.sourceforge.net/>. This

may be a better option if support for SGI hardware from before about 1996 is not required.

20.11 `imgfile` -- Support for SGI `imglib` files

Availability: **IRIX**.

The `imgfile` module allows Python programs to access SGI `imglib` image files (also known as `.rgb` files). The module is far from complete, but is provided anyway since the functionality that there is enough in some cases. Currently, colormap files are not supported.

The module defines the following variables and functions:

exception error

This exception is raised on all errors, such as unsupported file type, etc.

getsizes(*file*)

This function returns a tuple (x, y, z) where x and y are the size of the image in pixels and z is the number of bytes per pixel. Only 3 byte RGB pixels and 1 byte greyscale pixels are currently supported.

read(*file*)

This function reads and decodes the image on the specified file, and returns it as a Python string. The string has either 1 byte greyscale pixels or 4 byte RGBA pixels. The bottom left pixel is the first in the string. This format is suitable to pass to `gl.rectwrite()`, for instance.

readscaled(*file*, x , y , *filter*[, *blur*])

This function is identical to `read` but it returns an image that is scaled to the given x and y sizes. If the *filter* and *blur* parameters are omitted scaling is done by simply dropping or duplicating pixels, so the result will be less than perfect, especially for computer-generated images.

Alternatively, you can specify a filter to use to smooth the image after scaling. The filter forms supported are `'impulse'`, `'box'`, `'triangle'`, `'quadratic'` and `'gaussian'`. If a filter is specified

blur is an optional parameter specifying the blurriness of the filter. It defaults to 1.0.

`readscaled()` makes no attempt to keep the aspect ratio correct, so that is the users' responsibility.

ttob(*flag*)

This function sets a global flag which defines whether the scan lines of the image are read or written from bottom to top (*flag* is zero, compatible with SGI GL) or from top to bottom (*flag* is one, compatible with X). The default is zero.

write(*file, data, x, y, z*)

This function writes the RGB or greyscale data in *data* to image file *file*. *x* and *y* give the size of the image, *z* is 1 for 1 byte greyscale images or 3 for RGB images (which are stored as 4 byte values of which only the lower three bytes are used). These are the formats returned by `gl.glrectread()`.

Previous: [20.11 imgfile](#) Up: [20. SGI IRIX Specific](#) Next: [21. SunOS Specific Services](#)

20.12 jpeg -- Read and write JPEG files

Availability: **IRIX**.

The module `jpeg` provides access to the jpeg compressor and decompressor written by the Independent JPEG Group (IJG). JPEG is a standard for compressing pictures; it is defined in ISO 10918. For details on JPEG or the Independent JPEG Group software refer to the JPEG standard or the documentation provided with the software.

A portable interface to JPEG image files is available with the Python Imaging Library (PIL) by Fredrik Lundh. Information on PIL is available at <http://www.pythonware.com/products/pil/>.

The `jpeg` module defines an exception and some functions.

exception error

Exception raised by `compress()` and `decompress()` in case of errors.

compress(*data*, *w*, *h*, *b*)

Treat *data* as a pixmap of width *w* and height *h*, with *b* bytes per pixel. The data is in SGI GL order, so the first pixel is in the lower-left corner. This means that `gl.glRectread()` return data can immediately be passed to `compress()`. Currently only 1 byte and 4 byte pixels are allowed, the former being treated as greyscale and the latter as RGB color.

`compress()` returns a string that contains the compressed picture, in JFIF format.

decompress(*data*)

Data is a string containing a picture in JFIF format. It returns a tuple (*data*, *width*, *height*, *bytesperpixel*). Again, the data is suitable to pass to `gl.glRectwrite()`.

setoption(*name*, *value*)

Set various options. Subsequent `compress()` and `decompress()` calls will use these options. The following options are available:

Option	Effect
'forcegray'	Force output to be grayscale, even if input is RGB.
'quality'	Set the quality of the compressed image to a value between 0 and 100 (default is 75). This only affects compression.
'optimize'	Perform Huffman table optimization. Takes longer, but results in smaller compressed image. This only affects compression.
'smooth'	Perform inter-block smoothing on uncompressed image. Only useful for low-quality images. This only affects decompression.

See Also:

JPEG Still Image Data Compression Standard

The canonical reference for the JPEG image format, by Pennebaker and Mitchell.

[Information Technology - Digital Compression and Coding of Continuous-tone Still Images - Requirements and Guidelines](#)

The ISO standard for JPEG is also published as ITU T.81. This is available online in PDF form.

21.1 sunaudiodev -- Access to Sun audio hardware

Availability: **SunOS**.

This module allows you to access the Sun audio interface. The Sun audio hardware is capable of recording and playing back audio data in u-LAW format with a sample rate of 8K per second. A full description can be found in the *audio(7I)* manual page.

The module [SUNAUDIODEV](#) defines constants which may be used with this module.

This module defines the following variables and functions:

exception error

This exception is raised on all errors. The argument is a string describing what went wrong.

open(*mode*)

This function opens the audio device and returns a Sun audio device object. This object can then be used to do I/O on. The *mode* parameter is one of 'r' for record-only access, 'w' for play-only access, 'rw' for both and 'control' for access to the control device. Since only one process is allowed to have the recorder or player open at the same time it is a good idea to open the device only for the activity needed. See *audio(7I)* for details.

As per the manpage, this module first looks in the environment variable `AUDIODEV` for the base audio device filename. If not found, it falls back to `/dev/audio`. The control device is calculated by appending ```ctl"` to the base audio device.

21.1.1 Audio Device Objects

The audio device objects are returned by `open()` define the following methods (except `control` objects which only provide `getinfo()`, `setinfo()`, `fileno()`, and `drain()`):

close()

This method explicitly closes the device. It is useful in situations where deleting the object does not immediately close it since there are other references to it. A closed device should not be used again.

fileno()

Returns the file descriptor associated with the device. This can be used to set up `SIGPOLL` notification, as described below.

drain()

This method waits until all pending output is processed and then returns. Calling this method is often not necessary: destroying the object will automatically close the audio device and this will do an implicit drain.

flush()

This method discards all pending output. It can be used avoid the slow response to a user's stop request (due to buffering of up to one second of sound).

getinfo()

This method retrieves status information like input and output volume, etc. and returns it in the form of an audio status object. This object has no methods but it contains a number of attributes describing the current device status. The names and meanings of the attributes are described in `<sun/audioio.h>` and in the *audio(7I)* manual page. Member names are slightly different from their C counterparts: a status object is only a single structure. Members of the `play` substructure have "o_" prepended to their name and members of the `record` structure have "i_". So, the C member `play.sample_rate` is accessed as `o_sample_rate`, `record.gain` as `i_gain` and `monitor_gain` plainly as

`monitor_gain`.

ibufcount()

This method returns the number of samples that are buffered on the recording side, i.e. the program will not block on a `read()` call of so many samples.

obufcount()

This method returns the number of samples buffered on the playback side. Unfortunately, this number cannot be used to determine a number of samples that can be written without blocking since the kernel output queue length seems to be variable.

read(*size*)

This method reads *size* samples from the audio input and returns them as a Python string. The function blocks until enough data is available.

setinfo(*status*)

This method sets the audio device status parameters. The *status* parameter is an device status object as returned by `getinfo()` and possibly modified by the program.

write(*samples*)

Write is passed a Python string containing audio samples to be played. If there is enough buffer space free it will immediately return, otherwise it will block.

The audio device supports asynchronous notification of various events, through the SIGPOLL signal. Here's an example of how you might enable this in Python:

```
def handle_sigpoll(signum, frame):
    print 'I got a SIGPOLL update'

import fcntl, signal, STROPTS

signal.signal(signal.SIGPOLL, handle_sigpoll)
fcntl.ioctl(audio_obj.fileno(), STROPTS.I_SETSIG, STROPTS.S_MSG)
```

22.1.1 File Operations

locking(*fd*, *mode*, *nbytes*)

Lock part of a file based on file descriptor *fd* from the C runtime. Raises `IOError` on failure. The locked region of the file extends from the current file position for *nbytes* bytes, and may continue beyond the end of the file. *mode* must be one of the `LK_*` constants listed below. Multiple regions in a file may be locked at the same time, but may not overlap. Adjacent regions are not merged; they must be unlocked individually.

LK_LOCK

LK_RLCK

Locks the specified bytes. If the bytes cannot be locked, the program immediately tries again after 1 second. If, after 10 attempts, the bytes cannot be locked, `IOError` is raised.

LK_NBLCK

LK_NBRLCK

Locks the specified bytes. If the bytes cannot be locked, `IOError` is raised.

LK_UNLCK

Unlocks the specified bytes, which must have been previously locked.

setmode(*fd*, *flags*)

Set the line-end translation mode for the file descriptor *fd*. To set it to text mode, *flags* should be `os.O_TEXT`; for binary, it should be `os.O_BINARY`.

open_osfhandle(*handle*, *flags*)

Create a C runtime file descriptor from the file handle *handle*. The *flags* parameter should be a bit-wise OR of `os.O_APPEND`, `os.O_RDONLY`, and `os.O_TEXT`. The returned file descriptor may be used as a parameter to `os.fdopen()` to create a file object.

get_osfhandle(*fd*)

Return the file handle for the file descriptor *fd*. Raises `IOError` if *fd* is not recognized.

Previous: [22.1.1 File Operations](#) **Up:** [22.1 msvcrt - Useful](#) **Next:** [22.1.3 Other Functions](#)

22.1.2 Console I/O

kbhit()

Return true if a keypress is waiting to be read.

getch()

Read a keypress and return the resulting character. Nothing is echoed to the console. This call will block if a keypress is not already available, but will not wait for Enter to be pressed. If the pressed key was a special function key, this will return '\000' or '\xe0'; the next call will return the keycode. The control-c keypress cannot be read with this function.

getche()

Similar to `getch()`, but the keypress will be echoed if it represents a printable character.

putch(char)

Print the character *char* to the console without buffering.

ungetch(char)

Cause the character *char* to be "pushed back" into the console buffer; it will be the next character read by `getch()` or `getche()`.

Previous: [22.1.2 Console I/O](#) Up: [22.1 msvcrt - Useful](#) Next: [22.2 _winreg - Windows](#)

22.1.3 Other Functions

heapmin()

Force the `malloc()` heap to clean itself up and return unused blocks to the operating system. This only works on Windows NT. On failure, this raises `IOError`.

Previous: [22.1.2 Console I/O](#) Up: [22.1 msvcrt - Useful](#) Next: [22.2 _winreg - Windows](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

Previous: [22.1.3 Other Functions](#) **Up:** [22. MS Windows Specific](#) **Next:** [22.2.1 Registry Handle Objects](#)

22.2 `_winreg` - Windows registry access

Availability: **Windows**.

New in version 2.0.

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a handle object is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

This module exposes a very low-level interface to the Windows registry; it is expected that in the future a new `winreg` module will be created offering a higher-level interface to the registry API.

This module offers the following functions:

CloseKey(*hkey*)

Closes a previously opened registry key. The *hkey* argument specifies a previously opened key.

Note that if *hkey* is not closed using this method (or via `handle.Close()`), it is closed when the *hkey* object is destroyed by Python.

ConnectRegistry(*computer_name*, *key*)

Establishes a connection to a predefined registry handle on another computer, and returns a *handle object*

computer_name is the name of the remote computer, of the form `r"\computername"`. If `None`, the local computer is used.

key is the predefined handle to connect to.

The return value is the handle of the opened key. If the function fails, an `EnvironmentError` exception is raised.

CreateKey(*key*, *sub_key*)

Creates or opens the specified key, returning a *handle object*

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the key this method opens or creates.

If *key* is one of the predefined keys, *sub_key* may be **None**. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key

The return value is the handle of the opened key. If the function fails, an **EnvironmentError** exception is raised.

DeleteKey(*key*, *sub_key*)

Deletes the specified key.

key is an already open key, or any one of the predefined HKEY_* constants.

sub_key is a string that must be a subkey of the key identified by the *key* parameter. This value must not be **None**, and the key may not have subkeys.

This method can not delete keys with subkeys.

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an **EnvironmentError** exception is raised.

DeleteValue(*key*, *value*)

Removes a named value from a registry key.

key is an already open key, or one of the predefined HKEY_* constants.

value is a string that identifies the value to remove.

EnumKey(*key*, *index*)

Enumerates subkeys of an open registry key, returning a string.

key is an already open key, or any one of the predefined `HKEY_*` constants.

index is an integer that identifies the index of the key to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until an `EnvironmentError` exception is raised, indicating, no more values are available.

EnumValue(*key*, *index*)

Enumerates values of an open registry key, returning a tuple.

key is an already open key, or any one of the predefined `HKEY_*` constants.

index is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until an `EnvironmentError` exception is raised, indicating no more values.

The result is a tuple of 3 items:

Index	Meaning
0	A string that identifies the value name
1	An object that holds the value data, and whose type depends on the underlying registry type
2	An integer that identifies the type of the value data

FlushKey(*key*)

Writes all the attributes of a key to the registry.

key is an already open key, or one of the predefined `HKEY_*` constants.

It is not necessary to call `RegFlushKey` to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike `CloseKey()`, the `FlushKey()` method returns only when all the data has been written to the registry. An application should only call `FlushKey()` if it requires absolute certainty that registry changes are on disk.

If you don't know whether a `FlushKey()` call is required, it probably isn't.

RegLoadKey(*key*, *sub_key*, *file_name*)

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

key is an already open key, or any of the predefined `HKEY_*` constants.

sub_key is a string that identifies the *sub_key* to load

file_name is the name of the file to load registry data from. This file must have been created with the `SaveKey()` function. Under the file allocation table (FAT) file system, the filename may not have an extension.

A call to `LoadKey()` fails if the calling process does not have the `SE_RESTORE_PRIVILEGE` privilege. Note that privileges are different than permissions - see the Win32 documentation for more details.

If *key* is a handle returned by `ConnectRegistry()`, then the path specified in *fileName* is relative to the remote computer.

The Win32 documentation implies *key* must be in the `HKEY_USER` or `HKEY_LOCAL_MACHINE` tree. This may or may not be true.

OpenKey(*key*, *sub_key*[, *res* = 0][, *sam* = `KEY_READ`])

Opens the specified key, returning a *handle object*

key is an already open key, or any one of the predefined `HKEY_*` constants.

sub_key is a string that identifies the *sub_key* to open

res is a reserved integer, and must be zero. The default is zero.

sam is an integer that specifies an access mask that describes the desired security access for the key. Default is `KEY_READ`

The result is a new handle to the specified key

If the function fails, `EnvironmentError` is raised.

OpenKeyEx()

The functionality of `OpenKeyEx()` is provided via `OpenKey()`, by the use of default arguments.

QueryInfoKey(*key*)

Returns information about a key, as a tuple.

key is an already open key, or one of the predefined `HKEY_*` constants.

The result is a tuple of 3 items:

Index	Meaning
0	An integer giving the number of sub keys this key has.
1	An integer giving the number of values this key has.
2	A long integer giving when the key was last modified (if available) as 100's of nanoseconds since Jan 1, 1600.

QueryValue(*key*, *sub_key*)

Retrieves the unnamed value for a key, as a string

key is an already open key, or one of the predefined `HKEY_*` constants.

sub_key is a string that holds the name of the subkey with which the value is associated. If this parameter is `NONE` or empty, the function retrieves the value set by the `SetValue()` method for the key identified by *key*.

Values in the registry have name, type, and data components. This method retrieves the data for a key's first value that has a NULL name. But the underlying API call doesn't return the type, *Lame Lame Lame*, DO NOT USE THIS!!!

QueryValueEx(*key*, *value_name*)

Retrieves the type and data for a specified value name associated with an open registry key.

key is an already open key, or one of the predefined `HKEY_*` constants.

value_name is a string indicating the value to query.

The result is a tuple of 2 items:

Index	Meaning
0	The value of the registry item.
1	An integer giving the registry type for this value.

SaveKey(*key*, *file_name*)

Saves the specified key, and all its subkeys to the specified file.

key is an already open key, or one of the predefined HKEY_* constants.

file_name is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the LoadKey(), ReplaceKey() or RestoreKey() methods.

If *key* represents a key on a remote computer, the path described by *file_name* is relative to the remote computer. The caller of this method must possess the SeBackupPrivilege security privilege. Note that privileges are different than permissions - see the Win32 documentation for more details.

This function passes NULL for *security_attributes* to the API.

SetValue(*key*, *sub_key*, *type*, *value*)

Associates a value with a specified key.

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the subkey with which the value is associated.

type is an integer that specifies the type of the data. Currently this must be REG_SZ, meaning only strings are supported. Use the SetValueEx() function for support for other data types.

value is a string that specifies the new value.

If the key specified by the *sub_key* parameter does not exist, the SetValue function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the *key* parameter must have been opened with KEY_SET_VALUE access.

SetValueEx(*key*, *value_name*, *reserved*, *type*, *value*)

Stores data in the value field of an open registry key.

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the subkey with which the value is associated.

type is an integer that specifies the type of the data. This should be one of the following constants defined in this module:

Constant	Meaning
REG_BINARY	Binary data in any form.
REG_DWORD	A 32-bit number.
REG_DWORD_LITTLE_ENDIAN	A 32-bit number in little-endian format.
REG_DWORD_BIG_ENDIAN	A 32-bit number in big-endian format.
REG_EXPAND_SZ	Null-terminated string containing references to environment variables ("%PATH%").
REG_LINK	A Unicode symbolic link.
REG_MULTI_SZ	A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)
REG_NONE	No defined value type.
REG_RESOURCE_LIST	A device-driver resource list.

REG_SZ

A null-terminated string.

reserved can be anything - zero is always passed to the API.

value is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the key parameter must have been opened with KEY_SET_VALUE access.

To open the key, use the `CreateKeyEx()` or `OpenKey()` methods.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

22.2.1 Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the `Close()` method on the object, or the `CloseKey()` function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for `__nonzero__()` - thus

```
if handle:
    print "Yes"
```

will print `YES` if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the builtin `int()` function), in which case the underlying Windows handle value is returned. You can also use the `Detach()` method to return the integer handle, and also disconnect the Windows handle from the handle object.

Close()

Closes the underlying Windows handle.

If the handle is already closed, no error is raised.

Detach()

Detaches the Windows handle from the handle object.

The result is an integer (or long on 64 bit Windows) that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the

handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.

22.3 winsound -- Sound-playing interface for Windows

Availability: **Windows**.

New in version 1.5.2.

The `winsound` module provides access to the basic sound-playing machinery provided by Windows platforms. It includes functions and several constants.

Beep(*frequency*, *duration*)

Beep the PC's speaker. The *frequency* parameter specifies frequency, in hertz, of the sound, and must be in the range 37 through 32,767. The *duration* parameter specifies the number of milliseconds the sound should last. If the system is not able to beep the speaker, `RuntimeError` is raised. **Note:** Under Windows 95 and 98, the Windows `Beep()` function exists but is useless (it ignores its arguments). In that case Python simulates it via direct port manipulation (added in version 2.1). It's unknown whether that will work on all systems. New in version 1.6.

PlaySound(*sound*, *flags*)

Call the underlying `PlaySound()` function from the Platform API. The *sound* parameter may be a filename, audio data as a string, or `NONE`. Its interpretation depends on the value of *flags*, which can be a bit-wise ORed combination of the constants described below. If the system indicates an error, `RuntimeError` is raised.

MessageBeep([*type*=`MB_OK`])

Call the underlying `MessageBeep()` function from the Platform API. This plays a sound as specified in the registry. The *type* argument specifies which sound to play; possible values are `-1`, `MB_ICONASTERISK`, `MB_ICONEXCLAMATION`, `MB_ICONHAND`, `MB_ICONQUESTION`, and `MB_OK`, all described below. The value `-1` produces a "simple beep"; this is the final fallback if a sound cannot be played otherwise. New in version 2.3.

SND_FILENAME

The *sound* parameter is the name of a WAV file. Do not use with SND_ALIAS.

SND_ALIAS

The *sound* parameter is a sound association name from the registry. If the registry contains no such name, play the system default sound unless SND_NODEFAULT is also specified. If no default sound is registered, raise RuntimeError. Do not use with SND_FILENAME.

All Win32 systems support at least the following; most systems support many more:

PlaySound() <i>name</i>	Corresponding Control Panel Sound name
'SystemAsterisk'	Asterisk
'SystemExclamation'	Exclamation
'SystemExit'	Exit Windows
'SystemHand'	Critical Stop
'SystemQuestion'	Question

For example:

```
import winsound
# Play Windows exit sound.
winsound.PlaySound("SystemExit", winsound.SND_ALIAS)

# Probably play Windows default sound, if any is registered (bec
# "*" probably isn't the registered name of any sound).
winsound.PlaySound("*", winsound.SND_ALIAS)
```

SND_LOOP

Play the sound repeatedly. The SND_ASYNC flag must also be used to avoid blocking. Cannot be used with SND_MEMORY.

SND_MEMORY

The *sound* parameter to PlaySound() is a memory image of a WAV file, as a string.

Note: This module does not support playing from a memory image

asynchronously, so a combination of this flag and `SND_ASYNC` will raise `RuntimeError`.

SND_PURGE

Stop playing all instances of the specified sound.

SND_ASYNC

Return immediately, allowing sounds to play asynchronously.

SND_NODEFAULT

If the specified sound cannot be found, do not play the system default sound.

SND_NOSTOP

Do not interrupt sounds currently playing.

SND_NOWAIT

Return immediately if the sound driver is busy.

MB_ICONASTERISK

Play the `SystemDefault` sound.

MB_ICONEXCLAMATION

Play the `SystemExclamation` sound.

MB_ICONHAND

Play the `SystemHand` sound.

MB_ICONQUESTION

Play the `SystemQuestion` sound.

MB_OK

Play the `SystemDefault` sound.

A.1 Frameworks

Frameworks tend to be harder to document, but are well worth the effort spent.

None at this time.

A.2 Miscellaneous useful utilities

Some of these are very old and/or not very robust; marked with ``hmm.''

bdb

-- A generic Python debugger base class (used by pdb).

ihooks

-- Import hook support (for [rexec](#); may become obsolete).

Previous: [A.1 Frameworks](#) Up: [A. Undocumented Modules](#) Next: [A.3 Platform specific modules](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

Previous: [A.2 Miscellaneous useful utilities](#) **Up:** [A. Undocumented Modules](#)
Next: [A.4 Multimedia](#)

A.3 Platform specific modules

These modules are used to implement the [os.path](#) module, and are not documented beyond this mention. There's little need to document these.

ntpath

-- Implementation of `os.path` on Win32, Win64, WinCE, and OS/2 platforms.

posixpath

-- Implementation of `os.path` on POSIX.

bsddb185

-- Backwards compatibility module for systems which still use the Berkeley DB 1.85 module. It is normally only available on certain BSD Unix-based systems. It should never be used directly.

Previous: [A.2 Miscellaneous useful utilities](#) Up: [A. Undocumented Modules](#)

Next: [A.4 Multimedia](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

Previous: [A.3 Platform specific modules](#) **Up:** [A. Undocumented Modules](#) **Next:**
[A.5 Obsolete](#)

A.4 Multimedia

audiodev

-- Platform-independent API for playing audio data.

linuxaudiodev

-- Play audio data on the Linux audio device. Replaced in Python 2.3 by the `ossaudiodev` module.

sunaudio

-- Interpret Sun audio headers (may become obsolete or a tool/demo).

toaiff

-- Convert "arbitrary" sound files to AIFF files; should probably become a tool or demo. Requires the external program `sox`.

Previous: [A.4 Multimedia](#) **Up:** [A. Undocumented Modules](#) **Next:** [A.6 SGI-specific Extension modules](#)

A.5 Obsolete

These modules are not normally available for import; additional work must be done to make them available.

Those which are written in Python will be installed into the directory `lib-old/` installed as part of the standard library. To use these, the directory must be added to `sys.path`, possibly using `PYTHONPATH`.

Obsolete extension modules written in C are not built by default. Under UNIX, these must be enabled by uncommenting the appropriate lines in `Modules/Setup` in the build tree and either rebuilding Python if the modules are statically linked, or building and installing the shared object if using dynamically-loaded extensions.

addpack

-- Alternate approach to packages. Use the built-in package support instead.

cmp

-- File comparison function. Use the newer [filecmp](#) instead.

cmpcache

-- Caching version of the obsolete `cmp` module. Use the newer [filecmp](#) instead.

codehack

-- Extract function name or line number from a function code object (these are now accessible as attributes: `co.co_name`, `func.func_name`, `co.co_firstlineno`).

dircmp

-- Class to build directory diff tools on (may become a demo or tool).
Deprecated since release 2.0. The [filecmp](#) module replaces `dircmp`.

dump

-- Print python code that reconstructs a variable.

fmt

-- Text formatting abstractions (too slow).

lockfile

-- Wrapper around FCNTL file locking (use `fcntl.lockf()`/`flock()` instead; see [fcntl](#)).

newdir

-- New `dir()` function (the standard `dir()` is now just as good).

Para

-- Helper for `fmt`.

poly

-- Polynomials.

regex

-- Emacs-style regular expression support; may still be used in some old code (extension module). Refer to the [Python 1.6 Documentation](#) for documentation.

regsub

-- Regular expression based string replacement utilities, for use with `regex` (extension module). Refer to the [Python 1.6 Documentation](#) for documentation.

tb

-- Print tracebacks, with a dump of local variables (use `pdb.pm()` or [traceback](#) instead).

timing

-- Measure time intervals to high resolution (use `time.clock()` instead). (This is an extension module.)

tzparse

-- Parse a timezone specification (unfinished; may disappear in the future, and does not work when the TZ environment variable is not set).

util

-- Useful functions that don't fit elsewhere.

whatsound

-- Recognize sound files; use [sndhdr](#) instead.

zmod

-- Compute properties of mathematical ``fields."''

The following modules are obsolete, but are likely to re-surface as tools or scripts:

find

-- Find files matching pattern in directory tree.

grep

-- **grep** implementation in Python.

packmail

-- Create a self-unpacking UNIX shell archive.

The following modules were documented in previous versions of this manual, but are now considered obsolete. The source for the documentation is still available as part of the documentation source archive.

ni

-- Import modules in ``packages." Basic package support is now built in. The built-in support is very similar to what is provided in this module.

rand

-- Old interface to the random number generator.

Python Library Reference

A.6 SGI-specific Extension modules

The following are SGI specific, and may be out of touch with the current version of reality.

c1

-- Interface to the SGI compression library.

sv

-- Interface to the "simple video" board on SGI Indigo (obsolete hardware).

B. Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python or its documentation.

Before submitting a report, you will be required to log into SourceForge; this will make it possible for the developers to contact you for additional information if needed. It is not possible to submit a bug report anonymously.

All bug reports should be submitted via the Python Bug Tracker on SourceForge (http://sourceforge.net/bugs/?group_id=5470). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the left side of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker (http://sourceforge.net/bugs/?group_id=5470). Select the "Submit a Bug" link at the top of the page to open the bug reporting form.

The submission form has a number of fields. The only fields that are required are the "Summary" and "Details" fields. For the summary, enter a *very* short description of the problem; less than ten words is good. In the Details field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include the version of Python you used, whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

The only other field that you may want to set is the "Category" field, which allows you to place the bug report into a broad category (such as "Documentation" or "Library").

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

C.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <http://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <http://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <http://www.zope.com/>). In 2001, the Python Software Foundation (PSF, see <http://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <http://www.opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL compatible?
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes
1.6	1.5.2	2000	CNRI	no
2.0	1.6	2000	BeOpen.com	no
1.6.1	1.6	2001	CNRI	no
2.1	2.0+1.6.1	2001	PSF	no
2.0.1	2.0+1.6.1	2001	PSF	yes
2.1.1	2.1+2.0.1	2001	PSF	yes
2.2	2.1.1	2001	PSF	yes

2.1.2	2.1.1	2002	PSF	yes
2.1.3	2.1.2	2002	PSF	yes
2.2.1	2.2	2002	PSF	yes
2.2.2	2.2.1	2002	PSF	yes
2.2.3	2.2.2	2002-2003	PSF	yes
2.3	2.2.2	2002-2003	PSF	yes
2.3.1	2.3	2002-2003	PSF	yes
2.3.2	2.3.1	2003	PSF	yes
2.3.3	2.3.2	2003	PSF	yes
2.3.4	2.3.3	2004	PSF	yes
2.3.5	2.3.4	2005	PSF	yes
2.4	2.3	2004	PSF	yes
2.4.1	2.4	2005	PSF	yes
2.4.2	2.4.1	2005	PSF	yes
2.4.3	2.4.2	2006	PSF	yes
2.4.4	2.4.3	2006	PSF	yes
2.5	2.4	2006	PSF	yes

Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

C.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.4.4

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.4.4 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.4.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.4.4 alone or in any derivative version prepared by Licensee.
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.4.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.4.4.
4. PSF is making Python 2.4.4 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.4.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS

OF PYTHON 2.4.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.4.4, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 2.4.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION

1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.
3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT

LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at <http://www.pythonlabs.com/logos.html> may be used according to the permissions granted on that web page.
7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to

reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: <http://hdl.handle.net/1895.22/1013>."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.
4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. This License Agreement shall be governed by the federal intellectual

property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```

Modified by Jack Jansen, CWI, July 1995:

- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. The version is still 5 times faster, though.
- Arguments more compliant with python standard

Release 2.4.4c1
11 October 2006

-
- [Front Matter](#)
 - [Contents](#)
 - [1. Introduction](#)
 - [1.1 Alternate Implementations](#)
 - [1.2 Notation](#)
 - [2. Lexical analysis](#)
 - [2.1 Line structure](#)
 - [2.1.1 Logical lines](#)
 - [2.1.2 Physical lines](#)
 - [2.1.3 Comments](#)
 - [2.1.4 Encoding declarations](#)
 - [2.1.5 Explicit line joining](#)
 - [2.1.6 Implicit line joining](#)
 - [2.1.7 Blank lines](#)
 - [2.1.8 Indentation](#)
 - [2.1.9 Whitespace between tokens](#)
 - [2.2 Other tokens](#)
 - [2.3 Identifiers and keywords](#)
 - [2.3.1 Keywords](#)
 - [2.3.2 Reserved classes of identifiers](#)
 - [2.4 Literals](#)
 - [2.4.1 String literals](#)
 - [2.4.2 String literal concatenation](#)

- [2.4.3 Numeric literals](#)
 - [2.4.4 Integer and long integer literals](#)
 - [2.4.5 Floating point literals](#)
 - [2.4.6 Imaginary literals](#)
 - [2.5 Operators](#)
 - [2.6 Delimiters](#)
- [3. Data model](#)
 - [3.1 Objects, values and types](#)
 - [3.2 The standard type hierarchy](#)
 - [3.3 Special method names](#)
 - [3.3.1 Basic customization](#)
 - [3.3.2 Customizing attribute access](#)
 - [3.3.3 Customizing class creation](#)
 - [3.3.4 Emulating callable objects](#)
 - [3.3.5 Emulating container types](#)
 - [3.3.6 Additional methods for emulation of sequence types](#)
 - [3.3.7 Emulating numeric types](#)
 - [3.3.8 Coercion rules](#)
- [4. Execution model](#)
 - [4.1 Naming and binding](#)
 - [4.1.1 Interaction with dynamic features](#)
 - [4.2 Exceptions](#)
- [5. Expressions](#)
 - [5.1 Arithmetic conversions](#)
 - [5.2 Atoms](#)
 - [5.2.1 Identifiers \(Names\)](#)
 - [5.2.2 Literals](#)
 - [5.2.3 Parenthesized forms](#)
 - [5.2.4 List displays](#)
 - [5.2.5 Generator expressions](#)
 - [5.2.6 Dictionary displays](#)
 - [5.2.7 String conversions](#)
 - [5.3 Primaries](#)
 - [5.3.1 Attribute references](#)
 - [5.3.2 Subscriptions](#)
 - [5.3.3 Slicings](#)
 - [5.3.4 Calls](#)
 - [5.4 The power operator](#)
 - [5.5 Unary arithmetic operations](#)

- [5.6 Binary arithmetic operations](#)
- [5.7 Shifting operations](#)
- [5.8 Binary bit-wise operations](#)
- [5.9 Comparisons](#)
- [5.10 Boolean operations](#)
- [5.11 Lambdas](#)
- [5.12 Expression lists](#)
- [5.13 Evaluation order](#)
- [5.14 Summary](#)
- [6. Simple statements](#)
 - [6.1 Expression statements](#)
 - [6.2 Assert statements](#)
 - [6.3 Assignment statements](#)
 - [6.3.1 Augmented assignment statements](#)
 - [6.4 The pass statement](#)
 - [6.5 The del statement](#)
 - [6.6 The print statement](#)
 - [6.7 The return statement](#)
 - [6.8 The yield statement](#)
 - [6.9 The raise statement](#)
 - [6.10 The break statement](#)
 - [6.11 The continue statement](#)
 - [6.12 The import statement](#)
 - [6.12.1 Future statements](#)
 - [6.13 The global statement](#)
 - [6.14 The exec statement](#)
- [7. Compound statements](#)
 - [7.1 The if statement](#)
 - [7.2 The while statement](#)
 - [7.3 The for statement](#)
 - [7.4 The try statement](#)
 - [7.5 Function definitions](#)
 - [7.6 Class definitions](#)
- [8. Top-level components](#)
 - [8.1 Complete Python programs](#)
 - [8.2 File input](#)
 - [8.3 Interactive input](#)
 - [8.4 Expression input](#)

- [A. History and License](#)
 - [A.1 History of the software](#)
 - [A.2 Terms and conditions for accessing or otherwise using Python](#)
 - [A.3 Licenses and Acknowledgements for Incorporated Software](#)

1. Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time -- or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document -- the implementation may change, and other implementations of the same language may work differently. On the other hand, there is currently only one Python implementation in widespread use (although alternate implementations exist), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you'll find short "implementation notes" sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are not documented here, but in the separate [Python Library Reference](#) document. A few built-in modules are mentioned when they interact in a significant way with the language definition.

1.1 Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

CPython

This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

Jython

Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at [the Jython website](#).

Python for .NET

This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. This was created by Brian Lloyd. For more information, see the [Python for .NET home page](#).

IronPython

An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see [the IronPython website](#).

PyPy

An implementation of Python written in Python; even the bytecode interpreter is written in Python. This is executed using CPython as the underlying interpreter. One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python). Additional information is available on [the PyPy project's home page](#).

Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what's covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you're using.

Previous: [1.1 Alternate Implementations](#) Up: [1. Introduction](#) Next: [2. Lexical analysis](#)

1.2 Notation

The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```
name      ::= lc letter (lc letter | "_")*  
lc_letter ::= "a"..."z"
```

[Download entire grammar as text.](#)

The first line says that a `name` is an `lc_letter` followed by a sequence of zero or more `lc_letters` and underscores. An `lc_letter` in turn is any of the single characters "a" through "z". (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and `::=`. A vertical bar (`|`) is used to separate alternatives; it is the least binding operator in this notation. A star (`*`) means zero or more repetitions of the preceding item; likewise, a plus (`+`) means one or more repetitions, and a phrase enclosed in square brackets (`[]`) means zero or one occurrences (in other words, the enclosed phrase is optional). The `*` and `+` operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of ASCII characters. A phrase between angular brackets (`< . . >`) gives an informal description of the symbol defined; e.g., this could be used to describe the notion of 'control character' if needed.

Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter ("Lexical Analysis") are lexical definitions;

uses in subsequent chapters are syntactic definitions.

2. Lexical analysis

A Python program is read by a *parser*. Input to the parser is a stream of *tokens*, generated by the *lexical analyzer*. This chapter describes how the lexical analyzer breaks a file into tokens.

Python uses the 7-bit ASCII character set for program text. New in version 2.3: An encoding declaration can be used to indicate that string literals and comments use an encoding different from ASCII. For compatibility with older versions, Python only warns if it finds 8-bit characters; those warnings should be corrected by either declaring an explicit encoding, or using escape sequences if those bytes are binary data, instead of characters.

The run-time character set depends on the I/O devices connected to the program but is generally a superset of ASCII.

Future compatibility note: It may be tempting to assume that the character set for 8-bit characters is ISO Latin-1 (an ASCII superset that covers most western languages that use the Latin alphabet), but it is possible that in the future Unicode text editors will become common. These generally use the UTF-8 encoding, which is also an ASCII superset, but with very different use for the characters with ordinals 128-255. While there is no consensus on this subject yet, it is unwise to assume either Latin-1 or UTF-8, even though the current implementation appears to favor Latin-1. This applies both to the source character set and the run-time character set.

Previous: [2.1 Line structure](#) Up: [2.1 Line structure](#) Next: [2.1.2 Physical lines](#)

2.1.1 Logical lines

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more *physical lines* by following the explicit or implicit *line joining* rules.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.1.1 Logical lines](#) Up: [2.1 Line structure](#) Next: [2.1.3 Comments](#)

2.1.2 Physical lines

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files, any of the standard platform line termination sequences can be used - the UNIX form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the `\n` character, representing ASCII LF, is the line terminator).

Previous: [2.1.2 Physical lines](#) **Up:** [2.1 Line structure](#) **Next:** [2.1.4 Encoding declarations](#)

2.1.3 Comments

A comment starts with a hash character (#) that is not part of a string literal, and ends at the end of the physical line. A comment signifies the end of the logical line unless the implicit line joining rules are invoked. Comments are ignored by the syntax; they are not tokens.

Previous: [2.1.2 Physical lines](#) Up: [2.1 Line structure](#) Next: [2.1.4 Encoding declarations](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.1.3 Comments](#) Up: [2.1 Line structure](#) Next: [2.1.5 Explicit line joining](#)

2.1.4 Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[=:]\s*([- \w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The recommended forms of this expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar's VIM. In addition, if the first bytes of the file are the UTF-8 byte-order mark ('`\xef\xbb\xbf`'), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft's **notepad**).

If an encoding is declared, the encoding name must be recognized by Python. The encoding is used for all lexical analysis, in particular to find the end of a string, and to interpret the contents of Unicode literals. String literals are converted to Unicode for syntactical analysis, then converted back to their original encoding before interpretation starts. The encoding declaration must appear on a line of its own.

Previous: [2.1.4 Encoding declarations](#) Up: [2.1 Line structure](#) Next: [2.1.6 Implicit line joining](#)

2.1.5 Explicit line joining

Two or more physical lines may be joined into logical lines using backslash characters (`\`), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```
if 1900 < year < 2100 and 1 <= month <= 12 \  
    and 1 <= day <= 31 and 0 <= hour < 24 \  
    and 0 <= minute < 60 and 0 <= second < 60:    # Looks like a valid  
    return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.

Previous: [2.1.4 Encoding declarations](#) Up: [2.1 Line structure](#) Next: [2.1.6 Implicit line joining](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.1.5 Explicit line joining](#) Up: [2.1 Line structure](#) Next: [2.1.7 Blank lines](#)

2.1.6 Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```
month_names = ['Januari', 'Februari', 'Maart',      # These are the
               'April',   'Mei',      'Juni',      # Dutch names
               'Juli',    'Augustus', 'September', # for the months
               'Oktober', 'November', 'December']  # of the year
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.

Previous: [2.1.5 Explicit line joining](#) Up: [2.1 Line structure](#) Next: [2.1.7 Blank lines](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

Previous: [2.1.6 Implicit line joining](#) Up: [2.1 Line structure](#) Next: [2.1.8 Indentation](#)

2.1.7 Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated). During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-eval-print loop. In the standard implementation, an entirely blank logical line (i.e. one containing not even whitespace or a comment) terminates a multi-line statement.

Previous: [2.1.6 Implicit line joining](#) Up: [2.1 Line structure](#) Next: [2.1.8 Indentation](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.1.7 Blank lines](#) **Up:** [2.1 Line structure](#) **Next:** [2.1.9 Whitespace between tokens](#)

2.1.8 Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

First, tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by UNIX). The total number of spaces preceding the first non-blank character then determines the line's indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

Cross-platform compatibility note: because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.

Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it *must* be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python

code:

```
def perm(l):
    # Compute the list of all permutations of l
    if len(l) <= 1:
        return [l]
    r = []
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(s)
        for x in p:
            r.append(l[:i+1] + x)
    return r
```

The following example shows various indentation errors:

```
def perm(l):
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(l[:i] + l[i+1:])
        for x in p:
            r.append(l[:i+1] + x)
    return r
```

error: first line indented
error: not indented
error: unexpected indent
error: inconsistent dedent

(Actually, the first three errors are detected by the parser; only the last error is found by the lexical analyzer -- the indentation of `return r` does not match a level popped off the stack.)

Previous: [2.1.7 Blank lines](#) Up: [2.1 Line structure](#) Next: [2.1.9 Whitespace between tokens](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.1.8 Indentation](#) Up: [2.1 Line structure](#) Next: [2.2 Other tokens](#)

2.1.9 Whitespace between tokens

Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., `ab` is one token, but `a b` is two tokens).

Previous: [2.1.8 Indentation](#) Up: [2.1 Line structure](#) Next: [2.2 Other tokens](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [2.1.9 Whitespace between tokens](#) **Up:** [2. Lexical analysis](#) **Next:** [2.3 Identifiers and keywords](#)

2.2 Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: *identifiers*, *keywords*, *literals*, *operators*, and *delimiters*. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.

			Python Reference Manual	<i>toc</i> CONTENTS	<i>i</i> INDEX		
Previous:			2.1.9 Whitespace between tokens	Up:	2. Lexical analysis	Next:	2.3 Identifiers and keywords

Release 2.4.4c1, documentation updated on 11 October 2006.

Previous: [2.2 Other tokens](#) Up: [2. Lexical analysis](#) Next: [2.3.1 Keywords](#)

2.3 Identifiers and keywords

Identifiers (also referred to as *names*) are described by the following lexical definitions:

```
identifier ::= (letter | "_") (letter | digit
               | "_")*
letter     ::= lowercase | uppercase
lowercase ::= "a"..."z"
uppercase ::= "A"..."Z"
digit     ::= "0"..."9"
```

[Download entire grammar as text.](#)

Identifiers are unlimited in length. Case is significant.

Subsections

- [2.3.1 Keywords](#)
- [2.3.2 Reserved classes of identifiers](#)

Previous: [2.3 Identifiers and keywords](#) **Up:** [2.3 Identifiers and keywords](#) **Next:**
[2.3.2 Reserved classes of](#)

2.3.1 Keywords

The following identifiers are used as reserved words, or *keywords* of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

<code>and</code>	<code>del</code>	<code>for</code>	<code>is</code>	<code>raise</code>
<code>assert</code>	<code>elif</code>	<code>from</code>	<code>lambda</code>	<code>return</code>
<code>break</code>	<code>else</code>	<code>global</code>	<code>not</code>	<code>try</code>
<code>class</code>	<code>except</code>	<code>if</code>	<code>or</code>	<code>while</code>
<code>continue</code>	<code>exec</code>	<code>import</code>	<code>pass</code>	<code>yield</code>
<code>def</code>	<code>finally</code>	<code>in</code>	<code>print</code>	

Note that although the identifier `as` can be used as part of the syntax of `import` statements, it is not currently a reserved word.

In Python 2.6, the identifier `as` will become a keyword.

Changed in version 2.4: `None` became a constant and is now recognized by the compiler as a name for the builtin object `None`. Although it is not a keyword, you cannot assign a different object to it.

Previous: [2.3.1 Keywords](#) **Up:** [2.3 Identifiers and keywords](#) **Next:** [2.4 Literals](#)

2.3.2 Reserved classes of identifiers

Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

— *

Not imported by `from module import *`. The special identifier `"_"` is used in the interactive interpreter to store the result of the last evaluation; it is stored in the `__builtin__` module. When not in interactive mode, `"_"` has no special meaning and is not defined. See section [6.12](#), `"The import statement."`

Note: The name `"_"` is often used in conjunction with internationalization; refer to the documentation for the [gettext module](#) for more information on this convention.

— *

System-defined names. These names are defined by the interpreter and its implementation (including the standard library); applications should not expect to define additional names using this convention. The set of names of this class defined by Python may be extended in future versions. See section [3.3](#), `"Special method names."`

— *

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between `"private"` attributes of base and derived classes. See section [5.2.1](#), `"Identifiers (Names)."`

Previous: [2.3.2 Reserved classes of literals](#) **Up:** [2. Lexical analysis](#) **Next:** [2.4.1 String literals](#)

2.4 Literals

Literals are notations for constant values of some built-in types.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

Previous: [2.4 Literals](#) Up: [2.4 Literals](#) Next: [2.4.2 String literal concatenation](#)

2.4.1 String literals

String literals are described by the following lexical definitions:

```
stringliteral ::= [stringprefix]  
              (shortstring |  
               longstring)  
  
stringprefix ::= "r" | "u" | "ur" | "R" |  
                "U" | "UR" | "Ur" | "uR"  
  
shortstring  ::= """ shortstringitem* """  
              | ''' shortstringitem*  
              | ""  
  
longstring   ::= """" longstringitem*  
              | "" "" longstringitem*  
  
shortstringitem ::= shortstringchar |  
                   escapeseq  
  
longstringitem  ::= longstringchar |  
                   escapeseq  
  
shortstringchar ::= <any source character  
                   except "\" or newline or  
                   the quote>  
  
longstringchar  ::= <any source character  
                   except "\">  
  
escapeseq       ::= "\" <any ASCII  
                   character>
```

[Download entire grammar as text.](#)

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the [stringprefix](#) and the rest of the string literal. The source character set is defined by the encoding declaration; it is ASCII if no encoding declaration is given in the source file; see section [2.1.4](#).

In plain English: String literals can be enclosed in matching single quotes (') or double quotes ("). They can also be enclosed in matching groups of three single or double quotes (these are generally referred to as *triple-quoted strings*). The backslash (\) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character. String literals may optionally be prefixed with a letter "r" or "R"; such strings are called *raw strings* and use different rules for interpreting backslash escape sequences. A prefix of "u" or "U" makes the string a Unicode string. Unicode strings use the Unicode character set as defined by the Unicode Consortium and ISO 10646. Some additional escape sequences, described below, are available in Unicode strings. The two prefix characters may be combined; in this case, "u" must appear before "r".

In triple-quoted strings, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the string. (A ``quote" is the character used to open the string, i.e. either ' or ".)

Unless an "r" or "R" prefix is present, escape sequences in strings are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

Escape Sequence	Meaning	Notes
<code>\newline</code>	Ignored	
<code>\\</code>	Backslash (\)	
<code>\'</code>	Single quote (')	
<code>\"</code>	Double quote (")	
<code>\a</code>	ASCII Bell (BEL)	
<code>\b</code>	ASCII Backspace (BS)	
<code>\f</code>	ASCII Formfeed (FF)	
<code>\n</code>	ASCII Linefeed (LF)	
<code>\N{name}</code>	Character named <i>name</i> in the Unicode database (Unicode only)	
<code>\r</code>	ASCII Carriage Return (CR)	
<code>\t</code>	ASCII Horizontal Tab (TAB)	
<code>\uxxxx</code>	Character with 16-bit hex value <i>xxxx</i> (Unicode only)	(1)

<code>\Uxxxxxxxx</code>	Character with 32-bit hex value <code>xxxxxxxx</code> (Unicode only)	(2)
<code>\v</code>	ASCII Vertical Tab (VT)	
<code>\ooo</code>	Character with octal value <code>ooo</code>	(3,5)
<code>\xhh</code>	Character with hex value <code>hh</code>	(4,5)

Notes:

- (1) Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.
- (2) Any Unicode character can be encoded this way, but characters outside the Basic Multilingual Plane (BMP) will be encoded using a surrogate pair if Python is compiled to use 16-bit code units (the default). Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.
- (3) As in Standard C, up to three octal digits are accepted.
- (4) Unlike in Standard C, at most two hex digits are accepted.
- (5) In a string literal, hexadecimal and octal escapes denote the byte with the given value; it is not necessary that the byte encodes a character in the source character set. In a Unicode literal, these escapes denote a Unicode character with the given value.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., *the backslash is left in the string*. (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences marked as ``(Unicode only)'' in the table above fall into the category of unrecognized escapes for non-Unicode string literals.

When an "r" or "R" prefix is present, a character following a backslash is included in the string without change, and *all backslashes are left in the string*. For example, the string literal `r"\n"` consists of two characters: a backslash and a lowercase "n". String quotes can be escaped with a backslash, but the

backslash remains in the string; for example, `r"\\"` is a valid string literal consisting of two characters: a backslash and a double quote; `r"\` is not a valid string literal (even a raw string cannot end in an odd number of backslashes). Specifically, *a raw string cannot end in a single backslash* (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the string, *not* as a line continuation.

When an "r" or "R" prefix is used in conjunction with a "u" or "U" prefix, then the `\uXXXX` and `\UXXXXXXXX` escape sequences are processed while *all other backslashes are left in the string*. For example, the string literal `ur"\u0062\n"` consists of three Unicode characters: ``LATIN SMALL LETTER B'`, ``REVERSE SOLIDUS'`, and ``LATIN SMALL LETTER N'`. Backslashes can be escaped with a preceding backslash; however, both remain in the string. As a result, `\uXXXX` escape sequences are only recognized when there are an odd number of backslashes.

Previous: [2.4.1 String literals](#) Up: [2.4 Literals](#) Next: [2.4.3 Numeric literals](#)

2.4.2 String literal concatenation

Multiple adjacent string literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, "hello" 'world' is equivalent to "helloworld". This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```
re.compile("[A-Za-z_]"      # letter or underscore
           "[A-Za-z0-9_]*"  # letter, digit or underscore
           )
```

Note that this feature is defined at the syntactical level, but implemented at compile time. The '+' operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component (even mixing raw strings and triple quoted strings).

Previous: [2.4.2 String literal concatenation](#) **Up:** [2.4 Literals](#) **Next:** [2.4.4 Integer and long](#)

2.4.3 Numeric literals

There are four types of numeric literals: plain integers, long integers, floating point numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator `'-'` and the literal `1`.

Previous: [2.4.2 String literal concatenation and long](#) Up: [2.4 Literals](#) Next: [2.4.4 Integer](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.4.3 Numeric literals](#) **Up:** [2.4 Literals](#) **Next:** [2.4.5 Floating point literals](#)

2.4.4 Integer and long integer literals

Integer and long integer literals are described by the following lexical definitions:

```
longinteger ::= integer ("l" | "L")
integer ::= decimalinteger |
           octinteger | hexinteger
decimalinteger ::= nonzerodigit digit* | "0"
octinteger ::= "0" octdigit+
hexinteger ::= "0" ("x" | "X") hexdigit+
nonzerodigit ::= "1"..."9"
octdigit ::= "0"..."7"
hexdigit ::= digit | "a"..."f" |
            "A"..."F"
```

[Download entire grammar as text.](#)

Although both lower case "l" and upper case "L" are allowed as suffix for long integers, it is strongly recommended to always use "L", since the letter "l" looks too much like the digit "1".

Plain integer literals that are above the largest representable plain integer (e.g., 2147483647 when using 32-bit arithmetic) are accepted as if they were long integers instead.^{2.1} There is no limit for long integer literals apart from what can be stored in available memory.

Some examples of plain integer literals (first row) and long integer literals (second and third rows):

7	2147483647	0177	
3L	79228162514264337593543950336L	0377L	0x100000000L
	79228162514264337593543950336		0xdeadbeef

Footnotes

... instead. [2.1](#)

In versions of Python prior to 2.4, octal and hexadecimal literals in the range just above the largest representable plain integer but below the largest unsigned 32-bit number (on a machine using 32-bit arithmetic), 4294967296, were taken as the negative plain integer obtained by subtracting 4294967296 from their unsigned value.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.4.4 Integer and long](#) **Up:** [2.4 Literals](#) **Next:** [2.4.6 Imaginary literals](#)

2.4.5 Floating point literals

Floating point literals are described by the following lexical definitions:

```
floatnumber ::= pointfloat | exponentfloat
pointfloat  ::= [intpart] fraction |
               intpart "."
exponentfloat ::= (intpart | pointfloat)
               exponent
intpart     ::= digit+
fraction    ::= "." digit+
exponent    ::= ("e" | "E") ["+" | "-"]
               digit+
```

[Download entire grammar as text.](#)

Note that the integer and exponent parts of floating point numbers can look like octal integers, but are interpreted using radix 10. For example, "077e010" is legal, and denotes the same number as "77e10". The allowed range of floating point literals is implementation-dependent. Some examples of floating point literals:

3.14 10. .001 1e100 3.14e-10 0e0

Note that numeric literals do not include a sign; a phrase like -1 is actually an expression composed of the unary operator - and the literal 1.

Previous: [2.4.5 Floating point literals](#) **Up:** [2.4 Literals](#) **Next:** [2.5 Operators](#)

2.4.6 Imaginary literals

Imaginary literals are described by the following lexical definitions:

```
imagnumber ::= (floatnumber | intpart) ("j"  
| "J")
```

[Download entire grammar as text.](#)

An imaginary literal yields a complex number with a real part of 0.0. Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., $(3+4j)$. Some examples of imaginary literals:

`3.14j` `10.j` `10j` `.001j` `1e100j` `3.14e-10j`

Previous: [2.4.5 Floating point literals](#) Up: [2.4 Literals](#) Next: [2.5 Operators](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [2.4.6 Imaginary literals](#) **Up:** [2. Lexical analysis](#) **Next:** [2.6 Delimiters](#)

2.5 Operators

The following tokens are operators:

+	-	*	**	/	//	%
<<	>>	&		^	~	
<	>	<=	>=	==	!=	<>

The comparison operators `<>` and `!=` are alternate spellings of the same operator. `!=` is the preferred spelling; `<>` is obsolescent.

Previous: [2.5 Operators](#) Up: [2. Lexical analysis](#) Next: [3. Data model](#)

2.6 Delimiters

The following tokens serve as delimiters in the grammar:

```
(      )      [      ]      {      }      @  
,      :      .      `      =      ;  
+=     -=     *=     /=     //=     %=  
&=    |=     ^=     >>=  <<=    **=
```

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis in slices. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical analyzer:

```
'      "      #      \
```

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

```
$      ?
```

3.1 Objects, values and types

Objects are Python's abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann's model of a "stored program computer," code is also represented by objects.)

Every object has an identity, a type and a value. An object's *identity* never changes once it has been created; you may think of it as the object's address in memory. The `'is'` operator compares the identity of two objects; the `id()` function returns an integer representing its identity (currently implemented as its address). An object's *type* is also unchangeable.^{3.1} An object's type determines the operations that the object supports (e.g., "does it have a length?") and also defines the possible values for objects of that type. The `type()` function returns an object's type (which is an object itself). The *value* of some objects can change. Objects whose value can change are said to be *mutable*; objects whose value is unchangeable once they are created are called *immutable*. (The value of an immutable container object that contains a reference to a mutable object can change when the latter's value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object's mutability is determined by its type; for instance, numbers, strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether -- it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable. (Implementation note: the current implementation uses a reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the [Python Library Reference](#) for information on controlling the collection of cyclic garbage.)

Note that the use of the implementation's tracing or debugging facilities may

keep objects alive that would normally be collectable. Also note that catching an exception with a `try...except` statement may keep objects alive.

Some objects contain references to "external" resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a `close()` method. Programs are strongly recommended to explicitly close such objects. The `try...finally` statement provides a convenient way to do this.

Some objects contain references to other objects; these are called *containers*. Examples of containers are tuples, lists and dictionaries. The references are part of a container's value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.

Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and value, while for mutable objects this is not allowed. E.g., after `a = 1; b = 1`, `a` and `b` may or may not refer to the same object with the value one, depending on the implementation, but after `c = []; d = []`, `c` and `d` are guaranteed to refer to two different, unique, newly created empty lists. (Note that `c = d = []` assigns the same object to both `c` and `d`.)

Footnotes

... unchangeable. [3.1](#)

Since Python 2.2, a gradual merging of types and classes has been started that makes this and a few other assertions made in this manual not 100% accurate and complete: for example, it is now possible in some cases to change an object's type, under certain controlled conditions. Until this

manual undergoes extensive revision, it must now be taken as authoritative only regarding ``classic classes'', that are still the default, for compatibility purposes, in Python 2.2 and 2.3.

3.2 The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.).

Some of the type descriptions below contain a paragraph listing 'special attributes.' These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `NONE`. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don't explicitly return anything. Its truth value is false.

NotImplemented

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `NotImplemented`. Numeric methods and rich comparison methods may return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback, depending on the operator.) Its truth value is true.

Ellipsis

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `Ellipsis`. It is used to indicate the presence of the `"..."` syntax in a slice. Its truth value is true.

Numbers

These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.

Python distinguishes between integers, floating point numbers, and complex numbers:

Integers

These represent elements from the mathematical set of integers (positive and negative).

There are three types of integers:

Plain integers

These represent numbers in the range -2147483648 through 2147483647. (The range may be larger on machines with a larger natural word size, but not smaller.) When the result of an operation would fall outside this range, the result is normally returned as a long integer (in some cases, the exception `OverflowError` is raised instead). For the purpose of shift and mask operations, integers are assumed to have a binary, 2's complement notation using 32 or more bits, and hiding no bits from the user (i.e., all 4294967296 different bit patterns correspond to different values).

Long integers

These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2's complement which gives the illusion of an infinite string of sign bits extending to the left.

Booleans

These represent the truth values `False` and `True`. The two objects representing the values `False` and `True` are the only Boolean objects. The Boolean type is a subtype of plain integers, and Boolean values behave like the values 0 and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings `"False"` or `"True"` are returned, respectively.

The rules for integer representation are intended to give the most

meaningful interpretation of shift and mask operations involving negative integers and the least surprises when switching between the plain and long integer domains. Any operation except left shift, if it yields a result in the plain integer domain without causing overflow, will yield the same result in the long integer domain or when using mixed operands.

Floating point numbers

These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these is dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.

Complex numbers

These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number z can be retrieved through the read-only attributes `z.real` and `z.imag`.

Sequences

These represent finite ordered sets indexed by non-negative numbers. The built-in function `len()` returns the number of items of a sequence. When the length of a sequence is n , the index set contains the numbers $0, 1, \dots, n-1$. Item i of sequence a is selected by `a[i]`.

Sequences also support slicing: `a[i:j]` selects all items with index k such that $i \leq k < j$. When used as an expression, a slice is a sequence of the same type. This implies that the index set is renumbered so that it starts at 0.

Some sequences also support "extended slicing" with a third "step" parameter: `a[i:j:k]` selects all items of a with index x where $x = i + n*k, n \geq 0$ and $i \leq x < j$.

Sequences are distinguished according to their mutability:

Immutable sequences

An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

Strings

The items of a string are characters. There is no separate character type; a character is represented by a string of one item. Characters represent (at least) 8-bit bytes. The built-in functions `chr()` and `ord()` convert between characters and nonnegative integers representing the byte values. Bytes with the values 0-127 usually represent the corresponding ASCII values, but the interpretation of values is up to the program. The string data type is also used to represent arrays of bytes, e.g., to hold data read from a file.

(On systems whose native character set is not ASCII, strings may use EBCDIC in their internal representation, provided the functions `chr()` and `ord()` implement a mapping between ASCII and EBCDIC, and string comparison preserves the ASCII order. Or perhaps someone can propose a better rule?)

Unicode

The items of a Unicode object are Unicode code units. A Unicode code unit is represented by a Unicode object of one item and can hold either a 16-bit or 32-bit value representing a Unicode ordinal (the maximum value for the ordinal is given in `sys.maxunicode`, and depends on how Python is configured at compile time). Surrogate pairs may be present in the Unicode object, and will be reported as two separate items. The built-in functions `unichr()` and `ord()` convert between code units and nonnegative integers representing the Unicode ordinals as defined in the Unicode Standard 3.0. Conversion from and to other encodings are possible through the Unicode method `encode()` and the built-in function `unicode()`.

Tuples

The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of expressions. A tuple of one item (a 'singleton') can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

Mutable sequences

Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and `del` (delete) statements.

There is currently a single intrinsic mutable sequence type:

Lists

The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

The extension module `array` provides an additional example of a mutable sequence type.

Mappings

These represent finite sets of objects indexed by arbitrary index sets. The subscript notation `a[k]` selects the item indexed by `k` from the mapping `a`; this can be used in expressions and as the target of assignments or `del` statements. The built-in function `len()` returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

Dictionaries

These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that

the efficient implementation of dictionaries requires a key's hash value to remain constant. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (e.g., 1 and 1.0) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are mutable; they can be created by the `{ . . . }` notation (see section [5.2.6](#), "Dictionary Displays").

The extension modules `dbm`, `gdbm`, and `bsddb` provide additional examples of mapping types.

Callable types

These are the types to which the function call operation (see section [5.3.4](#), "Calls") can be applied:

User-defined functions

A user-defined function object is created by a function definition (see section [7.5](#), "Function definitions"). It should be called with an argument list containing the same number of items as the function's formal parameter list.

Special attributes:

Attribute	Meaning	
<code>func_doc</code>	The function's documentation string, or <code>None</code> if unavailable	Writable
<code>__doc__</code>	Another way of spelling <code>func_doc</code>	Writable
<code>func_name</code>	The function's name	Writable
<code>__name__</code>	Another way of spelling <code>func_name</code>	Writable
<code>__module__</code>	The name of the module the function was defined in, or <code>None</code> if unavailable.	Writable
<code>func_defaults</code>	A tuple containing default argument values for those arguments that have defaults, or <code>None</code> if no arguments	Writable

	have a default value	
<code>func_code</code>	The code object representing the compiled function body.	Writable
<code>func_globals</code>	A reference to the dictionary that holds the function's global variables -- the global namespace of the module in which the function was defined.	Read-only
<code>func_dict</code>	The namespace supporting arbitrary function attributes.	Writable
<code>func_closure</code>	None or a tuple of cells that contain bindings for the function's free variables.	Read-only

Most of the attributes labelled ``Writable" check the type of the assigned value.

Changed in version 2.4: `func_name` is now writable.

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-defined functions. Function attributes on built-in functions may be supported in the future.*

Additional information about a function's definition can be retrieved from its code object; see the description of internal types below.

User-defined methods

A user-defined method object combines a class, a class instance (or `None`) and any callable object (normally a user-defined function).

Special read-only attributes: `im_self` is the class instance object, `im_func` is the function object; `im_class` is the class of `im_self` for bound methods or the class that asked for the method for unbound methods; `__doc__` is the method's documentation (same as `im_func.__doc__`); `__name__` is the method name (same as

`im_func.__name__`); `__module__` is the name of the module the method was defined in, or `None` if unavailable. Changed in version 2.2: `im_self` used to refer to the class that defined the method.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object, an unbound user-defined method object, or a class method object. When the attribute is a user-defined method object, a new method object is only created if the class from which it is being retrieved is the same as, or a derived class of, the class stored in the original method object; otherwise, the original method object is used as it is.

When a user-defined method object is created by retrieving a user-defined function object from a class, its `im_self` attribute is `None` and the method object is said to be unbound. When one is created by retrieving a user-defined function object from a class via one of its instances, its `im_self` attribute is the instance, and the method object is said to be bound. In either case, the new method's `im_class` attribute is the class from which the retrieval takes place, and its `im_func` attribute is the original function object.

When a user-defined method object is created by retrieving another method object from a class or instance, the behaviour is the same as for a function object, except that the `im_func` attribute of the new instance is not the original method object but its `im_func` attribute.

When a user-defined method object is created by retrieving a class method object from a class or instance, its `im_self` attribute is the class itself (the same as the `im_class` attribute), and its `im_func` attribute is the function object underlying the class method.

When an unbound user-defined method object is called, the underlying function (`im_func`) is called, with the restriction that the first argument must be an instance of the proper class (`im_class`) or of a

derived class thereof.

When a bound user-defined method object is called, the underlying function (`im_func`) is called, inserting the class instance (`im_self`) in front of the argument list. For instance, when `C` is a class which contains a definition for a function `f()`, and `x` is an instance of `C`, calling `x.f(1)` is equivalent to calling `C.f(x, 1)`.

When a user-defined method object is derived from a class method object, the "class instance" stored in `im_self` will actually be the class itself, so that calling either `x.f(1)` or `C.f(1)` is equivalent to calling `f(C, 1)` where `f` is the underlying function.

Note that the transformation from function object to (unbound or bound) method object happens each time the attribute is retrieved from the class or instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this *only* happens when the function is an attribute of the class.

Generator functions

A function or method which uses the `yield` statement (see section [6.8](#), "The `yield` statement") is called a *generator function*. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling the iterator's `next()` method will cause the function to execute until it provides a value using the `yield` statement. When the function executes a `return` statement or falls off the end, a `StopIteration` exception is raised and the iterator will have reached the end of the set of values to be returned.

Built-in functions

A built-in function object is a wrapper around a C function. Examples of built-in functions are `len()` and `math.sin()` (`math` is a standard built-in module). The number and type of the arguments are

determined by the C function. Special read-only attributes: `__doc__` is the function's documentation string, or `None` if unavailable; `__name__` is the function's name; `__self__` is set to `None` (but see the next item); `__module__` is the name of the module the function was defined in or `None` if unavailable.

Built-in methods

This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit extra argument. An example of a built-in method is `alist.append()`, assuming `alist` is a list object. In this case, the special read-only attribute `__self__` is set to the object denoted by `list`.

Class Types

Class types, or "new-style classes," are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override `__new__()`. The arguments of the call are passed to `__new__()` and, in the typical case, to `__init__()` to initialize the new instance.

Classic Classes

Class objects are described below. When a class object is called, a new class instance (also described below) is created and returned. This implies a call to the class's `__init__()` method if it has one. Any arguments are passed on to the `__init__()` method. If there is no `__init__()` method, the class must be called without arguments.

Class instances

Class instances are described below. Class instances are callable only when the class has a `__call__()` method; `x(arguments)` is a shorthand for `x.__call__(arguments)`.

Modules

Modules are imported by the `import` statement (see section [6.12](#), "The `import` statement"). A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the `func_globals` attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., `m.x` is equivalent to

`m.__dict__["x"]`. A module object does not contain the code object used to initialize the module (since it isn't needed once the initialization is done).

Attribute assignment updates the module's namespace dictionary, e.g., `m.x = 1` is equivalent to `m.__dict__["x"] = 1`.

Special read-only attribute: `__dict__` is the module's namespace as a dictionary object.

Predefined (writable) attributes: `__name__` is the module's name; `__doc__` is the module's documentation string, or `None` if unavailable; `__file__` is the pathname of the file from which the module was loaded, if it was loaded from a file. The `__file__` attribute is not present for C modules that are statically linked into the interpreter; for extension modules loaded dynamically from a shared library, it is the pathname of the shared library file.

Classes

Class objects are created by class definitions (see section [7.6](#), "Class definitions"). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., `C.x` is translated to `C.__dict__["x"]`. When the attribute name is not found there, the attribute search continues in the base classes. The search is depth-first, left-to-right in the order of occurrence in the base class list.

When a class attribute reference (for class `C`, say) would yield a user-defined function object or an unbound user-defined method object whose associated class is either `C` or one of its base classes, it is transformed into an unbound user-defined method object whose `im_class` attribute is `C`. When it would yield a class method object, it is transformed into a bound user-defined method object whose `im_class` and `im_self` attributes are both `C`. When it would yield a static method object, it is transformed into the object wrapped by the static method object. See section [3.3.2](#) for another way in which attributes retrieved from a class may differ from those actually contained in its `__dict__`.

Class attribute assignments update the class's dictionary, never the

dictionary of a base class.

A class object can be called (see above) to yield a class instance (see below).

Special attributes: `__name__` is the class name; `__module__` is the module name in which the class was defined; `__dict__` is the dictionary containing the class's namespace; `__bases__` is a tuple (possibly empty or a singleton) containing the base classes, in the order of their occurrence in the base class list; `__doc__` is the class's documentation string, or `None` if undefined.

Class instances

A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the search continues with the class attributes. If a class attribute is found that is a user-defined function object or an unbound user-defined method object whose associated class is the class (call it `C`) of the instance for which the attribute reference was initiated or one of its bases, it is transformed into a bound user-defined method object whose `im_class` attribute is `C` whose `im_self` attribute is the instance. Static method and class method objects are also transformed, as if they had been retrieved from class `C`; see above under ``Classes''. See section [3.3.2](#) for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's `__dict__`. If no class attribute is found, and the object's class has a `__getattr__()` method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's dictionary, never a class's dictionary. If the class has a `__setattr__()` or `__delattr__()` method, this is called instead of updating the instance dictionary directly.

Class instances can pretend to be numbers, sequences, or mappings if they have methods with certain special names. See section [3.3](#), ``Special method names.''

Special attributes: `__dict__` is the attribute dictionary; `__class__` is

the instance's class.

Files

A file object represents an open file. File objects are created by the `open()` built-in function, and also by `os.popen()`, `os.fdopen()`, and the `makefile()` method of socket objects (and perhaps by other functions or methods provided by extension modules). The objects `sys.stdin`, `sys.stdout` and `sys.stderr` are initialized to file objects corresponding to the interpreter's standard input, output and error streams. See the [Python Library Reference](#) for complete documentation of file objects.

Internal types

A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of the interpreter, but they are mentioned here for completeness.

Code objects

Code objects represent *byte-compiled* executable Python code, or *bytecode*. The difference between a code object and a function object is that the function object contains an explicit reference to the function's globals (the module in which it was defined), while a code object contains no context; also the default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: `co_name` gives the function name; `co_argcount` is the number of positional arguments (including arguments with default values); `co_nlocals` is the number of local variables used by the function (including arguments); `co_varnames` is a tuple containing the names of the local variables (starting with the argument names); `co_cellvars` is a tuple containing the names of local variables that are referenced by nested functions; `co_freevars` is a tuple containing the names of free variables; `co_code` is a string representing the sequence of bytecode instructions; `co_consts` is a tuple containing the literals used by the bytecode; `co_names` is a tuple containing the names used by the

bytecode; `co_filename` is the filename from which the code was compiled; `co_firstlineno` is the first line number of the function; `co_lnotab` is a string encoding the mapping from byte code offsets to line numbers (for details see the source code of the interpreter); `co_stacksize` is the required stack size (including local variables); `co_flags` is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for `co_flags`: bit `0x04` is set if the function uses the `"*arguments"` syntax to accept an arbitrary number of positional arguments; bit `0x08` is set if the function uses the `"**keywords"` syntax to accept arbitrary keyword arguments; bit `0x20` is set if the function is a generator.

Future feature declarations (`"from __future__ import division"`) also use bits in `co_flags` to indicate whether a code object was compiled with a particular feature enabled: bit `0x2000` is set if the function was compiled with future division enabled; bits `0x10` and `0x1000` were used in earlier versions of Python.

Other bits in `co_flags` are reserved for internal use.

If a code object represents a function, the first item in `co_consts` is the documentation string of the function, or `NONE` if undefined.

Frame objects

Frame objects represent execution frames. They may occur in traceback objects (see below).

Special read-only attributes: `f_back` is to the previous stack frame (towards the caller), or `NONE` if this is the bottom stack frame; `f_code` is the code object being executed in this frame; `f_locals` is the dictionary used to look up local variables; `f_globals` is used for global variables; `f_builtins` is used for built-in (intrinsic) names; `f_restricted` is a flag indicating whether the function is executing in restricted execution mode; `f_lasti` gives the precise instruction (this is an index into the bytecode string of the code object).

Special writable attributes: `f_trace`, if not `None`, is a function called at the start of each source code line (this is used by the debugger); `f_exc_type`, `f_exc_value`, `f_exc_traceback` represent the last exception raised in the parent frame provided another exception was ever raised in the current frame (in all other cases they are `None`); `f_lineno` is the current line number of the frame -- writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to `f_lineno`.

Traceback objects

Traceback objects represent a stack trace of an exception. A traceback object is created when an exception occurs. When the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section [7.4](#), "The `try` statement.") It is accessible as `sys.exc_traceback`, and also as the third item of the tuple returned by `sys.exc_info()`. The latter is the preferred interface, since it works correctly when the program is using multiple threads. When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as `sys.last_traceback`.

Special read-only attributes: `tb_next` is the next level in the stack trace (towards the frame where the exception occurred), or `None` if there is no next level; `tb_frame` points to the execution frame of the current level; `tb_lineno` gives the line number where the exception occurred; `tb_lasti` indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a `try` statement with no matching `except` clause or with a `finally` clause.

Slice objects

Slice objects are used to represent slices when *extended slice syntax* is used. This is a slice using two colons, or multiple slices or ellipses separated by commas, e.g., `a[i:j:step]`, `a[i:j, k:l]`, or

`a[... , i:j]`. They are also created by the built-in `slice()` function.

Special read-only attributes: `start` is the lower bound; `stop` is the upper bound; `step` is the step value; each is `None` if omitted. These attributes can have any type.

Slice objects support one method:

`indices(self, length)`

This method takes a single integer argument *length* and computes information about the extended slice that the slice object would describe if applied to a sequence of *length* items. It returns a tuple of three integers; respectively these are the *start* and *stop* indices and the *step* or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices. New in version 2.3.

Static method objects

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are not themselves callable, although the objects they wrap usually are. Static method objects are created by the built-in `staticmethod()` constructor.

Class method objects

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under "User-defined methods". Class method objects are created by the built-in `classmethod()` constructor.

3.3 Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python's approach to *operator overloading*, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named `__getitem__()`, and `x` is an instance of this class, then `x[i]` is equivalent to `x.__getitem__(i)`. Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined.

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the `NodeList` interface in the W3C's Document Object Model.)

Previous: [3.3 Special method names](#) **Up:** [3.3 Special method names](#) **Next:**
[3.3.2 Customizing attribute access](#)

3.3.1 Basic customization

`__new__(cls[, ...])`

Called to create a new instance of class *cls*. `__new__()` is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of `__new__()` should be the new object instance (usually an instance of *cls*).

Typical implementations create a new instance of the class by invoking the superclass's `__new__()` method using `"super(currentclass, cls).__new__(cls[, ...])"` with appropriate arguments and then modifying the newly-created instance as necessary before returning it.

If `__new__()` returns an instance of *cls*, then the new instance's `__init__()` method will be invoked like `"__init__(self[, ...])"`, where *self* is the new instance and the remaining arguments are the same as were passed to `__new__()`.

If `__new__()` does not return an instance of *cls*, then the new instance's `__init__()` method will not be invoked.

`__new__()` is intended mainly to allow subclasses of immutable types (like int, str, or tuple) to customize instance creation.

`__init__(self[, ...])`

Called when the instance is created. The arguments are those passed to the class constructor expression. If a base class has an `__init__()` method, the derived class's `__init__()` method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example: `"BaseClass.__init__(self, [args...])"`. As a special constraint on constructors, no value may be returned; doing so will cause a `TypeError` to be raised at runtime.

`__del__(self)`

Called when the instance is about to be destroyed. This is also called a destructor. If a base class has a `__del__()` method, the derived class's `__del__()` method, if any, must explicitly call it to ensure proper deletion of the base class part of the instance. Note that it is possible (though not recommended!) for the `__del__()` method to postpone destruction of the instance by creating a new reference to it. It may then be called at a later time when this new reference is deleted. It is not guaranteed that `__del__()` methods are called for objects that still exist when the interpreter exits.

Note: "`del x`" doesn't directly call `x.__del__()` -- the former decrements the reference count for `x` by one, and the latter is only called when `x`'s reference count reaches zero. Some common situations that may prevent the reference count of an object from going to zero include: circular references between objects (e.g., a doubly-linked list or a tree data structure with parent and child pointers); a reference to the object on the stack frame of a function that caught an exception (the traceback stored in `sys.exc_traceback` keeps the stack frame alive); or a reference to the object on the stack frame that raised an unhandled exception in interactive mode (the traceback stored in `sys.last_traceback` keeps the stack frame alive). The first situation can only be remedied by explicitly breaking the cycles; the latter two situations can be resolved by storing `None` in `sys.exc_traceback` or `sys.last_traceback`. Circular references which are garbage are detected when the option cycle detector is enabled (it's on by default), but can only be cleaned up if there are no Python-level `__del__()` methods involved. Refer to the documentation for the [gc module](#) for more information about how `__del__()` methods are handled by the cycle detector, particularly the description of the garbage value.

Warning: Due to the precarious circumstances under which `__del__()` methods are invoked, exceptions that occur during their execution are ignored, and a warning is printed to `sys.stderr` instead. Also, when `__del__()` is invoked in response to a module being deleted (e.g., when execution of the program is done), other globals referenced by the `__del__()` method may already have been deleted. For this reason, `__del__()` methods should do the absolute minimum needed to maintain external invariants. Starting with version 1.5, Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the `__del__()` method is called.

`__repr__(self)`

Called by the `repr()` built-in function and by string conversions (reverse quotes) to compute the "official" string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form "*<...some useful description...>*" should be returned. The return value must be a string object. If a class defines `__repr__()` but not `__str__()`, then `__repr__()` is also used when an "informal" string representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

`__str__(self)`

Called by the `str()` built-in function and by the `print` statement to compute the "informal" string representation of an object. This differs from `__repr__()` in that it does not have to be a valid Python expression: a more convenient or concise representation may be used instead. The return value must be a string object.

`__lt__(self, other)`

`__le__(self, other)`

`__eq__(self, other)`

`__ne__(self, other)`

`__gt__(self, other)`

`__ge__(self, other)`

New in version 2.1. These are the so-called "rich comparison" methods, and are called for comparison operators in preference to `__cmp__()` below. The correspondence between operator symbols and method names is as follows: $x < y$ calls `x.__lt__(y)`, $x \leq y$ calls `x.__le__(y)`, $x == y$ calls `x.__eq__(y)`, $x != y$ and $x <> y$ call `x.__ne__(y)`, $x > y$ calls `x.__gt__(y)`, and $x \geq y$ calls `x.__ge__(y)`. These methods can return any value, but if the comparison operator is used in a Boolean context, the return value should be interpretable as a Boolean value, else a `TypeError` will be raised. By convention, `False` is used for false and `True` for true.

There are no implied relationships among the comparison operators. The truth of $x == y$ does not imply that $x != y$ is false. Accordingly, when defining `__eq__()`, one should also define `__ne__()` so that the operators will behave as expected.

There are no reflected (swapped-argument) versions of these methods (to be used when the left argument does not support the operation but the right argument does); rather, `__lt__()` and `__gt__()` are each other's reflection, `__le__()` and `__ge__()` are each other's reflection, and `__eq__()` and `__ne__()` are their own reflection.

Arguments to rich comparison methods are never coerced. A rich comparison method may return `NotImplemented` if it does not implement the operation for a given pair of arguments.

`__cmp__(self, other)`

Called by comparison operations if rich comparison (see above) is not defined. Should return a negative integer if `self < other`, zero if `self == other`, a positive integer if `self > other`. If no `__cmp__()`, `__eq__()` or `__ne__()` operation is defined, class instances are

compared by object identity (``address"). See also the description of `__hash__()` for some important notes on creating objects which support custom comparison operations and are usable as dictionary keys. (Note: the restriction that exceptions are not propagated by `__cmp__()` has been removed since Python 1.5.)

`__rcmp__(self, other)`

Changed in version 2.1: No longer supported.

`__hash__(self)`

Called for the key object for dictionary operations, and by the built-in function `hash()`. Should return a 32-bit integer usable as a hash value for dictionary operations. The only required property is that objects which compare equal have the same hash value; it is advised to somehow mix together (e.g., using exclusive or) the hash values for the components of the object that also play a part in comparison of objects. If a class does not define a `__cmp__()` method it should not define a `__hash__()` operation either; if it defines `__cmp__()` or `__eq__()` but not `__hash__()`, its instances will not be usable as dictionary keys. If a class defines mutable objects and implements a `__cmp__()` or `__eq__()` method, it should not implement `__hash__()`, since the dictionary implementation requires that a key's hash value is immutable (if the object's hash value changes, it will be in the wrong hash bucket).

`__nonzero__(self)`

Called to implement truth value testing, and the built-in operation `bool()`; should return `False` or `True`, or their integer equivalents `0` or `1`. When this method is not defined, `__len__()` is called, if it is defined (see below). If a class defines neither `__len__()` nor `__nonzero__()`, all its instances are considered true.

`__unicode__(self)`

Called to implement `unicode()` builtin; should return a Unicode object. When this method is not defined, string conversion is attempted, and the result of string conversion is converted to Unicode using the system default encoding.

Previous: [3.3.1 Basic customization](#) **Up:** [3.3 Special method names](#) **Next:**
[3.3.2.1 More attribute access](#)

3.3.2 Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of `x.name`) for class instances.

`__getattr__`(*self*, *name*)

Called when an attribute lookup has not found the attribute in the usual places (i.e. it is not an instance attribute nor is it found in the class tree for `self`). *name* is the attribute name. This method should return the (computed) attribute value or raise an `AttributeError` exception.

Note that if the attribute is found through the normal mechanism, `__getattr__()` is not called. (This is an intentional asymmetry between `__getattr__()` and `__setattr__()`.) This is done both for efficiency reasons and because otherwise `__setattr__()` would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the `__getattribute__()` method below for a way to actually get total control in new-style classes.

`__setattr__`(*self*, *name*, *value*)

Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). *name* is the attribute name, *value* is the value to be assigned to it.

If `__setattr__()` wants to assign to an instance attribute, it should not simply execute `self.name = value` -- this would cause a recursive call to itself. Instead, it should insert the value in the dictionary of instance attributes, e.g., `self.__dict__[name] = value`. For new-style classes, rather than accessing the instance dictionary, it should call the base class method with the same name, for example, `object.__setattr__(self, name, value)`.

`__delattr__`(*self*, *name*)

Like `__setattr__()` but for attribute deletion instead of assignment.

This should only be implemented if "`del obj.name`" is meaningful for the object.

Previous: [3.3.2.4 __slots__](#) Up: [3.3 Special method names](#) Next: [3.3.4 Emulating callable objects](#)

3.3.3 Customizing class creation

By default, new-style classes are constructed using `type()`. A class definition is read into a separate namespace and the value of class name is bound to the result of `type(name, bases, dict)`.

When the class definition is read, if `__metaclass__` is defined then the callable assigned to it will be called instead of `type()`. This allows classes or functions to be written which monitor or alter the class creation process:

- Modifying the class dictionary prior to the class being created.
- Returning an instance of another class - essentially performing the role of a factory function.

`__metaclass__`

This variable can be any callable accepting arguments for `name`, `bases`, and `dict`. Upon class creation, the callable is used instead of the built-in `type()`. New in version 2.2.

The appropriate metaclass is determined by the following precedence rules:

- If `dict['__metaclass__']` exists, it is used.
- Otherwise, if there is at least one base class, its metaclass is used (this looks for a `__class__` attribute first and if not found, uses its type).
- Otherwise, if a global variable named `__metaclass__` exists, it is used.
- Otherwise, the old-style, classic metaclass (`types.ClassType`) is used.

The potential uses for metaclasses are boundless. Some ideas that have been explored including logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.

Emulating callable objects

*Release 2.4.4c1, documentation updated on 11 October 2006.

Previous: [3.3.4 Emulating callable objects](#) **Up:** [3.3 Special method names](#)
Next: [3.3.6 Additional methods for](#)

3.3.5 Emulating container types

The following methods can be defined to implement container objects. Containers usually are sequences (such as lists or tuples) or mappings (like dictionaries), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers k for which $0 \leq k < N$ where N is the length of the sequence, or slice objects, which define a range of items. (For backwards compatibility, the method `__getslice__()` (see below) can also be defined to handle simple, but not extended slices.) It is also recommended that mappings provide the methods `keys()`, `values()`, `items()`, `has_key()`, `get()`, `clear()`, `setdefault()`, `iterkeys()`, `itervalues()`, `iteritems()`, `pop()`, `popitem()`, `copy()`, and `update()` behaving similar to those for Python's standard dictionary objects. The `UserDict` module provides a `DictMixin` class to help create those methods from a base set of `__getitem__()`, `__setitem__()`, `__delitem__()`, and `keys()`. Mutable sequences should provide methods `append()`, `count()`, `index()`, `extend()`, `insert()`, `pop()`, `remove()`, `reverse()` and `sort()`, like Python standard list objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication (meaning repetition) by defining the methods `__add__()`, `__radd__()`, `__iadd__()`, `__mul__()`, `__rmul__()` and `__imul__()` described below; they should not define `__coerce__()` or other numerical operators. It is recommended that both mappings and sequences implement the `__contains__()` method to allow efficient use of the `in` operator; for mappings, `in` should be equivalent of `has_key()`; for sequences, it should search through the values. It is further recommended that both mappings and sequences implement the `__iter__()` method to allow efficient iteration through the container; for mappings, `__iter__()` should be the same as `iterkeys()`; for sequences, it should iterate through the values.

`__len__(self)`

Called to implement the built-in function `len()`. Should return the length of the object, an integer ≥ 0 . Also, an object that doesn't define a `__nonzero__()` method and whose `__len__()` method returns zero is

considered to be false in a Boolean context.

`__getitem__(self, key)`

Called to implement evaluation of `self[key]`. For sequence types, the accepted keys should be integers and slice objects. Note that the special interpretation of negative indexes (if the class wishes to emulate a sequence type) is up to the `__getitem__()` method. If `key` is of an inappropriate type, `TypeError` may be raised; if of a value outside the set of indexes for the sequence (after any special interpretation of negative values), `IndexError` should be raised. For mapping types, if `key` is missing (not in the container), `KeyError` should be raised. **Note:** for loops expect that an `IndexError` will be raised for illegal indexes to allow proper detection of the end of the sequence.

`__setitem__(self, key, value)`

Called to implement assignment to `self[key]`. Same note as for `__getitem__()`. This should only be implemented for mappings if the objects support changes to the values for keys, or if new keys can be added, or for sequences if elements can be replaced. The same exceptions should be raised for improper `key` values as for the `__getitem__()` method.

`__delitem__(self, key)`

Called to implement deletion of `self[key]`. Same note as for `__getitem__()`. This should only be implemented for mappings if the objects support removal of keys, or for sequences if elements can be removed from the sequence. The same exceptions should be raised for improper `key` values as for the `__getitem__()` method.

`__iter__(self)`

This method is called when an iterator is required for a container. This method should return a new iterator object that can iterate over all the objects in the container. For mappings, it should iterate over the keys of the container, and should also be made available as the method `iterkeys()`.

Iterator objects also need to implement this method; they are required to return themselves. For more information on iterator objects, see [`Iterator Types`](#) in the [Python Library Reference](#).

The membership test operators (`in` and `not in`) are normally implemented as an iteration through a sequence. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be a sequence.

`__contains__`(*self*, *item*)

Called to implement membership test operators. Should return true if *item* is in *self*, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.

Previous: [3.3.5 Emulating container types](#) **Up:** [3.3 Special method names](#)
Next: [3.3.7 Emulating numeric types](#)

3.3.6 Additional methods for emulation of sequence types

The following optional methods can be defined to further emulate sequence objects. Immutable sequences methods should at most only define `__getitem__()`; mutable sequences might define all three methods.

`__getslice__(self, i, j)`

Deprecated since release 2.0. Support slice objects as parameters to the `__getitem__()` method.

Called to implement evaluation of `self[i:j]`. The returned object should be of the same type as `self`. Note that missing `i` or `j` in the slice expression are replaced by zero or `sys.maxint`, respectively. If negative indexes are used in the slice, the length of the sequence is added to that index. If the instance does not implement the `__len__()` method, an `AttributeError` is raised. No guarantee is made that indexes adjusted this way are not still negative. Indexes which are greater than the length of the sequence are not modified. If no `__getslice__()` is found, a slice object is created instead, and passed to `__getitem__()` instead.

`__setslice__(self, i, j, sequence)`

Called to implement assignment to `self[i:j]`. Same notes for `i` and `j` as for `__getslice__()`.

This method is deprecated. If no `__setslice__()` is found, or for extended slicing of the form `self[i:j:k]`, a slice object is created, and passed to `__setitem__()`, instead of `__setslice__()` being called.

`__delslice__(self, i, j)`

Called to implement deletion of `self[i:j]`. Same notes for `i` and `j` as for `__getslice__()`. This method is deprecated. If no `__delslice__()` is found, or for extended slicing of the form `self[i:j:k]`, a slice object is created, and passed to `__delitem__()`, instead of `__delslice__()` being called.

Notice that these methods are only invoked when a single slice with a single colon is used, and the slice method is available. For slice operations involving extended slice notation, or in absence of the slice methods, `__getitem__()`, `__setitem__()` or `__delitem__()` is called with a slice object as argument.

The following example demonstrate how to make your program or module compatible with earlier versions of Python (assuming that methods `__getitem__()`, `__setitem__()` and `__delitem__()` support slice objects as arguments):

```
class MyClass:
    ...
    def __getitem__(self, index):
        ...
    def __setitem__(self, index, value):
        ...
    def __delitem__(self, index):
        ...

    if sys.version_info < (2, 0):
        # They won't be defined if version is at least 2.0 final

        def __getslice__(self, i, j):
            return self[max(0, i):max(0, j):]
        def __setslice__(self, i, j, seq):
            self[max(0, i):max(0, j):] = seq
        def __delslice__(self, i, j):
            del self[max(0, i):max(0, j):]
    ...
```

Note the calls to `max()`; these are necessary because of the handling of negative indices before the `__*slice__()` methods are called. When negative indexes are used, the `__*item__()` methods receive them as provided, but the `__*slice__()` methods get a "cooked" form of the index values. For each negative index value, the length of the sequence is added to the index before calling the method (which may still result in a negative index); this is the customary handling of negative indexes by the built-in sequence types, and the `__*item__()` methods are expected to do this as well. However, since they should already be doing that, negative indexes cannot be passed in; they must be constrained to the bounds of the sequence before being passed to the `__*item__()` methods. Calling `max(0, i)` conveniently returns the proper value.

Previous: [3.3.6 Additional methods for](#) **Up:** [3.3 Special method names](#) **Next:**
[3.3.8 Coercion rules](#)

3.3.7 Emulating numeric types

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

```
__add__( self, other)  
__sub__( self, other)  
__mul__( self, other)  
__floordiv__( self, other)  
__mod__( self, other)  
__divmod__( self, other)  
__pow__( self, other[, modulo])  
__lshift__( self, other)  
__rshift__( self, other)  
__and__( self, other)  
__xor__( self, other)  
__or__( self, other)
```

These methods are called to implement the binary arithmetic operations (+, -, *, //, %, `divmod()`, `pow()`, **, <<, >>, &, ^, |). For instance, to evaluate the expression `x+y`, where `x` is an instance of a class that has an `__add__()` method, `x.__add__(y)` is called. The `__divmod__()` method should be the equivalent to using `__floordiv__()` and `__mod__()`; it should not be related to `__truediv__()` (described below). Note that `__pow__()` should be defined to accept an optional third argument if the ternary version of the built-in `pow()` function is to be supported.

```
__div__( self, other)  
__truediv__( self, other)
```

The division operator (/) is implemented by these methods. The `__truediv__()` method is used when `__future__.division` is in

effect, otherwise `__div__()` is used. If only one of these two methods is defined, the object will not support division in the alternate context; `TypeError` will be raised instead.

`__radd__(self, other)`
`__rsub__(self, other)`
`__rmul__(self, other)`
`__rdiv__(self, other)`
`__rtruediv__(self, other)`
`__rfloordiv__(self, other)`
`__rmod__(self, other)`
`__rdivmod__(self, other)`
`__rpow__(self, other)`
`__rlshift__(self, other)`
`__rrshift__(self, other)`
`__rand__(self, other)`
`__rxor__(self, other)`
`__ror__(self, other)`

These methods are called to implement the binary arithmetic operations (+, -, *, /, %, `divmod()`, `pow()`, **, <<, >>, &, ^, |) with reflected (swapped) operands. These functions are only called if the left operand does not support the corresponding operation and the operands are of different types. [3.2](#) For instance, to evaluate the expression $x-y$, where y is an instance of a class that has an `__rsub__()` method, $y.__rsub__(x)$ is called if $x.__sub__(y)$ returns *NotImplemented*.

Note that ternary `pow()` will not try calling `__rpow__()` (the coercion rules would become too complicated).

Note: If the right operand's type is a subclass of the left operand's type and that subclass provides the reflected method for the operation, this method will be called before the left operand's non-reflected method. This behavior allows subclasses to override their ancestors' operations.

__iadd__(*self*, *other*)
__isub__(*self*, *other*)
__imul__(*self*, *other*)
__idiv__(*self*, *other*)
__itruediv__(*self*, *other*)
__ifloordiv__(*self*, *other*)
__imod__(*self*, *other*)
__ipow__(*self*, *other*[, *modulo*])
__ilshift__(*self*, *other*)
__irshift__(*self*, *other*)
__iand__(*self*, *other*)
__ixor__(*self*, *other*)
__ior__(*self*, *other*)

These methods are called to implement the augmented arithmetic operations ($+=$, $-=$, $*=$, $/=$, $\%=$, $**=$, $<<=$, $>>=$, $\&=$, $\^=$, $\|=$). These methods should attempt to do the operation in-place (modifying *self*) and return the result (which could be, but does not have to be, *self*). If a specific method is not defined, the augmented operation falls back to the normal methods. For instance, to evaluate the expression $x+=y$, where x is an instance of a class that has an `__iadd__()` method, `x.__iadd__(y)` is called. If x is an instance of a class that does not define a `__iadd__()` method, `x.__add__(y)` and `y.__radd__(x)` are considered, as with the evaluation of $x+y$.

__neg__(*self*)
__pos__(*self*)
__abs__(*self*)
__invert__(*self*)

Called to implement the unary arithmetic operations ($-$, $+$, `abs()` and \sim).

__complex__(*self*)
__int__(*self*)
__long__(*self*)

`__float__(self)`

Called to implement the built-in functions `complex()`, `int()`, `long()`, and `float()`. Should return a value of the appropriate type.

`__oct__(self)`

`__hex__(self)`

Called to implement the built-in functions `oct()` and `hex()`. Should return a string value.

`__coerce__(self, other)`

Called to implement "mixed-mode" numeric arithmetic. Should either return a 2-tuple containing *self* and *other* converted to a common numeric type, or `None` if conversion is impossible. When the common type would be the type of *other*, it is sufficient to return `None`, since the interpreter will also ask the other object to attempt a coercion (but sometimes, if the implementation of the other type cannot be changed, it is useful to do the conversion to the other type here). A return value of `NotImplemented` is equivalent to returning `None`.

Footnotes

... types. [3.2](#)

For operands of the same type, it is assumed that if the non-reflected method (such as `__add__()`) fails the operation is not supported, which is why the reflected method is not called.

[4. Execution model](#)

3.3.8 Coercion rules

This section used to document the rules for coercion. As the language has evolved, the coercion rules have become hard to document precisely; documenting what one version of one particular implementation does is undesirable. Instead, here are some informal guidelines regarding coercion. In Python 3.0, coercion will not be supported.

- If the left operand of a % operator is a string or Unicode object, no coercion takes place and the string formatting operation is invoked instead.
- It is no longer recommended to define a coercion operation. Mixed-mode operations on types that don't define coercion pass the original arguments to the operation.
- New-style classes (those derived from `object`) never invoke the `__coerce__()` method in response to a binary operator; the only time `__coerce__()` is invoked is when the built-in function `coerce()` is called.
- For most intents and purposes, an operator that returns `NotImplemented` is treated the same as one that is not implemented at all.
- Below, `__op__()` and `__rop__()` are used to signify the generic method names corresponding to an operator; `__iop__()` is used for the corresponding in-place operator. For example, for the operator `'+'`, `__add__()` and `__radd__()` are used for the left and right variant of the binary operator, and `__iadd__()` for the in-place variant.
- For objects `x` and `y`, first `x.__op__(y)` is tried. If this is not implemented or returns `NotImplemented`, `y.__rop__(x)` is tried. If this is also not implemented or returns `NotImplemented`, a `TypeError` exception is raised. But see the following exception:
- Exception to the previous item: if the left operand is an instance of a built-in type or a new-style class, and the right operand is an instance of a proper subclass of that type or class and overrides the base's `__rop__()` method,

the right operand's `__rop__()` method is tried *before* the left operand's `__op__()` method.

This is done so that a subclass can completely override binary operators. Otherwise, the left operand's `__op__()` method would always accept the right operand: when an instance of a given class is expected, an instance of a subclass of that class is always acceptable.

- When either operand type defines a coercion, this coercion is called before that type's `__op__()` or `__rop__()` method is called, but no sooner. If the coercion returns an object of a different type for the operand whose coercion is invoked, part of the process is redone using the new object.
- When an in-place operator (like ``+='`) is used, if the left operand implements `__iop__()`, it is invoked without any coercion. When the operation falls back to `__op__()` and/or `__rop__()`, the normal coercion rules apply.
- In `x+y`, if `x` is a sequence that implements sequence concatenation, sequence concatenation is invoked.
- In `x*y`, if one operand is a sequence that implements sequence repetition, and the other is an integer (`int` or `long`), sequence repetition is invoked.
- Rich comparisons (implemented by methods `__eq__()` and so on) never use coercion. Three-way comparison (implemented by `__cmp__()`) does use coercion under the same conditions as other binary operations use it.
- In the current implementation, the built-in numeric types `int`, `long` and `float` do not use coercion; the type `complex` however does use it. The difference can become apparent when subclassing these types. Over time, the type `complex` may be fixed to avoid coercion. All these types implement a `__coerce__()` method, for use by the built-in `coerce()` function.

4.1 Naming and binding

Names refer to objects. Names are introduced by name binding operations. Each occurrence of a name in the program text refers to the *binding* of that name established in the innermost function block containing the use.

A *block* is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified on the interpreter command line the first argument) is a code block. A script command (a command specified on the interpreter command line with the `-c` option) is a code block. The file read by the built-in function `execfile()` is a code block. The string argument passed to the built-in function `eval()` and to the `exec` statement is a code block. The expression read and evaluated by the built-in function `input()` is a code block.

A code block is executed in an *execution frame*. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block's execution has completed.

A *scope* defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods.

When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block's *environment*.

If a name is bound in a block, it is a local variable of that block. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a *free variable*.

When a name is not found at all, a `NameError` exception is raised. If the name

refers to a local variable that has not been bound, a `UnboundLocalError` exception is raised. `UnboundLocalError` is a subclass of `NameError`.

The following constructs bind names: formal parameters to functions, `import` statements, class and function definitions (these bind the class or function name in the defining block), and targets that are identifiers if occurring in an assignment, `for` loop header, or in the second position of an `except` clause header. The `import` statement of the form `from ... import *` binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a `del` statement is also considered bound for this purpose (though the actual semantics are to unbind the name). It is illegal to unbind a name that is referenced by an enclosing scope; the compiler will report a `SyntaxError`.

Each assignment or `import` statement occurs within a block defined by a class or function definition or at the module level (the top-level code block).

If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the `global` statement occurs within a block, all uses of the name specified in the statement refer to the binding of that name in the top-level namespace. Names are resolved in the top-level namespace by searching the global namespace, i.e. the namespace of the module containing the code block, and the builtin namespace, the namespace of the module `__builtin__`. The global namespace is searched first. If the name is not found there, the builtin namespace is searched. The `global` statement must precede all uses of the name.

The built-in namespace associated with the execution of a code block is actually found by looking up the name `__builtins__` in its global namespace; this should be a dictionary or a module (in the latter case the module's dictionary is used). By default, when in the `__main__` module, `__builtins__` is the built-in module `__builtin__` (note: no ```'s); when in any other module,

`__builtins__` is an alias for the dictionary of the `__builtin__` module itself. `__builtins__` can be set to a user-created dictionary to create a weak form of restricted execution.

Note: Users should not touch `__builtins__`; it is strictly an implementation detail. Users wanting to override values in the built-in namespace should `import` the `__builtin__` (no ``s'`) module and modify its attributes appropriately.

The namespace for a module is automatically created the first time a module is imported. The main module for a script is always called `__main__`.

The global statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

A class definition is an executable statement that may use and define names. These references follow the normal rules for name resolution. The namespace of the class definition becomes the attribute dictionary of the class. Names defined at the class scope are not visible in methods.

Subsections

- [4.1.1 Interaction with dynamic features](#)

Previous: [4.1 Naming and binding](#) Up: [4.1 Naming and binding](#) Next: [4.2 Exceptions](#)

4.1.1 Interaction with dynamic features

There are several cases where Python statements are illegal when used in conjunction with nested scopes that contain free variables.

If a variable is referenced in an enclosing scope, it is illegal to delete the name. An error will be reported at compile time.

If the wild card form of import -- `import *` -- is used in a function and the function contains or is a nested block with free variables, the compiler will raise a `SyntaxError`.

If `exec` is used in a function and the function contains or is a nested block with free variables, the compiler will raise a `SyntaxError` unless the `exec` explicitly specifies the local namespace for the `exec`. (In other words, `exec obj` would be illegal, but `exec obj in ns` would be legal.)

The `eval()`, `execfile()`, and `input()` functions and the `exec` statement do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces of the caller. Free variables are not resolved in the nearest enclosing namespace, but in the global namespace.^{4.1} The `exec` statement and the `eval()` and `execfile()` functions have optional arguments to override the global and local namespace. If only one namespace is specified, it is used for both.

Footnotes

... namespace.^{4.1}

This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.

Previous: [4.1 Naming and binding](#) **Up:** [4.1 Naming and binding](#) **Next:** [4.2 Exceptions](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [4.1.1 Interaction with dynamic Expressions](#) Up: [4. Execution model](#) Next: [5.](#)

4.2 Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is *raised* at the point where the error is detected; it may be *handled* by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a run-time error (such as division by zero). A Python program can also explicitly raise an exception with the `raise` statement. Exception handlers are specified with the `try ... except` statement. The `try ... finally` statement specifies cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the "termination" model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack backtrace, except when the exception is `SystemExit`.

Exceptions are identified by class instances. Selection of a matching `except` clause is based on object identity. The `except` clause must reference the same class or a base class of it.

When an exception is raised, an object (maybe `NONE`) is passed as the exception's *value*; this object does not affect the selection of an exception handler, but is passed to the selected exception handler as additional information. For class exceptions, this object must be an instance of the exception class being raised.

Warning: Messages to exceptions are not part of the Python API. Their contents may change from one version of Python to

the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the `try` statement in section [7.4](#) and `raise` statement in section [6.9](#).

5. Expressions

This chapter explains the meaning of the elements of expressions in Python.

Syntax Notes: In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

```
name ::= othername
```

and no semantics are given, the semantics of this form of `name` are the same as for `othername`.

5.1 Arithmetic conversions

When a description of an arithmetic operator below uses the phrase "the numeric arguments are converted to a common type," the arguments are coerced using the coercion rules listed at the end of chapter [3](#). If both arguments are standard numeric types, the following coercions are applied:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, if either argument is a long integer, the other is converted to long integer;
- otherwise, both must be plain integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string left argument to the '%' operator). Extensions can define their own coercions.

Previous: [5.1 Arithmetic conversions](#) **Up:** [5. Expressions](#) **Next:** [5.2.1 Identifiers \(Names\)](#)

5.2 Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in reverse quotes or in parentheses, brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

```
atom      ::= identifier | literal |  
           enclosure  
enclosure ::= parenth form | list display  
           | generator expression |

5.2.1 Identifiers (Names)

An identifier occurring as an atom is a name. See section [4.1](#) for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a `NameError` exception.

Private name mangling: When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a *private name* of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name in front of the name, with leading underscores removed, and a single underscore inserted in front of the class name. For example, the identifier `__spam` occurring in a class named `Ham` will be transformed to `_Ham__spam`. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is extremely long (longer than 255 characters), implementation defined truncation may happen. If the class name consists only of underscores, no transformation is done.

Previous: [5.2.1 Identifiers \(Names\)](#) **Up:** [5.2 Atoms](#) **Next:** [5.2.3 Parenthesized forms](#)

5.2.2 Literals

Python supports string literals and various numeric literals:

```
literal ::= stringliteral | integer |  
          longinteger  
          | floatnumber | imagnumber
```

[Download entire grammar as text.](#)

Evaluation of a literal yields an object of the given type (string, integer, long integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section [2.4](#) for details.

All literals correspond to immutable data types, and hence the object's identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.

Previous: [5.2.2 Literals](#) Up: [5.2 Atoms](#) Next: [5.2.4 List displays](#)

5.2.3 Parenthesized forms

A parenthesized form is an optional expression list enclosed in parentheses:

```
parenth_form ::= "(" [expression_list] ")"
```

[Download entire grammar as text.](#)

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression list.

An empty pair of parentheses yields an empty tuple object. Since tuples are immutable, the rules for literals apply (i.e., two occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma operator. The exception is the empty tuple, for which parentheses *are* required -- allowing unparenthesized ``nothing'' in expressions would cause ambiguities and allow common typos to pass uncaught.

Previous: [5.2.3 Parenthesized forms expressions](#) **Up:** [5.2 Atoms](#) **Next:** [5.2.5 Generator](#)

5.2.4 List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
test      ::= and test ( "or" and test )*
           | lambda form
testlist  ::= test ( "," test )* [ "," ]
list_display ::= "[" [listmaker] "]"
listmaker ::= expression ( list for | (
           "," expression )* [ "," ] )
list_iter ::= list for | list if
list_for  ::= "for" expression list "in"
           testlist [list iter]
list_if   ::= "if" test [list iter]
```

[Download entire grammar as text.](#)

A list display yields a new list object. Its contents are specified by providing either a list of expressions or a list comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a list comprehension is supplied, it consists of a single expression followed by at least one `for` clause and zero or more `for` or `if` clauses. In this case, the elements of the new list are those that would be produced by considering each of the `for` or `if` clauses a block, nesting from left to right, and evaluating the expression to produce a list element each time the innermost block is reached^{[5.1](#)}.

Footnotes

... reached^{[5.1](#)}

In Python 2.3, a list comprehension "leaks" the control variables of each

"for" it contains into the containing scope. However, this behavior is deprecated, and relying on it will not work once this bug is fixed in a future release

See [About this document...](#) for information on suggesting changes.

Previous: [5.2.4 List displays](#) Up: [5.2 Atoms](#) Next: [5.2.6 Dictionary displays](#)

5.2.5 Generator expressions

A generator expression is a compact generator notation in parentheses:

```
generator_expression ::= "(" test
                        genexpr\_for ")"
genexpr_for           ::= "for"
                        expression\_list
                        "in" test
                        [genexpr\_iter]
genexpr_iter          ::= genexpr\_for |
                        genexpr\_if
genexpr_if            ::= "if" test
                        [genexpr\_iter]
```

[Download entire grammar as text.](#)

A generator expression yields a new generator object. It consists of a single expression followed by at least one `for` clause and zero or more `for` or `if` clauses. The iterating values of the new generator are those that would be produced by considering each of the `for` or `if` clauses a block, nesting from left to right, and evaluating the expression to yield a value that is reached the innermost block for each iteration.

Variables used in the generator expression are evaluated lazily when the `next()` method is called for generator object (in the same fashion as normal generators). However, the leftmost `for` clause is immediately evaluated so that error produced by it can be seen before any other possible error in the code that handles the generator expression. Subsequent `for` clauses cannot be evaluated immediately since they may depend on the previous `for` loop. For example: "`(x*y for x in range(10) for y in bar(x))`".

The parentheses can be omitted on calls with only one argument. See section [5.3.4](#) for the detail.

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [5.2.5 Generator expressions](#) **Up:** [5.2 Atoms](#) **Next:** [5.2.7 String conversions](#)

5.2.6 Dictionary displays

A dictionary display is a possibly empty series of key/datum pairs enclosed in curly braces:

```
dict_display ::= "{" [key datum list] "}"
key_datum_list ::= key datum ("," key datum)* [","]
key_datum ::= expression ":" expression
```

[Download entire grammar as text.](#)

A dictionary display yields a new dictionary object.

The key/datum pairs are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum.

Restrictions on the types of the key values are listed earlier in section [3.2](#). (To summarize, the key type should be hashable, which excludes all mutable objects.) Clashes between duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.

Previous: [5.2.6 Dictionary displays](#) **Up:** [5.2 Atoms](#) **Next:** [5.3 Primaries](#)

5.2.7 String conversions

A string conversion is an expression list enclosed in reverse (a.k.a. backward) quotes:

```
string_conversion ::= "`" expression list
                  "`"
```

[Download entire grammar as text.](#)

A string conversion evaluates the contained expression list and converts the resulting object into a string according to rules specific to its type.

If the object is a string, a number, `None`, or a tuple, list or dictionary containing only objects whose type is one of these, the resulting string is a valid Python expression which can be passed to the built-in function `eval()` to yield an expression with the same value (or an approximation, if floating point numbers are involved).

(In particular, converting a string adds quotes around it and converts ``funny" characters to escape sequences that are safe to print.)

Recursive objects (for example, lists or dictionaries that contain a reference to themselves, directly or indirectly) use `". . ."` to indicate a recursive reference, and the result cannot be passed to `eval()` to get an equal value (`SyntaxError` will be raised instead).

The built-in function `repr()` performs exactly the same conversion in its argument as enclosing it in parentheses and reverse quotes does. The built-in function `str()` performs a similar but more user-friendly conversion.

Previous: [5.2.7 String conversions](#) **Up:** [5. Expressions](#) **Next:** [5.3.1 Attribute references](#)

5.3 Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

```
primary ::= atom | attributeref |  
          subscription | slicing | call
```

[Download entire grammar as text.](#)

Subsections

- [5.3.1 Attribute references](#)
- [5.3.2 Subscriptions](#)
- [5.3.3 Slicings](#)
- [5.3.4 Calls](#)

Previous: [5.2.7 String conversions](#) Up: [5. Expressions](#) Next: [5.3.1 Attribute references](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [5.3 Primaries](#) Up: [5.3 Primaries](#) Next: [5.3.2 Subscriptions](#)

5.3.1 Attribute references

An attribute reference is a primary followed by a period and a name:

```
attributeref ::= primary "." identifier
```

[Download entire grammar as text.](#)

The primary must evaluate to an object of a type that supports attribute references, e.g., a module, list, or an instance. This object is then asked to produce the attribute whose name is the identifier. If this attribute is not available, the exception `AttributeError` is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

Previous: [5.3 Primaries](#) Up: [5.3 Primaries](#) Next: [5.3.2 Subscriptions](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [5.3.1 Attribute references](#) Up: [5.3 Primaries](#) Next: [5.3.3 Slicings](#)

5.3.2 Subscriptions

A subscription selects an item of a sequence (string, tuple or list) or mapping (dictionary) object:

```
subscription ::= primary "[" expression list "]"
```

[Download entire grammar as text.](#)

The primary must evaluate to an object of a sequence or mapping type.

If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the subscription selects the value in the mapping that corresponds to that key. (The expression list is a tuple except if it has exactly one item.)

If the primary is a sequence, the expression (list) must evaluate to a plain integer. If this value is negative, the length of the sequence is added to it (so that, e.g., `x[-1]` selects the last item of `x`.) The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero).

A string's items are characters. A character is not a separate data type but a string of exactly one character.

Previous: [5.3.2 Subscriptions](#) Up: [5.3 Primaries](#) Next: [5.3.4 Calls](#)

5.3.3 Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in assignment or `del` statements. The syntax for a slicing:

```
slicing          ::= simple slicing | extended slicing
simple_slicing    ::= primary "[" short slice "]"
extended_slicing ::= primary "[" slice list "]"
slice_list       ::= slice item ("," slice item)* ["," "]
slice_item       ::= expression | proper slice | ellipsis
proper_slice     ::= short slice | long slice
short_slice      ::= [lower bound] ":" [upper bound]
long_slice       ::= short slice ":" [stride]
lower_bound      ::= expression
upper_bound      ::= expression
stride           ::= expression
ellipsis         ::= "..."
```

[Download entire grammar as text.](#)

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation as a slicing (this is the case if the slice list contains no

proper slice nor ellipses). Similarly, when the slice list has exactly one short slice and no trailing comma, the interpretation as a simple slicing takes priority over that as an extended slicing.

The semantics for a simple slicing are as follows. The primary must evaluate to a sequence object. The lower and upper bound expressions, if present, must evaluate to plain integers; defaults are zero and the `sys.maxint`, respectively. If either bound is negative, the sequence's length is added to it. The slicing now selects all items with index k such that $i \leq k < j$ where i and j are the specified lower and upper bounds. This may be an empty sequence. It is not an error if i or j lie outside the range of valid indexes (such items don't exist so they aren't selected).

The semantics for an extended slicing are as follows. The primary must evaluate to a mapping object, and it is indexed with a key that is constructed from the slice list, as follows. If the slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of an ellipsis slice item is the built-in `Ellipsis` object. The conversion of a proper slice is a slice object (see section [3.2](#)) whose `start`, `stop` and `step` attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting `None` for missing expressions.

Previous: [5.3.3 Slicings](#) Up: [5.3 Primaries](#) Next: [5.4 The power operator](#)

5.3.4 Calls

A call calls a callable object (e.g., a function) with a possibly empty series of arguments:

```
primary "(" [argument_list [","] | testgenexpr for ]
      ")"
call      ::= primary "("
           [argument_list [","] ] ")"
argument_list ::= positional_arguments [",",
           "*" expression]
           ["*",
           "*" expression]
           | keyword_arguments [",",
           "*" expression]
           ["*",
           "*" expression]
           | "*" expression
positional_arguments ::= expression (","
           expression)*
keyword_arguments    ::= keyword_item (","
           keyword_item)*
keyword_item         ::= identifier "=" expressio
```

[Download entire grammar as text.](#)

A trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances,

and certain class instances themselves are callable; extensions may define additional callable object types). All argument expressions are evaluated before the call is attempted. Please refer to section [7.5](#) for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a `TypeError` exception is raised. Otherwise, the value of the argument is placed in the slot, filling it (even if the expression is `None`, it fills the slot). When all arguments have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that don't specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a `TypeError` exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

If there are more positional arguments than there are formal parameter slots, a `TypeError` exception is raised, unless a formal parameter using the syntax `*identifier` is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a `TypeError` exception is raised, unless a formal parameter using the syntax `**identifier` is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax `*expression` appears in the function call, `expression` must evaluate to a sequence. Elements from this sequence are treated as if they were additional positional arguments; if there are positional arguments x_1, \dots, x_N , and `expression` evaluates to a sequence y_1, \dots, y_M , this is equivalent to a

call with M+N positional arguments $x_1, \dots, x_N, y_1, \dots, y_M$.

A consequence of this is that although the "`*expression`" syntax appears *after* any keyword arguments, it is processed *before* the keyword arguments (and the "`**expression`" argument, if any - see below). So:

```
>>> def f(a, b):
...     print a, b
...
>>> f(b=1, *(2,))
2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: f() got multiple values for keyword argument 'a'
>>> f(1, *(2,))
1 2
```

It is unusual for both keyword arguments and the "`*expression`" syntax to be used in the same call, so in practice this confusion does not arise.

If the syntax "`**expression`" appears in the function call, "`expression`" must evaluate to a (subclass of) dictionary, the contents of which are treated as additional keyword arguments. In the case of a keyword appearing in both "`expression`" and as an explicit keyword argument, a `TypeError` exception is raised.

Formal parameters using the syntax "`*identifier`" or "`**identifier`" cannot be used as positional argument slots or as keyword argument names. Formal parameters using the syntax "`(sublist)`" cannot be used as keyword argument names; the outermost sublist corresponds to a single unnamed argument slot, and the argument value is assigned to the sublist using the usual tuple assignment rules after all other parameter processing is done.

A call always returns some value, possibly `None`, unless it raises an exception. How this value is computed depends on the type of the callable object.

If it is--

a user-defined function:

The code block for the function is executed, passing it the argument list.

The first thing the code block will do is bind the formal parameters to the

arguments; this is described in section [7.5](#). When the code block executes a `return` statement, this specifies the return value of the function call.

a built-in function or method:

The result is up to the interpreter; see the [Python Library Reference](#) for the descriptions of built-in functions and methods.

a class object:

A new instance of that class is returned.

a class instance method:

The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:

The class must define a `__call__()` method; the effect is then the same as if that method was called.

	Python Reference Manual		
Previous: 5.3.3 Slicings Up: 5.3 Primaries Next: 5.4 The power operator			

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [5.3.4 Calls](#) Up: [5. Expressions](#) Next: [5.5 Unary arithmetic operations](#)

5.4 The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

```
power ::= primary [ "*" u\_expr ]
```

[Download entire grammar as text.](#)

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands).

The power operator has the same semantics as the built-in `pow()` function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type. The result type is that of the arguments after coercion.

With mixed operand types, the coercion rules for binary arithmetic operators apply. For int and long int operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `10**2` returns `100`, but `10** - 2` returns `0.01`. (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised).

Raising `0.0` to a negative power results in a `ZeroDivisionError`. Raising a negative number to a fractional power results in a `ValueError`.

Previous: [5.4 The power operator arithmetic operations](#) **Up:** [5. Expressions](#) **Next:** [5.6 Binary](#)

5.5 Unary arithmetic operations

All unary arithmetic (and bit-wise) operations have the same priority:

```
u_expr ::= power | "-" u_expr | "+" u_expr |
        "~" u_expr
```

[Download entire grammar as text.](#)

The unary - (minus) operator yields the negation of its numeric argument.

The unary + (plus) operator yields its numeric argument unchanged.

The unary ~ (invert) operator yields the bit-wise inversion of its plain or long integer argument. The bit-wise inversion of x is defined as $-(x+1)$. It only applies to integral numbers.

In all three cases, if the argument does not have the proper type, a `TypeError` exception is raised.

Previous: [5.5 Unary arithmetic operations](#) Up: [5. Expressions](#) Next: [5.7 Shifting operations](#)

5.6 Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

```
m_expr ::= u_expr | m_expr "*" u_expr |
         m_expr "//" u_expr | m_expr "/"
         u_expr
         | m_expr "%" u_expr
a_expr ::= m_expr | a_expr "+" m_expr |
         a_expr "-" m_expr
```

[Download entire grammar as text.](#)

The * (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer (plain or long) and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

The / (division) and // (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Plain or long integer division yields an integer of the same type; the result is that of mathematical division with the `floor` function applied to the result. Division by zero raises the `ZeroDivisionError` exception.

The % (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the `ZeroDivisionError` exception. The arguments may be floating point numbers, e.g., `3.14%0.7` equals `0.34` (since `3.14` equals `4*0.7 + 0.34`.) The modulo operator always yields a result with the same sign as its second operand (or zero); the absolute value of the result is strictly smaller than the absolute value of the second operand^{[5.2](#)}.

The integer division and modulo operators are connected by the following identity: $x == (x/y)*y + (x\%y)$. Integer division and modulo are also connected with the built-in function `divmod()`: `divmod(x, y) == (x/y, x%y)`. These identities don't hold for floating point numbers; there similar identities hold approximately where `x/y` is replaced by `floor(x/y)` or `floor(x/y) - 1`^{5.3}.

In addition to performing the modulo operation on numbers, the `%` operator is also overloaded by string and unicode objects to perform string formatting (also known as interpolation). The syntax for string formatting is described in the [Python Library Reference](#), section "Sequence Types".

Deprecated since release 2.3. The floor division operator, the modulo operator, and the `divmod()` function are no longer defined for complex numbers. Instead, convert to a floating point number using the `abs()` function if appropriate.

The `+` (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

The `-` (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.

Footnotes

... operand^{5.2}

While $\text{abs}(x\%y) < \text{abs}(y)$ is true mathematically, for floats it may not be true numerically due to roundoff. For example, and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that `-1e-100 % 1e100` have the same sign as `1e100`, the computed result is `-1e-100 + 1e100`, which is numerically exactly equal to `1e100`. Function `fmod()` in the `math` module returns a result whose sign matches the sign of the first argument instead, and so returns `-1e-100` in

this case. Which approach is more appropriate depends on the application.
... 1 [5.3](#)

If x is very close to an exact integer multiple of y , it's possible for `floor(x/y)` to be one larger than $(x - x\%y)/y$ due to rounding. In such cases, Python returns the latter result, in order to preserve that `divmod(x, y)[0] * y + x % y` be very close to x .

Python Reference Manual

INDEX

Previous: [5.5 Unary arithmetic operations](#) Up: [5. Expressions](#) Next: [5.7 Shifting operations](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [5.6 Binary arithmetic operations](#) **Up:** [5. Expressions](#) **Next:** [5.8 Binary bit-wise operations](#)

5.7 Shifting operations

The shifting operations have lower priority than the arithmetic operations:

```
shift_expr ::= a\_expr | shift\_expr ( "<<" |  
" >>" ) a\_expr
```

[Download entire grammar as text.](#)

These operators accept plain or long integers as arguments. The arguments are converted to a common type. They shift the first argument to the left or right by the number of bits given by the second argument.

A right shift by n bits is defined as division by $\text{pow}(2, n)$. A left shift by n bits is defined as multiplication with $\text{pow}(2, n)$; for plain integers there is no overflow check so in that case the operation drops bits and flips the sign if the result is not less than $\text{pow}(2, 31)$ in absolute value. Negative shift counts raise a `ValueError` exception.

Previous: [5.7 Shifting operations](#) **Up:** [5. Expressions](#) **Next:** [5.9 Comparisons](#)

5.8 Binary bit-wise operations

Each of the three bitwise operations has a different priority level:

```
and_expr ::= shift\_expr | and\_expr "&"
           shift\_expr
xor_expr ::= and\_expr | xor\_expr "^"
           and\_expr
or_expr  ::= xor\_expr | or\_expr "|" xor\_expr
```

[Download entire grammar as text.](#)

The & operator yields the bitwise AND of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The ^ operator yields the bitwise XOR (exclusive OR) of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The | operator yields the bitwise (inclusive) OR of its arguments, which must be plain or long integers. The arguments are converted to a common type.

Previous: [5.8 Binary bit-wise operations](#) **Up:** [5. Expressions](#) **Next:** [5.10 Boolean operations](#)

5.9 Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like $a < b < c$ have the interpretation that is conventional in mathematics:

```
comparison ::= or_expr ( comp_operator
                        or_expr )*
comp_operator ::= "<" | ">" | "==" | ">=" |
                 "<=" | "<>" | "!="
                 | "is" ["not"] | ["not"]
                 "in"
```

[Download entire grammar as text.](#)

Comparisons yield boolean values: True or False.

Comparisons can be chained arbitrarily, e.g., $x < y \leq z$ is equivalent to $x < y$ and $y \leq z$, except that y is evaluated only once (but in both cases z is not evaluated at all when $x < y$ is found to be false).

Formally, if a, b, c, \dots, y, z are expressions and opa, opb, \dots, opy are comparison operators, then $a opa b opb c \dots y opy z$ is equivalent to $a opa b$ and $b opb c$ and $\dots y opy z$, except that each expression is evaluated at most once.

Note that $a opa b opb c$ doesn't imply any kind of comparison between a and c , so that, e.g., $x < y > z$ is perfectly legal (though perhaps not pretty).

The forms $<>$ and $!=$ are equivalent; for consistency with C, $!=$ is preferred; where $!=$ is mentioned below $<>$ is also accepted. The $<>$ spelling is considered obsolescent.

The operators $<$, $>$, $==$, $>=$, $<=$, and $!=$ compare the values of two objects. The objects need not have the same type. If both are numbers, they are converted to a common type. Otherwise, objects of different types *always* compare unequal, and are ordered consistently but arbitrarily. You can control comparison behavior

of objects of non-builtin types by defining a `__cmp__` method or rich comparison methods like `__gt__`, described in section [3.3](#).

(This unusual definition of comparison was used to simplify the definition of operations like sorting and the `in` and `not in` operators. In the future, the comparison rules for objects of different types are likely to change.)

Comparison of objects of the same type depends on the type:

- Numbers are compared arithmetically.
- Strings are compared lexicographically using the numeric equivalents (the result of the built-in function `ord()`) of their characters. Unicode and 8-bit strings are fully interoperable in this behavior.
- Tuples and lists are compared lexicographically using comparison of corresponding elements. This means that to compare equal, each element must compare equal and the two sequences must be of the same type and have the same length.

If not equal, the sequences are ordered the same as their first differing elements. For example, `cmp([1, 2, x], [1, 2, y])` returns the same as `cmp(x, y)`. If the corresponding element does not exist, the shorter sequence is ordered first (for example, `[1, 2] < [1, 2, 3]`).

- Mappings (dictionaries) compare equal if and only if their sorted (key, value) lists compare equal. [5.4](#) Outcomes other than equality are resolved consistently, but are not otherwise defined. [5.5](#)
- Most other objects of builtin types compare unequal unless they are the same object; the choice whether one object is considered smaller or larger than another one is made arbitrarily but consistently within one execution of a program.

The operators `in` and `not in` test for set membership. `x in s` evaluates to true if `x` is a member of the set `s`, and false otherwise. `x not in s` returns the negation of `x in s`. The set membership test has traditionally been bound to sequences; an object is a member of a set if the set is a sequence and contains an element equal to that object. However, it is possible for an object to support

membership tests without being a sequence. In particular, dictionaries support membership testing as a nicer way of spelling `key in dict`; other mapping types may follow suit.

For the list and tuple types, `x in y` is true if and only if there exists an index i such that `x == y[i]` is true.

For the Unicode and string types, `x in y` is true if and only if x is a substring of y . An equivalent test is `y.find(x) != -1`. Note, x and y need not be the same type; consequently, `u'ab' in 'abc'` will return `True`. Empty strings are always considered to be a substring of any other string, so `"" in "abc"` will return `True`. Changed in version 2.3: Previously, x was required to be a string of length 1.

For user-defined classes which define the `__contains__()` method, `x in y` is true if and only if `y.__contains__(x)` is true.

For user-defined classes which do not define `__contains__()` and do define `__getitem__()`, `x in y` is true if and only if there is a non-negative integer index i such that `x == y[i]`, and all lower integer indices do not raise `IndexError` exception. (If any other exception is raised, it is as if `in` raised that exception).

The operator `not in` is defined to have the inverse true value of `in`.

The operators `is` and `is not` test for object identity: `x is y` is true if and only if x and y are the same object. `x is not y` yields the inverse truth value.

Footnotes

... equal. [5.4](#)

The implementation computes this efficiently, without constructing lists or sorting.

... defined. [5.5](#)

Earlier versions of Python used lexicographic comparison of the sorted

(key, value) lists, but this was very expensive for the common case of comparing for equality. An even earlier version of Python compared dictionaries by identity only, but this caused surprises because people expected to be able to test a dictionary for emptiness by comparing it to `{}`.

5.10 Boolean operations

Boolean operations have the lowest priority of all Python operations:

```
expression ::= or test | lambda form
or_test    ::= and test | or test "or"
            and test
and_test   ::= not test | and test "and"
            not test
not_test   ::= comparison | "not" not test
```

[Download entire grammar as text.](#)

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: `False`, `None`, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true.

The operator `not` yields `True` if its argument is false, `False` otherwise.

The expression `x and y` first evaluates `x`; if `x` is false, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

The expression `x or y` first evaluates `x`; if `x` is true, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

(Note that neither `and` nor `or` restrict the value and type they return to `False` and `True`, but rather return the last evaluated argument. This is sometimes useful, e.g., if `s` is a string that should be replaced by a default value if it is empty, the expression `s or 'foo'` yields the desired value. Because `not` has to invent a value anyway, it does not bother to return a value of the same type as its argument, so e.g., `not 'foo'` yields `False`, not `' '`.)

5.11 Lambdas

```
lambda_form ::= "lambda" [parameter list]:  
              expression
```

[Download entire grammar as text.](#)

Lambda forms (lambda expressions) have the same syntactic position as expressions. They are a shorthand to create anonymous functions; the expression `lambda arguments: expression` yields a function object. The unnamed object behaves like a function object defined with

```
def name(arguments):  
    return expression
```

See section [7.5](#) for the syntax of parameter lists. Note that functions created with lambda forms cannot contain statements.

Previous: [5.11 Lambdas](#) Up: [5. Expressions](#) Next: [5.13 Evaluation order](#)

5.12 Expression lists

```
expression_list ::= expression ( "," "expression" )* [ ",", "]"
```

[Download entire grammar as text.](#)

An expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

The trailing comma is required only to create a single tuple (a.k.a. a *singleton*); it is optional in all other cases. A single expression without a trailing comma doesn't create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: ().)

Previous: [5.12 Expression lists](#) Up: [5. Expressions](#) Next: [5.14 Summary](#)

5.13 Evaluation order

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

```
expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
func(expr1, expr2, *expr3, **expr4)
expr3, expr4 = expr1, expr2
```

5.14 Summary

The following table summarizes the operator precedences in Python, from lowest precedence (least binding) to highest precedence (most binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for comparisons, including tests, which all have the same precedence and chain from left to right -- see section [5.9](#) - and exponentiation, which groups from right to left).

Operator	Description
<code>lambda</code>	Lambda expression
<code>or</code>	Boolean OR
<code>and</code>	Boolean AND
<code>not x</code>	Boolean NOT
<code>in, not in</code>	Membership tests
<code>is, is not</code>	Identity tests
<code><, <=, >, >=, <>, !=, ==</code>	Comparisons
<code> </code>	Bitwise OR
<code>^</code>	Bitwise XOR
<code>&</code>	Bitwise AND
<code><<, >></code>	Shifts
<code>+, -</code>	Addition and subtraction
<code>*, /, %</code>	Multiplication, division, remainder
<code>+x, -x</code>	Positive, negative
<code>~x</code>	Bitwise not
<code>**</code>	Exponentiation
<code>x.attribute</code>	Attribute reference
<code>x[index]</code>	Subscription
<code>x[index:index]</code>	Slicing
<code>f(arguments . . .)</code>	Function call
<code>(expressions . . .)</code>	Binding or tuple display
<code>[expressions . . .]</code>	List display

<code>{key: datum . . . }</code>	Dictionary display

6. Simple statements

Simple statements are comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::= expression stmt
            | assert stmt
            | assignment stmt
            | augmented assignment stmt
            | pass stmt
            | del stmt
            | print stmt
            | return stmt
            | yield stmt
            | raise stmt
            | break stmt
            | continue stmt
            | import stmt
            | global stmt
            | exec stmt
```

Previous: [6. Simple statements](#) Up: [6. Simple statements](#) Next: [6.2 Assert statements](#)

6.1 Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value `None`). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::= expression\_list
```

[Download entire grammar as text.](#)

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not `None`, it is converted to a string using the built-in `repr()` function and the resulting string is written to standard output (see section [6.6](#)) on a line by itself. (Expression statements yielding `None` are not written, so that procedure calls do not cause any output.)

Previous: [6.1 Expression statements](#) **Up:** [6. Simple statements](#) **Next:** [6.3 Assignment statements](#)

6.2 Assert statements

Assert statements are a convenient way to insert debugging assertions into a program:

```
assert_stmt ::= "assert" expression [", "expression]
```

[Download entire grammar as text.](#)

The simple form, "assert `expression`", is equivalent to

```
if __debug__:
    if not expression: raise AssertionError
```

The extended form, "assert `expression1`, `expression2`", is equivalent to

```
if __debug__:
    if not expression1: raise AssertionError, expression2
```

These equivalences assume that `__debug__` and `AssertionError` refer to the built-in variables with those names. In the current implementation, the built-in variable `__debug__` is `True` under normal circumstances, `False` when optimization is requested (command line option `-O`). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to `__debug__` are illegal. The value for the built-in variable is determined when the interpreter starts.

Previous: [6.2 Assert statements](#) **Up:** [6. Simple statements](#) **Next:** [6.3.1 Augmented assignment statements](#)

6.3 Assignment statements

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

```
assignment_stmt ::= (target_list "=")+  
                  expression_list  
target_list      ::= target ("," target)*  
                  [","]  
target           ::= identifier  
                  | "(" target_list ")"  
                  | "[" target_list "]"  
                  | attributeref  
                  | subscription  
                  | slicing
```

[Download entire grammar as text.](#)

(See section [5.3](#) for the syntax definitions for the last three symbols.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section [3.2](#)).

Assignment of an object to a target list is recursively defined as follows.

- If the target list is a single target: The object is assigned to that target.
- If the target list is a comma-separated list of targets: The object must be a

sequence with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets. (This rule is relaxed as of Python 1.5; in earlier versions, the object had to be a tuple. Since strings are sequences, an assignment like "a, b = "xy"" is now legal as long as the string has the right length.)

Assignment of an object to a single target is recursively defined as follows.

- If the target is an identifier (name):
 - If the name does not occur in a `global` statement in the current code block: the name is bound to the object in the current local namespace.
 - Otherwise: the name is bound to the object in the current global namespace.

The name is rebound if it was already bound. This may cause the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor (if it has one) to be called.

- If the target is a target list enclosed in parentheses or in square brackets: The object must be a sequence with the same number of items as there are targets in the target list, and its items are assigned, from left to right, to the corresponding targets.
- If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, `TypeError` is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an exception (usually but not necessarily `AttributeError`).
- If the target is a subscription: The primary expression in the reference is evaluated. It should yield either a mutable sequence object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

If the primary is a mutable sequence object (such as a list), the subscript must yield a plain integer. If it is negative, the sequence's length is added to it. The resulting value must be a nonnegative integer less than the

sequence's length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, `IndexError` is raised (assignment to a subscripted sequence cannot add new items to a list).

If the primary is a mapping object (such as a dictionary), the subscript must have a type compatible with the mapping's key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

- If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence's length. The bounds should evaluate to (small) integers. If either bound is negative, the sequence's length is added to it. The resulting bounds are clipped to lie between zero and the sequence's length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned sequence, thus changing the length of the target sequence, if the object allows it.

(In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.)

WARNING: Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are `safe' (for example "`a, b = b, a`" swaps two variables), overlaps *within* the collection of assigned-to variables are not safe! For instance, the following program prints "`[0, 2]`":

```
x = [0, 1]
i = 0
i, x[i] = 1, 2
print x
```

[6.4 The pass statement](#)

6.3.1 Augmented assignment statements

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```
augmented_assignment_stmt ::= target augop
                             expression list
augop                       ::= "+=" | "-=" |
                             "*=" | "/=" |
                             "%=" | "**="
                             | ">>=" | "<<="
                             | "&=" | "^=" |
                             "|="
```

[Download entire grammar as text.](#)

(See section [5.3](#) for the syntax definitions for the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like `x += 1` can be rewritten as `x = x + 1` to achieve a similar, but not exactly equal effect. In the augmented version, `x` is only evaluated once. Also, when possible, the actual operation is performed *in-place*, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible *in-place* behavior, the binary operation performed by augmented assignment is the same as the normal binary operations.

For targets which are attribute references, the initial value is retrieved with a `getattr()` and the result is assigned with a `setattr()`. Notice that the two methods do not necessarily refer to the same variable. When `getattr()` refers

to a class variable, `setattr()` still writes to an instance variable. For example:

```
class A:
    x = 3      # class variable
a = A()
a.x += 1     # writes a.x as 4 leaving A.x as 3
```

6.4 The pass statement

```
pass_stmt ::= "pass"
```

Download entire grammar as text.

`pass` is a null operation -- when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```
def f(arg): pass      # a function that does nothing (yet)

class C: pass        # a class with no methods (yet)
```

Previous: [6.4 The pass statement](#) **Up:** [6. Simple statements](#) **Next:** [6.6 The print statement](#)

6.5 The `del` statement

```
del_stmt ::= "del" target\_list
```

[Download entire grammar as text.](#)

Deletion is recursively defined very similar to the way assignment is defined. Rather than spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

It is illegal to delete a name from the local namespace if it occurs as a free variable in a nested block.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).

Previous: [6.5 The del statement](#) Up: [6. Simple statements](#) Next: [6.7 The return statement](#)

6.6 The `print` statement

```
print_stmt ::= "print" ( [expression (","  
                        expression)* [",,"]  
                        | ">>" expression [(", "  
                        expression)+ [",,"] ] )
```

[Download entire grammar as text.](#)

`print` evaluates each expression in turn and writes the resulting object to standard output (see below). If an object is not a string, it is first converted to a string using the rules for string conversions. The (resulting or original) string is then written. A space is written before each object is (converted and) written, unless the output system believes it is positioned at the beginning of a line. This is the case (1) when no characters have yet been written to standard output, (2) when the last character written to standard output is `"\n"`, or (3) when the last write operation on standard output was not a `print` statement. (In some cases it may be functional to write an empty string to standard output for this reason.)

Note: Objects which act like file objects but which are not the built-in file objects often do not properly emulate this aspect of the file object's behavior, so it is best not to rely on this.

A `"\n"` character is written at the end, unless the `print` statement ends with a comma. This is the only action if the statement contains just the keyword `print`.

Standard output is defined as the file object named `stdout` in the built-in module `sys`. If no such object exists, or if it does not have a `write()` method, a `RuntimeError` exception is raised.

`print` also has an extended form, defined by the second portion of the syntax described above. This form is sometimes referred to as ```print chevron`." In this form, the first expression after the `>>` must evaluate to a ```file-like`" object, specifically an object that has a `write()` method as described above. With this extended form, the subsequent expressions are printed to this file object. If the first expression evaluates to `None`, then `sys.stdout` is used as the file for

output.

6.7 The return statement

```
return_stmt ::= "return" [expression list]
```

[Download entire grammar as text.](#)

`return` may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else `None` is substituted.

`return` leaves the current function call with the expression list (or `None`) as return value.

When `return` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the function.

In a generator function, the `return` statement is not allowed to include an [expression list](#). In that context, a bare `return` indicates that the generator is done and will cause `StopIteration` to be raised.

Previous: [6.7 The return statement](#) **Up:** [6. Simple statements](#) **Next:** [6.9 The raise statement](#)

6.8 The `yield` statement

```
yield_stmt ::= "yield" expression list
```

[Download entire grammar as text.](#)

The `yield` statement is only used when defining a generator function, and is only used in the body of the generator function. Using a `yield` statement in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator iterator, or more commonly, a generator. The body of the generator function is executed by calling the generator's `next()` method repeatedly until it raises an exception.

When a `yield` statement is executed, the state of the generator is frozen and the value of [expression list](#) is returned to `next()`'s caller. By "frozen" we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack: enough information is saved so that the next time `next()` is invoked, the function can proceed exactly as if the `yield` statement were just another external call.

The `yield` statement is not allowed in the `try` clause of a `try ... finally` construct. The difficulty is that there's no guarantee the generator will ever be resumed, hence no guarantee that the `finally` block will ever get executed.

Note: In Python 2.2, the `yield` statement is only allowed when the `generators` feature has been enabled. It will always be enabled in Python 2.3. This `__future__` import statement can be used to enable the feature:

```
from __future__ import generators
```

6.9 The raise statement

```
raise_stmt ::= "raise" [expression [",",  
                        expression [",", expression]]]
```

[Download entire grammar as text.](#)

If no expressions are present, `raise` re-raises the last exception that was active in the current scope. If no exception is active in the current scope, a `TypeError` exception is raised indicating that this is an error (if running under `IDLE`, a `Queue.Empty` exception is raised instead).

Otherwise, `raise` evaluates the expressions to get three objects, using `NONE` as the value of omitted expressions. The first two objects are used to determine the *type* and *value* of the exception.

If the first object is an instance, the type of the exception is the class of the instance, the instance itself is the value, and the second object must be `NONE`.

If the first object is a class, it becomes the type of the exception. The second object is used to determine the exception value: If it is an instance of the class, the instance becomes the exception value. If the second object is a tuple, it is used as the argument list for the class constructor; if it is `NONE`, an empty argument list is used, and any other object is treated as a single argument to the constructor. The instance so created by calling the constructor is used as the exception value.

If a third object is present and not `NONE`, it must be a traceback object (see section [3.2](#)), and it is substituted instead of the current location as the place where the exception occurred. If the third object is present and not a traceback object or `NONE`, a `TypeError` exception is raised. The three-expression form of `raise` is useful to re-raise an exception transparently in an `except` clause, but `raise` with no expressions should be preferred if the exception to be re-raised was the most recently active exception in the current scope.

Additional information on exceptions can be found in section [4.2](#), and information about handling exceptions is in section [7.4](#).

6.10 The break statement

```
break_stmt ::= "break"
```

[Download entire grammar as text.](#)

`break` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional `else` clause if the loop has one.

If a `for` loop is terminated by `break`, the loop control target keeps its current value.

When `break` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the loop.

Previous: [6.10 The break statement](#) **Up:** [6. Simple statements](#) **Next:** [6.12 The import statement](#)

6.11 The `continue` statement

```
continue_stmt ::= "continue"
```

[Download entire grammar as text.](#)

`continue` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition or `finally` statement within that loop.^{6.1} It continues with the next cycle of the nearest enclosing loop.

Footnotes

... loop.^{6.1}

It may occur within an `except` or `else` clause. The restriction on occurring in the `try` clause is implementor's laziness and will eventually be lifted.

Previous: [6.10 The break statement](#) Up: [6. Simple statements](#) Next: [6.12 The import statement](#)

Previous: [6.11 The continue statement](#) **Up:** [6. Simple statements](#) **Next:** [6.12.1 Future statements](#)

6.12 The `import` statement

```
import_stmt ::= "import" module ["as" name]
              ( "," module ["as" name] )*
              | "from" module "import"
                identifier ["as" name]
                  ( "," identifier ["as"
                                     name] )*
              | "from" module "import" "("
                identifier ["as" name]
                  ( "," identifier ["as"
                                     name] )* ["," "]"
              | "from" module "import" "*"

module      ::= ( identifier "." )* identifier
```

[Download entire grammar as text.](#)

Import statements are executed in two steps: (1) find a module, and initialize it if necessary; (2) define a name or names in the local namespace (of the scope where the `import` statement occurs). The first form (without `from`) repeats these steps for each identifier in the list. The form with `from` performs step (1) once, and then performs step (2) repeatedly.

In this context, to ``initialize" a built-in or extension module means to call an initialization function that the module must provide for the purpose (in the reference implementation, the function's name is obtained by prepending string ``init" to the module's name); to ``initialize" a Python-coded module means to execute the module's body.

The system maintains a table of modules that have been or are being initialized, indexed by module name. This table is accessible as `sys.modules`. When a module name is found in this table, step (1) is finished. If not, a search for a module definition is started. When a module is found, it is loaded. Details of the module searching and loading process are implementation and platform specific. It generally involves searching for a ``built-in" module with the given name and then searching a list of locations given as `sys.path`.

If a built-in module is found, its built-in initialization code is executed and step (1) is finished. If no matching file is found, `ImportError` is raised. If a file is found, it is parsed, yielding an executable code block. If a syntax error occurs, `SyntaxError` is raised. Otherwise, an empty module of the given name is created and inserted in the module table, and then the code block is executed in the context of this module. Exceptions during this execution terminate step (1).

When step (1) finishes without raising an exception, step (2) can begin.

The first form of `import` statement binds the module name in the local namespace to the module object, and then goes on to import the next identifier, if any. If the module name is followed by `as`, the name following `as` is used as the local name for the module.

The `from` form does not bind the module name: it goes through the list of identifiers, looks each one of them up in the module found in step (1), and binds the name in the local namespace to the object thus found. As with the first form of `import`, an alternate local name can be supplied by specifying "`as localname`". If a name is not found, `ImportError` is raised. If the list of identifiers is replaced by a star ("`*`"), all public names defined in the module are bound in the local namespace of the `import` statement..

The *public names* defined by a module are determined by checking the module's namespace for a variable named `__all__`; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in `__all__` are all considered public and are required to exist. If `__all__` is not defined, the set of public names includes all names found in the module's namespace which do not begin with an underscore character ("`_`"). `__all__` should contain the entire public API. It is intended to avoid accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The `from` form with "`*`" may only occur in a module scope. If the wild card form of import -- "`import *`" -- is used in a function and the function contains or is a nested block with free variables, the compiler will raise a `SyntaxError`.

Hierarchical module names: when the module names contains one or more dots, the module search path is carried out differently. The sequence of

identifiers up to the last dot is used to find a ``package"; the final identifier is then searched inside the package. A package is generally a subdirectory of a directory on `sys.path` that has a file `__init__.py`. [XXX Can't be bothered to spell this out right now; see the URL <http://www.python.org/doc/essays/packages.html> for more details, also about how the module search works from inside a package.]

The built-in function `__import__()` is provided to support applications that determine which modules need to be loaded dynamically; refer to [Built-in Functions](#) in the [Python Library Reference](#) for additional information.

6.12.1 Future statements

A *future statement* is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python. The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

```
future_statement ::= "from" "__future__"
                  "import" feature ["as"
                  name] ("," feature
                  ["as" name])*
                  | "from" "__future__"
                  "import" "(" feature
                  ["as" name] (","
                  feature ["as" name])*
                  [","] ")"
feature           ::= identifier
name             ::= identifier
```

A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The features recognized by Python 2.3 are "generators", "division" and "nested_scopes". "generators" and "nested_scopes" are redundant in 2.3 because they are always enabled.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible

syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module `__future__`, described later, and it will be imported in the usual way at the time the future statement is executed.

The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```
import __future__ [as name]
```

That is not a future statement; it's an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by an `exec` statement or calls to the builtin functions `compile()` and `execfile()` that occur in a module `M` containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can, starting with Python 2.2 be controlled by optional arguments to `compile()` -- see the documentation of that function in the [Python Library Reference](#) for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the `-i` option, is passed a script name to execute, and the script includes a future statement, it will be in effect in the interactive session started after the script is executed.

Previous: [6.12.1 Future statements](#) **Up:** [6. Simple statements](#) **Next:** [6.14 The exec statement](#)

6.13 The `global` statement

```
global_stmt ::= "global" identifier (","  
              identifier)*
```

[Download entire grammar as text.](#)

The `global` statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without `global`, although free variables may refer to globals without being declared global.

Names listed in a `global` statement must not be used in the same code block textually preceding that `global` statement.

Names listed in a `global` statement must not be defined as formal parameters or in a `for` loop control target, `class` definition, function definition, or `import` statement.

(The current implementation does not enforce the latter two restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.)

Programmer's note: the `global` is a directive to the parser. It applies only to code parsed at the same time as the `global` statement. In particular, a `global` statement contained in an `exec` statement does not affect the code block *containing* the `exec` statement, and code contained in an `exec` statement is unaffected by `global` statements in the code containing the `exec` statement. The same applies to the `eval()`, `execfile()` and `compile()` functions.

Previous: [6.13 The global statement](#) Up: [6. Simple statements](#) Next: [7. Compound statements](#)

6.14 The `exec` statement

```
exec_stmt ::= "exec" expression ["in"  
          expression ["," expression]]
```

[Download entire grammar as text.](#)

This statement supports dynamic execution of Python code. The first expression should evaluate to either a string, an open file object, or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed (unless a syntax error occurs). If it is an open file, the file is parsed until EOF and executed. If it is a code object, it is simply executed. In all cases, the code that's executed is expected to be valid as file input (see section [8.2](#), "File input"). Be aware that the `return` and `yield` statements may not be used outside of function definitions even within the context of code passed to the `EXEC` statement.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only the first expression after `in` is specified, it should be a dictionary, which will be used for both the global and the local variables. If two expressions are given, they are used for the global and local variables, respectively. If provided, *locals* can be any mapping object. Changed in version 2.4: formerly *locals* was required to be a dictionary.

As a side effect, an implementation may insert additional keys into the dictionaries given besides those corresponding to variable names set by the executed code. For example, the current implementation may add a reference to the dictionary of the built-in module `__builtin__` under the key `__builtins__` (!).

Programmer's hints: dynamic evaluation of expressions is supported by the built-in function `eval()`. The built-in functions `globals()` and `locals()` return the current global and local dictionary, respectively, which may be useful to pass around for use by `exec`.

Previous: [6.14 The exec statement](#) **Up:** [Python Reference Manual](#) **Next:** [7.1 The if statement](#)

7. Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The `if`, `while` and `for` statements implement traditional control flow constructs. `try` specifies exception handlers and/or cleanup code for a group of statements. Function and class definitions are also syntactically compound statements.

Compound statements consist of one or more 'clauses.' A clause consists of a header and a 'suite.' The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header's colon, or it can be one or more indented statements on subsequent lines. Only the latter form of suite can contain nested compound statements; the following is illegal, mostly because it wouldn't be clear to which `if` clause a following `else` clause would belong:

```
if test1: if test2: print x
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the `print` statements are executed:

```
if x < y < z: print x; print y; print z
```

Summarizing:

```
compound_stmt ::= if_stmt
                | while_stmt
                | for_stmt
                | try_stmt
```

```

suite ::= funcdef
       | classdef
       | stmt\_list NEWLINE |
         NEWLINE INDENT statement+
         DEDENT
statement ::= stmt\_list NEWLINE |
             compound\_stmt
stmt_list ::= simple\_stmt (";"
                 simple\_stmt)* [";"]

```

[Download entire grammar as text.](#)

Note that statements always end in a NEWLINE possibly followed by a DEDENT. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the 'dangling else' problem is solved in Python by requiring nested if statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.

Subsections

- [7.1 The if statement](#)
- [7.2 The while statement](#)
- [7.3 The for statement](#)
- [7.4 The try statement](#)
- [7.5 Function definitions](#)
- [7.6 Class definitions](#)

Previous: [7. Compound statements](#) **Up:** [7. Compound statements](#) **Next:** [7.2](#)
[The while statement](#)

7.1 The `if` statement

The `if` statement is used for conditional execution:

```
if_stmt ::= "if" expression ":" suite
          ( "elif" expression ":" suite )*
          ["else" ":" suite]
```

[Download entire grammar as text.](#)

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section [5.10](#) for the definition of true and false); then that suite is executed (and no other part of the `if` statement is executed or evaluated). If all expressions are false, the suite of the `else` clause, if present, is executed.

Previous: [7.1 The if statement](#) Up: [7. Compound statements](#) Next: [7.3 The for statement](#)

7.2 The while statement

The `while` statement is used for repeated execution as long as an expression is true:

```
while_stmt ::= "while" expression ":" suite
            ["else" ":" suite]
```

[Download entire grammar as text.](#)

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the `else` clause, if present, is executed and the loop terminates.

A `break` statement executed in the first suite terminates the loop without executing the `else` clause's suite. A `continue` statement executed in the first suite skips the rest of the suite and goes back to testing the expression.

Previous: [7.2 The while statement](#) **Up:** [7. Compound statements](#) **Next:** [7.4 The try statement](#)

7.3 The for statement

The `for` statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::= "for" target_list "in"
           expression_list ":" suite
           ["else" ":" suite]
```

[Download entire grammar as text.](#)

The expression list is evaluated once; it should yield an iterable object. An iterator is created for the result of the `expression_list`. The suite is then executed once for each item provided by the iterator, in the order of ascending indices. Each item in turn is assigned to the target list using the standard rules for assignments, and then the suite is executed. When the items are exhausted (which is immediately when the sequence is empty), the suite in the `else` clause, if present, is executed, and the loop terminates.

A `break` statement executed in the first suite terminates the loop without executing the `else` clause's suite. A `continue` statement executed in the first suite skips the rest of the suite and continues with the next item, or with the `else` clause if there was no next item.

The suite may assign to the variable(s) in the target list; this does not affect the next item assigned to it.

The target list is not deleted when the loop is finished, but if the sequence is empty, it will not have been assigned to at all by the loop. Hint: the built-in function `range()` returns a sequence of integers suitable to emulate the effect of Pascal's `for i := a to b do`; e.g., `range(3)` returns the list `[0, 1, 2]`.

Warning: There is a subtlety when the sequence is being modified by the loop (this can only occur for mutable sequences, i.e. lists). An internal counter is used to keep track of which item is used next, and this is incremented on each iteration. When this counter has reached the length of the sequence the loop

terminates. This means that if the suite deletes the current (or a previous) item from the sequence, the next item will be skipped (since it gets the index of the current item which has already been treated). Likewise, if the suite inserts an item in the sequence before the current item, the current item will be treated again the next time through the loop. This can lead to nasty bugs that can be avoided by making a temporary copy using a slice of the whole sequence, e.g.,

```
for x in a[:]:
    if x < 0: a.remove(x)
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.3 The for statement](#) **Up:** [7. Compound statements](#) **Next:** [7.5 Function definitions](#)

7.4 The try statement

The `try` statement specifies exception handlers and/or cleanup code for a group of statements:

```
try_stmt      ::= try\_exc\_stmt | try\_fin\_stmt
try_exc_stmt  ::= "try" ":" suite
                ("except" [expression [",",
target]] ":" suite)+
                ["else" ":" suite]
try_fin_stmt  ::= "try" ":" suite "finally"
                ":" suite
```

[Download entire grammar as text.](#)

There are two forms of `try` statement: `try...except` and `try...finally`. These forms cannot be mixed (but they can be nested in each other).

The `try...except` form specifies one or more exception handlers (the `except` clauses). When no exception occurs in the `try` clause, no exception handler is executed. When an exception occurs in the `try` suite, a search for an exception handler is started. This search inspects the `except` clauses in turn until one is found that matches the exception. An expression-less `except` clause, if present, must be last; it matches any exception. For an `except` clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is "compatible" with the exception. An object is compatible with an exception if it is either the object that identifies the exception, or (for exceptions that are classes) it is a base class of the exception, or it is a tuple containing an item that is compatible with the exception. Note that the object identities must match, i.e. it must be the same object, not just an object with the same value.

If no `except` clause matches the exception, the search for an exception handler continues in the surrounding code and on the invocation stack.

If the evaluation of an expression in the header of an `except` clause raises an exception, the original search for a handler is canceled and a search starts for the

new exception in the surrounding code and on the call stack (it is treated as if the entire `try` statement raised the exception).

When a matching `except` clause is found, the exception's parameter is assigned to the target specified in that `except` clause, if present, and the `except` clause's suite is executed. All `except` clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire `try` statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the `try` clause of the inner handler, the outer handler will not handle the exception.)

Before an `except` clause's suite is executed, details about the exception are assigned to three variables in the `sys` module: `sys.exc_type` receives the object identifying the exception; `sys.exc_value` receives the exception's parameter; `sys.exc_traceback` receives a traceback object (see section [3.2](#)) identifying the point in the program where the exception occurred. These details are also available through the `sys.exc_info()` function, which returns a tuple (`exc_type`, `exc_value`, `exc_traceback`). Use of the corresponding variables is deprecated in favor of this function, since their use is unsafe in a threaded program. As of Python 1.5, the variables are restored to their previous values (before the call) when returning from a function that handled an exception.

The optional `else` clause is executed if and when control flows off the end of the `try` clause. [7.1](#) Exceptions in the `else` clause are not handled by the preceding `except` clauses.

The `try...finally` form specifies a 'cleanup' handler. The `try` clause is executed. When no exception occurs, the `finally` clause is executed. When an exception occurs in the `try` clause, the exception is temporarily saved, the `finally` clause is executed, and then the saved exception is re-raised. If the `finally` clause raises another exception or executes a `return` or `break` statement, the saved exception is lost. The exception information is not available to the program during execution of the `finally` clause.

When a `return`, `break` or `continue` statement is executed in the `try` suite of a `try...finally` statement, the `finally` clause is also executed 'on the way out.' A `continue` statement is illegal in the `finally` clause. (The reason

is a problem with the current implementation -- this restriction may be lifted in the future).

Additional information on exceptions can be found in section [4.2](#), and information on using the `raise` statement to generate exceptions may be found in section [6.9](#).

Footnotes

... clause. [7.1](#)

Currently, control ``flows off the end" except in the case of an exception or the execution of a `return`, `continue`, or `break` statement.

Previous: [7.4 The try statement](#) **Up:** [7. Compound statements](#) **Next:** [7.6 Class definitions](#)

7.5 Function definitions

A function definition defines a user-defined function object (see section [3.2](#)):

```
funcdef ::= [decorators] "def"  
         funcname "("  
         [parameter_list] ")" ":"  
         suite  
  
decorators ::= decorator+  
decorator ::= "@" dotted_name ["(" [argument_list [",","]]  
                                ")] NEWLINE  
dotted_name ::= identifier "."  
             identifier)*  
parameter_list ::= (defparameter ",")*  
                ( "*" identifier [, "***"  
                identifier  
                | "***" identifier  
                | defparameter [",","] )  
defparameter ::= parameter ["="  
                             expression]  
sublist ::= parameter (","  
                      parameter)* [","]  
parameter ::= identifier | "(" sublist  
            ")"  
funcname ::= identifier
```

[Download entire grammar as text.](#)

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.

The function definition does not execute the function body; this gets executed only when the function is called.

A function definition may be wrapped by one or more decorator expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code:

```
@f1(arg)
@f2
def func(): pass
```

is equivalent to:

```
def func(): pass
func = f1(arg)(f2(func))
```

When one or more top-level parameters have the form *parameter = expression*, the function is said to have "default parameter values." For a parameter with a default value, the corresponding argument may be omitted from a call, in which case the parameter's default value is substituted. If a parameter has a default value, all following parameters must also have a default value -- this is a syntactic restriction that is not expressed by the grammar.

Default parameter values are evaluated when the function definition is executed. This means that the expression is evaluated once, when the function is defined, and that that same "pre-computed" value is used for each call. This is especially important to understand when a default parameter is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default value is in effect modified. This is generally not what was intended. A way around this is to use `NONE` as the default, and explicitly test for it in the body of the function, e.g.:

```
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
    penguin.append("property of the zoo")
    return penguin
```

Function call semantics are described in more detail in section [5.3.4](#). A function

call always assigns values to all parameters mentioned in the parameter list, either from position arguments, from keyword arguments, or from default values. If the form `**identifier` is present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form `*identifier` is present, it is initialized to a new dictionary receiving any excess keyword arguments, defaulting to a new empty dictionary.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda forms, described in section [5.11](#). Note that the lambda form is merely a shorthand for a simplified function definition; a function defined in a `def` statement can be passed around or assigned to another name just like a function defined by a lambda form. The `def` form is actually more powerful since it allows the execution of multiple statements.

Programmer's note: Functions are first-class objects. A `def` form executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the `def`. See section [4.1](#) for details.

Previous: [7.5 Function definitions](#) **Up:** [7. Compound statements](#) **Next:** [8. Top-level components](#)

7.6 Class definitions

A class definition defines a class object (see section [3.2](#)):

```
classdef ::= "class" classname
           [inheritance] ":" suite
inheritance ::= "(" expression\_list ")"
classname ::= identifier
```

[Download entire grammar as text.](#)

A class definition is an executable statement. It first evaluates the inheritance list, if present. Each item in the inheritance list should evaluate to a class object or class type which allows subclassing. The class's suite is then executed in a new execution frame (see section [4.1](#)), using a newly created local namespace and the original global namespace. (Usually, the suite contains only function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.

Programmer's note: Variables defined in the class definition are class variables; they are shared by all instances. To define instance variables, they must be given a value in the `__init__()` method or in another method. Both class and instance variables are accessible through the notation `self.name`, and an instance variable hides a class variable with the same name when accessed in this way. Class variables with immutable values can be used as defaults for instance variables. For new-style classes, descriptors can be used to create instance variables with different implementation details.

See [About this document..](#) for information on suggesting changes.

8. Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.

Subsections

- [8.1 Complete Python programs](#)
- [8.2 File input](#)
- [8.3 Interactive input](#)
- [8.4 Expression input](#)

Previous: [7.6 Class definitions](#) Up: [Python Reference Manual](#) Next: [8.1 Complete Python programs](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

Previous: [8. Top-level components](#) Up: [8. Top-level components](#) Next: [8.2 File input](#)

8.1 Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for `SYS` (various system services), `__builtin__` (built-in functions, exceptions and `None`) and `__main__`. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of `__main__`.

Under UNIX, a complete program can be passed to the interpreter in three forms: with the `-c` *string* command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.

Previous: [8.1 Complete Python programs](#) **Up:** [8. Top-level components](#) **Next:** [8.3 Interactive input](#)

8.2 File input

All input read from non-interactive files has the same form:

```
file_input ::= (NEWLINE | statement)*
```

[Download entire grammar as text.](#)

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the `EXEC` statement;

Previous: [8.1 Complete Python programs](#) Up: [8. Top-level components](#) Next:
[8.3 Interactive input](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [8.2 File input](#) Up: [8. Top-level components](#) Next: [8.4 Expression input](#)

8.3 Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::= [stmt_list] NEWLINE |  
                    compound_stmt NEWLINE
```

[Download entire grammar as text.](#)

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.

Previous: [8.2 File input](#) Up: [8. Top-level components](#) Next: [8.4 Expression input](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [8.3 Interactive input](#) **Up:** [8. Top-level components](#) **Next:** [A. History and License](#)

8.4 Expression input

There are two forms of expression input. Both ignore leading whitespace. The string argument to `eval()` must have the following form:

```
eval_input ::= expression list NEWLINE*
```

[Download entire grammar as text.](#)

The input line read by `input()` must have the following form:

```
input_input ::= expression list NEWLINE
```

[Download entire grammar as text.](#)

Note: to read `raw' input line without interpretation, you can use the built-in function `raw_input()` or the `readline()` method of file objects.

A.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <http://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <http://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <http://www.zope.com/>). In 2001, the Python Software Foundation (PSF, see <http://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <http://www.opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL compatible?
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes
1.6	1.5.2	2000	CNRI	no
2.0	1.6	2000	BeOpen.com	no
1.6.1	1.6	2001	CNRI	no
2.1	2.0+1.6.1	2001	PSF	no
2.0.1	2.0+1.6.1	2001	PSF	yes
2.1.1	2.1+2.0.1	2001	PSF	yes
2.2	2.1.1	2001	PSF	yes

2.1.2	2.1.1	2002	PSF	yes
2.1.3	2.1.2	2002	PSF	yes
2.2.1	2.2	2002	PSF	yes
2.2.2	2.2.1	2002	PSF	yes
2.2.3	2.2.2	2002-2003	PSF	yes
2.3	2.2.2	2002-2003	PSF	yes
2.3.1	2.3	2002-2003	PSF	yes
2.3.2	2.3.1	2003	PSF	yes
2.3.3	2.3.2	2003	PSF	yes
2.3.4	2.3.3	2004	PSF	yes
2.3.5	2.3.4	2005	PSF	yes
2.4	2.3	2004	PSF	yes
2.4.1	2.4	2005	PSF	yes
2.4.2	2.4.1	2005	PSF	yes
2.4.3	2.4.2	2006	PSF	yes
2.4.4	2.4.3	2006	PSF	yes
2.5	2.4	2006	PSF	yes

Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

A.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.4.4

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.4.4 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.4.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.4.4 alone or in any derivative version prepared by Licensee.
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.4.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.4.4.
4. PSF is making Python 2.4.4 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.4.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS

OF PYTHON 2.4.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.4.4, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 2.4.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION

1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.
3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT

LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at <http://www.pythonlabs.com/logos.html> may be used according to the permissions granted on that web page.
7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to

reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: <http://hdl.handle.net/1895.22/1013>."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.
4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. This License Agreement shall be governed by the federal intellectual

property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```

Modified by Jack Jansen, CWI, July 1995:

- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. The version is still 5 times faster, though.
- Arguments more compliant with python standard

1. Using Python on a Macintosh

Python on a Macintosh running Mac OS X is in principle very similar to Python on any other UNIXplatform, but there are a number of additional features such as the IDE and the Package Manager that are worth pointing out.

Python on Mac OS 9 or earlier can be quite different from Python on Unix or Windows, but is beyond the scope of this manual, as that platform is no longer supported, starting with Python 2.4. See <http://www.cwi.nl/~jack/macpython> for installers for the latest 2.3 release for Mac OS 9 and related documentation.

CONTENTS MODULES INDEX

Previous: [Contents](#) Up: [Macintosh Library Modules](#) Next: [1.1 Getting and Installing](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [1. Using Python on](#) Up: [1. Using Python on](#) Next: [1.1.1 How to run](#)

1.1 Getting and Installing MacPython

Mac OS X 10.3 comes with Python 2.3 pre-installed by Apple. This installation does not come with the IDE and other additions, however, so to get these you need to install the **MacPython for Panther additions** from the MacPython website, <http://www.cwi.nl/~jack/macpython>.

For MacPython 2.4, or for any MacPython on earlier releases of Mac OS X, you need to install a full distribution from the same website.

What you get after installing is a number of things:

- A MacPython-2.3 folder in your Applications folder. In here you find the PythonIDE Integrated Development Environment; PythonLauncher, which handles double-clicking Python scripts from the Finder; and the Package Manager.
- A fairly standard UNIX commandline Python interpreter in `/usr/local/bin/python`, but without the usual `/usr/local/lib/python`.
- A framework `/Library/Frameworks/Python.framework`, where all the action really is, but which you usually do not have to be aware of.

To uninstall MacPython you can simply remove these three things.

If you use the "additions" installer to install on top of an existing Apple-Python you will not get the framework and the commandline interpreter, as they have been installed by Apple already, in `/System/Library/Frameworks/Python.framework` and `/usr/bin/python`, respectively. You should in principle never modify or delete these, as they are Apple-controlled and may be used by Apple- or third-party software.

PythonIDE contains an Apple Help Viewer book called "MacPython Help" which you can access through its help menu. If you are completely new to Python you should start reading the IDE introduction in that document.

If you are familiar with Python on other UNIX platforms you should read the section on running Python scripts from the UNIX shell.

Subsections

- [1.1.1 How to run a Python script](#)
- [1.1.2 Running scripts with a GUI](#)

Previous: [1.1 Getting and Installing](#) **Up:** [1.1 Getting and Installing](#) **Next:** [1.1.2 Running scripts with](#)

1.1.1 How to run a Python script

Your best way to get started with Python on Mac OS X is through the PythonIDE integrated development environment, see section [1.2](#) and use the Help menu when the IDE is running.

If you want to run Python scripts from the Terminal window command line or from the Finder you first need an editor to create your script. Mac OS X comes with a number of standard UNIX command line editors, **vim** and **emacs** among them. If you want a more Mac-like editor **BBedit** or **TextWrangler** from Bare Bones Software (see <http://www.barebones.com/products/bbedit/index.shtml>) are good choices. **AppleWorks** or any other word processor that can save files in ASCII is also a possibility, including **TextEdit** which is included with OS X.

To run your script from the Terminal window you must make sure that `/usr/local/bin` is in your shell search path.

To run your script from the Finder you have two options:

- Drag it to **PythonLauncher**
- Select **PythonLauncher** as the default application to open your script (or any `.py` script) through the finder Info window and double-click it.

PythonLauncher has various preferences to control how your script is launched. Option-dragging allows you to change these for one invocation, or use its Preferences menu to change things globally.

1.1.2 Running scripts with a GUI

There is one Mac OS X quirk that you need to be aware of: programs that talk to the Aqua window manager (in other words, anything that has a GUI) need to be run in a special way. Use **pythonw** instead of **python** to start such scripts.

1.1.3 configuration

MacPython honours all standard UNIX environment variables such as PYTHONPATH, but setting these variables for programs started from the Finder is non-standard as the Finder does not read your .profile or .cshrc at startup. You need to create a file ~/.MacOSX/environment.plist. See Apple's Technical Document QA1067 for details.

Installing additional Python packages is most easily done through the Package Manager, see the MacPython Help Book for details.

1.2 The IDE

The **Python IDE** (Integrated Development Environment) is a separate application that acts as a text editor for your Python code, a class browser, a graphical debugger, and more.

The online Python Help contains a quick walkthrough of the IDE that shows the major features and how to use them.

Previous: [1.2.1 Using the ``Python](#) Up: [1.2 The IDE](#) Next: [1.2.3 Executing a script](#)

1.2.2 Writing a Python Script

In addition to using the **Python IDE** interactively, you can also type out a complete Python program, saving it incrementally, and execute it or smaller selections of it.

You can create a new script, open a previously saved script, and save your currently open script by selecting the appropriate item in the ``File" menu. Dropping a Python script onto the **Python IDE** will open it for editing.

When the **Python IDE** saves a script, it uses the creator code settings which are available by clicking on the small black triangle on the top right of the document window, and selecting ``save options". The default is to save the file with the **Python IDE** as the creator, this means that you can open the file for editing by simply double-clicking on its icon. You might want to change this behaviour so that it will be opened by the **PythonLauncher**, and run. To do this simply choose ``PythonLauncher" from the ``save options". Note that these options are associated with the *file* not the application.

Previous: [1.2.1 Using the ``Python](#) Up: [1.2 The IDE](#) Next: [1.2.3 Executing a script](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

Previous: [1.2.2 Writing a Python](#) Up: [1.2 The IDE](#) Next: [1.2.4 ``Save as" versus](#)

1.2.3 Executing a script from within the IDE

You can run the script in the frontmost window of the **Python IDE** by hitting the run all button. You should be aware, however that if you use the Python convention "if `__name__ == '__main__':`" the script will *not* be `__main__` by default. To get that behaviour you must select the `Run as __main__` option from the small black triangle on the top right of the document window. Note that this option is associated with the *file* not the application. It *will* stay active after a save, however; to shut this feature off simply select it again.

Previous: [1.2.3 Executing a script](#) **Up:** [1.2 The IDE](#) **Next:** [1.3 The Package Manager](#)

1.2.4 ``Save as" versus ``Save as Applet"

When you are done writing your Python script you have the option of saving it as an ``applet" (by selecting ``Save as applet" from the ``File" menu). This has a significant advantage in that you can drop files or folders onto it, to pass them to the applet the way command-line users would type them onto the command-line to pass them as arguments to the script. However, you should make sure to save the applet as a separate file, do not overwrite the script you are writing, because you will not be able to edit it again.

Accessing the items passed to the applet via ``drag-and-drop" is done using the standard `sys.argv` mechanism. See the general documentation for more

Note that saving a script as an applet will not make it runnable on a system without a Python installation.

[Modules](#)

1.3 The Package Manager

Historically MacPython came with a number of useful extension packages included, because most Macintosh users do not have access to a development environment and C compiler. For Mac OS X that bundling is no longer done, but a new mechanism has been made available to allow easy access to extension packages.

The Python Package Manager helps you installing additional packages that enhance Python. It determines the exact MacOS version and Python version you have and uses that information to download a database that has packages that are tested and tried on that combination. In other words: if something is in your Package Manager window but does not work you are free to blame the database maintainer.

PackageManager then checks which of the packages you have installed and which ones are not. This should also work when you have installed packages outside of PackageManager. You can select packages and install them, and PackageManager will work out the requirements and install these too.

Often PackageManager will list a package in two flavors: binary and source. Binary should always work, source will only work if you have installed the Apple Developer Tools. PackageManager will warn you about this, and also about other external dependencies.

PackageManager is available as a separate application and also as a function of the IDE, through the File->Package Manager menu entry.

2. MacPython Modules

The following modules are only available on the Macintosh, and are documented here:

macpath	MacOS path manipulation functions.
macfs	Support for FSSpec, the Alias Manager, finder aliases, and the Standard File package.
ic	Access to Internet Config.
MacOS	Access to Mac OS-specific interpreter features.
macostools	Convenience routines for file manipulation.
findertools	Wrappers around the finder 's Apple Events interface.
EasyDialogs	Basic Macintosh dialogs.
FrameWork	Interactive application framework.
autoGIL	Global Interpreter Lock handling in event loops.

2.1 macpath -- MacOS path manipulation functions

This module is the Mac OS 9 (and earlier) implementation of the `os.path` module. It can be used to manipulate old-style Macintosh pathnames on Mac OS X (or any other platform). Refer to the [Python Library Reference](#) for documentation of `os.path`.

The following functions are available in this module: `normcase()`, `normpath()`, `isabs()`, `join()`, `split()`, `isdir()`, `isfile()`, `walk()`, `exists()`. For other functions available in `os.path` dummy counterparts are available.

See [About this document...](#) for information on suggesting changes.

Previous: [2.1 macpath](#) Up: [2. MacPython Modules](#) Next: [2.2.1 FSSpec Objects](#)

2.2 macfs -- Various file system services

Availability: **Macintosh**.

Deprecated since release 2.3. The macfs module should be considered obsolete. For FSSpec, FSRef and Alias handling use the [Carbon.File](#) or [Carbon.Folder](#) module. For file dialogs use the [EasyDialogs](#) module. Also, this module is known to not work correctly with UFS partitions.

This module provides access to Macintosh FSSpec handling, the Alias Manager, **finder** aliases and the Standard File package.

Whenever a function or method expects a *file* argument, this argument can be one of three things: (1) a full or partial Macintosh pathname, (2) an FSSpec object or (3) a 3-tuple (*wdRefNum*, *parID*, *name*) as described in *Inside Macintosh: Files*. An FSSpec can point to a non-existing file, as long as the folder containing the file exists. Under MacPython the same is true for a pathname, but not under unix-Pyton because of the way pathnames and FSRefs works. See Apple's documentation for details.

A description of aliases and the Standard File package can also be found there.

FSSpec(*file*)

Create an FSSpec object for the specified file.

RawFSSpec(*data*)

Create an FSSpec object given the raw data for the C structure for the FSSpec as a string. This is mainly useful if you have obtained an FSSpec structure over a network.

RawAlias(*data*)

Create an Alias object given the raw data for the C structure for the alias as a string. This is mainly useful if you have obtained an FSSpec structure over a network.

FInfo()

Create a zero-filled FInfo object.

ResolveAliasFile(*file*)

Resolve an alias file. Returns a 3-tuple (*fsspec*, *isfolder*, *aliased*) where *fsspec* is the resulting FSSpec object, *isfolder* is true if *fsspec* points to a folder and *aliased* is true if the file was an alias in the first place (otherwise the FSSpec object for the file itself is returned).

StandardGetFile([*type*, ...])

Present the user with a standard "open input file" dialog. Optionally, you can pass up to four 4-character file types to limit the files the user can choose from. The function returns an FSSpec object and a flag indicating that the user completed the dialog without cancelling.

PromptGetFile(*prompt*[, *type*, ...])

Similar to StandardGetFile() but allows you to specify a prompt which will be displayed at the top of the dialog.

StandardPutFile(*prompt*[, *default*])

Present the user with a standard "open output file" dialog. *prompt* is the prompt string, and the optional *default* argument initializes the output file name. The function returns an FSSpec object and a flag indicating that the user completed the dialog without cancelling.

GetDirectory([*prompt*])

Present the user with a non-standard "select a directory" dialog. You have to first open the directory before clicking on the "select current directory" button. *prompt* is the prompt string which will be displayed at the top of the dialog. Return an FSSpec object and a success-indicator.

SetFolder([*fsspec*])

Set the folder that is initially presented to the user when one of the file selection dialogs is presented. *fsspec* should point to a file in the folder, not the folder itself (the file need not exist, though). If no argument is passed the folder will be set to the current directory, i.e. what `os.getcwd()`

returns.

Note that starting with System 7.5 the user can change Standard File behaviour with the "general controls" control panel, thereby making this call inoperative.

FindFolder(*where*, *which*, *create*)

Locates one of the "special" folders that Mac OS knows about, such as the trash or the Preferences folder. *where* is the disk to search, *which* is the 4-character string specifying which folder to locate. Setting *create* causes the folder to be created if it does not exist. Returns a (*vrefnum*, *dirid*) tuple.

The constants for *where* and *which* can be obtained from the standard module *Carbon.Folders*.

NewAliasMinimalFromFullPath(*pathname*)

Return a minimal `alias` object that points to the given file, which must be specified as a full pathname. This is the only way to create an `Alias` pointing to a non-existing file.

FindApplication(*creator*)

Locate the application with 4-character creator code *creator*. The function returns an `FSSpec` object pointing to the application.

Previous: [2.2 macfs](#) Up: [2.2 macfs](#) Next: [2.2.2 Alias Objects](#)

2.2.1 FSSpec Objects

data

The raw data from the FSSpec object, suitable for passing to other applications, for instance.

as_pathname()

Return the full pathname of the file described by the FSSpec object.

as_tuple()

Return the (*wdRefNum*, *parID*, *name*) tuple of the file described by the FSSpec object.

NewAlias([file])

Create an Alias object pointing to the file described by this FSSpec. If the optional *file* parameter is present the alias will be relative to that file, otherwise it will be absolute.

NewAliasMinimal()

Create a minimal alias pointing to this file.

GetCreatorType()

Return the 4-character creator and type of the file.

SetCreatorType(creator, type)

Set the 4-character creator and type of the file.

GetFInfo()

Return a FInfo object describing the finder info for the file.

SetFInfo(finfo)

Set the finder info for the file to the values given as *finfo* (an FInfo object).

GetDates()

Return a tuple with three floating point values representing the creation date, modification date and backup date of the file.

SetDates(*crdate*, *moddate*, *backupdate*)

Set the creation, modification and backup date of the file. The values are in the standard floating point format used for times throughout Python.

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

Previous: [2.2.1 FSSpec Objects](#) Up: [2.2 macfs](#) Next: [2.2.3 FInfo Objects](#)

2.2.2 Alias Objects

data

The raw data for the Alias record, suitable for storing in a resource or transmitting to other programs.

Resolve([file])

Resolve the alias. If the alias was created as a relative alias you should pass the file relative to which it is. Return the FSSpec for the file pointed to and a flag indicating whether the Alias object itself was modified during the search process. If the file does not exist but the path leading up to it does exist a valid fsspec is returned.

GetInfo(num)

An interface to the C routine `GetAliasInfo()`.

Update(file[, file2])

Update the alias to point to the *file* given. If *file2* is present a relative alias will be created.

Note that it is currently not possible to directly manipulate a resource as an Alias object. Hence, after calling `Update()` or after `Resolve()` indicates that the alias has changed the Python program is responsible for getting the `data` value from the Alias object and modifying the resource.

	Macintosh Library Modules				
Previous:	2.2.1 FSSpec Objects	Up:	2.2 macfs	Next:	2.2.3 FInfo Objects

Release 2.4.4c1, documentation updated on 11 October 2006.

2.2.3 FInfo Objects

See *Inside Macintosh: Files* for a complete description of what the various fields mean.

Creator

The 4-character creator code of the file.

Type

The 4-character type code of the file.

Flags

The finder flags for the file as 16-bit integer. The bit values in *Flags* are defined in standard module MACFS.

Location

A Point giving the position of the file's icon in its folder.

Fldr

The folder the file is in (as an integer).

Previous: [2.2.3 FInfo Objects](#) Up: [2. MacPython Modules](#) Next: [2.3.1 IC Objects](#)

2.3 `ic` -- Access to Internet Config

Availability: **Macintosh**.

This module provides access to various internet-related preferences set through **System Preferences** or the **Finder**.

There is a low-level companion module `icglue` which provides the basic Internet Config access functionality. This low-level module is not documented, but the docstrings of the routines document the parameters and the routine names are the same as for the Pascal or C API to Internet Config, so the standard IC programmers' documentation can be used if this module is needed.

The `ic` module defines the `error` exception and symbolic names for all error codes Internet Config can produce; see the source for details.

exception error

Exception raised on errors in the `ic` module.

The `ic` module defines the following class and function:

class IC([*signature*[, *ic*]])

Create an Internet Config object. The signature is a 4-character creator code of the current application (default 'Pyth') which may influence some of ICs settings. The optional *ic* argument is a low-level `icglue.icinstance` created beforehand, this may be useful if you want to get preferences from a different config file, etc.

launchurl(*url*[, *hint*])

parseurl(*data*[, *start*[, *end*[, *hint*]]])

mapfile(*file*)

maptypecreator(*type*, *creator*[, *filename*])

settypecreator(*file*)

These functions are ``shortcuts'' to the methods of the same name, described below.

Previous: [2.3 ic](#) Up: [2.3 ic](#) Next: [2.4 MacOS](#)

2.3.1 IC Objects

IC objects have a mapping interface, hence to obtain the mail address you simply get `ic['MailAddress']`. Assignment also works, and changes the option in the configuration file.

The module knows about various datatypes, and converts the internal IC representation to a "logical" Python data structure. Running the `ic` module standalone will run a test program that lists all keys and values in your IC database, this will have to serve as documentation.

If the module does not know how to represent the data it returns an instance of the `ICOpaqueData` type, with the raw data in its `data` attribute. Objects of this type are also acceptable values for assignment.

Besides the dictionary interface, IC objects have the following methods:

launchurl(*url*[, *hint*])

Parse the given URL, launch the correct application and pass it the URL. The optional *hint* can be a scheme name such as `'mailto:'`, in which case incomplete URLs are completed with this scheme. If *hint* is not provided, incomplete URLs are invalid.

parseurl(*data*[, *start*[, *end*[, *hint*]]])

Find an URL somewhere in *data* and return start position, end position and the URL. The optional *start* and *end* can be used to limit the search, so for instance if a user clicks in a long text field you can pass the whole text field and the click-position in *start* and this routine will return the whole URL in which the user clicked. As above, *hint* is an optional scheme used to complete incomplete URLs.

mapfile(*file*)

Return the mapping entry for the given *file*, which can be passed as either a filename or an `FSSpec()` result, and which need not exist.

The mapping entry is returned as a tuple (*version*, *type*, *creator*,

postcreator, *flags*, *extension*, *appname*, *postappname*, *mimetype*, *entryname*), where *version* is the entry version number, *type* is the 4-character filetype, *creator* is the 4-character creator type, *postcreator* is the 4-character creator code of an optional application to post-process the file after downloading, *flags* are various bits specifying whether to transfer in binary or ascii and such, *extension* is the filename extension for this file type, *appname* is the printable name of the application to which this file belongs, *postappname* is the name of the postprocessing application, *mimetype* is the MIME type of this file and *entryname* is the name of this entry.

maptypecreator(*type*, *creator*[, *filename*])

Return the mapping entry for files with given 4-character *type* and *creator* codes. The optional *filename* may be specified to further help finding the correct entry (if the creator code is '????', for instance).

The mapping entry is returned in the same format as for *mapfile*.

settypecreator(*file*)

Given an existing *file*, specified either as a filename or as an `FSSpec()` result, set its creator and type correctly based on its extension. The finder is told about the change, so the finder icon will be updated quickly.

Previous: [2.3.1 IC Objects](#) Up: [2. MacPython Modules](#) Next: [2.5 macostools](#)

2.4 MacOS -- Access to Mac OS interpreter features

Availability: **Macintosh**.

This module provides access to MacOS specific functionality in the Python interpreter, such as how the interpreter eventloop functions and the like. Use with care.

Note the capitalization of the module name; this is a historical artifact.

runtimeModel

Always 'macho', from Python 2.4 on. In earlier versions of Python the value could also be 'ppc' for the classic Mac OS 8 runtime model or 'carbon' for the Mac OS 9 runtime model.

linkModel

The way the interpreter has been linked. As extension modules may be incompatible between linking models, packages could use this information to give more decent error messages. The value is one of 'static' for a statically linked Python, 'framework' for Python in a Mac OS X framework, 'shared' for Python in a standard unix shared library. Older Pythons could also have the value 'cfm' for Mac OS 9-compatible Python.

exception Error

This exception is raised on MacOS generated errors, either from functions in this module or from other mac-specific modules like the toolbox interfaces. The arguments are the integer error code (the `OSErr` value) and a textual description of the error code. Symbolic names for all known error codes are defined in the standard module [macerrors](#).

GetErrorString(*errno*)

Return the textual description of MacOS error code *errno*.

DebugStr(*message* [, *object*])

On Mac OS X the string is simply printed to stderr (on older Mac OS systems more elaborate functionality was available), but it provides a convenient location to attach a breakpoint in a low-level debugger like **gdb**.

SysBeep()

Ring the bell.

GetTicks()

Get the number of clock ticks (1/60th of a second) since system boot.

GetCreatorAndType(*file*)

Return the file creator and file type as two four-character strings. The *file* parameter can be a pathname or an FSSpec or FSRef object.

SetCreatorAndType(*file*, *creator*, *type*)

Set the file creator and file type. The *file* parameter can be a pathname or an FSSpec or FSRef object. *creator* and *type* must be four character strings.

openrf(*name* [, *mode*])

Open the resource fork of a file. Arguments are the same as for the built-in function `open()`. The object returned has file-like semantics, but it is not a Python file object, so there may be subtle differences.

WMAvailable()

Checks whether the current process has access to the window manager. The method will return `False` if the window manager is not available, for instance when running on Mac OS X Server or when logged in via ssh, or when the current interpreter is not running from a fullblown application bundle. A script runs from an application bundle either when it has been started with **pythonw** instead of **python** or when running as an applet.

2.5 macostools -- Convenience routines for file manipulation

Availability: **Macintosh**.

This module contains some convenience routines for file-manipulation on the Macintosh. All file parameters can be specified as pathnames, FSRef or FSSpec objects. This module expects a filesystem which supports forked files, so it should not be used on UFS partitions.

The `macostools` module defines the following functions:

copy(*src*, *dst*[, *createpath*[, *copytimes*]])

Copy file *src* to *dst*. If *createpath* is non-zero the folders leading to *dst* are created if necessary. The method copies data and resource fork and some finder information (creator, type, flags) and optionally the creation, modification and backup times (default is to copy them). Custom icons, comments and icon position are not copied.

copytree(*src*, *dst*)

Recursively copy a file tree from *src* to *dst*, creating folders as needed. *src* and *dst* should be specified as pathnames.

mkalias(*src*, *dst*)

Create a finder alias *dst* pointing to *src*.

touched(*dst*)

Tell the finder that some bits of finder-information such as creator or type for file *dst* has changed. The file can be specified by pathname or fsspec. This call should tell the finder to redraw the files icon.

BUFSIZ

The buffer size for `copy`, default 1 megabyte.

Note that the process of creating finder aliases is not specified in the Apple

documentation. Hence, aliases created with `mkalias()` could conceivably have incompatible behaviour in some cases.

2.6 findertools -- The finder's Apple Events interface

Availability: **Macintosh**.

This module contains routines that give Python programs access to some functionality provided by the finder. They are implemented as wrappers around the AppleEvent interface to the finder.

All file and folder parameters can be specified either as full pathnames, or as FSRef or FSSpec objects.

The `findertools` module defines the following functions:

launch(*file*)

Tell the finder to launch *file*. What launching means depends on the file: applications are started, folders are opened and documents are opened in the correct application.

Print(*file*)

Tell the finder to print a file. The behaviour is identical to selecting the file and using the print command in the finder's file menu.

copy(*file*, *destdir*)

Tell the finder to copy a file or folder *file* to folder *destdir*. The function returns an `Alias` object pointing to the new file.

move(*file*, *destdir*)

Tell the finder to move a file or folder *file* to folder *destdir*. The function returns an `Alias` object pointing to the new file.

sleep()

Tell the finder to put the Macintosh to sleep, if your machine supports it.

restart()

Tell the finder to perform an orderly restart of the machine.

shutdown()

Tell the finder to perform an orderly shutdown of the machine.

2.7 EasyDialogs -- Basic Macintosh dialogs

Availability: **Macintosh**.

The `EasyDialogs` module contains some simple dialogs for the Macintosh. All routines take an optional resource ID parameter *id* with which one can override the `DLOG` resource used for the dialog, provided that the dialog items correspond (both type and item number) to those in the default `DLOG` resource. See source code for details.

The `EasyDialogs` module defines the following functions:

Message(*str*[, *id*[, *ok*]])

Displays a modal dialog with the message text *str*, which should be at most 255 characters long. The button text defaults to ``OK'', but is set to the string argument *ok* if the latter is supplied. Control is returned when the user clicks the ``OK'' button.

AskString(*prompt*[, *default*[, *id*[, *ok*[, *cancel*]]]])

Asks the user to input a string value via a modal dialog. *prompt* is the prompt message, and the optional *default* supplies the initial value for the string (otherwise "" is used). The text of the ``OK'' and ``Cancel'' buttons can be changed with the *ok* and *cancel* arguments. All strings can be at most 255 bytes long. `AskString()` returns the string entered or `None` in case the user cancelled.

AskPassword(*prompt*[, *default*[, *id*[, *ok*[, *cancel*]]]])

Asks the user to input a string value via a modal dialog. Like `AskString()`, but with the text shown as bullets. The arguments have the same meaning as for `AskString()`.

AskYesNoCancel(*question*[, *default*[, *yes*[, *no*[, *cancel*[, *id*]]]]])

Presents a dialog with prompt *question* and three buttons labelled ``Yes'',

``No", and ``Cancel". Returns 1 for ``Yes", 0 for ``No" and -1 for ``Cancel". The value of *default* (or 0 if *default* is not supplied) is returned when the RETURN key is pressed. The text of the buttons can be changed with the *yes*, *no*, and *cancel* arguments; to prevent a button from appearing, supply "" for the corresponding argument.

ProgressBar([*title*[, *maxval*[, *label*[, *id*]]]])

Displays a modeless progress-bar dialog. This is the constructor for the `ProgressBar` class described below. *title* is the text string displayed (default ``Working..."), *maxval* is the value at which progress is complete (default 0, indicating that an indeterminate amount of work remains to be done), and *label* is the text that is displayed above the progress bar itself.

GetArgv([*optionlist* [*commandlist* [, *addoldfile* [, *addnewfile* [, *addfolder* [, *id*]]]]]])

Displays a dialog which aids the user in constructing a command-line argument list. Returns the list in `sys.argv` format, suitable for passing as an argument to `getopt.getopt()`. *addoldfile*, *addnewfile*, and *addfolder* are boolean arguments. When nonzero, they enable the user to insert into the command line paths to an existing file, a (possibly) not-yet-existent file, and a folder, respectively. (Note: Option arguments must appear in the command line before file and folder arguments in order to be recognized by `getopt.getopt()`.) Arguments containing spaces can be specified by enclosing them within single or double quotes. A `SystemExit` exception is raised if the user presses the ``Cancel" button.

optionlist is a list that determines a popup menu from which the allowed options are selected. Its items can take one of two forms: *optstr* or (*optstr*, *descr*). When present, *descr* is a short descriptive string that is displayed in the dialog while this option is selected in the popup menu. The correspondence between *optstrs* and command-line arguments is:

<i>optstr</i> format	Command-line format
x	-x (short option)
x: or x=	-x (short option with value)
xyz	--xyz (long option)
xyz: or xyz=	--xyz (long option with value)

commandlist is a list of items of the form *cmdstr* or (*cmdstr*, *descr*), where *descr* is as above. The *cmdstrs* will appear in a popup menu. When chosen, the text of *cmdstr* will be appended to the command line as is, except that a trailing ":" or "=" (if present) will be trimmed off.

New in version 2.0.

```
[message] [, typeList] [, defaultLocation] [,
defaultOptionFlags] [, location] [, clientName] [,
AskFileForOpen( windowTitle] [, actionButtonLabel] [,
cancelButtonLabel] [, preferenceKey] [, popupExtension]
[, eventProc] [, previewProc] [, filterProc] [, wanted] )
```

Post a dialog asking the user for a file to open, and return the file selected or **NONE** if the user cancelled. *message* is a text message to display, *typeList* is a list of 4-char filetypes allowable, *defaultLocation* is the pathname, **FSSpec** or **FSRef** of the folder to show initially, *location* is the (x, y) position on the screen where the dialog is shown, *actionButtonLabel* is a string to show instead of "Open" in the OK button, *cancelButtonLabel* is a string to show instead of "Cancel" in the cancel button, *wanted* is the type of value wanted as a return: **str**, **unicode**, **FSSpec**, **FSRef** and subtypes thereof are acceptable.

For a description of the other arguments please see the Apple Navigation Services documentation and the **EasyDialogs** source code.

```
[message] [, savedFileName] [, defaultLocation] [,
defaultOptionFlags] [, location] [, clientName] [,
AskFileForSave( windowTitle] [, actionButtonLabel] [,
cancelButtonLabel] [, preferenceKey] [, popupExtension]
[, fileType] [, fileCreator] [, eventProc] [, wanted] )
```

Post a dialog asking the user for a file to save to, and return the file selected or **NONE** if the user cancelled. *savedFileName* is the default for the file name to save to (the return value). See **AskFileForOpen()** for a description of the other arguments.

```
[message] [, defaultLocation] [, defaultOptionFlags] [, location]
```

AskFolder([, *clientName*] [, *windowTitle*] [, *actionButtonLabel*] [, *cancelButtonLabel*] [, *preferenceKey*] [, *popupExtension*] [, *eventProc*] [, *filterProc*] [, *wanted*])

Post a dialog asking the user to select a folder, and return the folder selected or `None` if the user cancelled. See `AskFileForOpen()` for a description of the arguments.

2.7.1 ProgressBar Objects

`ProgressBar` objects provide support for modeless progress-bar dialogs. Both determinate (thermometer style) and indeterminate (barber-pole style) progress bars are supported. The bar will be determinate if its maximum value is greater than zero; otherwise it will be indeterminate. Changed in version 2.2: Support for indeterminate-style progress bars was added.

The dialog is displayed immediately after creation. If the dialog's "Cancel" button is pressed, or if `Cmd-.` or `ESC` is typed, the dialog window is hidden and `KeyboardInterrupt` is raised (but note that this response does not occur until the progress bar is next updated, typically via a call to `inc()` or `set()`). Otherwise, the bar remains visible until the `ProgressBar` object is discarded.

`ProgressBar` objects possess the following attributes and methods:

curval

The current value (of type integer or long integer) of the progress bar. The normal access methods coerce `curval` between 0 and `maxval`. This attribute should not be altered directly.

maxval

The maximum value (of type integer or long integer) of the progress bar; the progress bar (thermometer style) is full when `curval` equals `maxval`. If `maxval` is 0, the bar will be indeterminate (barber-pole). This attribute should not be altered directly.

title(*newstr*)

Sets the text in the title bar of the progress dialog to *newstr*.

label(*newstr*)

Sets the text in the progress box of the progress dialog to *newstr*.

set(*value* [, *max*])

Sets the progress bar's `curval` to *value*, and also `maxval` to *max* if the latter is provided. *value* is first coerced between 0 and `maxval`. The

thermometer bar is updated to reflect the changes, including a change from indeterminate to determinate or vice versa.

inc([n])

Increments the progress bar's `curval` by *n*, or by `1` if *n* is not provided. (Note that *n* may be negative, in which case the effect is a decrement.) The progress bar is updated to reflect the change. If the bar is indeterminate, this causes one ``spin'' of the barber pole. The resulting `curval` is coerced between `0` and `maxval` if incrementing causes it to fall outside this range.

2.8 Framework -- Interactive application framework

Availability: **Macintosh**.

The `Framework` module contains classes that together provide a framework for an interactive Macintosh application. The programmer builds an application by creating subclasses that override various methods of the base classes, thereby implementing the functionality wanted. Overriding functionality can often be done on various different levels, i.e. to handle clicks in a single dialog window in a non-standard way it is not necessary to override the complete event handling.

Work on the `Framework` has pretty much stopped, now that `PyObjC` is available for full Cocoa access from Python, and the documentation describes only the most important functionality, and not in the most logical manner at that. Examine the source or the examples for more details. The following are some comments posted on the MacPython newsgroup about the strengths and limitations of `Framework`:

The strong point of `Framework` is that it allows you to break into the control-flow at many different places. [W](#), for instance, uses a different way to enable/disable menus and that plugs right in leaving the rest intact. The weak points of `Framework` are that it has no abstract command interface (but that shouldn't be difficult), that its dialog support is minimal and that its control/toolbar support is non-existent.

The `Framework` module defines the following functions:

Application()

An object representing the complete application. See below for a description of the methods. The default `__init__()` routine creates an empty window dictionary and a menu bar with an apple menu.

MenuBar()

An object representing the menubar. This object is usually not created by

the user.

Menu(*bar*, *title*[, *after*])

An object representing a menu. Upon creation you pass the **MenuBar** the menu appears in, the *title* string and a position (1-based) *after* where the menu should appear (default: at the end).

MenuItem(*menu*, *title*[, *shortcut*, *callback*])

Create a menu item object. The arguments are the menu to create, the item title string and optionally the keyboard shortcut and a callback routine. The callback is called with the arguments menu-id, item number within menu (1-based), current front window and the event record.

Instead of a callable object the callback can also be a string. In this case menu selection causes the lookup of a method in the topmost window and the application. The method name is the callback string with 'domenu_' prepended.

Calling the **MenuBar** `fixmenudimstate()` method sets the correct dimming for all menu items based on the current front window.

Separator(*menu*)

Add a separator to the end of a menu.

SubMenu(*menu*, *label*)

Create a submenu named *label* under menu *menu*. The menu object is returned.

Window(*parent*)

Creates a (modeless) window. *Parent* is the application object to which the window belongs. The window is not displayed until later.

DialogWindow(*parent*)

Creates a modeless dialog window.

windowbounds(*width*, *height*)

Return a (*left*, *top*, *right*, *bottom*) tuple suitable for creation of a

window of given width and height. The window will be staggered with respect to previous windows, and an attempt is made to keep the whole window on-screen. However, the window will however always be the exact size given, so parts may be offscreen.

setwatchcursor()

Set the mouse cursor to a watch.

setarrowcursor()

Set the mouse cursor to an arrow.

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [2.8 FrameWork](#) Up: [2.8 FrameWork](#) Next: [2.8.2 Window Objects](#)

2.8.1 Application Objects

Application objects have the following methods, among others:

makeusermenus()

Override this method if you need menus in your application. Append the menus to the attribute `menubar`.

getabouttext()

Override this method to return a text string describing your application. Alternatively, override the `do_about()` method for more elaborate "about" messages.

mainloop([mask[, wait]])

This routine is the main event loop, call it to set your application rolling. *Mask* is the mask of events you want to handle, *wait* is the number of ticks you want to leave to other concurrent application (default 0, which is probably not a good idea). While raising *self* to exit the mainloop is still supported it is not recommended: call `self._quit()` instead.

The event loop is split into many small parts, each of which can be overridden. The default methods take care of dispatching events to windows and dialogs, handling drags and resizes, Apple Events, events for non-FrameWork windows, etc.

In general, all event handlers should return 1 if the event is fully handled and 0 otherwise (because the front window was not a FrameWork window, for instance). This is needed so that update events and such can be passed on to other windows like the Sioux console window. Calling `MacOS.HandleEvent()` is not allowed within *our_dispatch* or its callees, since this may result in an infinite loop if the code is called through the Python inner-loop event handler.

asyncevents(onoff)

Call this method with a nonzero parameter to enable asynchronous event handling. This will tell the inner interpreter loop to call the application

event handler *async_dispatch* whenever events are available. This will cause FrameWork window updates and the user interface to remain working during long computations, but will slow the interpreter down and may cause surprising results in non-reentrant code (such as FrameWork itself). By default *async_dispatch* will immediately call *our_dispatch* but you may override this to handle only certain events asynchronously. Events you do not handle will be passed to Sioux and such.

The old on/off value is returned.

`_quit()`

Terminate the running `mainloop()` call at the next convenient moment.

`do_char(c, event)`

The user typed character *c*. The complete details of the event can be found in the *event* structure. This method can also be provided in a `Window` object, which overrides the application-wide handler if the window is frontmost.

`do_dialogevent(event)`

Called early in the event loop to handle modeless dialog events. The default method simply dispatches the event to the relevant dialog (not through the `DialogWindow` object involved). Override if you need special handling of dialog events (keyboard shortcuts, etc).

`idle(event)`

Called by the main event loop when no events are available. The null-event is passed (so you can look at mouse position, etc).

Previous: [2.8.1 Application Objects](#) **Up:** [2.8 FrameWork](#) **Next:** [2.8.3 ControlsWindow Object](#)

2.8.2 Window Objects

Window objects have the following methods, among others:

open()

Override this method to open a window. Store the MacOS window-id in `self.wid` and call the `do_postopen()` method to register the window with the parent application.

close()

Override this method to do any special processing on window close. Call the `do_postclose()` method to cleanup the parent state.

do_postresize() (*width, height, macoswindowid*)

Called after the window is resized. Override if more needs to be done than calling `InvalRect`.

do_contentclick() (*local, modifiers, event*)

The user clicked in the content part of a window. The arguments are the coordinates (window-relative), the key modifiers and the raw event.

do_update() (*macoswindowid, event*)

An update event for the window was received. Redraw the window.

do_activate() (*activate, event*)

The window was activated (*activate* == 1) or deactivated (*activate* == 0). Handle things like focus highlighting, etc.

Previous: [2.8.2 Window Objects](#) **Up:** [2.8 FrameWork](#) **Next:** [2.8.4 ScrolledWindow Object](#)

2.8.3 ControlsWindow Object

ControlsWindow objects have the following methods besides those of Window objects:

do_controlhit(*window*, *control*, *pcode*, *event*)

Part *pcode* of control *control* was hit by the user. Tracking and such has already been taken care of.

Previous: [2.8.2 Window Objects](#) Up: [2.8 FrameWork](#) Next: [2.8.4 ScrolledWindow Object](#)

Previous: [2.8.3 ControlsWindow Object](#) **Up:** [2.8 FrameWork](#) **Next:** [2.8.5 DialogWindow Objects](#)

2.8.4 ScrolledWindow Object

ScrolledWindow objects are ControlsWindow objects with the following extra methods:

scrollbars([*wantx*[, *wanty*]])

Create (or destroy) horizontal and vertical scrollbars. The arguments specify which you want (default: both). The scrollbars always have minimum 0 and maximum 32767.

getscrollbarvalues()

You must supply this method. It should return a tuple (*x*, *y*) giving the current position of the scrollbars (between 0 and 32767). You can return None for either to indicate the whole document is visible in that direction.

updatescrollbars()

Call this method when the document has changed. It will call `getscrollbarvalues()` and update the scrollbars.

scrollbar_callback(*which*, *what*, *value*)

Supplied by you and called after user interaction. *which* will be 'x' or 'y', *what* will be '-', '--', 'set', '++' or '+'. For 'set', *value* will contain the new scrollbar position.

scalebarvalues(*absmin*, *absmax*, *curmin*, *curmax*)

Auxiliary method to help you calculate values to return from `getscrollbarvalues()`. You pass document minimum and maximum value and topmost (leftmost) and bottommost (rightmost) visible values and it returns the correct number or None.

do_activate(*onoff*, *event*)

Takes care of dimming/highlighting scrollbars when a window becomes frontmost. If you override this method, call this one at the end of your method.

do_postresize(*width*, *height*, *window*)

Moves scrollbars to the correct position. Call this method initially if you override it.

do_controlhit(*window*, *control*, *pcode*, *event*)

Handles scrollbar interaction. If you override it call this method first, a nonzero return value indicates the hit was in the scrollbars and has been handled.

2.8.5 DialogWindow Objects

DialogWindow objects have the following methods besides those of Window objects:

open(*resid*)

Create the dialog window, from the DLOG resource with id *resid*. The dialog object is stored in `self.wid`.

do_itemhit(*item*, *event*)

Item number *item* was hit. You are responsible for redrawing toggle buttons, etc.

Previous: [2.8.5 DialogWindow Objects](#) **Up:** [2. MacPython Modules](#) **Next:** [3. MacPython OSA Modules](#)

2.9 autoGIL -- Global Interpreter Lock handling in event loops

Availability: **Macintosh**.

The `autoGIL` module provides a function `installAutoGIL` that automatically locks and unlocks Python's Global Interpreter Lock when running an event loop.

exception `AutoGILError`

Raised if the observer callback cannot be installed, for example because the current thread does not have a run loop.

`installAutoGIL()`

Install an observer callback in the event loop (`CFRunLoop`) for the current thread, that will lock and unlock the Global Interpreter Lock (GIL) at appropriate times, allowing other Python threads to run while the event loop is idle.

Availability: OSX 10.1 or later.

Previous: [2.9 autoGIL](#) Up: [Macintosh Library Modules](#) Next: [3.1 gensuitemodule](#)

3. MacPython OSA Modules

This chapter describes the current implementation of the Open Scripting Architecture (OSA, also commonly referred to as AppleScript) for Python, allowing you to control scriptable applications from your Python program, and with a fairly pythonic interface. Development on this set of modules has stopped, and a replacement is expected for Python 2.5.

For a description of the various components of AppleScript and OSA, and to get an understanding of the architecture and terminology, you should read Apple's documentation. The "Applescript Language Guide" explains the conceptual model and the terminology, and documents the standard suite. The "Open Scripting Architecture" document explains how to use OSA from an application programmers point of view. In the Apple Help Viewer these books are located in the Developer Documentation, Core Technologies section.

As an example of scripting an application, the following piece of AppleScript will get the name of the frontmost **Finder** window and print it:

```
tell application "Finder"
    get name of window 1
end tell
```

In Python, the following code fragment will do the same:

```
import Finder

f = Finder.Finder()
print f.get(f.window(1).name)
```

As distributed the Python library includes packages that implement the standard suites, plus packages that interface to a small number of common applications.

To send AppleEvents to an application you must first create the Python package interfacing to the terminology of the application (what **Script Editor** calls the "Dictionary"). This can be done from within the **PythonIDE** or by running the `gensuitemodule.py` module as a standalone program from the command line.

The generated output is a package with a number of modules, one for every suite

used in the program plus an `__init__` module to glue it all together. The Python inheritance graph follows the AppleScript inheritance graph, so if a program's dictionary specifies that it includes support for the Standard Suite, but extends one or two verbs with extra arguments then the output suite will contain a module `Standard_Suite` that imports and re-exports everything from `StdSuites.Standard_Suite` but overrides the methods that have extra functionality. The output of `gensuitemodule` is pretty readable, and contains the documentation that was in the original AppleScript dictionary in Python docstrings, so reading it is a good source of documentation.

The output package implements a main class with the same name as the package which contains all the AppleScript verbs as methods, with the direct object as the first argument and all optional parameters as keyword arguments. AppleScript classes are also implemented as Python classes, as are comparisons and all the other thingies.

The main Python class implementing the verbs also allows access to the properties and elements declared in the AppleScript class "application". In the current release that is as far as the object orientation goes, so in the example above we need to use `f.get(f.window(1).name)` instead of the more Pythonic `f.window(1).name.get()`.

If an AppleScript identifier is not a Python identifier the name is mangled according to a small number of rules:

- spaces are replaced with underscores
- other non-alphanumeric characters are replaced with `_XX_` where `XX` is the hexadecimal character value
- any Python reserved word gets an underscore appended

Python also has support for creating scriptable applications in Python, but The following modules are relevant to MacPython AppleScript support:

gensuitemodule	Create a stub package from an OSA dictionary
aetools	Basic support for sending Apple Events
aepack	Conversion between Python variables and AppleEvent data containers.
aetypes	Python representation of the Apple Event Object Model.

[MiniAERFrame](#)

Support to act as an Open Scripting Architecture (OSA) server ("Apple Events").

In addition, support modules have been pre-generated for Finder, Terminal, Explorer, Netscape, CodeWarrior, SystemEvents and StdSuites.

3.1 gensuitemodule -- Generate OSA stub packages

Availability: **Macintosh**.

The `gensuitemodule` module creates a Python package implementing stub code for the AppleScript suites that are implemented by a specific application, according to its AppleScript dictionary.

It is usually invoked by the user through the **PythonIDE**, but it can also be run as a script from the command line (pass **--help** for help on the options) or imported from Python code. For an example of its use see `Mac/scripts/genallsuites.py` in a source distribution, which generates the stub packages that are included in the standard library.

It defines the following public functions:

is_scriptable(*application*)

Returns true if *application*, which should be passed as a pathname, appears to be scriptable. Take the return value with a grain of salt: **Internet Explorer** appears not to be scriptable but definitely is.

processfile(*application*[, *output*, *basepkgname*, *edit_modnames*, *creatorsignature*, *dump*, *verbose*])

Create a stub package for *application*, which should be passed as a full pathname. For a `.app` bundle this is the pathname to the bundle, not to the executable inside the bundle; for an unbundled CFM application you pass the filename of the application binary.

This function asks the application for its OSA terminology resources, decodes these resources and uses the resultant data to create the Python code for the package implementing the client stubs.

output is the pathname where the resulting package is stored, if not specified a standard "save file as" dialog is presented to the user.

`basepkgname` is the base package on which this package will build, and defaults to `StdSuites`. Only when generating `StdSuites` itself do you need to specify this. `edit_modnames` is a dictionary that can be used to change modulenames that are too ugly after name mangling. `creator_signature` can be used to override the 4-char creator code, which is normally obtained from the `PkgInfo` file in the package or from the CFM file creator signature. When `dump` is given it should refer to a file object, and `processfile` will stop after decoding the resources and dump the Python representation of the terminology resources to this file. `verbose` should also be a file object, and specifying it will cause `processfile` to tell you what it is doing.

`processfile_fromresource`(*application*[, *output*, *basepkgname*,
edit_modnames, *creatorsignature*, *dump*,
verbose])

This function does the same as `processfile`, except that it uses a different method to get the terminology resources. It opens `application` as a resource file and reads all "aete" and "aeut" resources from this file.

Previous: [3.1 gensuitemodule](#) Up: [3. MacPython OSA Modules](#) Next: [3.3 aepack](#)

3.2 `aetools` -- OSA client support

Availability: **Macintosh**.

The `aetools` module contains the basic functionality on which Python AppleScript client support is built. It also imports and re-exports the core functionality of the `aetypes` and `aepack` modules. The stub packages generated by `gensuitemodule` import the relevant portions of `aetools`, so usually you do not need to import it yourself. The exception to this is when you cannot use a generated suite package and need lower-level access to scripting.

The `aetools` module itself uses the AppleEvent support provided by the `Carbon.AE` module. This has one drawback: you need access to the window manager, see section [1.1.2](#) for details. This restriction may be lifted in future releases.

The `aetools` module defines the following functions:

`packevent`(*ae*, *parameters*, *attributes*)

Stores parameters and attributes in a pre-created `Carbon.AE.AEDesc` object. `parameters` and `attributes` are dictionaries mapping 4-character OSA parameter keys to Python objects. The objects are packed using `aepack.pack()`.

`unpackevent`(*ae*[, *formodulename*])

Recursively unpacks a `Carbon.AE.AEDesc` event to Python objects. The function returns the parameter dictionary and the attribute dictionary. The `formodulename` argument is used by generated stub packages to control where AppleScript classes are looked up.

`keysubst`(*arguments*, *keydict*)

Converts a Python keyword argument dictionary `arguments` to the format required by `packevent` by replacing the keys, which are Python identifiers, by the four-character OSA keys according to the mapping specified in `keydict`. Used by the generated suite packages.

enumsbst(*arguments*, *key*, *edict*)

If the `arguments` dictionary contains an entry for `key` convert the value for that entry according to dictionary `edict`. This converts human-readable Python enumeration names to the OSA 4-character codes. Used by the generated suite packages.

The `aertools` module defines the following class:

class TalkTo([*signature=None*, *start=0*, *timeout=0*])

Base class for the proxy used to talk to an application. `signature` overrides the class attribute `_signature` (which is usually set by subclasses) and is the 4-char creator code defining the application to talk to. `start` can be set to true to enable running the application on class instantiation. `timeout` can be specified to change the default timeout used while waiting for an `AppleEvent` reply.

_start()

Test whether the application is running, and attempt to start it if not.

send(*code*, *subcode*[, *parameters*, *attributes*])

Create the `AppleEvent Carbon.AE.AEDesc` for the verb with the OSA designation code, `subcode` (which are the usual 4-character strings), pack the `parameters` and `attributes` into it, send it to the target application, wait for the reply, unpack the reply with `unpackevent` and return the reply `appleevent`, the unpacked return values as a dictionary and the return attributes.

Previous: [3.2 aetools](#) Up: [3. MacPython OSA Modules](#) Next: [3.4 aetypes](#)

3.3 aepack -- Conversion between Python variables and AppleEvent data containers

Availability: **Macintosh**.

The `aepack` module defines functions for converting (packing) Python variables to AppleEvent descriptors and back (unpacking). Within Python the AppleEvent descriptor is handled by Python objects of built-in type `AEDesc`, defined in module [Carbon.AE](#).

The `aepack` module defines the following functions:

pack(*x* [, *forcetype*])

Returns an `AEDesc` object containing a conversion of Python value *x*. If *forcetype* is provided it specifies the descriptor type of the result. Otherwise, a default mapping of Python types to Apple Event descriptor types is used, as follows:

Python type	descriptor type
FSSpec	typeFSS
FSRef	typeFSRef
Alias	typeAlias
integer	typeLong (32 bit integer)
float	typeFloat (64 bit floating point)
string	typeText
unicode	typeUnicodeText
list	typeAEList
dictionary	typeAERecord
instance	<i>see below</i>

If *x* is a Python instance then this function attempts to call an `__aepack__`() method. This method should return an `AEDesc` object.

If the conversion `x` is not defined above, this function returns the Python string representation of a value (the `repr()` function) encoded as a text descriptor.

unpack(`x`[, `formodulename`])

`x` must be an object of type `AEDesc`. This function returns a Python object representation of the data in the Apple Event descriptor `x`. Simple AppleEvent data types (integer, text, float) are returned as their obvious Python counterparts. Apple Event lists are returned as Python lists, and the list elements are recursively unpacked. Object references (ex. `line 3 of document 1`) are returned as instances of `aetypes.ObjectSpecifier`, unless `formodulename` is specified. AppleEvent descriptors with descriptor type `typeFSS` are returned as `FSSpec` objects. AppleEvent record descriptors are returned as Python dictionaries, with 4-character string keys and elements recursively unpacked.

The optional `formodulename` argument is used by the stub packages generated by `gensuitemodule`, and ensures that the OSA classes for object specifiers are looked up in the correct module. This ensures that if, say, the Finder returns an object specifier for a window you get an instance of `Finder.Window` and not a generic `aetypes.Window`. The former knows about all the properties and elements a window has in the Finder, while the latter knows no such things.

3.4 aetypes -- AppleEvent objects

Availability: **Macintosh**.

The `aetypes` defines classes used to represent Apple Event data descriptors and Apple Event object specifiers.

Apple Event data is contained in descriptors, and these descriptors are typed. For many descriptors the Python representation is simply the corresponding Python type: `typeText` in OSA is a Python string, `typeFloat` is a float, etc. For OSA types that have no direct Python counterpart this module declares classes. Packing and unpacking instances of these classes is handled automatically by `aepack`.

An object specifier is essentially an address of an object implemented in a Apple Event server. An Apple Event specifier is used as the direct object for an Apple Event or as the argument of an optional parameter. The `aetypes` module contains the base classes for OSA classes and properties, which are used by the packages generated by `gensuitemodule` to populate the classes and properties in a given suite.

For reasons of backward compatibility, and for cases where you need to script an application for which you have not generated the stub package this module also contains object specifiers for a number of common OSA classes such as `Document`, `Window`, `Character`, etc.

The `AEObjects` module defines the following classes to represent Apple Event descriptor data:

class Unknown(*type*, *data*)

The representation of OSA descriptor data for which the `aepack` and `aetypes` modules have no support, i.e. anything that is not represented by the other classes here and that is not equivalent to a simple Python value.

class Enum(*enum*)

An enumeration value with the given 4-character string value.

class InsertionLoc(*of, pos*)

Position *pos* in object *of*.

class Boolean(*bool*)

A boolean.

class StyledText(*style, text*)

Text with style information (font, face, etc) included.

class AEText(*script, style, text*)

Text with script system and style information included.

class Int1Text(*script, language, text*)

Text with script system and language information included.

class Int1WritingCode(*script, language*)

Script system and language information.

class QDPoint(*v, h*)

A quickdraw point.

class QDRectangle(*v0, h0, v1, h1*)

A quickdraw rectangle.

class RGBColor(*r, g, b*)

A color.

class Type(*type*)

An OSA type value with the given 4-character name.

class Keyword(*name*)

An OSA keyword with the given 4-character name.

class Range(*start, stop*)

A range.

class Ordinal(*abso*)

Non-numeric absolute positions, such as "firs", first, or "midd", middle.

class Logical(*logc, term*)

The logical expression of applying operator `logc` to `term`.

class Comparison(*obj1, relo, obj2*)

The comparison `relo` of `obj1` to `obj2`.

The following classes are used as base classes by the generated stub packages to represent AppleScript classes and properties in Python:

class ComponentItem(*which[, fr]*)

Abstract baseclass for an OSA class. The subclass should set the class attribute `want` to the 4-character OSA class code. Instances of subclasses of this class are equivalent to AppleScript Object Specifiers. Upon instantiation you should pass a selector in `which`, and optionally a parent object in `fr`.

class NProperty(*fr*)

Abstract baseclass for an OSA property. The subclass should set the class attributes `want` and `which` to designate which property we are talking about. Instances of subclasses of this class are Object Specifiers.

class ObjectSpecifier(*want, form, seld[, fr]*)

Base class of `ComponentItem` and `NProperty`, a general OSA Object Specifier. See the Apple Open Scripting Architecture documentation for the parameters. Note that this class is not abstract.

Previous: 3.3 aepack	Up: 3. MacPython OSA Modules	Next: 3.5 MiniAEFrame		

Previous: [3.4 aetypes](#) Up: [3. MacPython OSA Modules](#) Next: [3.5.1 AEServer Objects](#)

3.5 MiniAEFrame -- Open Scripting Architecture server support

Availability: **Macintosh**.

The module `MiniAEFrame` provides a framework for an application that can function as an Open Scripting Architecture (OSA) server, i.e. receive and process `AppleEvents`. It can be used in conjunction with [Framework](#) or standalone. As an example, it is used in `PythonCGISlave`.

The `MiniAEFrame` module defines the following classes:

class AEServer()

A class that handles `AppleEvent` dispatch. Your application should subclass this class together with either `MiniApplication` or `Framework.Application`. Your `__init__()` method should call the `__init__()` method for both classes.

class MiniApplication()

A class that is more or less compatible with `Framework.Application` but with less functionality. Its event loop supports the apple menu, command-dot and `AppleEvents`; other events are passed on to the Python interpreter and/or `Sioux`. Useful if your application wants to use `AEServer` but does not provide its own windows, etc.

Subsections

- [3.5.1 AEServer Objects](#)

See [About this document..](#) for information on suggesting changes.

Previous: [3.5 MiniAEFrame](#) Up: [3.5 MiniAEFrame](#) Next: [4. MacOS Toolbox Modules](#)

3.5.1 AEServer Objects

installaehandler(*classe*, *type*, *callback*)

Installs an AppleEvent handler. *classe* and *type* are the four-character OSA Class and Type designators, '****' wildcards are allowed. When a matching AppleEvent is received the parameters are decoded and your callback is invoked.

callback(*_object*, ***kwargs*)

Your callback is called with the OSA Direct Object as first positional parameter. The other parameters are passed as keyword arguments, with the 4-character designator as name. Three extra keyword parameters are passed: *_class* and *_type* are the Class and Type designators and *_attributes* is a dictionary with the AppleEvent attributes.

The return value of your method is packed with `aertools.packevent()` and sent as reply.

Note that there are some serious problems with the current design. AppleEvents which have non-identifier 4-character designators for arguments are not implementable, and it is not possible to return an error to the originator. This will be addressed in a future release.

4. MacOS Toolbox Modules

There are a set of modules that provide interfaces to various MacOS toolboxes. If applicable the module will define a number of Python objects for the various structures declared by the toolbox, and operations will be implemented as methods of the object. Other operations will be implemented as functions in the module. Not all operations possible in C will also be possible in Python (callbacks are often a problem), and parameters will occasionally be different in Python (input and output buffers, especially). All methods and functions have a `__doc__` string describing their arguments and return values, and for additional description you are referred to [Inside Macintosh](#) or similar works.

These modules all live in a package called `Carbon`. Despite that name they are not all part of the Carbon framework: `CF` is really in the CoreFoundation framework and `Qt` is in the QuickTime framework. The normal use pattern is

```
from Carbon import AE
```

Warning! These modules are not yet documented. If you wish to contribute documentation of any of these modules, please get in touch with docs@python.org.

Carbon.AE	Interface to the Apple Events toolbox.
Carbon.AH	Interface to the Apple Help manager.
Carbon.App	Interface to the Appearance Manager.
Carbon.CF	Interface to the Core Foundation.
Carbon.CG	Interface to the Component Manager.
Carbon.CaronEvt	Interface to the Carbon Event Manager.
Carbon.Cm	Interface to the Component Manager.
Carbon.Ctl	Interface to the Control Manager.
Carbon.Dlg	Interface to the Dialog Manager.
Carbon.Evt	Interface to the classic Event Manager.
Carbon.Fm	Interface to the Font Manager.
Carbon.Folder	Interface to the Folder Manager.
Carbon.Help	Interface to the Carbon Help Manager.

<u>Carbon.List</u>	Interface to the List Manager.
<u>Carbon.Menu</u>	Interface to the Menu Manager.
<u>Carbon.Mlte</u>	Interface to the MultiLingual Text Editor.
<u>Carbon.Qd</u>	Interface to the QuickDraw toolbox.
<u>Carbon.Qdoffs</u>	Interface to the QuickDraw Offscreen APIs.
<u>Carbon.Qt</u>	Interface to the QuickTime toolbox.
<u>Carbon.Res</u>	Interface to the Resource Manager and Handles.
<u>Carbon.Scrap</u>	Interface to the Carbon Scrap Manager.
<u>Carbon.Snd</u>	Interface to the Sound Manager.
<u>Carbon.TE</u>	Interface to TextEdit.
<u>Carbon.Win</u>	Interface to the Window Manager.
<u>ColorPicker</u>	Interface to the standard color selection dialog.

5.3 `cfmfile` -- Code Fragment Resource module

Availability: **Macintosh**.

`cfmfile` is a module that understands Code Fragments and the accompanying ``cfrg" resources. It can parse them and merge them, and is used by `BuildApplication` to combine all plugin modules to a single executable.

Deprecated since release 2.4. <

A.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <http://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <http://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <http://www.zope.com/>). In 2001, the Python Software Foundation (PSF, see <http://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <http://www.opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL compatible?
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes
1.6	1.5.2	2000	CNRI	no
2.0	1.6	2000	BeOpen.com	no
1.6.1	1.6	2001	CNRI	no
2.1	2.0+1.6.1	2001	PSF	no
2.0.1	2.0+1.6.1	2001	PSF	yes
2.1.1	2.1+2.0.1	2001	PSF	yes
2.2	2.1.1	2001	PSF	yes

2.1.2	2.1.1	2002	PSF	yes
2.1.3	2.1.2	2002	PSF	yes
2.2.1	2.2	2002	PSF	yes
2.2.2	2.2.1	2002	PSF	yes
2.2.3	2.2.2	2002-2003	PSF	yes
2.3	2.2.2	2002-2003	PSF	yes
2.3.1	2.3	2002-2003	PSF	yes
2.3.2	2.3.1	2003	PSF	yes
2.3.3	2.3.2	2003	PSF	yes
2.3.4	2.3.3	2004	PSF	yes
2.3.5	2.3.4	2005	PSF	yes
2.4	2.3	2004	PSF	yes
2.4.1	2.4	2005	PSF	yes
2.4.2	2.4.1	2005	PSF	yes
2.4.3	2.4.2	2006	PSF	yes
2.4.4	2.4.3	2006	PSF	yes
2.5	2.4	2006	PSF	yes

Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

A.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.4.4

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.4.4 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.4.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.4.4 alone or in any derivative version prepared by Licensee.
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.4.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.4.4.
4. PSF is making Python 2.4.4 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.4.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS

OF PYTHON 2.4.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.4.4, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 2.4.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION

1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.
3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT

LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at <http://www.pythonlabs.com/logos.html> may be used according to the permissions granted on that web page.
7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to

reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: <http://hdl.handle.net/1895.22/1013>."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.
4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. This License Agreement shall be governed by the federal intellectual

property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

```

Modified by Jack Jansen, CWI, July 1995:

- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. The version is still 5 times faster, though.
- Arguments more compliant with python standard

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [1. Extending Python with](#) Up: [1. Extending Python with](#) Next: [1.2](#)
[Intermezzo: Errors and](#)

1.1 A Simple Example

Let's create an extension module called "spam" (the favorite food of Monty Python fans...) and let's say we want to create a Python interface to the C library function `system()`.^{1.1} This function takes a null-terminated character string as argument and returns an integer. We want this function to be callable from Python as follows:

```
>>> import spam
>>> status = spam.system("ls -l")
```

Begin by creating a file `spammodule.c`. (Historically, if a module is called "spam", the C file containing its implementation is called `spammodule.c`; if the module name is very long, like "spammify", the module name can be just `spammify.c`.)

The first line of our file can be:

```
#include <Python.h>
```

which pulls in the Python API (you can add a comment describing the purpose of the module and a copyright notice if you like).

Warning: Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

All user-visible symbols defined by `Python.h` have a prefix of "Py" or "PY", except those defined in standard header files. For convenience, and since they are used extensively by the Python interpreter, "`Python.h`" includes a few standard header files: `<stdio.h>`, `<string.h>`, `<errno.h>`, and `<stdlib.h>`. If the latter header file does not exist on your system, it declares the functions `malloc()`, `free()` and `realloc()` directly.

The next thing we add to our module file is the C function that will be called

when the Python expression `"spam.system(string)"` is evaluated (we'll see shortly how it ends up being called):

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    return Py_BuildValue("i", sts);
}
```

There is a straightforward translation from the argument list in Python (for example, the single expression `"ls -l"`) to the arguments passed to the C function. The C function always has two arguments, conventionally named *self* and *args*.

The *self* argument is only used when the C function implements a built-in method, not a function. In the example, *self* will always be a `NULL` pointer, since we are defining a function, not a method. (This is done so that the interpreter doesn't have to understand two different types of C functions.)

The *args* argument will be a pointer to a Python tuple object containing the arguments. Each item of the tuple corresponds to an argument in the call's argument list. The arguments are Python objects -- in order to do anything with them in our C function we have to convert them to C values. The function `PyArg_ParseTuple()` in the Python API checks the argument types and converts them to C values. It uses a template string to determine the required types of the arguments as well as the types of the C variables into which to store the converted values. More about this later.

`PyArg_ParseTuple()` returns true (nonzero) if all arguments have the right type and its components have been stored in the variables whose addresses are passed. It returns false (zero) if an invalid argument list was passed. In the latter case it also raises an appropriate exception so the calling function can return `NULL` immediately (as we saw in the example).

Footnotes

...system().[1.1](#)

An interface for this function already exists in the standard module `os` -- it was chosen as a simple and straightforward example.

1.2 Intermezzo: Errors and Exceptions

An important convention throughout the Python interpreter is the following: when a function fails, it should set an exception condition and return an error value (usually a NULL pointer). Exceptions are stored in a static global variable inside the interpreter; if this variable is NULL no exception has occurred. A second global variable stores the ``associated value" of the exception (the second argument to `raise`). A third variable contains the stack traceback in case the error originated in Python code. These three variables are the C equivalents of the Python variables `sys.exc_type`, `sys.exc_value` and `sys.exc_traceback` (see the section on module `sys` in the [Python Library Reference](#)). It is important to know about them to understand how errors are passed around.

The Python API defines a number of functions to set various types of exceptions.

The most common one is `PyErr_SetString()`. Its arguments are an exception object and a C string. The exception object is usually a predefined object like `PyExc_ZeroDivisionError`. The C string indicates the cause of the error and is converted to a Python string object and stored as the ``associated value" of the exception.

Another useful function is `PyErr_SetFromErrno()`, which only takes an exception argument and constructs the associated value by inspection of the global variable `errno`. The most general function is `PyErr_SetObject()`, which takes two object arguments, the exception and its associated value. You don't need to `Py_INCREF()` the objects passed to any of these functions.

You can test non-destructively whether an exception has been set with `PyErr_Occurred()`. This returns the current exception object, or NULL if no exception has occurred. You normally don't need to call `PyErr_Occurred()` to see whether an error occurred in a function call, since you should be able to tell from the return value.

When a function f that calls another function g detects that the latter fails, f

should itself return an error value (usually `NULL` or `-1`). It should *not* call one of the `PyErr_*`() functions -- one has already been called by *g*. *f*'s caller is then supposed to also return an error indication to *its* caller, again *without* calling `PyErr_*`(), and so on -- the most detailed cause of the error was already reported by the function that first detected it. Once the error reaches the Python interpreter's main loop, this aborts the currently executing Python code and tries to find an exception handler specified by the Python programmer.

(There are situations where a module can actually give a more detailed error message by calling another `PyErr_*`() function, and in such cases it is fine to do so. As a general rule, however, this is not necessary, and can cause information about the cause of the error to be lost: most operations can fail for a variety of reasons.)

To ignore an exception set by a function call that failed, the exception condition must be cleared explicitly by calling `PyErr_Clear`(). The only time C code should call `PyErr_Clear`() is if it doesn't want to pass the error on to the interpreter but wants to handle it completely by itself (possibly by trying something else, or pretending nothing went wrong).

Every failing `malloc`() call must be turned into an exception -- the direct caller of `malloc`() (or `realloc`()) must call `PyErr_NoMemory`() and return a failure indicator itself. All the object-creating functions (for example, `PyInt_FromLong`()) already do this, so this note is only relevant to those who call `malloc`() directly.

Also note that, with the important exception of `PyArg_ParseTuple`() and friends, functions that return an integer status usually return a positive value or zero for success and `-1` for failure, like UNIX system calls.

Finally, be careful to clean up garbage (by making `Py_XDECREF`() or `Py_DECREF`() calls for objects you have already created) when you return an error indicator!

The choice of which exception to raise is entirely yours. There are predeclared C objects corresponding to all built-in Python exceptions, such as `PyExc_ZeroDivisionError`, which you can use directly. Of course, you should choose exceptions wisely -- don't use `PyExc_TypeError` to mean that a file couldn't be opened (that should probably be `PyExc_IOError`). If

something's wrong with the argument list, the `PyArg_ParseTuple()` function usually raises `PyExc_TypeError`. If you have an argument whose value must be in a particular range or must satisfy other conditions, `PyExc_ValueError` is appropriate.

You can also define a new exception that is unique to your module. For this, you usually declare a static object variable at the beginning of your file:

```
static PyObject *SpamError;
```

and initialize it in your module's initialization function (`initspam()`) with an exception object (leaving out the error checking for now):

```
PyMODINIT_FUNC
initspam(void)
{
    PyObject *m;

    m = Py_InitModule("spam", SpamMethods);
    if (m == NULL)
        return;

    SpamError = PyErr_NewException("spam.error", NULL, NULL);
    Py_INCREF(SpamError);
    PyModule_AddObject(m, "error", SpamError);
}
```

Note that the Python name for the exception object is `spam.error`. The `PyErr_NewException()` function may create a class with the base class being `Exception` (unless another class is passed in instead of `NULL`), described in the [Python Library Reference](#) under ``Built-in Exceptions."''

Note also that the `SpamError` variable retains a reference to the newly created exception class; this is intentional! Since the exception could be removed from the module by external code, an owned reference to the class is needed to ensure that it will not be discarded, causing `SpamError` to become a dangling pointer. Should it become a dangling pointer, C code which raises the exception could cause a core dump or other unintended side effects.

We discuss the use of `PyMODINIT_FUNC` as a function return type later in this sample.

Extending and Embedding the Python Interpreter

1.3 Back to the Example

Going back to our example function, you should now be able to understand this statement:

```
if (!PyArg_ParseTuple(args, "s", &command))
    return NULL;
```

It returns `NULL` (the error indicator for functions returning object pointers) if an error is detected in the argument list, relying on the exception set by `PyArg_ParseTuple()`. Otherwise the string value of the argument has been copied to the local variable `command`. This is a pointer assignment and you are not supposed to modify the string to which it points (so in Standard C, the variable `command` should properly be declared as `"const char *command"`).

The next statement is a call to the UNIX function `system()`, passing it the string we just got from `PyArg_ParseTuple()`:

```
sts = system(command);
```

Our `spam.system()` function must return the value of `sts` as a Python object. This is done using the function `Py_BuildValue()`, which is something like the inverse of `PyArg_ParseTuple()`: it takes a format string and an arbitrary number of C values, and returns a new Python object. More info on `Py_BuildValue()` is given later.

```
return Py_BuildValue("i", sts);
```

In this case, it will return an integer object. (Yes, even integers are objects on the heap in Python!)

If you have a C function that returns no useful argument (a function returning `void`), the corresponding Python function must return `None`. You need this idiom to do so (which is implemented by the `Py_RETURN_NONE` macro):

```
Py_INCREF(Py_None);
return Py_None;
```

Py_None is the C name for the special Python object None. It is a genuine Python object rather than a NULL pointer, which means ``error" in most contexts, as we have seen.

1.4 The Module's Method Table and Initialization Function

I promised to show how `spam_system()` is called from Python programs. First, we need to list its name and address in a "method table":

```
static PyMethodDef SpamMethods[] = {
    ...
    {"system", spam_system, METH_VARARGS,
     "Execute a shell command."},
    ...
    {NULL, NULL, 0, NULL}          /* Sentinel */
};
```

Note the third entry ("METH_VARARGS"). This is a flag telling the interpreter the calling convention to be used for the C function. It should normally always be "METH_VARARGS" or "METH_VARARGS | METH_KEYWORDS"; a value of 0 means that an obsolete variant of `PyArg_ParseTuple()` is used.

When using only "METH_VARARGS", the function should expect the Python-level parameters to be passed in as a tuple acceptable for parsing via `PyArg_ParseTuple()`; more information on this function is provided below.

The METH_KEYWORDS bit may be set in the third field if keyword arguments should be passed to the function. In this case, the C function should accept a third "PyObject *" parameter which will be a dictionary of keywords. Use `PyArg_ParseTupleAndKeywords()` to parse the arguments to such a function.

The method table must be passed to the interpreter in the module's initialization function. The initialization function must be named `inittestname()`, where *name* is the name of the module, and should be the only non-`static` item defined in the module file:

```
PyMODINIT_FUNC
inittestname(void)
{
    (void) Py_InitModule("spam", SpamMethods);
}
```

Note that `PyMODINIT_FUNC` declares the function as `void` return type, declares any special linkage declarations required by the platform, and for C++ declares the function as `extern "C"`.

When the Python program imports module `spam` for the first time, `initspam()` is called. (See below for comments about embedding Python.) It calls `Py_InitModule()`, which creates a "module object" (which is inserted in the dictionary `sys.modules` under the key "`spam`"), and inserts built-in function objects into the newly created module based upon the table (an array of `PyMethodDef` structures) that was passed as its second argument. `Py_InitModule()` returns a pointer to the module object that it creates (which is unused here). It may abort with a fatal error for certain errors, or return `NULL` if the module could not be initialized satisfactorily.

When embedding Python, the `initspam()` function is not called automatically unless there's an entry in the `_PyImport_Inittab` table. The easiest way to handle this is to statically initialize your statically-linked modules by directly calling `initspam()` after the call to `Py_Initialize()`:

```
int
main(int argc, char *argv[])
{
    /* Pass argv[0] to the Python interpreter */
    Py_SetProgramName(argv[0]);

    /* Initialize the Python interpreter.  Required. */
    Py_Initialize();

    /* Add a static module */
    initspam();
}
```

An example may be found in the file `Demo/embed/demo.c` in the Python source distribution.

Note: Removing entries from `sys.modules` or importing compiled modules into multiple interpreters within a process (or following a `fork()` without an intervening `exec()`) can create problems for some extension modules. Extension module authors should exercise caution when initializing internal data structures. Note also that the `reload()` function can be used with extension modules, and will call the module initialization function (`initspam()` in the example), but will not load the module again if it was loaded from a dynamically

loadable object file (.so on UNIX, .dll on Windows).

A more substantial example module is included in the Python source distribution as `Modules/xxmodule.c`. This file may be used as a template or simply read as an example. The **`modulator.py`** script included in the source distribution or Windows install provides a simple graphical user interface for declaring the functions and objects which a module should implement, and can generate a template which can be filled in. The script lives in the `Tools/modulator/` directory; see the `README` file there for more information.

Previous: [1.4 The Module's Method Calling Python Functions](#) **Up:** [1. Extending Python with](#) **Next:** [1.6](#)

1.5 Compilation and Linkage

There are two more things to do before you can use your new extension: compiling and linking it with the Python system. If you use dynamic loading, the details may depend on the style of dynamic loading your system uses; see the chapters about building extension modules (chapter [3](#)) and additional information that pertains only to building on Windows (chapter [4](#)) for more information about this.

If you can't use dynamic loading, or if you want to make your module a permanent part of the Python interpreter, you will have to change the configuration setup and rebuild the interpreter. Luckily, this is very simple on UNIX: just place your file (`spammodule.c` for example) in the `Modules/` directory of an unpacked source distribution, add a line to the file `Modules/Setup.local` describing your file:

```
spam spammodule.o
```

and rebuild the interpreter by running **make** in the toplevel directory. You can also run **make** in the `Modules/` subdirectory, but then you must first rebuild `Makefile` there by running `make Makefile`. (This is necessary each time you change the `Setup` file.)

If your module requires additional libraries to link with, these can be listed on the line in the configuration file as well, for instance:

```
spam spammodule.o -lX11
```

[Extracting Parameters in](#)

1.6 Calling Python Functions from C

So far we have concentrated on making C functions callable from Python. The reverse is also useful: calling Python functions from C. This is especially the case for libraries that support so-called "callback" functions. If a C interface makes use of callbacks, the equivalent Python often needs to provide a callback mechanism to the Python programmer; the implementation will require calling the Python callback functions from a C callback. Other uses are also imaginable.

Fortunately, the Python interpreter is easily called recursively, and there is a standard interface to call a Python function. (I won't dwell on how to call the Python parser with a particular string as input -- if you're interested, have a look at the implementation of the `-c` command line option in `Python/pythonmain.c` from the Python source code.)

Calling a Python function is easy. First, the Python program must somehow pass you the Python function object. You should provide a function (or some other interface) to do this. When this function is called, save a pointer to the Python function object (be careful to `Py_INCREF()` it!) in a global variable -- or wherever you see fit. For example, the following function might be part of a module definition:

```
static PyObject *my_callback = NULL;

static PyObject *
my_set_callback(PyObject *dummy, PyObject *args)
{
    PyObject *result = NULL;
    PyObject *temp;

    if (PyArg_ParseTuple(args, "O:set_callback", &temp)) {
        if (!PyCallable_Check(temp)) {
            PyErr_SetString(PyExc_TypeError, "parameter must be call
            return NULL;
        }
        Py_XINCRREF(temp);          /* Add a reference to new callback
        Py_XDECREF(my_callback);   /* Dispose of previous callback */
        my_callback = temp;        /* Remember new callback */
        /* Boilerplate to return "None" */
        Py_INCREF(Py_None);
        result = Py_None;
    }
}
```

```

    return result;
}

```

This function must be registered with the interpreter using the METH_VARARGS flag; this is described in section [1.4](#), "The Module's Method Table and Initialization Function." The PyArg_ParseTuple() function and its arguments are documented in section [1.7](#), "Extracting Parameters in Extension Functions."

The macros Py_XINCRF() and Py_XDECREF() increment/decrement the reference count of an object and are safe in the presence of NULL pointers (but note that *temp* will not be NULL in this context). More info on them in section [1.10](#), "Reference Counts."

Later, when it is time to call the function, you call the C function PyEval_CallObject(). This function has two arguments, both pointers to arbitrary Python objects: the Python function, and the argument list. The argument list must always be a tuple object, whose length is the number of arguments. To call the Python function with no arguments, pass an empty tuple; to call it with one argument, pass a singleton tuple. Py_BuildValue() returns a tuple when its format string consists of zero or more format codes between parentheses. For example:

```

int arg;
PyObject *arglist;
PyObject *result;
...
arg = 123;
...
/* Time to call the callback */
arglist = Py_BuildValue("i", arg);
result = PyEval_CallObject(my_callback, arglist);
Py_DECREF(arglist);

```

PyEval_CallObject() returns a Python object pointer: this is the return value of the Python function. PyEval_CallObject() is "reference-count-neutral" with respect to its arguments. In the example a new tuple was created to serve as the argument list, which is Py_DECREF()-ed immediately after the call.

The return value of PyEval_CallObject() is "new": either it is a brand new object, or it is an existing object whose reference count has been

incremented. So, unless you want to save it in a global variable, you should somehow `Py_DECREF()` the result, even (especially!) if you are not interested in its value.

Before you do this, however, it is important to check that the return value isn't `NULL`. If it is, the Python function terminated by raising an exception. If the C code that called `PyEval_CallObject()` is called from Python, it should now return an error indication to its Python caller, so the interpreter can print a stack trace, or the calling Python code can handle the exception. If this is not possible or desirable, the exception should be cleared by calling `PyErr_Clear()`. For example:

```
if (result == NULL)
    return NULL; /* Pass error back */
...use result...
Py_DECREF(result);
```

Depending on the desired interface to the Python callback function, you may also have to provide an argument list to `PyEval_CallObject()`. In some cases the argument list is also provided by the Python program, through the same interface that specified the callback function. It can then be saved and used in the same manner as the function object. In other cases, you may have to construct a new tuple to pass as the argument list. The simplest way to do this is to call `Py_BuildValue()`. For example, if you want to pass an integral event code, you might use the following code:

```
PyObject *arglist;
...
arglist = Py_BuildValue("(l)", eventcode);
result = PyEval_CallObject(my_callback, arglist);
Py_DECREF(arglist);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```

Note the placement of `"Py_DECREF(arglist)"` immediately after the call, before the error check! Also note that strictly spoken this code is not complete: `Py_BuildValue()` may run out of memory, and this should be checked.

1.7 Extracting Parameters in Extension Functions

The `PyArg_ParseTuple()` function is declared as follows:

```
int PyArg_ParseTuple(PyObject *arg, char *format, ...);
```

The *arg* argument must be a tuple object containing an argument list passed from Python to a C function. The *format* argument must be a format string, whose syntax is explained in [`Parsing arguments and building values`](#) in the [Python/C API Reference Manual](#). The remaining arguments must be addresses of variables whose type is determined by the format string.

Note that while `PyArg_ParseTuple()` checks that the Python arguments have the required types, it cannot check the validity of the addresses of C variables passed to the call: if you make mistakes there, your code will probably crash or at least overwrite random bits in memory. So be careful!

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Some example calls:

```
int ok;
int i, j;
long k, l;
const char *s;
int size;

ok = PyArg_ParseTuple(args, ""); /* No arguments */
/* Python call: f() */

ok = PyArg_ParseTuple(args, "s", &s); /* A string */
/* Possible Python call: f('whoops!') */

ok = PyArg_ParseTuple(args, "lls", &k, &l, &s); /* Two longs and
/* Possible Python call: f(1, 2, 'three') */

ok = PyArg_ParseTuple(args, "(ii)s#", &i, &j, &s, &size);
/* A pair of ints and a string, whose size is also returned
/* Possible Python call: f((1, 2), 'three') */
```

```

{
    const char *file;
    const char *mode = "r";
    int bufsize = 0;
    ok = PyArg_ParseTuple(args, "s|si", &file, &mode, &bufsize);
    /* A string, and optionally another string and an integer */
    /* Possible Python calls:
       f('spam')
       f('spam', 'w')
       f('spam', 'wb', 100000) */
}

{
    int left, top, right, bottom, h, v;
    ok = PyArg_ParseTuple(args, "((ii)(ii))(ii)",
        &left, &top, &right, &bottom, &h, &v);
    /* A rectangle and a point */
    /* Possible Python call:
       f(((0, 0), (400, 300)), (10, 10)) */
}

{
    Py_complex c;
    ok = PyArg_ParseTuple(args, "D:myfunction", &c);
    /* a complex, also providing a function name for errors */
    /* Possible Python call: myfunction(1+2j) */
}

```

Previous: [1.6 Calling Python Functions](#)
Up: [1. Extending Python with](#)
Next: [1.8 Keyword Parameters for](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
 See [About this document...](#) for information on suggesting changes.

Previous: [1.7 Extracting Parameters in Building Arbitrary Values](#) **Up:** [1. Extending Python with](#) **Next:** [1.9](#)

1.8 Keyword Parameters for Extension Functions

The `PyArg_ParseTupleAndKeywords()` function is declared as follows:

```
int PyArg_ParseTupleAndKeywords(PyObject *arg, PyObject *kwdict,
                                char *format, char *kwlist[], ...);
```

The *arg* and *format* parameters are identical to those of the `PyArg_ParseTuple()` function. The *kwdict* parameter is the dictionary of keywords received as the third parameter from the Python runtime. The *kwlist* parameter is a NULL-terminated list of strings which identify the parameters; the names are matched with the type information from *format* from left to right. On success, `PyArg_ParseTupleAndKeywords()` returns true, otherwise it returns false and raises an appropriate exception.

Note: Nested tuples cannot be parsed when using keyword arguments! Keyword parameters passed in which are not present in the *kwlist* will cause `TypeError` to be raised.

Here is an example module which uses keywords, based on an example by Geoff Philbrick (philbrick@hks.com):

```
#include "Python.h"

static PyObject *
keywdarg_parrot(PyObject *self, PyObject *args, PyObject *keywds)
{
    int voltage;
    char *state = "a stiff";
    char *action = "voom";
    char *type = "Norwegian Blue";

    static char *kwlist[] = {"voltage", "state", "action", "type", N

    if (!PyArg_ParseTupleAndKeywords(args, keywds, "i|sss", kwlist,
                                     &voltage, &state, &action, &typ

        return NULL;

    printf("-- This parrot wouldn't %s if you put %i Volts through i
           action, voltage);
    printf("-- Lovely plumage, the %s -- It's %s!\n", type, state);
```

```

    Py_INCREF(Py_None);

    return Py_None;
}

static PyMethodDef keywdarg_methods[] = {
    /* The cast of the function is necessary since PyCFunction value
     * only take two PyObject* parameters, and keywdarg_parrot() tak
     * three.
     */
    {"parrot", (PyCFunction)keywdarg_parrot, METH_VARARGS | METH_KEYW,
     "Print a lovely skit to standard output."},
    {NULL, NULL, 0, NULL} /* sentinel */
};

void
initkeywdarg(void)
{
    /* Create the module and add the functions */
    Py_InitModule("keywdarg", keywdarg_methods);
}

```

[1.10 Reference Counts](#)

1.9 Building Arbitrary Values

This function is the counterpart to `PyArg_ParseTuple()`. It is declared as follows:

```
PyObject *Py_BuildValue(char *format, ...);
```

It recognizes a set of format units similar to the ones recognized by `PyArg_ParseTuple()`, but the arguments (which are input to the function, not output) must not be pointers, just values. It returns a new Python object, suitable for returning from a C function called from Python.

One difference with `PyArg_ParseTuple()`: while the latter requires its first argument to be a tuple (since Python argument lists are always represented as tuples internally), `Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

Examples (to the left the call, to the right the resulting Python value):

<code>Py_BuildValue("")</code>	<code>None</code>
<code>Py_BuildValue("i", 123)</code>	<code>123</code>
<code>Py_BuildValue("iii", 123, 456, 789)</code>	<code>(123, 456, 789)</code>
<code>Py_BuildValue("s", "hello")</code>	<code>'hello'</code>
<code>Py_BuildValue("ss", "hello", "world")</code>	<code>('hello', 'world')</code>
<code>Py_BuildValue("s#", "hello", 4)</code>	<code>'hell'</code>
<code>Py_BuildValue("()")</code>	<code>()</code>
<code>Py_BuildValue("(i)", 123)</code>	<code>(123,)</code>
<code>Py_BuildValue("(ii)", 123, 456)</code>	<code>(123, 456)</code>

1.10 Reference Counts

In languages like C or C++, the programmer is responsible for dynamic allocation and deallocation of memory on the heap. In C, this is done using the functions `malloc()` and `free()`. In C++, the operators `new` and `delete` are used with essentially the same meaning and we'll restrict the following discussion to the C case.

Every block of memory allocated with `malloc()` should eventually be returned to the pool of available memory by exactly one call to `free()`. It is important to call `free()` at the right time. If a block's address is forgotten but `free()` is not called for it, the memory it occupies cannot be reused until the program terminates. This is called a *memory leak*. On the other hand, if a program calls `free()` for a block and then continues to use the block, it creates a conflict with re-use of the block through another `malloc()` call. This is called *using freed memory*. It has the same bad consequences as referencing uninitialized data -- core dumps, wrong results, mysterious crashes.

Common causes of memory leaks are unusual paths through the code. For instance, a function may allocate a block of memory, do some calculation, and then free the block again. Now a change in the requirements for the function may add a test to the calculation that detects an error condition and can return prematurely from the function. It's easy to forget to free the allocated memory block when taking this premature exit, especially when it is added later to the code. Such leaks, once introduced, often go undetected for a long time: the error exit is taken only in a small fraction of all calls, and most modern machines have plenty of virtual memory, so the leak only becomes apparent in a long-running process that uses the leaking function frequently. Therefore, it's important to prevent leaks from happening by having a coding convention or strategy that minimizes this kind of errors.

Since Python makes heavy use of `malloc()` and `free()`, it needs a strategy to avoid memory leaks as well as the use of freed memory. The chosen method is called *reference counting*. The principle is simple: every object contains a counter, which is incremented when a reference to the object is stored somewhere, and which is decremented when a reference to it is deleted. When the counter reaches zero, the last reference to the object has been deleted and the

object is freed.

An alternative strategy is called *automatic garbage collection*. (Sometimes, reference counting is also referred to as a garbage collection strategy, hence my use of "automatic" to distinguish the two.) The big advantage of automatic garbage collection is that the user doesn't need to call `free()` explicitly. (Another claimed advantage is an improvement in speed or memory usage -- this is no hard fact however.) The disadvantage is that for C, there is no truly portable automatic garbage collector, while reference counting can be implemented portably (as long as the functions `malloc()` and `free()` are available -- which the C Standard guarantees). Maybe some day a sufficiently portable automatic garbage collector will be available for C. Until then, we'll have to live with reference counts.

While Python uses the traditional reference counting implementation, it also offers a cycle detector that works to detect reference cycles. This allows applications to not worry about creating direct or indirect circular references; these are the weakness of garbage collection implemented using only reference counting. Reference cycles consist of objects which contain (possibly indirect) references to themselves, so that each object in the cycle has a reference count which is non-zero. Typical reference counting implementations are not able to reclaim the memory belonging to any objects in a reference cycle, or referenced from the objects in the cycle, even though there are no further references to the cycle itself.

The cycle detector is able to detect garbage cycles and can reclaim them so long as there are no finalizers implemented in Python (`__del__()` methods). When there are such finalizers, the detector exposes the cycles through the [gc module](#) (specifically, the `garbage` variable in that module). The `gc` module also exposes a way to run the detector (the `collect()` function), as well as configuration interfaces and the ability to disable the detector at runtime. The cycle detector is considered an optional component; though it is included by default, it can be disabled at build time using the `--without-cycle-gc` option to the `configure` script on UNIX platforms (including Mac OS X) or by removing the definition of `WITH_CYCLE_GC` in the `pyconfig.h` header on other platforms. If the cycle detector is disabled in this way, the `gc` module will not be available.

1.10.1 Reference Counting in Python

There are two macros, `Py_INCREF(x)` and `Py_DECREF(x)`, which handle the incrementing and decrementing of the reference count. `Py_DECREF()` also frees the object when the count reaches zero. For flexibility, it doesn't call `free()` directly -- rather, it makes a call through a function pointer in the object's *type object*. For this purpose (and others), every object also contains a pointer to its type object.

The big question now remains: when to use `Py_INCREF(x)` and `Py_DECREF(x)`? Let's first introduce some terms. Nobody "owns" an object; however, you can *own a reference* to an object. An object's reference count is now defined as the number of owned references to it. The owner of a reference is responsible for calling `Py_DECREF()` when the reference is no longer needed. Ownership of a reference can be transferred. There are three ways to dispose of an owned reference: pass it on, store it, or call `Py_DECREF()`. Forgetting to dispose of an owned reference creates a memory leak.

It is also possible to *borrow*^{1.2} a reference to an object. The borrower of a reference should not call `Py_DECREF()`. The borrower must not hold on to the object longer than the owner from which it was borrowed. Using a borrowed reference after the owner has disposed of it risks using freed memory and should be avoided completely.^{1.3}

The advantage of borrowing over owning a reference is that you don't need to take care of disposing of the reference on all possible paths through the code -- in other words, with a borrowed reference you don't run the risk of leaking when a premature exit is taken. The disadvantage of borrowing over owning is that there are some subtle situations where in seemingly correct code a borrowed reference can be used after the owner from which it was borrowed has in fact disposed of it.

A borrowed reference can be changed into an owned reference by calling `Py_INCREF()`. This does not affect the status of the owner from which the reference was borrowed -- it creates a new owned reference, and gives full owner responsibilities (the new owner must dispose of the reference properly, as well as the previous owner).

Footnotes

...borrow [1.2](#)

The metaphor of ``borrowing" a reference is not completely correct: the owner still has a copy of the reference.

... completely. [1.3](#)

Checking that the reference count is at least 1 **does not work** -- the reference count itself could be in freed memory and may thus be reused for another object!

[1.10.3 Thin Ice](#)

1.10.2 Ownership Rules

Whenever an object reference is passed into or out of a function, it is part of the function's interface specification whether ownership is transferred with the reference or not.

Most functions that return a reference to an object pass on ownership with the reference. In particular, all functions whose function it is to create a new object, such as `PyInt_FromLong()` and `Py_BuildValue()`, pass ownership to the receiver. Even if the object is not actually new, you still receive ownership of a new reference to that object. For instance, `PyInt_FromLong()` maintains a cache of popular values and can return a reference to a cached item.

Many functions that extract objects from other objects also transfer ownership with the reference, for instance `PyObject_GetAttrString()`. The picture is less clear, here, however, since a few common routines are exceptions: `PyTuple_GetItem()`, `PyList_GetItem()`, `PyDict_GetItem()`, and `PyDict_GetItemString()` all return references that you borrow from the tuple, list or dictionary.

The function `PyImport_AddModule()` also returns a borrowed reference, even though it may actually create the object it returns: this is possible because an owned reference to the object is stored in `sys.modules`.

When you pass an object reference into another function, in general, the function borrows the reference from you -- if it needs to store it, it will use `Py_INCREF()` to become an independent owner. There are exactly two important exceptions to this rule: `PyTuple_SetItem()` and `PyList_SetItem()`. These functions take over ownership of the item passed to them -- even if they fail! (Note that `PyDict_SetItem()` and friends don't take over ownership -- they are "normal.")

When a C function is called from Python, it borrows references to its arguments from the caller. The caller owns a reference to the object, so the borrowed reference's lifetime is guaranteed until the function returns. Only when such a borrowed reference must be stored or passed on, it must be turned into an owned reference by calling `Py_INCREF()`.

The object reference returned from a C function that is called from Python must be an owned reference -- ownership is transferred from the function to its caller.

Previous: [1.10.2 Ownership Rules](#) **Up:** [1.10 Reference Counts](#) **Next:** [1.10.4 NULL Pointers](#)

1.10.3 Thin Ice

There are a few situations where seemingly harmless use of a borrowed reference can lead to problems. These all have to do with implicit invocations of the interpreter, which can cause the owner of a reference to dispose of it.

The first and most important case to know about is using `Py_DECREF()` on an unrelated object while borrowing a reference to a list item. For instance:

```
void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);

    PyList_SetItem(list, 1, PyInt_FromLong(0L));
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

This function first borrows a reference to `list[0]`, then replaces `list[1]` with the value `0`, and finally prints the borrowed reference. Looks harmless, right? But it's not!

Let's follow the control flow into `PyList_SetItem()`. The list owns references to all its items, so when item 1 is replaced, it has to dispose of the original item 1. Now let's suppose the original item 1 was an instance of a user-defined class, and let's further suppose that the class defined a `__del__()` method. If this class instance has a reference count of 1, disposing of it will call its `__del__()` method.

Since it is written in Python, the `__del__()` method can execute arbitrary Python code. Could it perhaps do something to invalidate the reference to `item` in `bug()`? You bet! Assuming that the list passed into `bug()` is accessible to the `__del__()` method, it could execute a statement to the effect of `"del list[0]"`, and assuming this was the last reference to that object, it would free the memory associated with it, thereby invalidating `item`.

The solution, once you know the source of the problem, is easy: temporarily increment the reference count. The correct version of the function reads:

```
void
```

```

no_bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);

    Py_INCREF(item);
    PyList_SetItem(list, 1, PyInt_FromLong(0L));
    PyObject_Print(item, stdout, 0);
    Py_DECREF(item);
}

```

This is a true story. An older version of Python contained variants of this bug and someone spent a considerable amount of time in a C debugger to figure out why his `__del__()` methods would fail...

The second case of problems with a borrowed reference is a variant involving threads. Normally, multiple threads in the Python interpreter can't get in each other's way, because there is a global lock protecting Python's entire object space. However, it is possible to temporarily release this lock using the macro `Py_BEGIN_ALLOW_THREADS`, and to re-acquire it using `Py_END_ALLOW_THREADS`. This is common around blocking I/O calls, to let other threads use the processor while waiting for the I/O to complete. Obviously, the following function has the same problem as the previous one:

```

void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);
    Py_BEGIN_ALLOW_THREADS
    ...some blocking I/O call...
    Py_END_ALLOW_THREADS
    PyObject_Print(item, stdout, 0); /* BUG! */
}

```

1.10.4 NULL Pointers

In general, functions that take object references as arguments do not expect you to pass them NULL pointers, and will dump core (or cause later core dumps) if you do so. Functions that return object references generally return NULL only to indicate that an exception occurred. The reason for not testing for NULL arguments is that functions often pass the objects they receive on to other function -- if each function were to test for NULL, there would be a lot of redundant tests and the code would run more slowly.

It is better to test for NULL only at the ``source:" when a pointer that may be NULL is received, for example, from `malloc()` or from a function that may raise an exception.

The macros `Py_INCREF()` and `Py_DECREF()` do not check for NULL pointers -- however, their variants `Py_XINCREASEF()` and `Py_XDECREASEF()` do.

The macros for checking for a particular object type (`Pytype_Check()`) don't check for NULL pointers -- again, there is much code that calls several of these in a row to test an object against various different expected types, and this would generate redundant tests. There are no variants with NULL checking.

The C function calling mechanism guarantees that the argument list passed to C functions (`args` in the examples) is never NULL -- in fact it guarantees that it is always a tuple.[1.4](#)

It is a severe error to ever let a NULL pointer ``escape" to the Python user.

Footnotes

... tuple.[1.4](#)

These guarantees don't hold when you use the ``old" style calling convention -- this is still found in much existing code.

1.11 Writing Extensions in C++

It is possible to write extension modules in C++. Some restrictions apply. If the main program (the Python interpreter) is compiled and linked by the C compiler, global or static objects with constructors cannot be used. This is not a problem if the main program is linked by the C++ compiler. Functions that will be called by the Python interpreter (in particular, module initialization functions) have to be declared using `extern "C"`. It is unnecessary to enclose the Python header files in `extern "C" { ... }` -- they use this form already if the symbol `__cplusplus` is defined (all recent C++ compilers define this symbol).

Previous: [1.11 Writing Extensions in](#) **Up:** [1. Extending Python with](#) **Next:** [2. Defining New Types](#)

1.12 Providing a C API for an Extension Module

Many extension modules just provide new functions and types to be used from Python, but sometimes the code in an extension module can be useful for other extension modules. For example, an extension module could implement a type "collection" which works like lists without order. Just like the standard Python list type has a C API which permits extension modules to create and manipulate lists, this new collection type should have a set of C functions for direct manipulation from other extension modules.

At first sight this seems easy: just write the functions (without declaring them `static`, of course), provide an appropriate header file, and document the C API. And in fact this would work if all extension modules were always linked statically with the Python interpreter. When modules are used as shared libraries, however, the symbols defined in one module may not be visible to another module. The details of visibility depend on the operating system; some systems use one global namespace for the Python interpreter and all extension modules (Windows, for example), whereas others require an explicit list of imported symbols at module link time (AIX is one example), or offer a choice of different strategies (most Unices). And even if symbols are globally visible, the module whose functions one wishes to call might not have been loaded yet!

Portability therefore requires not to make any assumptions about symbol visibility. This means that all symbols in extension modules should be declared `static`, except for the module's initialization function, in order to avoid name clashes with other extension modules (as discussed in section [1.4](#)). And it means that symbols that *should* be accessible from other extension modules must be exported in a different way.

Python provides a special mechanism to pass C-level information (pointers) from one extension module to another one: CObjects. A CObject is a Python data type which stores a pointer (`void *`). CObjects can only be created and accessed via their C API, but they can be passed around like any other Python object. In particular, they can be assigned to a name in an extension module's namespace. Other extension modules can then import this module, retrieve the

value of this name, and then retrieve the pointer from the CObject.

There are many ways in which CObjects can be used to export the C API of an extension module. Each name could get its own CObject, or all C API pointers could be stored in an array whose address is published in a CObject. And the various tasks of storing and retrieving the pointers can be distributed in different ways between the module providing the code and the client modules.

The following example demonstrates an approach that puts most of the burden on the writer of the exporting module, which is appropriate for commonly used library modules. It stores all C API pointers (just one in the example!) in an array of `void` pointers which becomes the value of a CObject. The header file corresponding to the module provides a macro that takes care of importing the module and retrieving its C API pointers; client modules only have to call this macro before accessing the C API.

The exporting module is a modification of the `spam` module from section [1.1](#). The function `spam.system()` does not call the C library function `system()` directly, but a function `PySpam_System()`, which would of course do something more complicated in reality (such as adding ```spam``` to every command). This function `PySpam_System()` is also exported to other extension modules.

The function `PySpam_System()` is a plain C function, declared `static` like everything else:

```
static int
PySpam_System(const char *command)
{
    return system(command);
}
```

The function `spam_system()` is modified in a trivial way:

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = PySpam_System(command);
}
```

```
    return Py_BuildValue("i", sts);
}
```

In the beginning of the module, right after the line

```
#include "Python.h"
```

two more lines must be added:

```
#define SPAM_MODULE
#include "spammodule.h"
```

The `#define` is used to tell the header file that it is being included in the exporting module, not a client module. Finally, the module's initialization function must take care of initializing the C API pointer array:

```
PyMODINIT_FUNC
initspam(void)
{
    PyObject *m;
    static void *PySpam_API[PySpam_API_pointers];
    PyObject *c_api_object;

    m = Py_InitModule("spam", SpamMethods);
    if (m == NULL)
        return;

    /* Initialize the C API pointer array */
    PySpam_API[PySpam_System_NUM] = (void *)PySpam_System;

    /* Create a CObject containing the API pointer array's address */
    c_api_object = PyCObject_FromVoidPtr((void *)PySpam_API, NULL);

    if (c_api_object != NULL)
        PyModule_AddObject(m, "_C_API", c_api_object);
}
```

Note that `PySpam_API` is declared `static`; otherwise the pointer array would disappear when `initspam()` terminates!

The bulk of the work is in the header file `spammodule.h`, which looks like this:

```
#ifndef Py_SPAMMODULE_H
#define Py_SPAMMODULE_H
#ifdef __cplusplus
extern "C" {
#endif
```

```

/* Header file for spammodule */

/* C API functions */
#define PySpam_System_NUM 0
#define PySpam_System_RETURN int
#define PySpam_System_PROTO (const char *command)

/* Total number of C API pointers */
#define PySpam_API_pointers 1

#ifdef SPAM_MODULE
/* This section is used when compiling spammodule.c */

static PySpam_System_RETURN PySpam_System PySpam_System_PROTO;

#else
/* This section is used in modules that use spammodule's API */

static void **PySpam_API;

#define PySpam_System \
  (*(PySpam_System_RETURN (*)(PySpam_System_PROTO)) PySpam_API[PySpam_S

/* Return -1 and set exception on error, 0 on success. */
static int
import_spam(void)
{
    PyObject *module = PyImport_ImportModule("spam");

    if (module != NULL) {
        PyObject *c_api_object = PyObject_GetAttrString(module, "_C_
        if (c_api_object == NULL)
            return -1;
        if (PyObject_Check(c_api_object))
            PySpam_API = (void **)PyObject_AsVoidPtr(c_api_object);
        Py_DECREF(c_api_object);
    }
    return 0;
}

#endif

#ifdef __cplusplus
}
#endif

#endif /* !defined(Py_SPAMMODULE_H) */

```

All that a client module must do in order to have access to the function `PySpam_System()` is to call the function (or rather macro)

`import_spam()` in its initialization function:

```
PyMODINIT_FUNC
initclient(void)
{
    PyObject *m;

    m = Py_InitModule("client", ClientMethods);
    if (m == NULL)
        return;
    if (import_spam() < 0)
        return;
    /* additional initialization can happen here */
}
```

The main disadvantage of this approach is that the file `spammodule.h` is rather complicated. However, the basic structure is the same for each function that is exported, so it has to be learned only once.

Finally it should be mentioned that CObjects offer additional functionality, which is especially useful for memory allocation and deallocation of the pointer stored in a CObject. The details are described in the [Python/C API Reference Manual](#) in the section ```CObjects``` and in the implementation of CObjects (files `Include/cobject.h` and `Objects/cobject.c` in the Python source code distribution).

2. Defining New Types

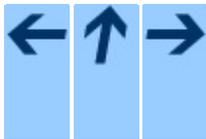

As mentioned in the last chapter, Python allows the writer of an extension module to define new types that can be manipulated from Python code, much like strings and lists in core Python.

This is not hard; the code for all extension types follows a pattern, but there are some details that you need to understand before you can get started.

Note: The way new types are defined changed dramatically (and for the better) in Python 2.2. This document documents how to define new types for Python 2.2 and later. If you need to support older versions of Python, you will need to refer to older versions of this documentation.

Previous: [2. Defining New Types](#) **Up:** [2. Defining New Types](#) **Next:** [2.1.1 Adding data and](#)

2.1 The Basics

The Python runtime sees all Python objects as variables of type `PyObject*`. A `PyObject` is not a very magnificent object - it just contains the refcount and a pointer to the object's "type object". This is where the action is; the type object determines which (C) functions get called when, for instance, an attribute gets looked up on an object or it is multiplied by another object. These C functions are called "type methods" to distinguish them from things like `[] .append` (which we call "object methods").

So, if you want to define a new object type, you need to create a new type object.

This sort of thing can only be explained by example, so here's a minimal, but complete, module that defines a new type:

```
#include <Python.h>

typedef struct {
    PyObject_HEAD
    /* Type-specific fields go here. */
} noddy_NoddyObject;

static PyTypeObject noddy_NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0, /*ob_size*/
    "noddy.Noddy", /*tp_name*/
    sizeof(noddy_NoddyObject), /*tp_basicsize*/
    0, /*tp_itemsize*/
    0, /*tp_dealloc*/
    0, /*tp_print*/
    0, /*tp_getattr*/
    0, /*tp_setattr*/
    0, /*tp_compare*/
    0, /*tp_repr*/
    0, /*tp_as_number*/
    0, /*tp_as_sequence*/
    0, /*tp_as_mapping*/
    0, /*tp_hash */
    0, /*tp_call*/
    0, /*tp_str*/
    0, /*tp_getattro*/
    0, /*tp_setattro*/
    0, /*tp_as_buffer*/
    Py_TPFLAGS_DEFAULT, /*tp_flags*/
    "Noddy objects", /* tp_doc */
}
```

```

};

static PyMethodDef noddy_methods[] = {
    {NULL} /* Sentinel */
};

#ifdef PyMODINIT_FUNC /* declarations for DLL import/export */
#define PyMODINIT_FUNC void
#endif
PyMODINIT_FUNC
initnoddy(void)
{
    PyObject* m;

    noddy_NoddyType.tp_new = PyType_GenericNew;
    if (PyType_Ready(&noddy_NoddyType) < 0)
        return;

    m = Py_InitModule3("noddy", noddy_methods,
                      "Example module that creates an extension typ

    Py_INCREF(&noddy_NoddyType);
    PyModule_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType);
}

```

Download as text (original file name: noddy.c).

Now that's quite a bit to take in at once, but hopefully bits will seem familiar from the last chapter.

The first bit that will be new is:

```

typedef struct {
    PyObject_HEAD
} noddy_NoddyObject;

```

This is what a Noddy object will contain--in this case, nothing more than every Python object contains, namely a refcount and a pointer to a type object. These are the fields the `PyObject_HEAD` macro brings in. The reason for the macro is to standardize the layout and to enable special debugging fields in debug builds. Note that there is no semicolon after the `PyObject_HEAD` macro; one is included in the macro definition. Be wary of adding one by accident; it's easy to do from habit, and your compiler might not complain, but someone else's probably will! (On Windows, MSVC is known to call this an error and refuse to compile the code.)

For contrast, let's take a look at the corresponding definition for standard Python integers:

```
typedef struct {
    PyObject_HEAD
    long ob_ival;
} PyIntObject;
```

Moving on, we come to the crunch -- the type object.

```
static PyTypeObject noddy_NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0, /*ob_size*/
    "noddy.Noddy", /*tp_name*/
    sizeof(noddy_NoddyObject), /*tp_basicsize*/
    0, /*tp_itemsize*/
    0, /*tp_dealloc*/
    0, /*tp_print*/
    0, /*tp_getattr*/
    0, /*tp_setattr*/
    0, /*tp_compare*/
    0, /*tp_repr*/
    0, /*tp_as_number*/
    0, /*tp_as_sequence*/
    0, /*tp_as_mapping*/
    0, /*tp_hash */
    0, /*tp_call*/
    0, /*tp_str*/
    0, /*tp_getattro*/
    0, /*tp_setattro*/
    0, /*tp_as_buffer*/
    Py_TPFLAGS_DEFAULT, /*tp_flags*/
    "Noddy objects", /* tp_doc */
};
```

Now if you go and look up the definition of `PyTypeObject` in `object.h` you'll see that it has many more fields than the definition above. The remaining fields will be filled with zeros by the C compiler, and it's common practice to not specify them explicitly unless you need them.

This is so important that we're going to pick the top of it apart still further:

```
PyObject_HEAD_INIT(NULL)
```

This line is a bit of a wart; what we'd like to write is:

```
PyObject_HEAD_INIT(&PyType_Type)
```

as the type of a type object is ``type``, but this isn't strictly conforming C and some compilers complain. Fortunately, this member will be filled in for us by `PyType_Ready()`.

```
0, /* ob_size */
```

The `ob_size` field of the header is not used; its presence in the type structure is a historical artifact that is maintained for binary compatibility with extension modules compiled for older versions of Python. Always set this field to zero.

```
"noddy.Noddy", /* tp_name */
```

The name of our type. This will appear in the default textual representation of our objects and in some error messages, for example:

```
>>> "" + noddy.new_noddy()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: cannot add type "noddy.Noddy" to string
```

Note that the name is a dotted name that includes both the module name and the name of the type within the module. The module in this case is `noddy` and the type is `Noddy`, so we set the type name to `noddy.Noddy`.

```
sizeof(noddy_NoddyObject), /* tp_basicsize */
```

This is so that Python knows how much memory to allocate when you call `PyObject_New()`.

Note: If you want your type to be subclassable from Python, and your type has the same `tp_basicsize` as its base type, you may have problems with multiple inheritance. A Python subclass of your type will have to list your type first in its `__bases__`, or else it will not be able to call your type's `__new__` method without getting an error. You can avoid this problem by ensuring that your type has a larger value for `tp_basicsize` than its base type does. Most of the time, this will be true anyway, because either your base type will be `object`, or else you will be adding data members to your base type, and therefore increasing its size.

```
0, /* tp_itemsize */
```

This has to do with variable length objects like lists and strings. Ignore this for

now.

Skipping a number of type methods that we don't provide, we set the class flags to `Py_TPFLAGS_DEFAULT`.

```
Py_TPFLAGS_DEFAULT,          /*tp_flags*/
```

All types should include this constant in their flags. It enables all of the members defined by the current version of Python.

We provide a doc string for the type in `tp_doc`.

```
"Noddy objects",            /* tp_doc */
```

Now we get into the type methods, the things that make your objects different from the others. We aren't going to implement any of these in this version of the module. We'll expand this example later to have more interesting behavior.

For now, all we want to be able to do is to create new `Noddy` objects. To enable object creation, we have to provide a `tp_new` implementation. In this case, we can just use the default implementation provided by the API function `PyType_GenericNew()`. We'd like to just assign this to the `tp_new` slot, but we can't, for portability sake. On some platforms or compilers, we can't statically initialize a structure member with a function defined in another C module, so, instead, we'll assign the `tp_new` slot in the module initialization function just before calling `PyType_Ready()`:

```
noddy_NoddyType.tp_new = PyType_GenericNew;  
if (PyType_Ready(&noddy_NoddyType) < 0)  
    return;
```

All the other type methods are `NULL`, so we'll go over them later -- that's for a later section!

Everything else in the file should be familiar, except for some code in `initnoddy()`:

```
if (PyType_Ready(&noddy_NoddyType) < 0)  
    return;
```

This initializes the `Noddy` type, filling in a number of members, including `ob_type` that we initially set to `NULL`.

```
PyModule_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType);
```

This adds the type to the module dictionary. This allows us to create **Noddy** instances by calling the **Noddy** class:

```
>>> import noddy
>>> mynoddy = noddy.Noddy()
```

That's it! All that remains is to build it; put the above code in a file called **noddy.c** and

```
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",
      ext_modules=[Extension("noddy", ["noddy.c"])]])
```

in a file called **setup.py**; then typing

```
$ python setup.py build
```

at a shell should produce a file **noddy.so** in a subdirectory; move to that directory and fire up Python -- you should be able to `import noddy` and play around with **Noddy** objects.

That wasn't so hard, was it?

Of course, the current **Noddy** type is pretty uninteresting. It has no data and doesn't do anything. It can't even be subclassed.

2.1.1 Adding data and methods to the Basic example

Let's expend the basic example to add some data and methods. Let's also make the type usable as a base class. We'll create a new module, `noddy2` that adds these capabilities:

```
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last; /* last name */
    int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    self->ob_type->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->last = PyString_FromString("");
        if (self->last == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->number = 0;
    }
}
```

```

    }

    return (PyObject *)self;
}

static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|00i", kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}

static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
     "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
     "last name"},
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyString_FromString("%s %s");
    }

```

```

        if (format == NULL)
            return NULL;
    }

    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }

    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }

    args = Py_BuildValue("OO", self->first, self->last);
    if (args == NULL)
        return NULL;

    result = PyString_Format(format, args);
    Py_DECREF(args);

    return result;
}

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    },
    {NULL} /* Sentinel */
};

static PyTypeObject NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0, /*ob_size*/
    "noddy.Noddy", /*tp_name*/
    sizeof(Noddy), /*tp_basicsize*/
    0, /*tp_itemsize*/
    (destructor)Noddy_dealloc, /*tp_dealloc*/
    0, /*tp_print*/
    0, /*tp_getattr*/
    0, /*tp_setattr*/
    0, /*tp_compare*/
    0, /*tp_repr*/
    0, /*tp_as_number*/
    0, /*tp_as_sequence*/
    0, /*tp_as_mapping*/
    0, /*tp_hash */
    0, /*tp_call*/
    0, /*tp_str*/
    0, /*tp_getattro*/
    0, /*tp_setattro*/
    0, /*tp_as_buffer*/

```

```

Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE, /*tp_flags*/
"Noddy objects",          /* tp_doc */
0,                        /* tp_traverse */
0,                        /* tp_clear */
0,                        /* tp_richcompare */
0,                        /* tp_weaklistoffset */
0,                        /* tp_iter */
0,                        /* tp_iternext */
Noddy_methods,          /* tp_methods */
Noddy_members,         /* tp_members */
0,                        /* tp_getset */
0,                        /* tp_base */
0,                        /* tp_dict */
0,                        /* tp_descr_get */
0,                        /* tp_descr_set */
0,                        /* tp_dictoffset */
(initproc)Noddy_init,   /* tp_init */
0,                        /* tp_alloc */
Noddy_new,              /* tp_new */
};

static PyMethodDef module_methods[] = {
    {NULL} /* Sentinel */
};

#ifdef PyMODINIT_FUNC /* declarations for DLL import/export */
#define PyMODINIT_FUNC void
#endif
PyMODINIT_FUNC
initnoddy2(void)

    PyModule_AddObject(m, "Noddy", (PyObject *)&NoddyType);
}

```

[Download as text \(original file name: noddy2.c\).](#)

This version of the module has a number of changes.

We've added an extra include:

```
#include "structmember.h"
```

This include provides declarations that we use to handle attributes, as described a bit later.

The name of the Noddy object structure has been shortened to `Noddy`. The type object name has been shortened to `NoddyType`.

The `Noddy` type now has three data attributes, *first*, *last*, and *number*. The *first* and *last* variables are Python strings containing first and last names. The *number* attribute is an integer.

The object structure is updated accordingly:

```
typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;
```

Because we now have data to manage, we have to be more careful about object allocation and deallocation. At a minimum, we need a deallocation method:

```
static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    self->ob_type->tp_free((PyObject*)self);
}
```

which is assigned to the `tp_dealloc` member:

```
(destructor)Noddy_dealloc, /*tp_dealloc*/
```

This method decrements the reference counts of the two Python attributes. We use `Py_XDECREF()` here because the `first` and `last` members could be `NULL`. It then calls the `tp_free` member of the object's type to free the object's memory. Note that the object's type might not be `NoddyType`, because the object may be an instance of a subclass.

We want to make sure that the first and last names are initialized to empty strings, so we provide a new method:

```

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL)
            {
                Py_DECREF(self);
                return NULL;
            }

        self->last = PyString_FromString("");
        if (self->last == NULL)
            {
                Py_DECREF(self);
                return NULL;
            }

        self->number = 0;
    }

    return (PyObject *)self;
}

```

and install it in the `tp_new` member:

```

Noddy_new, /* tp_new */

```

The `new` member is responsible for creating (as opposed to initializing) objects of the type. It is exposed in Python as the `__new__()` method. See the paper titled "Unifying types and classes in Python" for a detailed discussion of the `__new__()` method. One reason to implement a new method is to assure the initial values of instance variables. In this case, we use the new method to make sure that the initial values of the members `first` and `last` are not `NULL`. If we didn't care whether the initial values were `NULL`, we could have used `PyType_GenericNew()` as our new method, as we did before. `PyType_GenericNew()` initializes all of the instance variable members to `NULL`.

The new method is a static method that is passed the type being instantiated and any arguments passed when the type was called, and that returns the new object created. New methods always accept positional and keyword arguments, but they often ignore the arguments, leaving the argument handling to initializer

methods. Note that if the type supports subclassing, the type passed may not be the type being defined. The new method calls the `tp_alloc` slot to allocate memory. We don't fill the `tp_alloc` slot ourselves. Rather `PyType_Ready()` fills it for us by inheriting it from our base class, which is `object` by default. Most types use the default allocation.

Note: If you are creating a co-operative `tp_new` (one that calls a base type's `tp_new` or `__new__`), you must *not* try to determine what method to call using method resolution order at runtime. Always statically determine what type you are going to call, and call its `tp_new` directly, or via `type->tp_base->tp_new`. If you do not do this, Python subclasses of your type that also inherit from other Python-defined classes may not work correctly. (Specifically, you may not be able to create instances of such subclasses without getting a `TypeError`.)

We provide an initialization function:

```
static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|00i", kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}
```

by filling the `tp_init` slot.

```
(initproc)Noddy_init,          /* tp_init */
```

The `tp_init` slot is exposed in Python as the `__init__()` method. It is used to initialize an object after it's created. Unlike the new method, we can't guarantee that the initializer is called. The initializer isn't called when unpickling objects and it can be overridden. Our initializer accepts arguments to provide initial values for our instance. Initializers always accept positional and keyword arguments.

Initializers can be called multiple times. Anyone can call the `__init__()` method on our objects. For this reason, we have to be extra careful when assigning the new values. We might be tempted, for example to assign the `first` member like this:

```
if (first) {
    Py_XDECREF(self->first);
    Py_INCREF(first);
    self->first = first;
}
```

But this would be risky. Our type doesn't restrict the type of the `first` member, so it could be any kind of object. It could have a destructor that causes code to be executed that tries to access the `first` member. To be paranoid and protect ourselves against this possibility, we almost always reassign members before decrementing their reference counts. When don't we have to do this?

- when we absolutely know that the reference count is greater than 1
- when we know that deallocation of the object [2.1](#) will not cause any calls back into our type's code
- when decrementing a reference count in a `tp_dealloc` handler when garbage-collections is not supported [2.2](#)
-

We want to want to expose our instance variables as attributes. There are a number of ways to do that. The simplest way is to define member definitions:

```
static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
     "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
```

```

        "last name"},
        {"number", T_INT, offsetof(Noddy, number), 0,
         "noddy number"},
        {NULL} /* Sentinel */
};

```

and put the definitions in the `tp_members` slot:

```

    Noddy_members,          /* tp_members */

```

Each member definition has a member name, type, offset, access flags and documentation string. See the "Generic Attribute Management" section below for details.

A disadvantage of this approach is that it doesn't provide a way to restrict the types of objects that can be assigned to the Python attributes. We expect the first and last names to be strings, but any Python objects can be assigned. Further, the attributes can be deleted, setting the C pointers to `NULL`. Even though we can make sure the members are initialized to non-`NULL` values, the members can be set to `NULL` if the attributes are deleted.

We define a single method, `name`, that outputs the objects name as the concatenation of the first and last names.

```

static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyString_FromString("%s %s");
        if (format == NULL)
            return NULL;
    }

    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }

    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }

    args = Py_BuildValue("OO", self->first, self->last);

```

```

    if (args == NULL)
        return NULL;

    result = PyString_Format(format, args);
    Py_DECREF(args);

    return result;
}

```

The method is implemented as a C function that takes a `Noddy` (or `Noddy` subclass) instance as the first argument. Methods always take an instance as the first argument. Methods often take positional and keyword arguments as well, but in this case we don't take any and don't need to accept a positional argument tuple or keyword argument dictionary. This method is equivalent to the Python method:

```

def name(self):
    return "%s %s" % (self.first, self.last)

```

Note that we have to check for the possibility that our `first` and `last` members are `NULL`. This is because they can be deleted, in which case they are set to `NULL`. It would be better to prevent deletion of these attributes and to restrict the attribute values to be strings. We'll see how to do that in the next section.

Now that we've defined the method, we need to create an array of method definitions:

```

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    },
    {NULL} /* Sentinel */
};

```

and assign them to the `tp_methods` slot:

```

    Noddy_methods, /* tp_methods */

```

Note that we used the `METH_NOARGS` flag to indicate that the method is passed no arguments.

Finally, we'll make our type usable as a base class. We've written our methods carefully so far so that they don't make any assumptions about the type of the

object being created or used, so all we need to do is to add the `Py_TPFLAGS_BASETYPE` to our class flag definition:

```
Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE, /*tp_flags*/
```

We rename `initnoddy()` to `initnoddy2()` and update the module name passed to `Py_InitModule3()`.

Finally, we update our `setup.py` file to build the new module:

```
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",

Footnotes

... object^{[2.1](#)}

This is true when we know that the object is a basic type, like a string or a float

... supported^{[2.2](#)}

We relied on this in the `tp_dealloc` handler in this example, because our type doesn't support garbage collection. Even if a type supports garbage collection, there are calls that can be made to ```untrack``` the object from garbage collection, however, these calls are advanced and not covered here.

2.1.2 Providing finer control over data attributes

In this section, we'll provide finer control over how the `first` and `last` attributes are set in the Noddy example. In the previous version of our module, the instance variables `first` and `last` could be set to non-string values or even deleted. We want to make sure that these attributes always contain strings.

```
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    self->ob_type->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->last = PyString_FromString("");
        if (self->last == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->number = 0;
    }
}
```

```

    return (PyObject *)self;
}

static int

```

[Download as text \(original file name: nodd3.c\).](#)

To provide greater control, over the **first** and **last** attributes, we'll use custom getter and setter functions. Here are the functions for getting and setting

the `first` attribute:

```
Noddy_getfirst(Noddy *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Noddy_setfirst(Noddy *self, PyObject *value, void *closure)
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete the first attrib
        return -1;
    }

    if (! PyString_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
            "The first attribute value must be a string");
        return -1;
    }

    Py_DECREF(self->first);
    Py_INCREF(value);
    self->first = value;

    return 0;
}
```

The getter function is passed a `Noddy` object and a `closure`, which is void pointer. In this case, the closure is ignored. (The closure supports an advanced usage in which definition data is passed to the getter and setter. This could, for example, be used to allow a single set of getter and setter functions that decide the attribute to get or set based on data in the closure.)

The setter function is passed the `Noddy` object, the new value, and the closure. The new value may be `NULL`, in which case the attribute is being deleted. In our setter, we raise an error if the attribute is deleted or if the attribute value is not a string.

We create an array of `PyGetSetDef` structures:

```
static PyGetSetDef Noddy_getseters[] = {
    {"first",
     (getter)Noddy_getfirst, (setter)Noddy_setfirst,
     "first name",
     NULL},
}
```

```

        {"last",
         (getter)Noddy_getlast, (setter)Noddy_setlast,
         "last name",
         NULL},
        {NULL} /* Sentinel */
};

```

and register it in the `tp_getset` slot:

```

        Noddy_getseters,          /* tp_getset */

```

to register out attribute getters and setters.

The last item in a `PyGetSetDef` structure is the closure mentioned above. In this case, we aren't using the closure, so we just pass `NULL`.

We also remove the member definitions for these attributes:

```

static PyMemberDef Noddy_members[] = {
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

```

We also need to update the `tp_init` handler to only allow strings^{2.3} to be passed:

```

static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|SSi", kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }

    if (last) {
        tmp = self->last;

```

```
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }
    return 0;
}
```

With these changes, we can assure that the `first` and `last` members are never `NULL` so we can remove checks for `NULL` values in almost all cases. This means that most of the `Py_XDECREF()` calls can be converted to `Py_DECREF()` calls. The only place we can't change these calls is in the deallocator, where there is the possibility that the initialization of these members failed in the constructor.

We also rename the module initialization function and module name in the initialization function, as we did before, and we add an extra definition to the `setup.py` file.

Footnotes

... strings^{2.3}

We now know that the `first` and `last` members are strings, so perhaps we could be less careful about decrementing their reference counts, however, we accept instances of string subclasses. Even though deallocating normal strings won't call back into our objects, we can't guarantee that deallocating an instance of a string subclass won't. call back into out objects.

Previous: [2.1.2 Providing finer control](#) **Up:** [2.1 The Basics](#) **Next:** [2.2 Type Methods](#)

2.1.3 Supporting cyclic garbage collection

Python has a cyclic-garbage collector that can identify unneeded objects even when their reference counts are not zero. This can happen when objects are involved in cycles. For example, consider:

```
>>> l = []
>>> l.append(l)
>>> del l
```

In this example, we create a list that contains itself. When we delete it, it still has a reference from itself. Its reference count doesn't drop to zero. Fortunately, Python's cyclic-garbage collector will eventually figure out that the list is garbage and free it.

In the second version of the Noddy example, we allowed any kind of object to be stored in the `first` or `last` attributes^{2.4}. This means that Noddy objects can participate in cycles:

```
>>> import noddy2
>>> n = noddy2.Noddy()
>>> l = [n]
>>> n.first = l
```

This is pretty silly, but it gives us an excuse to add support for the cyclic-garbage collector to the Noddy example. To support cyclic garbage collection, types need to fill two slots and set a class flag that enables these slots:

```
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;

static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;

    if (self->first) {
```

```

        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }

    return 0;
}

static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);

    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);

    return 0;
}

Download as text (original file name: noddy4.c).

The traversal method provides access to subobjects that could participate in cycles:

```
static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;

    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }

    return 0;
}
```

For each subobject that can participate in cycles, we need to call the `visit()` function, which is passed to the traversal method. The `visit()` function takes as arguments the subobject and the extra argument `arg` passed to the traversal method. It returns an integer value that must be returned if it is non-zero.

Python 2.4 and higher provide a `Py_VISIT()` macro that automates calling visit functions. With `Py_VISIT()`, `Noddy_traverse()` can be simplified:

```
static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}
```

Note: Note that the `tp_traverse` implementation must name its arguments exactly `visit` and `arg` in order to use `Py_VISIT()`. This is to encourage uniformity across these boring implementations.

We also need to provide a method for clearing any subobjects that can participate in cycles. We implement the method and reimplement the deallocator to use it:

```

static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);

    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);

    return 0;
}

static void
Noddy_dealloc(Noddy* self)
{
    Noddy_clear(self);
    self->ob_type->tp_free((PyObject*)self);
}

```

Notice the use of a temporary variable in `Noddy_clear()`. We use the temporary variable so that we can set each member to `NULL` before decrementing its reference count. We do this because, as was discussed earlier, if the reference count drops to zero, we might cause code to run that calls back into the object. In addition, because we now support garbage collection, we also have to worry about code being run that triggers garbage collection. If garbage collection is run, our `tp_traverse` handler could get called. We can't take a chance of having `Noddy_traverse()` called when a member's reference count has dropped to zero and its value hasn't been set to `NULL`.

Python 2.4 and higher provide a `Py_CLEAR()` that automates the careful decrementing of reference counts. With `Py_CLEAR()`, the `Noddy_clear()` function can be simplified:

```

static int
Noddy_clear(Noddy *self)
{
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}

```

Finally, we add the `Py_TPFLAGS_HAVE_GC` flag to the class flags:

That's pretty much it. If we had written custom `tp_alloc` or `tp_free` slots, we'd need to modify them for cyclic-garbage collection. Most extensions will use the versions automatically provided.

Footnotes

... attributes^{2.4}

Even in the third version, we aren't guaranteed to avoid cycles. Instances of string subclasses are allowed and string subclasses could allow cycles even if normal strings don't.

2.2 Type Methods

This section aims to give a quick fly-by on the various type methods you can implement and what they do.

Here is the definition of `PyTypeObject`, with some fields only used in debug builds omitted:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>" */
    int tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    printfunc tp_print;
    getattrfunc tp_getattr;
    setattrfunc tp_setattr;
    cmpfunc tp_compare;
    reprfunc tp_repr;

    /* Method suites for standard classes */

    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility) */

    hashfunc tp_hash;
    ternaryfunc tp_call;
    reprfunc tp_str;
    getattrofunc tp_getattro;
    setattrofunc tp_setattro;

    /* Functions to access object as input/output buffer */
    PyBufferProcs *tp_as_buffer;

    /* Flags to define presence of optional/expanded features */
    long tp_flags;

    char *tp_doc; /* Documentation string */

    /* Assigned meaning in release 2.0 */
    /* call function for all accessible objects */
    traverseproc tp_traverse;
```

```

/* delete references to contained objects */
inquiry tp_clear;

/* Assigned meaning in release 2.1 */
/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Added in release 2.2 */
/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;
descrsetfunc tp_descr_set;
long tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new;
freefunc tp_free; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
PyObject *tp_cache;
PyObject *tp_subclasses;
PyObject *tp_weaklist;
} PyTypeObject;

```

[Download as text \(original file name: typestruct.h\).](#)

Now that's a *lot* of methods. Don't worry too much though - if you have a type you want to define, the chances are very good that you will only implement a handful of these.

As you probably expect by now, we're going to go over this and give more information about the various handlers. We won't go in the order they are defined in the structure, because there is a lot of historical baggage that impacts the ordering of the fields; be sure your type initialization keeps the fields in the right order! It's often easiest to find an example that includes all the fields you

need (even if they're initialized to 0) and then change the values to suit your new type.

```
char *tp_name; /* For printing */
```

The name of the type - as mentioned in the last section, this will appear in various places, almost entirely for diagnostic purposes. Try to choose something that will be helpful in such a situation!

```
int tp_basicsize, tp_itemsize; /* For allocation */
```

These fields tell the runtime how much memory to allocate when new objects of this type are created. Python has some built-in support for variable length structures (think: strings, lists) which is where the `tp_itemsize` field comes in. This will be dealt with later.

```
char *tp_doc;
```

Here you can put a string (or its address) that you want returned when the Python script references `obj.__doc__` to retrieve the doc string.

Now we come to the basic type methods--the ones most extension types will implement.

Previous: [2.2 Type Methods](#) Up: [2.2 Type Methods](#) Next: [2.2.2 Object Presentation](#)

2.2.1 Finalization and De-allocation

```
destructor tp_dealloc;
```

This function is called when the reference count of the instance of your type is reduced to zero and the Python interpreter wants to reclaim it. If your type has memory to free or other clean-up to perform, put it here. The object itself needs to be freed here as well. Here is an example of this function:

```
static void
newdatatype_dealloc(newdatatypeobject * obj)
{
    free(obj->obj_UnderlyingDatatypePtr);
    obj->ob_type->tp_free(obj);
}
```

One important requirement of the deallocator function is that it leaves any pending exceptions alone. This is important since deallocators are frequently called as the interpreter unwinds the Python stack; when the stack is unwound due to an exception (rather than normal returns), nothing is done to protect the deallocators from seeing that an exception has already been set. Any actions which a deallocator performs which may cause additional Python code to be executed may detect that an exception has been set. This can lead to misleading errors from the interpreter. The proper way to protect against this is to save a pending exception before performing the unsafe action, and restoring it when done. This can be done using the `PyErr_Fetch()` and `PyErr_Restore()` functions:

```
static void
my_dealloc(PyObject *obj)
{
    PyObject *self = (PyObject *) obj;
    PyObject *cbresult;

    if (self->my_callback != NULL) {
        PyObject *err_type, *err_value, *err_traceback;
        int have_error = PyErr_Occurred() ? 1 : 0;

        if (have_error)
            PyErr_Fetch(&err_type, &err_value, &err_traceback);

        cbresult = PyObject_CallObject(self->my_callback, NULL);
        if (cbresult == NULL)
            PyErr_WriteUnraisable(self->my_callback);
    }
}
```

```
    else
        Py_DECREF(cbresult);

    if (have_error)
        PyErr_Restore(err_type, err_value, err_traceback);

    Py_DECREF(self->my_callback);
}
obj->ob_type->tp_free((PyObject*)self);
}
```

[2.2.3 Attribute Management](#)

2.2.2 Object Presentation

In Python, there are three ways to generate a textual representation of an object: the `repr()` function (or equivalent back-tick syntax), the `str()` function, and the `print` statement. For most objects, the `print` statement is equivalent to the `str()` function, but it is possible to special-case printing to a `FILE*` if necessary; this should only be done if efficiency is identified as a problem and profiling suggests that creating a temporary string object to be written to a file is too expensive.

These handlers are all optional, and most types at most need to implement the `tp_str` and `tp_repr` handlers.

```
reprfunc tp_repr;
reprfunc tp_str;
printfunc tp_print;
```

The `tp_repr` handler should return a string object containing a representation of the instance for which it is called. Here is a simple example:

```
static PyObject *
newdatatype_repr(newdatatypeobject * obj)
{
    return PyString_FromFormat("Repr-ified_newdatatype{{size:\%d}}",
                               obj->obj_UnderlyingDatatypePtr->size)
}
```

If no `tp_repr` handler is specified, the interpreter will supply a representation that uses the type's `tp_name` and a uniquely-identifying value for the object.

The `tp_str` handler is to `str()` what the `tp_repr` handler described above is to `repr()`; that is, it is called when Python code calls `str()` on an instance of your object. Its implementation is very similar to the `tp_repr` function, but the resulting string is intended for human consumption. If `tp_str` is not specified, the `tp_repr` handler is used instead.

Here is a simple example:

```
static PyObject *
newdatatype_str(newdatatypeobject * obj)
{
```

```

        return PyString_FromFormat("Stringified_newdatatype{{size:%d}}"
                                   obj->obj_UnderlyingDatatypePtr->size)
    }

```

The print function will be called whenever Python needs to "print" an instance of the type. For example, if 'node' is an instance of type `TreeNode`, then the print function is called when Python code calls:

```
print node
```

There is a flags argument and one flag, `Py_PRINT_RAW`, and it suggests that you print without string quotes and possibly without interpreting escape sequences.

The print function receives a file object as an argument. You will likely want to write to that file object.

Here is a sample print function:

```

static int
newdatatype_print(newdatatypeobject *obj, FILE *fp, int flags)
{
    if (flags & Py_PRINT_RAW) {
        fprintf(fp, "<{newdatatype object--size: %d}>",
               obj->obj_UnderlyingDatatypePtr->size);
    }
    else {
        fprintf(fp, "\\<{newdatatype object--size: %d}>\\\"",
               obj->obj_UnderlyingDatatypePtr->size);
    }
    return 0;
}

```

Previous: [2.2.2 Object Presentation](#) **Up:** [2.2 Type Methods](#) **Next:** [2.2.3.1 Generic Attribute Management](#)

2.2.3 Attribute Management

For every object which can support attributes, the corresponding type must provide the functions that control how the attributes are resolved. There needs to be a function which can retrieve attributes (if any are defined), and another to set attributes (if setting attributes is allowed). Removing an attribute is a special case, for which the new value passed to the handler is `NULL`.

Python supports two pairs of attribute handlers; a type that supports attributes only needs to implement the functions for one pair. The difference is that one pair takes the name of the attribute as a `char *`, while the other accepts a `PyObject *`. Each type can use whichever pair makes more sense for the implementation's convenience.

```
getattrofunc tp_getattr;          /* char * version */
setattrofunc tp_setattr;
/* ... */
getattrofunc tp_getattrofunc;    /* PyObject * version */
setattrofunc tp_setattrofunc;
```

If accessing attributes of an object is always a simple operation (this will be explained shortly), there are generic implementations which can be used to provide the `PyObject *` version of the attribute management functions. The actual need for type-specific attribute handlers almost completely disappeared starting with Python 2.2, though there are many examples which have not been updated to use some of the new generic mechanism that is available.

Next: [2.2.5 Abstract Protocol Support](#)

2.2.4 Object Comparison

```
cmpfunc tp_compare;
```

The `tp_compare` handler is called when comparisons are needed and the object does not implement the specific rich comparison method which matches the requested comparison. (It is always used if defined and the `PyObject_Compare()` or `PyObject_Cmp()` functions are used, or if `cmp()` is used from Python.) It is analogous to the `__cmp__()` method. This function should return `-1` if *obj1* is less than *obj2*, `0` if they are equal, and `1` if *obj1* is greater than *obj2*. (It was previously allowed to return arbitrary negative or positive integers for less than and greater than, respectively; as of Python 2.2, this is no longer allowed. In the future, other return values may be assigned a different meaning.)

A `tp_compare` handler may raise an exception. In this case it should return a negative value. The caller has to test for the exception using `PyErr_Occurred()`.

Here is a sample implementation:

```
static int
newdatatype_compare(newdatatypeobject * obj1, newdatatypeobject * ob
{
    long result;

    if (obj1->obj_UnderlyingDatatypePtr->size <
        obj2->obj_UnderlyingDatatypePtr->size) {
        result = -1;
    }
    else if (obj1->obj_UnderlyingDatatypePtr->size >
             obj2->obj_UnderlyingDatatypePtr->size) {
        result = 1;
    }
    else {
        result = 0;
    }
    return result;
}
```

2.2.5 Abstract Protocol Support

Python supports a variety of *abstract* protocols; the specific interfaces provided to use these interfaces are documented in the [Python/C API Reference Manual](#) in the chapter ["Abstract Objects Layer."](#)

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-NULL. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```
PyNumberMethods  tp_as_number;  
PySequenceMethods tp_as_sequence;  
PyMappingMethods tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type `PyNumberMethods`, `PySequenceMethods`, or `PyMappingMethods`, respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of each of these in the `Objects` directory of the Python source distribution.

```
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a moderately pointless example:

```
static long  
newdatatype_hash(newdatatypeobject *obj)  
{  
    long result;  
    result = obj->obj_UnderlyingDatatypePtr->size;  
    result = result * 3;  
    return result;  
}
```

```
ternaryfunc tp_call;
```

This function is called when an instance of your data type is "called", for example, if `obj1` is an instance of your data type and the Python script contains `obj1('hello')`, the `tp_call` handler is invoked.

This function takes three arguments:

1. *arg1* is the instance of the data type which is the subject of the call. If the call is `obj1('hello')`, then *arg1* is `obj1`.
2. *arg2* is a tuple containing the arguments to the call. You can use `PyArg_ParseTuple()` to extract the arguments.
3. *arg3* is a dictionary of keyword arguments that were passed. If this is non-NULL and you support keyword arguments, use `PyArg_ParseTupleAndKeywords()` to extract the arguments. If you do not want to support keyword arguments and this is non-NULL, raise a `TypeError` with a message saying that keyword arguments are not supported.

Here is a desultory example of the implementation of the call function.

```
/* Implement the call function.
 * obj1 is the instance receiving the call.
 * obj2 is a tuple containing the arguments to the call, in this
 * case 3 strings.
 */
static PyObject *
newdatatype_call(newdatatypeobject *obj, PyObject *args, PyObject *o
{
    PyObject *result;
    char *arg1;
    char *arg2;
    char *arg3;

    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &arg2, &arg3)) {
        return NULL;
    }
    result = PyString_FromFormat(
        "Returning -- value: [%d] arg1: [%s] arg2: [%s] arg3: [%s]",
        obj->obj_UnderlyingDatatypePtr->size,
        arg1, arg2, arg3);
    printf("\%s", PyString_AS_STRING(result));
    return result;
}
```

```
}
```

XXX some fields need to be added here...

```
/* Added in release 2.2 */  
/* Iterators */  
getiterfunc tp_iter;  
iternextfunc tp_iternext;
```

These functions provide support for the iterator protocol. Any object which wishes to support iteration over its contents (which may be generated during iteration) must implement the `tp_iter` handler. Objects which are returned by a `tp_iter` handler must implement both the `tp_iter` and `tp_iternext` handlers. Both handlers take exactly one parameter, the instance for which they are being called, and return a new reference. In the case of an error, they should set an exception and return `NULL`.

For an object which represents an iterable collection, the `tp_iter` handler must return an iterator object. The iterator object is responsible for maintaining the state of the iteration. For collections which can support multiple iterators which do not interfere with each other (as lists and tuples do), a new iterator should be created and returned. Objects which can only be iterated over once (usually due to side effects of iteration) should implement this handler by returning a new reference to themselves, and should also implement the `tp_iternext` handler. File objects are an example of such an iterator.

Iterator objects should implement both handlers. The `tp_iter` handler should return a new reference to the iterator (this is the same as the `tp_iter` handler for objects which can only be iterated over destructively). The `tp_iternext` handler should return a new reference to the next object in the iteration if there is one. If the iteration has reached the end, it may return `NULL` without setting an exception or it may set `StopIteration`; avoiding the exception can yield slightly better performance. If an actual error occurs, it should set an exception and return `NULL`.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.2.5 Abstract Protocol Support](#) **Up:** [2.2 Type Methods](#) **Next:** [3. Building C and](#)

2.2.6 More Suggestions

Remember that you can omit most of these functions, in which case you provide 0 as a value. There are type definitions for each of the functions you must provide. They are in `object.h` in the Python include directory that comes with the source distribution of Python.

In order to learn how to implement any specific method for your new data type, do the following: Download and unpack the Python source distribution. Go the `Objects` directory, then search the C source files for `tp_` plus the function you want (for example, `tp_print` or `tp_compare`). You will find examples of the function you want to implement.

When you need to verify that an object is an instance of the type you are implementing, use the `PyObject_TypeCheck` function. A sample of its use might be something like the following:

```
if (! PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mything");
    return NULL;
}
```

Previous: [2.2.6 More Suggestions](#) **Up:** [Extending and Embedding the](#) **Next:**
[3.1 Distributing your extension](#)

3. Building C and C++ Extensions with distutils

Starting in Python 1.4, Python provides, on UNIX, a special make file for building make files for building dynamically-linked extensions and custom interpreters. Starting with Python 2.0, this mechanism (known as related to Makefile.pre.in, and Setup files) is no longer supported. Building custom interpreters was rarely used, and extension modules can be built using distutils.

Building an extension module using distutils requires that distutils is installed on the build machine, which is included in Python 2.x and available separately for Python 1.5. Since distutils also supports creation of binary packages, users don't necessarily need a compiler and distutils to install the extension.

A distutils package contains a driver script, `setup.py`. This is a plain Python file, which, in the most simple case, could look like this:

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       ext_modules = [module1])
```

With this `setup.py`, and a file `demo.c`, running

```
python setup.py build
```

will compile `demo.c`, and produce an extension module named "demo" in the build directory. Depending on the system, the module file will end up in a subdirectory `build/lib.system`, and may have a name like `demo.so` or `demo.pyd`.

In the `setup.py`, all execution is performed by calling the "setup" function. This takes a variable number of keyword arguments, of which the example above uses only a subset. Specifically, the example specifies meta-information to

build packages, and it specifies the contents of the package. Normally, a package will contain of addition modules, like Python source modules, documentation, subpackages, etc. Please refer to the distutils documentation in [Distributing Python Modules](#) to learn more about the features of distutils; this section explains building extension modules only.

It is common to pre-compute arguments to `setup`, to better structure the driver script. In the example above, the `ext_modules` argument to `setup` is a list of extension modules, each of which is an instance of the `Extension`. In the example, the instance defines an extension named `demo` which is build by compiling a single source file, `demo.c`.

In many cases, building an extension is more complex, since additional preprocessor defines and libraries may be needed. This is demonstrated in the example below.

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    define_macros = [('MAJOR_VERSION', '1'),
                                     ('MINOR_VERSION', '0')],
                    include_dirs = ['/usr/local/include'],
                    libraries = ['tcl83'],
                    library_dirs = ['/usr/local/lib'],
                    sources = ['demo.c'])

setup (name = 'PackageName',
      version = '1.0',
      description = 'This is a demo package',
      author = 'Martin v. Loewis',
      author_email = 'martin@v.loewis.de',
      url = 'http://www.python.org/doc/current/ext/building.html',
      long_description = '''
This is really just a demo package.
''',
      ext_modules = [module1])
```

In this example, `setup` is called with additional meta-information, which is recommended when distribution packages have to be built. For the extension itself, it specifies preprocessor defines, include directories, library directories, and libraries. Depending on the compiler, distutils passes this information in different ways to the compiler. For example, on UNIX, this may result in the compilation commands

```
gcc -DNDEBUG -g -O3 -Wall -Wstrict-prototypes -fPIC -DMAJOR_VERSION=
```

```
gcc -shared build/temp.linux-i686-2.2/demo.o -L/usr/local/lib -ltcl8
```

These lines are for demonstration purposes only; distutils users should trust that distutils gets the invocations right.

Previous: [3. Building C and](#) Up: [3. Building C and](#) Next: [4. Building C and](#)

3.1 Distributing your extension modules

When an extension has been successfully build, there are three ways to use it.

End-users will typically want to install the module, they do so by running

```
python setup.py install
```

Module maintainers should produce source packages; to do so, they run

```
python setup.py sdist
```

In some cases, additional files need to be included in a source distribution; this is done through a MANIFEST.in file; see the distutils documentation for details.

If the source distribution has been build successfully, maintainers can also create binary distributions. Depending on the platform, one of the following commands can be used to do so.

```
python setup.py bdist_wininst  
python setup.py bdist_rpm  
python setup.py bdist_dumb
```

4. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the UNIX programmer interested in producing software which can be successfully built on both UNIX and Windows.

Module authors are encouraged to use the distutils approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

Note: This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as "XY"; in practice, "X" will be the major version number and "Y" will be the minor version number of the Python release you're working with. For example, if you are using Python 2.2.1, "XY" will actually be "22".

Previous: [4. Building C and Between Unix](#) **Up:** [4. Building C and](#) **Next:** [4.2 Differences](#)

4.1 A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on UNIX: use the [distutils](#) package to control the build process, or do things manually. The [distutils](#) approach works well for most extensions; documentation on using [distutils](#) to build and package extension modules is available in [Distributing Python Modules](#). This section describes the manual approach to building Python extensions written in C or C++.

To build extensions using these instructions, you need to have a copy of the Python sources of the same version as your installed Python. You will need Microsoft Visual C++ "Developer Studio"; project files are supplied for VC++ version 7.1, but you can use older versions of VC++. Notice that you should use the same version of VC++ that was used to build Python itself. The example files described here are distributed with the Python sources in the `PC\example_nt\` directory.

1. Copy the example files

The `example_nt` directory is a subdirectory of the `PC` directory, in order to keep all the PC-specific files under the same directory in the source distribution. However, the `example_nt` directory can't actually be used from this location. You first need to copy or move it up one level, so that `example_nt` is a sibling of the `PC` and `Include` directories. Do all your work from within this new location.

2. Open the project

From VC++, use the `File > Open Solution` dialog (not `File > Open!`). Navigate to and select the file `example.sln`, in the *copy* of the `example_nt` directory you made above. Click `Open`.

3. Build the example DLL

In order to check that everything is set up right, try building:

1. Select a configuration. This step is optional. Choose `Build > Configuration Manager > Active Solution Configuration` and select either `Release` or `Debug`. If you skip this step, VC++ will use the `Debug` configuration by default.

2. Build the DLL. Choose Build > Build Solution. This creates all intermediate and result files in a subdirectory called either Debug or Release, depending on which configuration you selected in the preceding step.

4. Testing the debug-mode DLL

Once the Debug build has succeeded, bring up a DOS box, and change to the `example_nt\Debug` directory. You should now be able to repeat the following session (C> is the DOS prompt, >>> is the Python prompt; note that build information and various debug output from Python may not match this screen dump exactly):

```
C>..\..\PCbuild\python_d
Adding parser accelerators ...
Done.
Python 2.2 (#28, Dec 19 2001, 23:26:37) [MSC 32 bit (Intel)] on
Type "copyright", "credits" or "license" for more information.
>>> import example
[4897 refs]
>>> example.foo()
Hello, world
[4903 refs]
>>>
```

Congratulations! You've successfully built your first Python extension module.

5. Creating your own project

Choose a name and create a directory for it. Copy your C sources into it. Note that the module source file name does not necessarily have to match the module name, but the name of the initialization function should match the module name -- you can only import a module `spam` if its initialization function is called `initspam()`, and it should call `Py_InitModule()` with the string `"spam"` as its first argument (use the minimal `example.c` in this directory as a guide). By convention, it lives in a file called `spam.c` or `spammodule.c`. The output file should be called `spam.dll` or `spam.pyd` (the latter is supported to avoid confusion with a system library `spam.dll` to which your module could be a Python interface) in Release mode, or `spam_d.dll` or `spam_d.pyd` in Debug mode.

Now your options are:

1. Copy `example.sln` and `example.vcproj`, rename them to `spam.*`, and edit them by hand, or
2. Create a brand new project; instructions are below.

In either case, copy `example_nt\example.def` to `spam\spam.def`, and edit the new `spam.def` so its second line contains the string ``init spam'`. If you created a new project yourself, add the file `spam.def` to the project now. (This is an annoying little file with only two lines. An alternative approach is to forget about the `.def` file, and add the option **`/export:initspam`** somewhere to the Link settings, by manually editing the setting in Project Properties dialog).

6. Creating a brand new project

Use the `File > New > Project` dialog to create a new Project Workspace. Select `Visual C++ Projects/Win32/ Win32 Project`, enter the name ("`spam`"), and make sure the Location is set to parent of the `spam` directory you have created (which should be a direct subdirectory of the Python build tree, a sibling of `Include` and `PC`). Select `Win32` as the platform (in my version, this is the only choice). Make sure the `Create new workspace` radio button is selected. Click `OK`.

You should now create the file `spam.def` as instructed in the previous section. Add the source files to the project, using `Project > Add Existing Item`. Set the pattern to `*.*` and select both `spam.c` and `spam.def` and click `OK`. (Inserting them one by one is fine too.)

Now open the `Project > spam properties` dialog. You only need to change a few settings. Make sure `All Configurations` is selected from the `Settings for:` dropdown list. Select the `C/C++` tab. Choose the `General` category in the popup menu at the top. Type the following text in the entry box labeled `Additional Include Directories`:

```
..\Include,..\PC
```

Then, choose the `General` category in the `Linker` tab, and enter

```
..\PCbuild
```

in the text box labelled `Additional library Directories`.

Now you need to add some mode-specific settings:

Select Release in the Configuration dropdown list. Choose the Link tab, choose the Input category, and append `pythonXY.lib` to the list in the Additional Dependencies box.

Select Debug in the Configuration dropdown list, and append `pythonXY_d.lib` to the list in the Additional Dependencies box. Then click the C/C++ tab, select Code Generation, and select Multi-threaded Debug DLL from the Runtime library dropdown list.

Select Release again from the Configuration dropdown list. Select Multi-threaded DLL from the Runtime library dropdown list.

If your module creates a new type, you may have trouble with this line:

```
PyObject_HEAD_INIT(&PyType_Type)
```

Change it to:

```
PyObject_HEAD_INIT(NULL)
```

and add the following to the module initialization function:

```
MyObject_Type.ob_type = &PyType_Type;
```

Refer to section 3 of the [Python FAQ](#) for details on why you must do this.

4.2 Differences Between UNIX and Windows

UNIX and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In UNIX, a shared object (.SO) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file's code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (.dll) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program's memory; instead, the code already uses the DLL's lookup table, and the lookup table is modified at runtime to point to the functions and data.

In UNIX, there is only one type of library file (.a) which contains code from several object files (.o). During the link step to create a shared object file (.SO), the linker may find that it doesn't know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called .lib). A static library is like a UNIX .a file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should

share another block of code A. On UNIX, you would *not* pass `A.a` to the linker for `B.so` and `C.so`; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building `A.dll` will also build `A.lib`. You *do* pass `A.lib` to the linker for B and C. `A.lib` does not contain code; it just contains information which will be used at runtime to access A's code.

In Windows, using an import library is sort of like using `"import spam"`; it gives you access to spam's names, but does not create a separate copy. On UNIX, linking with a library is more like `"from spam import *"`; it does create a separate copy.

Previous: [4.2 Differences Between Unix](#) Up: [4. Building C and](#) Next: [5.](#)
[Embedding Python in](#)

4.3 Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work (though Borland seems to). The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you must pass `pythonXY.lib` to the linker. To build two DLLs, `spam` and `ni` (which uses C functions found in `spam`), you could use these commands:

```
cl /LD /I/python/include spam.c ../libs/pythonXY.lib
cl /LD /I/python/include ni.c spam.lib ../libs/pythonXY.lib
```

The first command created three files: `spam.obj`, `spam.dll` and `spam.lib`. `Spam.dll` does not contain any Python functions (such as `PyArg_ParseTuple()`), but it does know how to find the Python code thanks to `pythonXY.lib`.

The second command created `ni.dll` (and `.obj` and `.lib`), which knows how to find the necessary functions from `spam`, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any other modules (including Python) to be able to see your identifiers, you have to say `"_declspec(dllexport)"`, as in `"void _declspec(dllexport) initspam(void)"` or `"PyObject _declspec(dllexport) *NiGetSpamData(void)"`.

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify *ignore default libraries*. Add the correct `msvcrtxx.lib` to the list of libraries.

Previous: [4.3 Using DLLs in](#) Up: [Extending and Embedding the](#) Next: [5.1 Very High Level](#)

5. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python -- instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function `Py_Initialize()` (on Mac OS, call `PyMac_Initialize()` instead). There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to `PyRun_SimpleString()`, or you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to construct and use Python objects.

A simple demo of embedding Python can be found in the directory `Demo/embed/` of the source distribution.

Previous: [5. Embedding Python in Beyond Very High](#) **Up:** [5. Embedding Python in](#) **Next:** [5.2](#)

5.1 Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```
#include <Python.h>

int
main(int argc, char *argv[])
{
    Py_Initialize();
    PyRun_SimpleString("from time import time,ctime\n"
                      "print 'Today is',ctime(time())\n");
    Py_Finalize();
    return 0;
}
```

The above code first initializes the Python interpreter with `Py_Initialize()`, followed by the execution of a hard-coded Python script that print the date and time. Afterwards, the `Py_Finalize()` call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the `PyRun_SimpleFile()` function, which saves you the trouble of allocating memory space and loading the file contents.

5.2 Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and vice versa. Also, proper use of references and dealing with errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.

5.3 Pure Embedding

The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyObject *pName, *pModule, *pDict, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr, "Usage: call pythonfile funcname [args]\n");
        return 1;
    }

    Py_Initialize();
    pName = PyString_FromString(argv[1]);
    /* Error checking of pName left out */

    pModule = PyImport_Import(pName);
    Py_DECREF(pName);

    if (pModule != NULL) {
        pFunc = PyObject_GetAttrString(pModule, argv[2]);
        /* pFunc is a new reference */

        if (pFunc && PyCallable_Check(pFunc)) {
            pArgs = PyTuple_New(argc - 3);
            for (i = 0; i < argc - 3; ++i) {
                pValue = PyInt_FromLong(atoi(argv[i + 3]));
                if (!pValue) {
                    Py_DECREF(pArgs);
                    Py_DECREF(pModule);
                    fprintf(stderr, "Cannot convert argument\n");
                    return 1;
                }
            }
            /* pValue reference stolen here: */
            PyTuple_SetItem(pArgs, i, pValue);
        }
        pValue = PyObject_CallObject(pFunc, pArgs);
    }
}
```

```

        Py_DECREF(pArgs);
        if (pValue != NULL) {
            printf("Result of call: %ld\n", PyInt_AsLong(pValue));
            Py_DECREF(pValue);
        }
        else {
            Py_DECREF(pFunc);
            Py_DECREF(pModule);
            PyErr_Print();
            fprintf(stderr, "Call failed\n");
            return 1;
        }
    }
    else {
        if (PyErr_Occurred())
            PyErr_Print();
        fprintf(stderr, "Cannot find function \"%s\"\n", argv[2]);
    }
    Py_XDECREF(pFunc);
    Py_DECREF(pModule);
}
else {
    PyErr_Print();
    fprintf(stderr, "Failed to load \"%s\"\n", argv[1]);
    return 1;
}
Py_Finalize();
return 0;
}

```

Download as text (original file name: run-func.c).

This code loads a Python script using `argv[1]`, and calls the function named in `argv[2]`. Its integer arguments are the other values of the `argv` array. If you compile and link this program (let's call the finished executable **call**), and use it to execute a Python script, such as:

```

def multiply(a,b):
    print "Will compute", a, "times", b
    c = 0
    for i in range(0, a):
        c = c + b
    return c

```

then the result should be:

```

$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6

```

Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```
Py_Initialize();
pName = PyString_FromString(argv[1]);
/* Error checking of pName left out */
pModule = PyImport_Import(pName);
```

After initializing the interpreter, the script is loaded using `PyImport_Import()`. This routine needs a Python string as its argument, which is constructed using the `PyString_FromString()` data conversion routine.

```
pFunc = PyObject_GetAttrString(pModule, argv[2]);
/* pFunc is a new reference */

if (pFunc && PyCallable_Check(pFunc)) {
    ...
}
Py_XDECREF(pFunc);
```

Once the script is loaded, the name we're looking for is retrieved using `PyObject_GetAttrString()`. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either `NULL` or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.

Previous: [5.3 Pure Embedding](#) **Up:** [5. Embedding Python in](#) **Next:** [5.5](#)
[Embedding Python in](#)

5.4 Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```
static int numargs=0;

/* Return the number of arguments of the application command line */
static PyObject*
emb_numargs(PyObject *self, PyObject *args)
{
    if(!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return Py_BuildValue("i", numargs);
}

static PyMethodDef EmbMethods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the process."},
    {NULL, NULL, 0, NULL}
};
```

Insert the above code just above the `main()` function. Also, insert the following two statements directly after `Py_Initialize()`:

```
numargs = argc;
Py_InitModule("emb", EmbMethods);
```

These two lines initialize the `numargs` variable, and make the `emb.numargs()` function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```
import emb
print "Number of arguments", emb.numargs()
```

In a real application, the methods will expose an API of the application to

Python.

[5.6 Linking Requirements](#)

5.5 Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++.

See [About this document...](#) for information on suggesting changes.*

Previous: [5.5 Embedding Python in Reporting Bugs](#) **Up:** [5. Embedding Python in](#) **Next:** [A.](#)

5.6 Linking Requirements

While the **configure** script shipped with the Python sources will correctly build Python to export the symbols needed by dynamically linked extensions, this is not automatically inherited by applications which embed the Python library statically, at least on UNIX. This is an issue when the application is linked to the static runtime library (`libpython.a`) and needs to load dynamic extensions (implemented as `.SO` files).

The problem is that some entry points are defined by the Python runtime solely for extension modules to use. If the embedding application does not use any of these entry points, some linkers will not include those entries in the symbol table of the finished executable. Some additional options are needed to inform the linker not to remove these symbols.

Determining the right options to use for any given platform can be quite difficult, but fortunately the Python configuration already has those values. To retrieve them from an installed Python interpreter, start an interactive interpreter and have a short session like this:

```
>>> import distutils.sysconfig
>>> distutils.sysconfig.get_config_var('LINKFORSHARED')
'-xlinker -export-dynamic'
```

The contents of the string presented will be the options that should be used. If the string is empty, there's no need to add any additional options. The `LINKFORSHARED` definition corresponds to the variable of the same name in Python's top-level Makefile.

Previous: [5.5 Embedding Python in](#) Up: [5. Embedding Python in](#) Next: [A. Reporting Bugs](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

[B. History and License](#) **Next:**

A. Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python or its documentation.

Before submitting a report, you will be required to log into SourceForge; this will make it possible for the developers to contact you for additional information if needed. It is not possible to submit a bug report anonymously.

All bug reports should be submitted via the Python Bug Tracker on SourceForge (http://sourceforge.net/bugs/?group_id=5470). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the left side of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker (http://sourceforge.net/bugs/?group_id=5470). Select the "Submit a Bug" link at the top of the page to open the bug reporting form.

The submission form has a number of fields. The only fields that are required are the "Summary" and "Details" fields. For the summary, enter a *very* short description of the problem; less than ten words is good. In the Details field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include the version of Python you used, whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

The only other field that you may want to set is the "Category" field, which allows you to place the bug report into a broad category (such as "Documentation" or "Library").

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

B.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <http://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <http://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <http://www.zope.com/>). In 2001, the Python Software Foundation (PSF, see <http://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <http://www.opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL compatible?
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes
1.6	1.5.2	2000	CNRI	no
2.0	1.6	2000	BeOpen.com	no
1.6.1	1.6	2001	CNRI	no
2.1	2.0+1.6.1	2001	PSF	no
2.0.1	2.0+1.6.1	2001	PSF	yes
2.1.1	2.1+2.0.1	2001	PSF	yes
2.2	2.1.1	2001	PSF	yes

2.1.2	2.1.1	2002	PSF	yes
2.1.3	2.1.2	2002	PSF	yes
2.2.1	2.2	2002	PSF	yes
2.2.2	2.2.1	2002	PSF	yes
2.2.3	2.2.2	2002-2003	PSF	yes
2.3	2.2.2	2002-2003	PSF	yes
2.3.1	2.3	2002-2003	PSF	yes
2.3.2	2.3.1	2003	PSF	yes
2.3.3	2.3.2	2003	PSF	yes
2.3.4	2.3.3	2004	PSF	yes
2.3.5	2.3.4	2005	PSF	yes
2.4	2.3	2004	PSF	yes
2.4.1	2.4	2005	PSF	yes
2.4.2	2.4.1	2005	PSF	yes
2.4.3	2.4.2	2006	PSF	yes
2.4.4	2.4.3	2006	PSF	yes
2.5	2.4	2006	PSF	yes

Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

B.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.4.4

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.4.4 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.4.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.4.4 alone or in any derivative version prepared by Licensee.
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.4.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.4.4.
4. PSF is making Python 2.4.4 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.4.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS

OF PYTHON 2.4.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.4.4, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 2.4.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION

1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.
3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT

LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at <http://www.pythonlabs.com/logos.html> may be used according to the permissions granted on that web page.
7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to

reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: <http://hdl.handle.net/1895.22/1013>."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.
4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. This License Agreement shall be governed by the federal intellectual

property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

B.3.1 Mersenne Twister

The `_random` module includes code based on a download from <http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html>. The following are the verbatim comments from the original code:

```
A C-program for MT19937, with initialization improved 2002/1/26.  
Coded by Takuji Nishimura and Makoto Matsumoto.
```

```
Before using, initialize the state by using init_genrand(seed)  
or init_by_array(init_key, key_length).
```

```
Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura,  
All rights reserved.
```

```
Redistribution and use in source and binary forms, with or without  
modification, are permitted provided that the following conditions  
are met:
```

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in documentation and/or other materials provided with the distribution.
3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

1. Introduction

The Application Programmer's Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write *extension modules* for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as *embedding Python* in an application.

Writing an extension module is a relatively well-understood process, where a "cookbook" approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you're embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it's probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.

Previous: [1. Introduction](#) Up: [1. Introduction](#) Next: [1.2 Objects, Types and](#)

1.1 Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```
#include "Python.h"
```

This implies inclusion of the following standard headers: `<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`, and `<stdlib.h>` (if available).

Warning: Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

All user visible names defined by `Python.h` (except those defined by the included standard headers) have one of the prefixes `"Py"` or `"_Py"`. Names beginning with `"_Py"` are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

Important: user code should never define names that begin with `"Py"` or `"_Py"`. This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On UNIX, these are located in the directories `prefix/include/pythonversion/` and `exec_prefix/include/pythonversion/`, where `prefix` and `exec_prefix` are defined by the corresponding parameters to Python's **configure** script and `version` is `sys.version[:3]`. On Windows, the headers are installed in `prefix/include`, where `prefix` is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do *not* place the parent directories on the search path

and then use `"#include <python2.4/Python.h>";` this will break on multi-platform builds since the platform independent headers under prefix include the platform specific headers from `exec_prefix`.

C++ users should note that though the API is defined entirely using C, the header files do properly declare the entry points to be `extern "C"`, so there is no need to do anything special to use the API from C++.

1.2 Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type `PyObject*`. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type `PyObject`, only pointer variables of type `PyObject*` can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static `PyTypeObject` objects.

All Python objects (even Python integers) have a *type* and a *reference count*. An object's type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in the [Python Reference Manual](#)). For each of the well-known types there is a macro to check whether an object is of that type; for instance, "`PyList_Check(a)`" is true if (and only if) the object pointed to by *a* is a Python list.

Previous: [1.2 Objects, Types and Reference Count Details](#) **Up:** [1.2 Objects, Types and](#) **Next:** [1.2.1.1](#)

1.2.1 Reference Counts

The reference count is important because today's computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a reference to an object. Such a place could be another object, or a global (or static) C variable, or a local variable in some C function. When an object's reference count becomes zero, the object is deallocated. If it contains references to other objects, their reference count is decremented. Those other objects may be deallocated in turn, if this decrement makes their reference count become zero, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is ``don't do that.'')

Reference counts are always manipulated explicitly. The normal way is to use the macro `Py_INCREF()` to increment an object's reference count by one, and `Py_DECREF()` to decrement it by one. The `Py_DECREF()` macro is considerably more complex than the `Py_INCREF()` one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of decrementing the reference counts for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming `sizeof(long) >= sizeof(char*)`). Thus, the reference count increment is a simple operation.

It is not necessary to increment an object's reference count for every local variable that contains a pointer to an object. In theory, the object's reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn't changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to increment the reference count temporarily. An important situation where this arises is in objects that are passed as arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a

reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without incrementing its reference count. Some other operation might conceivably remove the object from the list, decrementing its reference count and possibly deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a `Py_DECREF()`, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with "PyObject_", "PyNumber_", "PySequence_" or "PyMapping_"). These operations always increment the reference count of the object they return. This leaves the caller with the responsibility to call `Py_DECREF()` when they are done with the result; this soon becomes second nature.

[1.3 Exceptions](#)

1.2.2 Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as `int`, `long`, `double` and `char*`. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.

Previous: [1.2.2 Types](#) Up: [1. Introduction](#) Next: [1.4 Embedding Python](#)

1.3 Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller's caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function's documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator -- usually `NULL` or `-1`. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with `PyErr_Occurred()`.

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function `PyErr_Occurred()` can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and `NULL` otherwise. There are a number of functions to set the exception state: `PyErr_SetString()` is the most common (though not the most general) function to set the exception state, and `PyErr_Clear()` clears the exception state.

The full exception state consists of three objects (all of which can be `NULL`): the exception type, the corresponding exception value, and the traceback. These have the same meanings as the Python objects `sys.exc_type`, `sys.exc_value`, and `sys.exc_traceback`; however, they are not the same: the Python objects represent the last exception being handled by a Python `try ... except` statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter's main loop, which takes care of transferring it to `sys.exc_type` and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the

exception state from Python code is to call the function `sys.exc_info()`, which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should *not* set another exception -- that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the `sum_sequence()` example above. It so happens that that example doesn't need to clean up any owned references when it detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```
def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1
```

Here is the corresponding C code, in all its glory:

```
int
incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *incremented_item = NU
    int rv = -1; /* Return value initialized to -1 (failure) */

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;
    }
```

```

        /* Clear the error and use zero: */
        PyErr_Clear();
        item = PyInt_FromLong(0L);
        if (item == NULL)
            goto error;
    }
    const_one = PyInt_FromLong(1L);
    if (const_one == NULL)
        goto error;

    incremented_item = PyNumber_Add(item, const_one);
    if (incremented_item == NULL)
        goto error;

    if (PyObject_SetItem(dict, key, incremented_item) < 0)
        goto error;
    rv = 0; /* Success */
    /* Continue with cleanup code */

error:
    /* Cleanup code, shared by success and failure path */

    /* Use Py_XDECREF() to ignore NULL references */
    Py_XDECREF(item);
    Py_XDECREF(const_one);
    Py_XDECREF(incremented_item);

    return rv; /* -1 for error, 0 for success */
}

```

This example represents an endorsed use of the `goto` statement in C! It illustrates the use of `PyErr_ExceptionMatches()` and `PyErr_Clear()` to handle specific exceptions, and the use of `Py_XDECREF()` to dispose of owned references that may be `NULL` (note the "X" in the name; `Py_DECREF()` would crash when confronted with a `NULL` reference). It is important that the variables used to hold owned references are initialized to `NULL` for this to work; likewise, the proposed return value is initialized to `-1` (failure) and only set to success after the final call made is successful.

Previous: [1.3 Exceptions](#) Up: [1. Introduction](#) Next: [2. The Very High](#)

1.4 Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is `Py_Initialize()`. This initializes the table of loaded modules, and creates the fundamental modules `__builtin__`, `__main__`, `sys`, and `exceptions`. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the "script argument list" (`sys.argv`). If this variable is needed by Python code that will be executed later, it must be set explicitly with a call to `PySys_SetArgv(argc, argv)` subsequent to the call to `Py_Initialize()`.

On most systems (in particular, on UNIX and Windows, although the details are slightly different), `Py_Initialize()` calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/python2.4` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable `PATH`).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in `/usr/local/lib/python2.4`. (In fact, this particular path is also the "fallback" location, used when no executable file named `python` is found along `PATH`.) The user can override this behavior by setting the environment variable `PYTHONHOME`, or insert additional directories in front of the standard path by setting `PYTHONPATH`.

The embedding application can steer the search by calling `Py_SetProgramName(file)` before calling `Py_Initialize()`. Note that `PYTHONHOME` still overrides this and `PYTHONPATH` is still inserted in front of the standard path. An application that requires total control has to provide its

own implementation of `Py_GetPath()`, `Py_GetPrefix()`, `Py_GetExecPrefix()`, and `Py_GetProgramFullPath()` (all defined in `Modules/getpath.c`).

Sometimes, it is desirable to "uninitialize" Python. For instance, the application may want to start over (make another call to `Py_Initialize()`) or the application is simply done with its use of Python and wants to free all memory allocated by Python. This can be accomplished by calling `Py_Finalize()`. The function `Py_IsInitialized()` returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter.

[3. Reference Counting](#)

2. The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are `Py_eval_input`, `Py_file_input`, and `Py_single_input`. These are described following the functions which accept them as parameters.

Note also that several of these functions take `FILE*` parameters. On particular issue which needs to be handled carefully is that the `FILE` structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that `FILE*` parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

int **Py_Main**(int *argc*, char ***argv*)

The main program for the standard interpreter. This is made available for programs which embed Python. The *argc* and *argv* parameters should be prepared exactly as those which are passed to a C program's `main()` function. It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be the integer passed to the `sys.exit()` function, 1 if the interpreter exits due to an exception, or 2 if the parameter list does not represent a valid Python command line.

int **PyRun_AnyFile**(FILE **fp*, const char **filename*)

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving *closeit* set to 0 and *flags* set to NULL.

int **PyRun_AnyFileFlags**(FILE **fp*, const char **filename*,
PyCompilerFlags **flags*)

This is a simplified interface to `PyRun_AnyFileExFlags()` below,

leaving the *closeit* argument set to 0.

int **PyRun_AnyFileEx**(FILE **fp*, const char **filename*, int *closeit*)

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the *flags* argument set to NULL.

int **PyRun_AnyFileExFlags**(FILE **fp*, const char **filename*, int *closeit*, PyCompilerFlags **flags*)

If *fp* refers to a file associated with an interactive device (console or terminal input or UNIX pseudo-terminal), return the value of `PyRun_InteractiveLoop()`, otherwise return the result of `PyRun_SimpleFile()`. If *filename* is NULL, this function uses "???" as the filename.

int **PyRun_SimpleString**(const char **command*)

This is a simplified interface to `PyRun_SimpleStringFlags()` below, leaving the *PyCompilerFlags** argument set to NULL.

int **PyRun_SimpleStringFlags**(const char **command*, PyCompilerFlags **flags*)

Executes the Python source code from *command* in the `__main__` module according to the *flags* argument. If `__main__` does not already exist, it is created. Returns 0 on success or -1 if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of *flags*, see below.

int **PyRun_SimpleFile**(FILE **fp*, const char **filename*)

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *closeit* set to 0 and *flags* set to NULL.

int **PyRun_SimpleFileFlags**(FILE **fp*, const char **filename*, PyCompilerFlags **flags*)

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *closeit* set to 0.

int **PyRun_SimpleFileEx**(FILE **fp*, const char **filename*, int *closeit*)

This is a simplified interface to `PyRun_SimpleFileExFlags()`

below, leaving *flags* set to NULL.

int **PyRun_SimpleFileExFlags**(FILE **fp*, const char **filename*, int *closeit*, PyCompilerFlags **flags*)

Similar to `PyRun_SimpleStringFlags()`, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file. If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags` returns.

int **PyRun_InteractiveOne**(FILE **fp*, const char **filename*)

This is a simplified interface to `PyRun_InteractiveOneFlags()` below, leaving *flags* set to NULL.

int **PyRun_InteractiveOneFlags**(FILE **fp*, const char **filename*, PyCompilerFlags **flags*)

Read and execute a single statement from a file associated with an interactive device according to the *flags* argument. If *filename* is NULL, "???" is used instead. The user will be prompted using `sys.ps1` and `sys.ps2`. Returns 0 when the input was executed successfully, -1 if there was an exception, or an error code from the `errcode.h` include file distributed as part of Python if there was a parse error. (Note that `errcode.h` is not included by `Python.h`, so must be included specifically if needed.)

int **PyRun_InteractiveLoop**(FILE **fp*, const char **filename*)

This is a simplified interface to `PyRun_InteractiveLoopFlags()` below, leaving *flags* set to NULL.

int **PyRun_InteractiveLoopFlags**(FILE **fp*, const char **filename*, PyCompilerFlags **flags*)

Read and execute statements from a file associated with an interactive device until EOF is reached. If *filename* is NULL, "???" is used instead. The user will be prompted using `sys.ps1` and `sys.ps2`. Returns 0 at EOF.

struct _node* **PyParser_SimpleParseString**(const char **str*, int *start*)

This is a simplified interface to `PyParser_SimpleParseStringFlagsFilename()` below,

PyCompilerFlags *flags)

*Return value: **New reference.***

Execute Python source code from *str* in the context specified by the dictionaries *globals* and *locals* with the compiler flags specified by *flags*. The parameter *start* specifies the start token that should be used to parse the source code.

Returns the result of executing the code as a Python object, or NULL if an exception was raised.

PyObject* **PyRun_File**(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals)

*Return value: **New reference.***

This is a simplified interface to PyRun_FileExFlags() below, leaving *closeit* set to 0 and *flags* set to NULL.

PyObject* **PyRun_FileEx**(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, int closeit)

*Return value: **New reference.***

This is a simplified interface to PyRun_FileExFlags() below, leaving *flags* set to NULL.

PyObject* **PyRun_FileFlags**(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

*Return value: **New reference.***

This is a simplified interface to PyRun_FileExFlags() below, leaving *closeit* set to 0.

PyObject* **PyRun_FileExFlags**(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, int closeit, PyCompilerFlags *flags)

*Return value: **New reference.***

Similar to PyRun_StringFlags(), but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file. If *closeit* is true, the file is closed before PyRun_FileExFlags() returns.

PyObject* **Py_CompileString**(const char **str*, const char **filename*, int *start*)

Return value: New reference.

This is a simplified interface to `Py_CompileStringFlags()` below, leaving *flags* set to NULL.

PyObject* **Py_CompileStringFlags**(const char **str*, const char **filename*, int *start*, PyCompilerFlags **flags*)

Return value: New reference.

Parse and compile the Python source code in *str*, returning the resulting code object. The start token is given by *start*; this can be used to constrain the code which can be compiled and should be `Py_eval_input`, `Py_file_input`, or `Py_single_input`. The filename specified by *filename* is used to construct the code object and may appear in tracebacks or `SyntaxError` exception messages. This returns NULL if the code cannot be parsed or compiled.

int **Py_eval_input**

The start symbol from the Python grammar for isolated expressions; for use with `Py_CompileString()`.

int **Py_file_input**

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with `Py_CompileString()`. This is the symbol to use when compiling arbitrarily long Python source code.

int **Py_single_input**

The start symbol from the Python grammar for a single statement; for use with `Py_CompileString()`. This is the symbol used for the interactive interpreter loop.

struct PyCompilerFlags

This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as `int flags`, and in cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import` can modify *flags*.

Whenever `PyCompilerFlags *flags` is `NULL`, `cf_flags` is treated as equal to `0`, and any modification due to `from __future__ import` is discarded.

```
struct PyCompilerFlags {
    int cf_flags;
}
```

int `CO_FUTURE_DIVISION`

This bit can be set in *flags* to cause division operator `/` to be interpreted as "true division" according to [PEP 238](#).

Previous: [2. The Very High](#) **Up:** [Python/C API Reference Manual](#) **Next:** [4. Exception Handling](#)

3. Reference Counting

The macros in this section are used for managing reference counts of Python objects.

void **Py_INCREF**(PyObject *o)

Increment the reference count for object *o*. The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use `Py_XINCREF ()`.

void **Py_XINCREF**(PyObject *o)

Increment the reference count for object *o*. The object may be `NULL`, in which case the macro has no effect.

void **Py_DECREF**(PyObject *o)

Decrement the reference count for object *o*. The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use `Py_XDECREF ()`. If the reference count reaches zero, the object's type's deallocation function (which must not be `NULL`) is invoked.

Warning: The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a `__del__ ()` method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before `Py_DECREF ()` is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable, update the list data structure, and then call `Py_DECREF ()` for the temporary variable.

void **Py_XDECREF**(PyObject *o)

Decrement the reference count for object *o*. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for `Py_DECREF ()`, and the same warning applies.

void **Py_CLEAR**(PyObject *o)

Decrement the reference count for object *o*. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for `Py_DECREF()`, except that the argument is also set to `NULL`. The warning for `Py_DECREF()` does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to `NULL` before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the value of a variable that might be traversed during garbage collection.

New in version 2.4.

The following functions are for runtime dynamic embedding of Python: `Py_IncRef(PyObject *o)`, `Py_DecRef(PyObject *o)`. They are simply exported function versions of `Py_XINCRF()` and `Py_XDECREF()`, respectively.

The following functions or macros are only for use within the interpreter core: `_Py_Dealloc()`, `_Py_ForgetReference()`, `_Py_NewReference()`, as well as the global variable `_Py_RefTotal`.

Previous: [3. Reference Counting](#) **Up:** [Python/C API Reference Manual](#) **Next:**
[4.1 Standard Exceptions](#)

4. Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the UNIX `errno` variable: there is a global indicator (per thread) of the last error that occurred. Most functions don't clear this on success, but will set it to indicate the cause of the error on failure. Most functions also return an error indicator, usually `NULL` if they are supposed to return a pointer, or `-1` if they return an integer (exception: the `PyArg_*()` functions return `1` for success and `0` for failure).

When a function must fail because some function it called failed, it generally doesn't set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should *not* continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

The error indicator consists of three Python objects corresponding to the Python variables `sys.exc_type`, `sys.exc_value` and `sys.exc_traceback`. API functions exist to interact with the error indicator in various ways. There is a separate error indicator for each thread.

`void PyErr_Print()`

Print a standard traceback to `sys.stderr` and clear the error indicator. Call this function only when the error indicator is set. (Otherwise it will cause a fatal error!)

`PyObject* PyErr_Occurred()`

Return value: **Borrowed reference.**

Test whether the error indicator is set. If set, return the exception *type* (the first argument to the last call to one of the `PyErr_Set*()` functions or to `PyErr_Restore()`). If not set, return `NULL`. You do not own a reference

to the return value, so you do not need to `Py_DECREF()` it. **Note:** Do not compare the return value to a specific exception; use `PyErr_ExceptionMatches()` instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)

`int PyErr_ExceptionMatches(PyObject *exc)`

Equivalent to

`"PyErr_GivenExceptionMatches(PyErr_Occurred(), exc)"`. This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.

`int PyErr_GivenExceptionMatches(PyObject *given, PyObject *exc)`

Return true if the *given* exception matches the exception in *exc*. If *exc* is a class object, this also returns true when *given* is an instance of a subclass. If *exc* is a tuple, all exceptions in the tuple (and recursively in subtuples) are searched for a match. If *given* is `NULL`, a memory access violation will occur.

`void PyErr_NormalizeException(PyObject**exc, PyObject**val, PyObject**tb)`

Under certain circumstances, the values returned by `PyErr_Fetch()` below can be "unnormalized", meaning that **exc* is a class object but **val* is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

`void PyErr_Clear()`

Clear the error indicator. If the error indicator is not set, there is no effect.

`void PyErr_Fetch(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)`

Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to `NULL`. If it is set, it will be cleared and you own a reference to each object retrieved. The value and traceback object may be `NULL` even when the type object is not. **Note:**

This function is normally only used by code that needs to handle exceptions or by code that needs to save and restore the error indicator temporarily.

void **PyErr_Restore**(PyObject **type*, PyObject **value*, PyObject **traceback*)

Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are NULL, the error indicator is cleared. Do not pass a NULL type and non-NULL value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don't understand this, don't use this function. I warned you.) **Note:** This function is normally only used by code that needs to save and restore the error indicator temporarily; use `PyErr_Fetch()` to save the current exception state.

void **PyErr_SetString**(PyObject **type*, char **message*)

This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. `PyExc_RuntimeError`. You need not increment its reference count. The second argument is an error message; it is converted to a string object.

void **PyErr_SetObject**(PyObject **type*, PyObject **value*)

This function is similar to `PyErr_SetString()` but lets you specify an arbitrary Python object for the "value" of the exception.

PyObject* **PyErr_Format**(PyObject **exception*, const char **format*, ...)

Return value: **Always NULL.**

This function sets the error indicator and returns NULL. *exception* should be a Python exception (class, not an instance). *format* should be a string, containing format codes, similar to `printf()`. The `width.precision` before a format code is parsed, but the width part is ignored.

Character	Meaning
c	Character, as an <code>int</code> parameter
d	Number in decimal, as an <code>int</code> parameter

x	Number in hexadecimal, as an <code>int</code> parameter
s	A string, as a <code>char *</code> parameter
p	A hex pointer, as a <code>void *</code> parameter

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

void **PyErr_SetNone**(PyObject **type*)

This is a shorthand for "PyErr_SetObject(*type*, Py_None)".

int **PyErr_BadArgument**()

This is a shorthand for "PyErr_SetString(PyExc_TypeError, *message*)", where *message* indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.

PyObject* **PyErr_NoMemory**()

Return value: **Always NULL.**

This is a shorthand for "PyErr_SetNone(PyExc_MemoryError)"; it returns NULL so an object allocation function can write "return PyErr_NoMemory();" when it runs out of memory.

PyObject* **PyErr_SetFromErrno**(PyObject **type*)

Return value: **Always NULL.**

This is a convenience function to raise an exception when a C library function has returned an error and set the C variable `errno`. It constructs a tuple object whose first item is the integer `errno` value and whose second item is the corresponding error message (gotten from `strerror()`), and then calls "PyErr_SetObject(*type*, *object*)". On UNIX, when the `errno` value is `EINTR`, indicating an interrupted system call, this calls `PyErr_CheckSignals()`, and if that set the error indicator, leaves it set to that. The function always returns NULL, so a wrapper function around a system call can write "return PyErr_SetFromErrno(*type*);" when the system call returns an error.

PyObject* **PyErr_SetFromErrnoWithFilename**(PyObject **type*, char **filename*)

Return value: **Always NULL.**

Similar to `PyErr_SetFromErrno()`, with the additional behavior that if *filename* is not `NULL`, it is passed to the constructor of *type* as a third parameter. In the case of exceptions such as `IOError` and `OSError`, this is used to define the `filename` attribute of the exception instance.

`PyObject*` **`PyErr_SetFromWindowsErr`**(`int ierr`)

Return value: **Always `NULL`.**

This is a convenience function to raise `WindowsError`. If called with *ierr* of `0`, the error code returned by a call to `GetLastError()` is used instead. It calls the Win32 function `FormatMessage()` to retrieve the Windows description of error code given by *ierr* or `GetLastError()`, then it constructs a tuple object whose first item is the *ierr* value and whose second item is the corresponding error message (gotten from `FormatMessage()`), and then calls "`PyErr_SetObject(PyExc_WindowsError, object)`". This function always returns `NULL`. Availability: Windows.

`PyObject*` **`PyErr_SetExcFromWindowsErr`**(`PyObject *type`, `int ierr`)

Return value: **Always `NULL`.**

Similar to `PyErr_SetFromWindowsErr()`, with an additional parameter specifying the exception type to be raised. Availability: Windows. New in version 2.3.

`PyObject*` **`PyErr_SetFromWindowsErrWithFilename`**(`int ierr`, `char *filename`)

Return value: **Always `NULL`.**

Similar to `PyErr_SetFromWindowsErr()`, with the additional behavior that if *filename* is not `NULL`, it is passed to the constructor of `WindowsError` as a third parameter. Availability: Windows.

`PyObject*` **`PyErr_SetExcFromWindowsErrWithFilename`**(`PyObject *type`, `int ierr`, `char *filename`)

Return value: **Always `NULL`.**

Similar to `PyErr_SetFromWindowsErrWithFilename()`, with an additional parameter specifying the exception type to be raised.

Availability: Windows. New in version 2.3.

void **PyErr_BadInternalCall**()

This is a shorthand for "PyErr_SetString(PyExc_TypeError, *message*)", where *message* indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

int **PyErr_Warn**(PyObject **category*, char **message*)

Issue a warning message. The *category* argument is a warning category (see below) or NULL; the *message* argument is a message string.

This function normally prints a warning message to *sys.stderr*; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case this will raise an exception. It is also possible that the function raises an exception because of a problem with the warning machinery (the implementation imports the `warnings` module to do the heavy lifting). The return value is 0 if no exception is raised, or -1 if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, `Py_DECREF ()` owned references and return an error value).

Warning categories must be subclasses of `Warning`; the default warning category is `RuntimeWarning`. The standard Python warning categories are available as global variables whose names are "PyExc_" followed by the Python exception name. These have the type `PyObject *`; they are all class objects. Their names are `PyExc_Warning`, `PyExc_UserWarning`, `PyExc_DeprecationWarning`, `PyExc_SyntaxWarning`, `PyExc_RuntimeWarning`, and `PyExc_FutureWarning`. `PyExc_Warning` is a subclass of `PyExc_Exception`; the other warning categories are subclasses of `PyExc_Warning`.

For information about warning control, see the documentation for the `warnings` module and the `-W` option in the command line documentation. There is no C API for warning control.

PyObject *category, char *message, char
int **PyErr_WarnExplicit**(*filename, int lineno, char *module, PyObject
*registry)

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function `warnings.warn_explicit()`, see there for more information. The *module* and *registry* arguments may be set to `NULL` to get the default effect described there.

int **PyErr_CheckSignals**()

This function interacts with Python's signal handling. It checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the `signal` module is supported, this can invoke a signal handler written in Python. In all cases, the default effect for `SIGINT` is to raise the `KeyboardInterrupt` exception. If an exception is raised the error indicator is set and the function returns `1`; otherwise the function returns `0`. The error indicator may or may not be cleared if it was previously set.

void **PyErr_SetInterrupt**()

This function simulates the effect of a `SIGINT` signal arriving -- the next time `PyErr_CheckSignals()` is called, `KeyboardInterrupt` will be raised. It may be called without holding the interpreter lock.

PyObject* **PyErr_NewException**(char *name, PyObject *base, PyObject
*dict)

Return value: **New reference.**

This utility function creates and returns a new exception object. The *name* argument must be the name of the new exception, a C string of the form `module.class`. The *base* and *dict* arguments are normally `NULL`. This creates a class object derived from the root for all exceptions, the built-in name `Exception` (accessible in C as `PyExc_Exception`). The `__module__` attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is set to the last part (after the last dot). The *base* argument can be used to specify an alternate base class. The *dict* argument can be used to specify a dictionary of class variables and methods.

void **PyErr_WriteUnraisable**(PyObject *obj)

This utility function prints a warning message to `sys.stderr` when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an `__del__()` method.

The function is called with a single argument *obj* that identifies the context in which the unraisable exception occurred. The repr of *obj* will be printed in the warning message.

Previous: [4. Exception Handling](#) **Up:** [4. Exception Handling](#) **Next:** [4.2 Deprecation of String](#)

4.1 Standard Exceptions

All standard Python exceptions are available as global variables whose names are "PyExc_" followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

C Name	Python Name	Notes
PyExc_Exception	Exception	(1)
PyExc_StandardError	StandardError	(1)
PyExc_ArithmeticError	ArithmeticError	(1)
PyExc_LookupError	LookupError	(1)
PyExc_AssertionError	AssertionError	
PyExc_AttributeError	AttributeError	
PyExc_EOFError	EOFError	
PyExc_EnvironmentError	EnvironmentError	(1)
PyExc_FloatingPointError	FloatingPointError	
PyExc_IOError	IOError	
PyExc_ImportError	ImportError	
PyExc_IndexError	IndexError	
PyExc_KeyError	KeyError	
PyExc_KeyboardInterrupt	KeyboardInterrupt	
PyExc_MemoryError	MemoryError	
PyExc_NameError	NameError	
PyExc_NotImplementedError	NotImplementedError	
PyExc_OSError	OSError	
PyExc_OverflowError	OverflowError	
PyExc_ReferenceError	ReferenceError	(2)
PyExc_RuntimeError	RuntimeError	
PyExc_SyntaxError	SyntaxError	
PyExc_SystemError	SystemError	
PyExc_SystemExit	SystemExit	
PyExc_TypeError	TypeError	

PyExc_ValueError	ValueError	
PyExc_WindowsError	WindowsError	(3)
PyExc_ZeroDivisionError	ZeroDivisionError	

Notes:

- (1) This is a base class for other standard exceptions.
- (2) This is the same as `weakref.ReferenceError`.
- (3) Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.

Previous: [4.1 Standard Exceptions](#) **Up:** [4. Exception Handling](#) **Next:** [5. Utilities](#)

4.2 Deprecation of String Exceptions

All exceptions built into Python or provided in the standard library are derived from `Exception`.

String exceptions are still supported in the interpreter to allow existing code to run unmodified, but this will also change in a future release.

5.1 Operating System Utilities

int **Py_FdIsInteractive**(FILE **fp*, char **filename*)

Return true (nonzero) if the standard I/O file *fp* with name *filename* is deemed interactive. This is the case for files for which "isatty(fileno(*fp*))" is true. If the global flag `Py_InteractiveFlag` is true, this function also returns true if the *filename* pointer is NULL or if the name is equal to one of the strings '<stdin>' or '???'.

long **PyOS_GetLastModificationTime**(char **filename*)

Return the time of last modification of the file *filename*. The result is encoded in the same way as the timestamp returned by the standard C library function `time()`.

void **PyOS_AfterFork**()

Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

int **PyOS_CheckStack**()

Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when `USE_STACKCHECK` is defined (currently on Windows using the Microsoft Visual C++ compiler). `USE_STACKCHECK` will be defined automatically; you should never change the definition in your own code.

PyOS_sighandler_t **PyOS_getsig**(int *i*)

Return the current signal handler for signal *i*. This is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.

PyOS_sighandler_t **PyOS_setsig**(int *i*, PyOS_sighandler_t *h*)

Set the signal handler for signal *i* to be *h*; return the old signal handler. This

is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.

5.2 Process Control

void **Py_FatalError**(const char **message*)

Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On UNIX, the standard C library function `abort()` is called which will attempt to produce a `core` file.

void **Py_Exit**(int *status*)

Exit the current process. This calls `Py_Finalize()` and then calls the standard C library function `exit(status)`.

int **Py_AtExit**(void (**func*) ())

Register a cleanup function to be called by `Py_Finalize()`. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, `Py_AtExit()` returns 0; on failure, it returns -1. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python's internal finalization will have completed before the cleanup function, no Python APIs should be called by *func*.

5.3 Importing Modules

PyObject* **PyImport_ImportModule**(char *name)

*Return value: **New reference.***

This is a simplified interface to `PyImport_ImportModuleEx()` below, leaving the *globals* and *locals* arguments set to `NULL`. When the *name* argument contains a dot (when it specifies a submodule of a package), the *fromlist* argument is set to the list `['*']` so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when *name* in fact specifies a subpackage instead of a submodule: the submodules specified in the package's `__all__` variable are loaded.) Return a new reference to the imported module, or `NULL` with an exception set on failure. Before Python 2.4, the module may still be created in the failure case -- examine `sys.modules` to find out. Starting with Python 2.4, a failing import of a module no longer leaves the module in `sys.modules`. Changed in version 2.4: failing imports remove incomplete module objects.

PyObject* **PyImport_ImportModuleEx**(char *name, PyObject *globals, PyObject *locals, PyObject *fromlist)

*Return value: **New reference.***

Import a module. This is best described by referring to the built-in Python function `__import__()`, as the standard `__import__()` function calls this function directly.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure (before Python 2.4, the module may still be created in this case). Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given. Changed in version 2.4: failing imports remove incomplete module objects.

PyObject* **PyImport_Import**(PyObject *name)

*Return value: **New reference.***

This is a higher-level interface that calls the current "import hook function". It invokes the `__import__()` function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment, e.g. by `rexec` or `ihooks`.

`PyObject*` **PyImport_ReloadModule**(`PyObject *m`)

Return value: **New reference.**

Reload a module. This is best described by referring to the built-in Python function `reload()`, as the standard `reload()` function calls this function directly. Return a new reference to the reloaded module, or `NULL` with an exception set on failure (the module still exists in this case).

`PyObject*` **PyImport_AddModule**(`char *name`)

Return value: **Borrowed reference.**

Return the module object corresponding to a module name. The *name* argument may be of the form `package.module`. First check the modules dictionary if there's one there, and if not, create a new one and insert it in the modules dictionary. Return `NULL` with an exception set on failure.

Note: This function does not load or import the module; if the module wasn't already loaded, you will get an empty module object. Use `PyImport_ImportModule()` or one of its variants to import a module. Package structures implied by a dotted name for *name* are not created if not already present.

`PyObject*` **PyImport_ExecCodeModule**(`char *name`, `PyObject *co`)

Return value: **New reference.**

Given a module name (possibly of the form `package.module`) and a code object read from a Python bytecode file or obtained from the built-in function `compile()`, load the module. Return a new reference to the module object, or `NULL` with an exception set if an error occurred. Before Python 2.4, the module could still be created in error cases. Starting with Python 2.4, *name* is removed from `sys.modules` in error cases, and even if *name* was already in `sys.modules` on entry to `PyImport_ExecCodeModule()`. Leaving incompletely initialized modules in `sys.modules` is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably

damaged with respect to the module author's intents) state.

This function will reload the module if it was already imported. See `PyImport_ReloadModule()` for the intended way to reload a module.

If *name* points to a dotted name of the form `package.module`, any package structures not already created will still not be created.

Changed in version 2.4: *name* is removed from `sys.modules` in error cases.

long **PyImport_GetMagicNumber()**

Return the magic number for Python bytecode files (a.k.a. `.pyc` and `.pyo` files). The magic number should be present in the first four bytes of the bytecode file, in little-endian byte order.

PyObject* **PyImport_GetModuleDict()**

Return value: Borrowed reference.

Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.

void **_PyImport_Init()**

Initialize the import mechanism. For internal use only.

void **PyImport_Cleanup()**

Empty the module table. For internal use only.

void **_PyImport_Fini()**

Finalize the import mechanism. For internal use only.

PyObject* **_PyImport_FindExtension(char *, char *)**

Return value: Borrowed reference.

For internal use only.

PyObject* **_PyImport_FixupExtension(char *, char *)**

For internal use only.

int **PyImport_ImportFrozenModule(char *name)**

Load a frozen module named *name*. Return 1 for success, 0 if the module is not found, and -1 with an exception set if the initialization failed. To access the imported module on a successful load, use

`PyImport_ImportModule()`. (Note the misnomer -- this function would reload the module if it was already imported.)

struct _frozen

This is the structure type definition for frozen module descriptors, as generated by the **freeze** utility (see `Tools/freeze/` in the Python source distribution). Its definition, found in `Include/import.h`, is:

```
struct _frozen {
    char *name;
    unsigned char *code;
    int size;
};
```

struct _frozen* PyImport_FrozenModules

This pointer is initialized to point to an array of `struct _frozen` records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

int PyImport_AppendInittab(char *name, void (*initfunc)(void))

Add a single module to the existing table of built-in modules. This is a convenience wrapper around `PyImport_ExtendInittab()`, returning -1 if the table could not be extended. The new module can be imported by the name *name*, and uses the function *initfunc* as the initialization function called on the first attempted import. This should be called before `Py_Initialize()`.

struct _inittab

Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. Programs which embed Python may use an array of these structures in conjunction with `PyImport_ExtendInittab()` to provide additional built-in modules. The structure is defined in `Include/import.h` as:

```
struct _inittab {
    char *name;
    void (*initfunc)(void);
};
```

int **PyImport_ExtendInittab**(struct _inittab *newtab)

Add a collection of modules to the table of built-in modules. The *newtab* array must end with a sentinel entry which contains NULL for the name field; failure to provide the sentinel value can result in a memory fault. Returns 0 on success or -1 if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This should be called before `Py_Initialize()`.

Previous: [5.3 Importing Modules](#) **Up:** [5. Utilities](#) **Next:** [5.5 Parsing arguments and](#)

5.4 Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the `marshal` module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 (new in Python 2.4) shares interned strings in the file, and upon unmarshalling. `Py_MARSHAL_VERSION` indicates the current file format (currently 1).

`void PyMarshal_WriteLongToFile(long value, FILE *file, int version)`
Marshal a `long` integer, *value*, to *file*. This will only write the least-significant 32 bits of *value*; regardless of the size of the native `long` type.

Changed in version 2.4: *version* indicates the file format.

`void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)`
Marshal a Python object, *value*, to *file*.

Changed in version 2.4: *version* indicates the file format.

`PyObject* PyMarshal_WriteObjectToString(PyObject *value, int version)`

Return value: **New reference.**

Return a string object containing the marshalled representation of *value*.

Changed in version 2.4: *version* indicates the file format.

The following functions allow marshalled values to be read back in.

XXX What about error detection? It appears that reading past the end of the file will always result in a negative numeric value (where that's relevant), but it's not

clear that negative values won't be handled properly when there's no error. What's the right way to tell? Should only non-negative values be written using these routines?

`long PyMarshal_ReadLongFromFile(FILE *file)`

Return a C `long` from the data stream in a `FILE*` opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of `long`.

`int PyMarshal_ReadShortFromFile(FILE *file)`

Return a C `short` from the data stream in a `FILE*` opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of `short`.

`PyObject* PyMarshal_ReadObjectFromFile(FILE *file)`

*Return value: **New reference.***

Return a Python object from the data stream in a `FILE*` opened for reading. On error, sets the appropriate exception (`EOFError` or `TypeError`) and returns `NULL`.

`PyObject* PyMarshal_ReadLastObjectFromFile(FILE *file)`

*Return value: **New reference.***

Return a Python object from the data stream in a `FILE*` opened for reading. Unlike `PyMarshal_ReadObjectFromFile()`, this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the de-serialization can operate from data in memory rather than reading a byte at a time from the file. Only use these variant if you are certain that you won't be reading anything else from the file. On error, sets the appropriate exception (`EOFError` or `TypeError`) and returns `NULL`.

`PyObject* PyMarshal_ReadObjectFromString(char *string, int len)`

*Return value: **New reference.***

Return a Python object from the data stream in a character buffer containing `len` bytes pointed to by `string`. On error, sets the appropriate exception (`EOFError` or `TypeError`) and returns `NULL`.

5.5 Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in [Extending and Embedding the Python Interpreter](#).

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.

A format string consists of zero or more ``format units`." A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

"s" (string or Unicode object) [const char *]

Convert a Python string or Unicode object to a C pointer to a character string. You must not provide storage for the string itself; a pointer to an existing string is stored into the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded NUL bytes; if it does, a `TypeError` exception is raised. Unicode objects are converted to C strings using the default encoding. If this conversion fails, a `UnicodeError` is raised.

"s#" (string, Unicode or any read buffer compatible object) [const char *, int]

This variant on "s" stores into two C variables, the first one a pointer to a character string, the second one its length. In this case the Python string may contain embedded null bytes. Unicode objects pass back a pointer to the default encoded string version of the object if such a conversion is

possible. All other read-buffer compatible objects pass back a reference to the raw internal data representation.

"z" (string or None) [const char *]

Like "s", but the Python object may also be None, in which case the C pointer is set to NULL.

"z#" (string or None or any read buffer compatible object) [const char *, int]

This is to "s#" as "z" is to "s".

"u" (Unicode object) [Py_UNICODE *]

Convert a Python Unicode object to a C pointer to a NUL-terminated buffer of 16-bit Unicode (UTF-16) data. As with "s", there is no need to provide storage for the Unicode data buffer; a pointer to the existing Unicode data is stored into the Py_UNICODE pointer variable whose address you pass.

"u#" (Unicode object) [Py_UNICODE *, int]

This variant on "u" stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length. Non-Unicode objects are handled by interpreting their read-buffer pointer as pointer to a Py_UNICODE array.

"es" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer]

This variant on "s" is used for encoding Unicode and objects convertible to Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a `const char *` which points to the name of an encoding as a NUL-terminated string, or NULL, in which case the default encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char **`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

`PyArg_ParseTuple()` will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust **buffer* to reference the newly

allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after use.

"et" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer]

Same as "es" except that 8-bit string objects are passed through without recoding them. Instead, the implementation assumes that the string object uses the encoding passed in as parameter.

"es#" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer, int *buffer_length]

This variant on "s#" is used for encoding Unicode and objects convertible to Unicode into a character buffer. Unlike the "es" format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a `const char *` which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case the default encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char **`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If **buffer* points a `NULL` pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set **buffer* to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after usage.

If **buffer* points to a non-`NULL` pointer (an already allocated buffer), `PyArg_ParseTuple()` will use this location as the buffer and interpret the initial value of **buffer_length* as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a `ValueError` will be set.

In both cases, **buffer_length* is set to the length of the encoded data without

the trailing NUL byte.

"et#" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer]

Same as "es#" except that string objects are passed through without recoding them. Instead, the implementation assumes that the string object uses the encoding passed in as parameter.

"b" (integer) [char]

Convert a Python integer to a tiny int, stored in a C char.

"B" (integer) [unsigned char]

Convert a Python integer to a tiny int without overflow checking, stored in a C unsigned char. New in version 2.3.

"h" (integer) [short int]

Convert a Python integer to a C short int.

"H" (integer) [unsigned short int]

Convert a Python integer to a C unsigned short int, without overflow checking. New in version 2.3.

"i" (integer) [int]

Convert a Python integer to a plain C int.

"I" (integer) [unsigned int]

Convert a Python integer to a C unsigned int, without overflow checking. New in version 2.3.

"l" (integer) [long int]

Convert a Python integer to a C long int.

"k" (integer) [unsigned long]

Convert a Python integer or long integer to a C unsigned long without overflow checking. New in version 2.3.

"L" (integer) [PY_LONG_LONG]

Convert a Python integer to a C long long. This format is only available on platforms that support long long (or _int64 on Windows).

"K" (integer) [unsigned PY_LONG_LONG]

Convert a Python integer or long integer to a C unsigned long long without overflow checking. This format is only available on platforms that support unsigned long long (or unsigned _int64 on Windows). New in version 2.3.

"c" (string of length 1) [char]

Convert a Python character, represented as a string of length 1, to a C char.

"f" (float) [float]

Convert a Python floating point number to a C float.

"d" (float) [double]

Convert a Python floating point number to a C double.

"D" (complex) [Py_complex]

Convert a Python complex number to a C Py_complex structure.

"O" (object) [PyObject*]

Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object's reference count is not increased. The pointer stored is not NULL.

"O!" (object) [PyObject*, PyObject*]

Store a Python object in a C object pointer. This is similar to "O", but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type PyObject*) into which the object pointer is stored. If the Python object does not have the required type, TypeError is raised.

"O&" (object) [converter, anything]

Convert a Python object to a C variable through a *converter* function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to void *. The *converter* function in turn is called as follows:

```
status = converter(object, address);
```

where *object* is the Python object to be converted and *address* is the `void*` argument that was passed to the `PyArg_Parse* ()` function. The returned *status* should be `1` for a successful conversion and `0` if the conversion has failed. When the conversion fails, the *converter* function should raise an exception.

"S" (string) [PyStringObject *]

Like "O" but requires that the Python object is a string object. Raises `TypeError` if the object is not a string object. The C variable may also be declared as `PyObject*`.

"U" (Unicode string) [PyUnicodeObject *]

Like "O" but requires that the Python object is a Unicode object. Raises `TypeError` if the object is not a Unicode object. The C variable may also be declared as `PyObject*`.

"t#" (read-only character buffer) [char *, int]

Like "s#", but accepts any object which implements the read-only buffer interface. The `char*` variable is set to point to the first byte of the buffer, and the `int` is set to the length of the buffer. Only single-segment buffer objects are accepted; `TypeError` is raised for all others.

"w" (read-write character buffer) [char *]

Similar to "s", but accepts any object which implements the read-write buffer interface. The caller must determine the length of the buffer by other means, or use "w#" instead. Only single-segment buffer objects are accepted; `TypeError` is raised for all others.

"w#" (read-write character buffer) [char *, int]

Like "s#", but accepts any object which implements the read-write buffer interface. The `char*` variable is set to point to the first byte of the buffer, and the `int` is set to the length of the buffer. Only single-segment buffer objects are accepted; `TypeError` is raised for all others.

"(items)" (tuple) [matching-items]

The object must be a Python sequence whose length is the number of format units in *items*. The C arguments must correspond to the individual format units in *items*. Format units for sequences may be nested.

Note: Prior to Python version 1.5.2, this format specifier only accepted a tuple containing the individual parameters, not an arbitrary sequence. Code which previously caused `TypeError` to be raised here may now proceed without an exception. This is not expected to be a problem for existing code.

It is possible to pass Python long integers where integers are requested; however no proper range checking is done -- the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C -- your mileage may vary).

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

"|"

Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value -- when an optional argument is not specified, `PyArg_ParseTuple()` does not touch the contents of the corresponding C variable(s).

":"

The list of format units ends here; the string after the colon is used as the function name in error messages (the "associated value" of the exception that `PyArg_ParseTuple()` raises).

";"

The list of format units ends here; the string after the semicolon is used as the error message *instead* of the default error message. Clearly, ":" and ";" mutually exclude each other.

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the *arg* object must match the format and the format must be exhausted. On success, the `PyArg_Parse*` () functions return true, otherwise they return false and raise an appropriate exception.

int **PyArg_ParseTuple**(PyObject *args, char *format, ...)

Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int **PyArg_VaParse**(PyObject *args, char *format, va_list vargs)

Identical to `PyArg_ParseTuple` (), except that it accepts a `va_list` rather than a variable number of arguments.

int **PyArg_ParseTupleAndKeywords**(PyObject *args, PyObject *kw,
char *format, char *keywords[],
...)

Parse the parameters of a function that takes both positional and keyword parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int **PyArg_VaParseTupleAndKeywords**(PyObject *args, PyObject *kw,
char *format, char *keywords[],
va_list vargs)

Identical to `PyArg_ParseTupleAndKeywords` (), except that it accepts a `va_list` rather than a variable number of arguments.

int **PyArg_Parse**(PyObject *args, char *format, ...)

Function used to deconstruct the argument lists of ``old-style" functions -- these are functions which use the `METH_OLDARGS` parameter parsing method. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.

int **PyArg_UnpackTuple**(PyObject *args, char *name, int min, int max, ...)

A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to

retrieve their parameters should be declared as `METH_VARARGS` in function or method tables. The tuple containing the actual parameters should be passed as *args*; it must actually be a tuple. The length of the tuple must be at least *min* and no more than *max*; *min* and *max* may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a `PyObject *` variable; these will be filled in with the values from *args*; they will contain borrowed references. The variables which correspond to optional parameters not given by *args* will not be filled in; these should be initialized by the caller. This function returns true on success and false if *args* is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the `_weakref` helper module for weak references:

```
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object, &callback) < 0)
        result = PyWeakref_NewRef(object, callback);
    }
    return result;
}
```

The call to `PyArg_UnpackTuple()` in this example is entirely equivalent to this call to `PyArg_ParseTuple()`:

```
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```

New in version 2.2.

`PyObject*` **Py_BuildValue**(char **format*, ...)

Return value: **New reference.**

Create a new value based on a format string similar to those accepted by the `PyArg_Parse*`() family of functions and a sequence of values. Returns the value or `NULL` in the case of an error; an exception will be raised if `NULL` is returned.

`Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the "s" and "s#" formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by `Py_BuildValue()`. In other words, if your code invokes `malloc()` and passes the allocated memory to `Py_BuildValue()`, your code is responsible for calling `free()` for that memory once `Py_BuildValue()` returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as "s#"). This can be used to make long format strings a tad more readable.

"s" (string) [char *]

Convert a null-terminated C string to a Python object. If the C string pointer is `NULL`, `None` is used.

"s#" (string) [char *, int]

Convert a C string and its length to a Python object. If the C string pointer is `NULL`, the length is ignored and `None` is returned.

"z" (string or None) [char *]

Same as "s".

"z#" (string or None) [char *, int]

Same as "s#".

"u" (Unicode string) [Py_UNICODE *]

Convert a null-terminated buffer of Unicode (UCS-2 or UCS-4) data to

a Python Unicode object. If the Unicode buffer pointer is NULL, None is returned.

"u#" (Unicode string) [Py_UNICODE *, int]

Convert a Unicode (UCS-2 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is NULL, the length is ignored and None is returned.

"i" (integer) [int]

Convert a plain C `int` to a Python integer object.

"b" (integer) [char]

Convert a plain C `char` to a Python integer object.

"h" (integer) [short int]

Convert a plain C `short int` to a Python integer object.

"l" (integer) [long int]

Convert a C `long int` to a Python integer object.

"B" (integer) [unsigned char]

Convert a C `unsigned char` to a Python integer object.

"H" (integer) [unsigned short int]

Convert a C `unsigned short int` to a Python integer object.

"I" (integer/long) [unsigned int]

Convert a C `unsigned int` to a Python integer object or a Python long integer object, if it is larger than `sys.maxint`.

"k" (integer/long) [unsigned long]

Convert a C `unsigned long` to a Python integer object or a Python long integer object, if it is larger than `sys.maxint`.

"L" (long) [PY_LONG_LONG]

Convert a C `long long` to a Python long integer object. Only available on platforms that support `long long`.

"K" (long) [unsigned PY_LONG_LONG]

Convert a C `unsigned long long` to a Python long integer object. Only available on platforms that support `unsigned long long`.

"c" (string of length 1) [char]

Convert a C `int` representing a character to a Python string of length 1.

"d" (float) [double]

Convert a C `double` to a Python floating point number.

"f" (float) [float]

Same as "d".

"D" (complex) [Py_complex *]

Convert a C `Py_complex` structure to a Python complex number.

"O" (object) [PyObject *]

Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a `NULL` pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, `Py_BuildValue()` will return `NULL` but won't raise an exception. If no exception has been raised yet, `SystemError` is set.

"S" (object) [PyObject *]

Same as "O".

"N" (object) [PyObject *]

Same as "O", except it doesn't increment the reference count on the object. Useful when the object is created by a call to an object constructor in the argument list.

"O&" (object) [converter, anything]

Convert *anything* to a Python object through a *converter* function. The function is called with *anything* (which should be compatible with `void *`) as its argument and should return a "new" Python object, or `NULL` if an error occurred.

" (*items*) " (**tuple**) [*matching-items*]

Convert a sequence of C values to a Python tuple with the same number of items.

" [*items*] " (**list**) [*matching-items*]

Convert a sequence of C values to a Python list with the same number of items.

" {*items*} " (**dictionary**) [*matching-items*]

Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the `SystemError` exception is set and `NULL` returned.

6. Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by `PyList_New()`, but whose items have not been set to some non-NULL value yet.

Previous: [6. Abstract Objects Layer](#) **Up:** [6. Abstract Objects Layer](#) **Next:** [6.2 Number Protocol](#)

6.1 Object Protocol

int **PyObject_Print**(PyObject *o, FILE *fp, int flags)

Print an object *o*, on file *fp*. Returns -1 on error. The flags argument is used to enable certain printing options. The only option currently supported is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`.

int **PyObject_HasAttrString**(PyObject *o, char *attr_name)

Returns 1 if *o* has the attribute *attr_name*, and 0 otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

PyObject* **PyObject_GetAttrString**(PyObject *o, char *attr_name)

Return value: **New reference.**

Retrieve an attribute named *attr_name* from object *o*. Returns the attribute value on success, or NULL on failure. This is the equivalent of the Python expression `o.attr_name`.

int **PyObject_HasAttr**(PyObject *o, PyObject *attr_name)

Returns 1 if *o* has the attribute *attr_name*, and 0 otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

PyObject* **PyObject_GetAttr**(PyObject *o, PyObject *attr_name)

Return value: **New reference.**

Retrieve an attribute named *attr_name* from object *o*. Returns the attribute value on success, or NULL on failure. This is the equivalent of the Python expression `o.attr_name`.

int **PyObject_SetAttrString**(PyObject *o, char *attr_name, PyObject *v)

Set the value of the attribute named *attr_name*, for object *o*, to the value *v*. Returns -1 on failure. This is the equivalent of the Python statement `o.attr_name = v`.

int **PyObject_SetAttr**(PyObject *o, PyObject *attr_name, PyObject *v)
Set the value of the attribute named *attr_name*, for object *o*, to the value *v*. Returns -1 on failure. This is the equivalent of the Python statement "*o.attr_name = v*".

int **PyObject_DeAttrString**(PyObject *o, char *attr_name)
Delete attribute named *attr_name*, for object *o*. Returns -1 on failure. This is the equivalent of the Python statement: "*del o.attr_name*".

int **PyObject_DeAttr**(PyObject *o, PyObject *attr_name)
Delete attribute named *attr_name*, for object *o*. Returns -1 on failure. This is the equivalent of the Python statement "*del o.attr_name*".

PyObject* **PyObject_RichCompare**(PyObject *o1, PyObject *o2, int *opid*)

Return value: New reference.

Compare the values of *o1* and *o2* using the operation specified by *opid*, which must be one of Py_LT, Py_LE, Py_EQ, Py_NE, Py_GT, or Py_GE, corresponding to <, <=, ==, !=, >, or >= respectively. This is the equivalent of the Python expression "*o1 op o2*", where *op* is the operator corresponding to *opid*. Returns the value of the comparison on success, or NULL on failure.

int **PyObject_RichCompareBool**(PyObject *o1, PyObject *o2, int *opid*)
Compare the values of *o1* and *o2* using the operation specified by *opid*, which must be one of Py_LT, Py_LE, Py_EQ, Py_NE, Py_GT, or Py_GE, corresponding to <, <=, ==, !=, >, or >= respectively. Returns -1 on error, 0 if the result is false, 1 otherwise. This is the equivalent of the Python expression "*o1 op o2*", where *op* is the operator corresponding to *opid*.

int **PyObject_Cmp**(PyObject *o1, PyObject *o2, int *result)
Compare the values of *o1* and *o2* using a routine provided by *o1*, if one exists, otherwise with a routine provided by *o2*. The result of the comparison is returned in *result*. Returns -1 on failure. This is the equivalent of the Python statement "*result = cmp(o1, o2)*".

int **PyObject_Compare**(PyObject *o1, PyObject *o2)

Compare the values of *o1* and *o2* using a routine provided by *o1*, if one exists, otherwise with a routine provided by *o2*. Returns the result of the comparison on success. On error, the value returned is undefined; use `PyErr_Occurred()` to detect an error. This is equivalent to the Python expression "`cmp(o1, o2)`".

PyObject* **PyObject_Repr**(PyObject *o)

Return value: **New reference.**

Compute a string representation of object *o*. Returns the string representation on success, NULL on failure. This is the equivalent of the Python expression "`repr(o)`". Called by the `repr()` built-in function and by reverse quotes.

PyObject* **PyObject_Str**(PyObject *o)

Return value: **New reference.**

Compute a string representation of object *o*. Returns the string representation on success, NULL on failure. This is the equivalent of the Python expression "`str(o)`". Called by the `str()` built-in function and by the `print` statement.

PyObject* **PyObject_Unicode**(PyObject *o)

Return value: **New reference.**

Compute a Unicode string representation of object *o*. Returns the Unicode string representation on success, NULL on failure. This is the equivalent of the Python expression "`unicode(o)`". Called by the `unicode()` built-in function.

int **PyObject_IsInstance**(PyObject *inst, PyObject *cls)

Returns `1` if *inst* is an instance of the class *cls* or a subclass of *cls*, or `0` if not. On error, returns `-1` and sets an exception. If *cls* is a type object rather than a class object, `PyObject_IsInstance()` returns `1` if *inst* is of type *cls*. If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`. If *inst* is not a class instance and *cls* is neither a type object, nor a class object, nor a tuple, *inst* must have a `__class__` attribute -- the class relationship of the value of that attribute with *cls* will be used to determine

the result of this function. New in version 2.1. Changed in version 2.2: Support for a tuple as the second argument added.

Subclass determination is done in a fairly straightforward way, but includes a wrinkle that implementors of extensions to the class system may want to be aware of. If *A* and *B* are class objects, *B* is a subclass of *A* if it inherits from *A* either directly or indirectly. If either is not a class object, a more general mechanism is used to determine the class relationship of the two objects. When testing if *B* is a subclass of *A*, if *A* is *B*, `PyObject_IsSubclass()` returns true. If *A* and *B* are different objects, *B*'s `__bases__` attribute is searched in a depth-first fashion for *A* -- the presence of the `__bases__` attribute is considered sufficient for this determination.

int **PyObject_IsSubclass**(PyObject **derived*, PyObject **cls*)

Returns **1** if the class *derived* is identical to or derived from the class *cls*, otherwise returns **0**. In case of an error, returns **-1**. If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be **1** when at least one of the checks returns **1**, otherwise it will be **0**. If either *derived* or *cls* is not an actual class object (or tuple), this function uses the generic algorithm described above. New in version 2.1. Changed in version 2.3: Older versions of Python did not support a tuple as the second argument.

int **PyCallable_Check**(PyObject **o*)

Determine if the object *o* is callable. Return **1** if the object is callable and **0** otherwise. This function always succeeds.

PyObject* **PyObject_Call**(PyObject **callable_object*, PyObject **args*,
PyObject **kw*)

Return value: **New reference.**

Call a callable Python object *callable_object*, with arguments given by the tuple *args*, and named arguments given by the dictionary *kw*. If no named arguments are needed, *kw* may be NULL. *args* must not be NULL, use an empty tuple if no arguments are needed. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "`apply(callable_object, args, kw)`" or "`callable_object(*args, **kw)`". New in version 2.2.

PyObject **callable_object*, PyObject

PyObject* **PyObject_CallObject**(*args)

Return value: **New reference.**

Call a callable Python object *callable_object*, with arguments given by the tuple *args*. If no arguments are needed, then *args* may be NULL. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "`apply(callable_object, args)`" or "`callable_object(*args)`".

PyObject* **PyObject_CallFunction**(PyObject *callable, char *format, ...)

Return value: **New reference.**

Call a callable Python object *callable*, with a variable number of C arguments. The C arguments are described using a `Py_BuildValue()` style format string. The format may be NULL, indicating that no arguments are provided. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "`apply(callable, args)`" or "`callable(*args)`".

PyObject* **PyObject_CallMethod**(PyObject *o, char *method, char *format, ...)

Return value: **New reference.**

Call the method named *method* of object *o* with a variable number of C arguments. The C arguments are described by a `Py_BuildValue()` format string that should produce a tuple. The format may be NULL, indicating that no arguments are provided. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "`o.method(args)`".

PyObject* **PyObject_CallFunctionObjArgs**(PyObject *callable, ..., NULL)

Return value: **New reference.**

Call a callable Python object *callable*, with a variable number of `PyObject *` arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success, or NULL on failure. New in version 2.2.

PyObject *o, PyObject

PyObject* **PyObject_CallMethodObjArgs**(*name, ..., NULL)

*Return value: **New reference.***

Calls a method of the object *o*, where the name of the method is given as a Python string object in *name*. It is called with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success, or NULL on failure. New in version 2.2.

int **PyObject_Hash**(PyObject *o)

Compute and return the hash value of an object *o*. On failure, return -1. This is the equivalent of the Python expression "hash(*o*)".

int **PyObject_IsTrue**(PyObject *o)

Returns 1 if the object *o* is considered to be true, and 0 otherwise. This is equivalent to the Python expression "not not *o*". On failure, return -1.

int **PyObject_Not**(PyObject *o)

Returns 0 if the object *o* is considered to be true, and 1 otherwise. This is equivalent to the Python expression "not *o*". On failure, return -1.

PyObject* **PyObject_Type**(PyObject *o)

*Return value: **New reference.***

When *o* is non-NULL, returns a type object corresponding to the object type of object *o*. On failure, raises SystemError and returns NULL. This is equivalent to the Python expression type(*o*). This function increments the reference count of the return value. There's really no reason to use this function instead of the common expression *o*->ob_type, which returns a pointer of type PyTypeObject*, except when the incremented reference count is needed.

int **PyObject_TypeCheck**(PyObject *o, PyTypeObject *type)

Return true if the object *o* is of type *type* or a subtype of *type*. Both parameters must be non-NULL. New in version 2.2.

int **PyObject_Length**(PyObject *o)

int **PyObject_Size**(PyObject *o)

Return the length of object *o*. If the object *o* provides either the sequence and mapping protocols, the sequence length is returned. On error, `-1` is returned. This is the equivalent to the Python expression `len(o)`.

`PyObject*` **PyObject_GetItem**(`PyObject *o`, `PyObject *key`)

Return value: **New reference.**

Return element of *o* corresponding to the object *key* or `NULL` on failure. This is the equivalent of the Python expression `o[key]`.

`int` **PyObject_SetItem**(`PyObject *o`, `PyObject *key`, `PyObject *v`)

Map the object *key* to the value *v*. Returns `-1` on failure. This is the equivalent of the Python statement `o[key] = v`.

`int` **PyObject_DelItem**(`PyObject *o`, `PyObject *key`)

Delete the mapping for *key* from *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[key]`.

`int` **PyObject_AsFileDescriptor**(`PyObject *o`)

Derives a file-descriptor from a Python object. If the object is an integer or long integer, its value is returned. If not, the object's `fileno()` method is called if it exists; the method must return an integer or long integer, which is returned as the file descriptor value. Returns `-1` on failure.

`PyObject*` **PyObject_Dir**(`PyObject *o`)

Return value: **New reference.**

This is equivalent to the Python expression `dir(o)`, returning a (possibly empty) list of strings appropriate for the object argument, or `NULL` if there was an error. If the argument is `NULL`, this is like the Python `dir()`, returning the names of the current locals; in this case, if no execution frame is active then `NULL` is returned but `PyErr_Occurred()` will return false.

`PyObject*` **PyObject_GetIter**(`PyObject *o`)

Return value: **New reference.**

This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises `TypeError` and returns `NULL` if the object cannot be

iterated.

Previous: [6.1 Object Protocol](#) Up: [6. Abstract Objects Layer](#) Next: [6.3 Sequence Protocol](#)

6.2 Number Protocol

int **PyNumber_Check**(PyObject *o)

Returns 1 if the object *o* provides numeric protocols, and false otherwise. This function always succeeds.

PyObject* **PyNumber_Add**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the result of adding *o1* and *o2*, or NULL on failure. This is the equivalent of the Python expression "*o1* + *o2*".

PyObject* **PyNumber_Subtract**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the result of subtracting *o2* from *o1*, or NULL on failure. This is the equivalent of the Python expression "*o1* - *o2*".

PyObject* **PyNumber_Multiply**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the result of multiplying *o1* and *o2*, or NULL on failure. This is the equivalent of the Python expression "*o1* * *o2*".

PyObject* **PyNumber_Divide**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the result of dividing *o1* by *o2*, or NULL on failure. This is the equivalent of the Python expression "*o1* / *o2*".

PyObject* **PyNumber_FloorDivide**(PyObject *o1, PyObject *o2)

Return value: New reference.

Return the floor of *o1* divided by *o2*, or NULL on failure. This is equivalent to the ``classic`` division of integers. New in version 2.2.

PyObject* **PyNumber_TrueDivide**(PyObject *o1, PyObject *o2)

Return value: New reference.

Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or NULL on failure. The return value is ``approximate``

because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. New in version 2.2.

PyObject* **PyNumber_Remainder**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

Returns the remainder of dividing *o1* by *o2*, or NULL on failure. This is the equivalent of the Python expression "*o1* % *o2*".

PyObject* **PyNumber_Divmod**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

See the built-in function `divmod()`. Returns NULL on failure. This is the equivalent of the Python expression "`divmod(o1, o2)`".

PyObject* **PyNumber_Power**(PyObject *o1, PyObject *o2, PyObject *o3)

*Return value: **New reference.***

See the built-in function `pow()`. Returns NULL on failure. This is the equivalent of the Python expression "`pow(o1, o2, o3)`", where *o3* is optional. If *o3* is to be ignored, pass `Py_NONE` in its place (passing NULL for *o3* would cause an illegal memory access).

PyObject* **PyNumber_Negative**(PyObject *o)

*Return value: **New reference.***

Returns the negation of *o* on success, or NULL on failure. This is the equivalent of the Python expression "`-o`".

PyObject* **PyNumber_Positive**(PyObject *o)

*Return value: **New reference.***

Returns *o* on success, or NULL on failure. This is the equivalent of the Python expression "`+o`".

PyObject* **PyNumber_Absolute**(PyObject *o)

*Return value: **New reference.***

Returns the absolute value of *o*, or NULL on failure. This is the equivalent of the Python expression "`abs(o)`".

PyObject* **PyNumber_Invert**(PyObject *o)

*Return value: **New reference.***

Returns the bitwise negation of *o* on success, or NULL on failure. This is the equivalent of the Python expression " $\sim o$ ".

PyObject* **PyNumber_Lshift**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the result of left shifting *o1* by *o2* on success, or NULL on failure. This is the equivalent of the Python expression " $o1 \ll o2$ ".

PyObject* **PyNumber_Rshift**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the result of right shifting *o1* by *o2* on success, or NULL on failure. This is the equivalent of the Python expression " $o1 \gg o2$ ".

PyObject* **PyNumber_And**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the ``bitwise and" of *o1* and *o2* on success and NULL on failure. This is the equivalent of the Python expression " $o1 \& o2$ ".

PyObject* **PyNumber_Xor**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the ``bitwise exclusive or" of *o1* by *o2* on success, or NULL on failure. This is the equivalent of the Python expression " $o1 \wedge o2$ ".

PyObject* **PyNumber_Or**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the ``bitwise or" of *o1* and *o2* on success, or NULL on failure. This is the equivalent of the Python expression " $o1 \mid o2$ ".

PyObject* **PyNumber_InPlaceAdd**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the result of adding *o1* and *o2*, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement " $o1 += o2$ ".

PyObject* **PyNumber_InPlaceSubtract**(PyObject **o1*, PyObject **o2*)

*Return value: **New reference.***

Returns the result of subtracting *o2* from *o1*, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement "*o1 -= o2*".

PyObject* **PyNumber_InPlaceMultiply**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Returns the result of multiplying *o1* and *o2*, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement "*o1 *= o2*".

PyObject* **PyNumber_InPlaceDivide**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Returns the result of dividing *o1* by *o2*, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement "*o1 /= o2*".

PyObject* **PyNumber_InPlaceFloorDivide**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Returns the mathematical floor of dividing *o1* by *o2*, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement "*o1 // = o2*". New in version 2.2.

PyObject* **PyNumber_InPlaceTrueDivide**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or NULL on failure. The return value is ``approximate" because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. The operation is done *in-place* when *o1* supports it. New in version 2.2.

PyObject* **PyNumber_InPlaceRemainder**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Returns the remainder of dividing *o1* by *o2*, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the

Python statement "`o1 %= o2`".

PyObject* **PyNumber_InPlacePower**(PyObject *o1, PyObject *o2,
PyObject *o3)

*Return value: **New reference.***

See the built-in function `pow()`. Returns NULL on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement "`o1 **= o2`" when `o3` is `Py_None`, or an in-place variant of "`pow(o1, o2, o3)`" otherwise. If `o3` is to be ignored, pass `Py_None` in its place (passing NULL for `o3` would cause an illegal memory access).

PyObject* **PyNumber_InPlaceLshift**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

Returns the result of left shifting `o1` by `o2` on success, or NULL on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement "`o1 <<= o2`".

PyObject* **PyNumber_InPlaceRshift**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

Returns the result of right shifting `o1` by `o2` on success, or NULL on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement "`o1 >>= o2`".

PyObject* **PyNumber_InPlaceAnd**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

Returns the ``bitwise and" of `o1` and `o2` on success and NULL on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement "`o1 &= o2`".

PyObject* **PyNumber_InPlaceXor**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

Returns the ``bitwise exclusive or" of `o1` by `o2` on success, or NULL on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement "`o1 ^= o2`".

PyObject* **PyNumber_InPlaceOr**(PyObject *o1, PyObject *o2)

*Return value: **New reference.***

Returns the ``bitwise or" of *o1* and *o2* on success, or NULL on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement "*o1* |= *o2*".

int **PyNumber_Coerce**(PyObject ***p1*, PyObject ***p2*)

This function takes the addresses of two variables of type PyObject *. If the objects pointed to by **p1* and **p2* have the same type, increment their reference count and return 0 (success). If the objects can be converted to a common numeric type, replace **p1* and **p2* by their converted value (with 'new' reference counts), and return 0. If no conversion is possible, or if some other error occurs, return -1 (failure) and don't increment the reference counts. The call PyNumber_Coerce(&*o1*, &*o2*) is equivalent to the Python statement "*o1*, *o2* = coerce(*o1*, *o2*)".

PyObject* **PyNumber_Int**(PyObject **o*)

Return value: **New reference.**

Returns the *o* converted to an integer object on success, or NULL on failure. If the argument is outside the integer range a long object will be returned instead. This is the equivalent of the Python expression "int(*o*)".

PyObject* **PyNumber_Long**(PyObject **o*)

Return value: **New reference.**

Returns the *o* converted to a long integer object on success, or NULL on failure. This is the equivalent of the Python expression "long(*o*)".

PyObject* **PyNumber_Float**(PyObject **o*)

Return value: **New reference.**

Returns the *o* converted to a float object on success, or NULL on failure. This is the equivalent of the Python expression "float(*o*)".

Previous: [6.2 Number Protocol](#) **Up:** [6. Abstract Objects Layer](#) **Next:** [6.4 Mapping Protocol](#)

6.3 Sequence Protocol

int **PySequence_Check**(PyObject *o)

Return 1 if the object provides sequence protocol, and 0 otherwise. This function always succeeds.

int **PySequence_Size**(PyObject *o)

Returns the number of objects in sequence *o* on success, and -1 on failure. For objects that do not provide sequence protocol, this is equivalent to the Python expression "`len(o)`".

int **PySequence_Length**(PyObject *o)

Alternate name for `PySequence_Size()`.

PyObject* **PySequence_Concat**(PyObject *o1, PyObject *o2)

Return value: New reference.

Return the concatenation of *o1* and *o2* on success, and NULL on failure. This is the equivalent of the Python expression "`o1 + o2`".

PyObject* **PySequence_Repeat**(PyObject *o, int count)

Return value: New reference.

Return the result of repeating sequence object *o* *count* times, or NULL on failure. This is the equivalent of the Python expression "`o * count`".

PyObject* **PySequence_InPlaceConcat**(PyObject *o1, PyObject *o2)

Return value: New reference.

Return the concatenation of *o1* and *o2* on success, and NULL on failure.

The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python expression "`o1 += o2`".

PyObject* **PySequence_InPlaceRepeat**(PyObject *o, int count)

Return value: New reference.

Return the result of repeating sequence object *o* *count* times, or NULL on failure. The operation is done *in-place* when *o* supports it. This is the equivalent of the Python expression "`o *= count`".

PyObject* **PySequence_GetItem**(PyObject *o, int i)

*Return value: **New reference.***

Return the *i*th element of *o*, or NULL on failure. This is the equivalent of the Python expression "*o*[*i*]".

PyObject* **PySequence_GetSlice**(PyObject *o, int i1, int i2)

*Return value: **New reference.***

Return the slice of sequence object *o* between *i1* and *i2*, or NULL on failure. This is the equivalent of the Python expression "*o*[*i1*:*i2*]".

int **PySequence_SetItem**(PyObject *o, int i, PyObject *v)

Assign object *v* to the *i*th element of *o*. Returns -1 on failure. This is the equivalent of the Python statement "*o*[*i*] = *v*". This function *does not* steal a reference to *v*.

int **PySequence_DelItem**(PyObject *o, int i)

Delete the *i*th element of object *o*. Returns -1 on failure. This is the equivalent of the Python statement "`del o[i]`".

int **PySequence_SetSlice**(PyObject *o, int i1, int i2, PyObject *v)

Assign the sequence object *v* to the slice in sequence object *o* from *i1* to *i2*. This is the equivalent of the Python statement "*o*[*i1*:*i2*] = *v*".

int **PySequence_DelSlice**(PyObject *o, int i1, int i2)

Delete the slice in sequence object *o* from *i1* to *i2*. Returns -1 on failure. This is the equivalent of the Python statement "`del o[i1:i2]`".

int **PySequence_Count**(PyObject *o, PyObject *value)

Return the number of occurrences of *value* in *o*, that is, return the number of keys for which *o*[*key*] == *value*. On failure, return -1. This is equivalent to the Python expression "*o*.count(*value*)".

int **PySequence_Contains**(PyObject *o, PyObject *value)

Determine if *o* contains *value*. If an item in *o* is equal to *value*, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression "*value* in *o*".

int **PySequence_Index**(PyObject *o, PyObject *value)

Return the first index i for which $o[i] == value$. On error, return -1 . This is equivalent to the Python expression " $o.index(value)$ ".

PyObject* **PySequence_List**(PyObject *o)

*Return value: **New reference.***

Return a list object with the same contents as the arbitrary sequence o . The returned list is guaranteed to be new.

PyObject* **PySequence_Tuple**(PyObject *o)

*Return value: **New reference.***

Return a tuple object with the same contents as the arbitrary sequence o or NULL on failure. If o is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression " $tuple(o)$ ".

PyObject* **PySequence_Fast**(PyObject *o, const char *m)

*Return value: **New reference.***

Returns the sequence o as a tuple, unless it is already a tuple or list, in which case o is returned. Use `PySequence_Fast_GET_ITEM()` to access the members of the result. Returns NULL on failure. If the object is not a sequence, raises `TypeError` with m as the message text.

PyObject* **PySequence_Fast_GET_ITEM**(PyObject *o, int i)

*Return value: **Borrowed reference.***

Return the i th element of o , assuming that o was returned by `PySequence_Fast()`, o is not NULL, and that i is within bounds.

PyObject** **PySequence_Fast_ITEMS**(PyObject *o)

Return the underlying array of PyObject pointers. Assumes that o was returned by `PySequence_Fast()` and o is not NULL. New in version 2.4.

PyObject* **PySequence_ITEM**(PyObject *o, int i)

*Return value: **New reference.***

Return the i th element of o or NULL on failure. Macro form of `PySequence_GetItem()` but without checking that

`PySequence_Check(o)` is true and without adjustment for negative indices. New in version 2.3.

int **PySequence_Fast_GET_SIZE**(PyObject *o)

Returns the length of *o*, assuming that *o* was returned by `PySequence_Fast()` and that *o* is not NULL. The size can also be gotten by calling `PySequence_Size()` on *o*, but `PySequence_Fast_GET_SIZE()` is faster because it can assume *o* is a list or tuple.

Previous: [6.2 Number Protocol](#) Up: [6. Abstract Objects Layer](#) Next: [6.4 Mapping Protocol](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [6.3 Sequence Protocol](#) **Up:** [6. Abstract Objects Layer](#) **Next:** [6.5 Iterator Protocol](#)

6.4 Mapping Protocol

int **PyMapping_Check**(PyObject *o)

Return 1 if the object provides mapping protocol, and 0 otherwise. This function always succeeds.

int **PyMapping_Length**(PyObject *o)

Returns the number of keys in object *o* on success, and -1 on failure. For objects that do not provide mapping protocol, this is equivalent to the Python expression "`len(o)`".

int **PyMapping_DelItemString**(PyObject *o, char *key)

Remove the mapping for object *key* from the object *o*. Return -1 on failure. This is equivalent to the Python statement "`del o[key]`".

int **PyMapping_DelItem**(PyObject *o, PyObject *key)

Remove the mapping for object *key* from the object *o*. Return -1 on failure. This is equivalent to the Python statement "`del o[key]`".

int **PyMapping_HasKeyString**(PyObject *o, char *key)

On success, return 1 if the mapping object has the key *key* and 0 otherwise. This is equivalent to the Python expression "`o.has_key(key)`". This function always succeeds.

int **PyMapping_HasKey**(PyObject *o, PyObject *key)

Return 1 if the mapping object has the key *key* and 0 otherwise. This is equivalent to the Python expression "`o.has_key(key)`". This function always succeeds.

PyObject* **PyMapping_Keys**(PyObject *o)

Return value: **New reference.**

On success, return a list of the keys in object *o*. On failure, return NULL. This is equivalent to the Python expression "`o.keys()`".

PyObject* **PyMapping_Values**(PyObject *o)

*Return value: **New reference.***

On success, return a list of the values in object *o*. On failure, return NULL. This is equivalent to the Python expression "`o.values()`".

PyObject* **PyMapping_Items**(PyObject **o*)

*Return value: **New reference.***

On success, return a list of the items in object *o*, where each item is a tuple containing a key-value pair. On failure, return NULL. This is equivalent to the Python expression "`o.items()`".

PyObject* **PyMapping_GetItemString**(PyObject **o*, char **key*)

*Return value: **New reference.***

Return element of *o* corresponding to the object *key* or NULL on failure. This is the equivalent of the Python expression "`o[key]`".

int **PyMapping_SetItemString**(PyObject **o*, char **key*, PyObject **v*)

Map the object *key* to the value *v* in object *o*. Returns -1 on failure. This is the equivalent of the Python statement "`o[key] = v`".

Previous: [6.4 Mapping Protocol](#) **Up:** [6. Abstract Objects Layer](#) **Next:** [6.6 Buffer Protocol](#)

6.5 Iterator Protocol

New in version 2.2.

There are only a couple of functions specifically for working with iterators.

int **PyIter_Check**(PyObject *o)

Return true if the object *o* supports the iterator protocol.

PyObject* **PyIter_Next**(PyObject *o)

Return value: **New reference.**

Return the next value from the iteration *o*. If the object is an iterator, this retrieves the next value from the iteration, and returns **NULL** with no exception set if there are no remaining items. If the object is not an iterator, **TypeError** is raised, or if there is an error in retrieving the item, returns **NULL** and passes along the exception.

To write a loop which iterates over an iterator, the C code should look something like this:

```
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
    /* propagate error */
}

while (item = PyIter_Next(iterator)) {
    /* do something with item */
    ...
    /* release reference when done */
    Py_DECREF(item);
}

Py_DECREF(iterator);

if (PyErr_Occurred()) {
    /* propagate error */
}
else {
    /* continue doing useful work */
}
```

6.6 Buffer Protocol

int **PyObject_AsCharBuffer**(PyObject *obj, const char **buffer, int *buffer_len)

Returns a pointer to a read-only memory location useable as character-based input. The *obj* argument must support the single-segment character buffer interface. On success, returns 0, sets *buffer* to the memory location and *buffer_len* to the buffer length. Returns -1 and sets a `TypeError` on error. New in version 1.6.

int **PyObject_AsReadBuffer**(PyObject *obj, const void **buffer, int *buffer_len)

Returns a pointer to a read-only memory location containing arbitrary data. The *obj* argument must support the single-segment readable buffer interface. On success, returns 0, sets *buffer* to the memory location and *buffer_len* to the buffer length. Returns -1 and sets a `TypeError` on error. New in version 1.6.

int **PyObject_CheckReadBuffer**(PyObject *o)

Returns 1 if *o* supports the single-segment readable buffer interface. Otherwise returns 0. New in version 2.2.

int **PyObject_AsWriteBuffer**(PyObject *obj, void **buffer, int *buffer_len)

Returns a pointer to a writable memory location. The *obj* argument must support the single-segment, character buffer interface. On success, returns 0, sets *buffer* to the memory location and *buffer_len* to the buffer length. Returns -1 and sets a `TypeError` on error. New in version 1.6.

Previous: [6.6 Buffer Protocol](#) **Up:** [Python/C API Reference Manual](#) **Next:** [7.1 Fundamental Objects](#)

7. Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use `PyDict_Check()`. The chapter is structured like the "family tree" of Python object types.

Warning: While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for NULL being passed instead of a valid object. Allowing NULL to be passed in can cause memory access violations and immediate termination of the interpreter.

Previous: [7.1 Fundamental Objects](#) **Up:** [7.1 Fundamental Objects](#) **Next:** [7.1.2 The None Object](#)

7.1.1 Type Objects

PyTypeObject

The C structure of the objects used to describe built-in types.

PyObject* PyType_Type

This is the type object for type objects; it is the same object as `types.TypeType` in the Python layer.

int PyType_Check(PyObject *o)

Return true if the object *o* is a type object, including instances of types derived from the standard type object. Return false in all other cases.

int PyType_CheckExact(PyObject *o)

Return true if the object *o* is a type object, but not a subtype of the standard type object. Return false in all other cases. New in version 2.2.

int PyType_HasFeature(PyObject *o, int *feature*)

Return true if the type object *o* sets the feature *feature*. Type features are denoted by single bit flags.

int PyType_IS_GC(PyObject *o)

Return true if the type object includes support for the cycle detector; this tests the type flag `Py_TPFLAGS_HAVE_GC`. New in version 2.0.

int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)

Return true if *a* is a subtype of *b*. New in version 2.2.

PyObject* PyType_GenericAlloc(PyTypeObject *type, int *nitems*)

Return value: *New reference*.

New in version 2.2.

PyObject* PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwargs)

Return value: *New reference*.

New in version 2.2.

int **PyType_Ready**(PyTypeObject *type)

Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return 0 on success, or return -1 and sets an exception on error. New in version 2.2.

Previous: [7.1 Fundamental Objects](#) Up: [7.1 Fundamental Objects](#) Next: [7.1.2 The None Object](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.1.1 Type Objects](#) **Up:** [7.1 Fundamental Objects](#) **Next:** [7.2 Numeric Objects](#)

7.1.2 The None Object

Note that the `PyObject` for `None` is not directly exposed in the Python/C API. Since `None` is a singleton, testing for object identity (using `"=="` in C) is sufficient. There is no `PyNone_Check()` function for the same reason.

`PyObject*` **Py_None**

The Python `None` object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_NONE

Properly handle returning `Py_None` from within a C function.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.2 Numeric Objects](#) **Up:** [7.2 Numeric Objects](#) **Next:** [7.2.2 Boolean Objects](#)

7.2.1 Plain Integer Objects

PyObject PyIntObject

This subtype of `PyObject` represents a Python integer object.

PyObject PyInt_Type

This instance of `PyObject` represents the Python plain integer type. This is the same object as `types.IntType`.

int PyInt_Check(PyObject *o)

Return true if `o` is of type `PyInt_Type` or a subtype of `PyInt_Type`. Changed in version 2.2: Allowed subtypes to be accepted.

int PyInt_CheckExact(PyObject *o)

Return true if `o` is of type `PyInt_Type`, but not a subtype of `PyInt_Type`. New in version 2.2.

PyObject* PyInt_FromString(char *str, char **pend, int base)

Return value: **New reference.**

Return a new `PyIntObject` or `PyLongObject` based on the string value in `str`, which is interpreted according to the radix in `base`. If `pend` is non-NULL, `*pend` will point to the first character in `str` which follows the representation of the number. If `base` is 0, the radix will be determined based on the leading characters of `str`: if `str` starts with '0x' or '0X', radix 16 will be used; if `str` starts with '0', radix 8 will be used; otherwise radix 10 will be used. If `base` is not 0, it must be between 2 and 36, inclusive. Leading spaces are ignored. If there are no digits, `ValueError` will be raised. If the string represents a number too large to be contained within the machine's long `int` type and overflow warnings are being suppressed, a `PyLongObject` will be returned. If overflow warnings are not being suppressed, NULL will be returned in this case.

PyObject* PyInt_FromLong(long ival)

Return value: **New reference.**

Create a new integer object with a value of `ival`.

The current implementation keeps an array of integer objects for all integers between -1 and 100, when you create an int in that range you actually just get back a reference to the existing object. So it should be possible to change the value of 1. I suspect the behaviour of Python in this case is undefined. :-)

long **PyInt_AsLong**(PyObject *io)

Will first attempt to cast the object to a `PyIntObject`, if it is not already one, and then return its value.

long **PyInt_AS_LONG**(PyObject *io)

Return the value of the object `io`. No error checking is performed.

unsigned long **PyInt_AsUnsignedLongMask**(PyObject *io)

Will first attempt to cast the object to a `PyIntObject` or `PyLongObject`, if it is not already one, and then return its value as unsigned long. This function does not check for overflow. New in version 2.3.

unsigned long long **PyInt_AsUnsignedLongLongMask**(PyObject *io)

Will first attempt to cast the object to a `PyIntObject` or `PyLongObject`, if it is not already one, and then return its value as unsigned long long, without checking for overflow. New in version 2.3.

long **PyInt_GetMax**()

Return the system's idea of the largest integer it can handle (`LONG_MAX`, as defined in the system header files).

Previous: [7.2.1 Plain Integer Objects](#) **Up:** [7.2 Numeric Objects](#) **Next:** [7.2.3 Long Integer Objects](#)

7.2.2 Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, `Py_False` and `Py_True`. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

`int PyBool_Check(PyObject *o)`

Return true if `o` is of type `PyBool_Type`. New in version 2.3.

`PyObject* Py_False`

The Python `False` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`PyObject* Py_True`

The Python `True` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`Py_RETURN_FALSE`

Return `Py_False` from a function, properly incrementing its reference count. New in version 2.4.

`Py_RETURN_TRUE`

Return `Py_True` from a function, properly incrementing its reference count. New in version 2.4.

`PyObject* PyBool_FromLong(long v)`

*Return value: **New reference.***

Return a new reference to `Py_True` or `Py_False` depending on the truth value of `v`. New in version 2.3.

See [About this document..](#) for information on suggesting changes.

Previous: [7.2.2 Boolean Objects](#) **Up:** [7.2 Numeric Objects](#) **Next:** [7.2.4 Floating Point Objects](#)

7.2.3 Long Integer Objects

PyLongObject

This subtype of `PyObject` represents a Python long integer object.

PyTypeObject PyLong_Type

This instance of `PyTypeObject` represents the Python long integer type. This is the same object as `types.LongType`.

int PyLong_Check(PyObject *p)

Return true if its argument is a `PyLongObject` or a subtype of `PyLongObject`. Changed in version 2.2: Allowed subtypes to be accepted.

int PyLong_CheckExact(PyObject *p)

Return true if its argument is a `PyLongObject`, but not a subtype of `PyLongObject`. New in version 2.2.

PyObject* PyLong_FromLong(long v)

*Return value: **New reference.***

Return a new `PyLongObject` object from `v`, or `NULL` on failure.

PyObject* PyLong_FromUnsignedLong(unsigned long v)

*Return value: **New reference.***

Return a new `PyLongObject` object from a C `unsigned long`, or `NULL` on failure.

PyObject* PyLong_FromLongLong(long long v)

*Return value: **New reference.***

Return a new `PyLongObject` object from a C `long long`, or `NULL` on failure.

PyObject* PyLong_FromUnsignedLongLong(unsigned long long v)

*Return value: **New reference.***

Return a new `PyLongObject` object from a C `unsigned long long`, or `NULL` on failure.

PyObject* **PyLong_FromDouble**(double v)

Return value: **New reference.**

Return a new PyLongObject object from the integer part of v, or NULL on failure.

PyObject* **PyLong_FromString**(char *str, char **pend, int base)

Return value: **New reference.**

Return a new PyLongObject based on the string value in str, which is interpreted according to the radix in base. If pend is non-NULL, *pend will point to the first character in str which follows the representation of the number. If base is 0, the radix will be determined based on the leading characters of str: if str starts with '0x' or '0X', radix 16 will be used; if str starts with '0', radix 8 will be used; otherwise radix 10 will be used. If base is not 0, it must be between 2 and 36, inclusive. Leading spaces are ignored. If there are no digits, ValueError will be raised.

PyObject* **PyLong_FromUnicode**(Py_UNICODE *u, int length, int base)

Return value: **New reference.**

Convert a sequence of Unicode digits to a Python long integer value. The first parameter, u, points to the first character of the Unicode string, length gives the number of characters, and base is the radix for the conversion. The radix must be in the range [2, 36]; if it is out of range, ValueError will be raised. New in version 1.6.

PyObject* **PyLong_FromVoidPtr**(void *p)

Return value: **New reference.**

Create a Python integer or long integer from the pointer p. The pointer value can be retrieved from the resulting value using PyLong_AsVoidPtr(). New in version 1.5.2.

long **PyLong_AsLong**(PyObject *pylong)

Return a C long representation of the contents of pylong. If pylong is greater than LONG_MAX, an OverflowError is raised.

unsigned long **PyLong_AsUnsignedLong**(PyObject *pylong)

Return a C unsigned long representation of the contents of pylong. If pylong is greater than ULONG_MAX, an OverflowError is raised.

`long long PyLong_AsLongLong(PyObject *pylong)`

Return a C `long long` from a Python long integer. If *pylong* cannot be represented as a `long long`, an `OverflowError` will be raised. New in version 2.2.

`unsigned long long PyLong_AsUnsignedLongLong(PyObject *pylong)`

Return a C `unsigned long long` from a Python long integer. If *pylong* cannot be represented as an `unsigned long long`, an `OverflowError` will be raised if the value is positive, or a `TypeError` will be raised if the value is negative. New in version 2.2.

`unsigned long PyLong_AsUnsignedLongMask(PyObject *io)`

Return a C `unsigned long` from a Python long integer, without checking for overflow. New in version 2.3.

`unsigned long PyLong_AsUnsignedLongLongMask(PyObject *io)`

Return a C `unsigned long long` from a Python long integer, without checking for overflow. New in version 2.3.

`double PyLong_AsDouble(PyObject *pylong)`

Return a C `double` representation of the contents of *pylong*. If *pylong* cannot be approximately represented as a `double`, an `OverflowError` exception is raised and `-1.0` will be returned.

`void* PyLong_AsVoidPtr(PyObject *pylong)`

Convert a Python integer or long integer *pylong* to a C `void` pointer. If *pylong* cannot be converted, an `OverflowError` will be raised. This is only assured to produce a usable `void` pointer for values created with `PyLong_FromVoidPtr()`. New in version 1.5.2.

Previous: [7.2.3 Long Integer Objects](#) **Up:** [7.2 Numeric Objects](#) **Next:** [7.2.5 Complex Number Objects](#)

7.2.4 Floating Point Objects

PyFloatObject

This subtype of `PyObject` represents a Python floating point object.

PyObject PyFloat_Type

This instance of `PyObject` represents the Python floating point type. This is the same object as `types.FloatType`.

int PyFloat_Check(PyObject *p)

Return true if its argument is a `PyFloatObject` or a subtype of `PyFloatObject`. Changed in version 2.2: Allowed subtypes to be accepted.

int PyFloat_CheckExact(PyObject *p)

Return true if its argument is a `PyFloatObject`, but not a subtype of `PyFloatObject`. New in version 2.2.

PyObject* PyFloat_FromString(PyObject *str, char **pend)

Return value: **New reference.**

Create a `PyFloatObject` object based on the string value in `str`, or NULL on failure. The `pend` argument is ignored. It remains only for backward compatibility.

PyObject* PyFloat_FromDouble(double v)

Return value: **New reference.**

Create a `PyFloatObject` object from `v`, or NULL on failure.

double PyFloat_AsDouble(PyObject *pyfloat)

Return a C `double` representation of the contents of `pyfloat`.

double PyFloat_AS_DOUBLE(PyObject *pyfloat)

Return a C `double` representation of the contents of `pyfloat`, but without error checking.

7.2.5 Complex Number Objects

Python's complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.

Subsections

- [7.2.5.1 Complex Numbers as C Structures](#)

Previous: [7.3 Sequence Objects](#) **Up:** [7.3 Sequence Objects](#) **Next:** [7.3.2 Unicode Objects](#)

7.3.1 String Objects

These functions raise `TypeError` when expecting a string parameter and are called with a non-string parameter.

PyStringObject

This subtype of `PyObject` represents a Python string object.

PyTypeObject PyString_Type

This instance of `PyTypeObject` represents the Python string type; it is the same object as `types.StringType` in the Python layer. .

int PyString_Check(PyObject *o)

Return true if the object `o` is a string object or an instance of a subtype of the string type. Changed in version 2.2: Allowed subtypes to be accepted.

int PyString_CheckExact(PyObject *o)

Return true if the object `o` is a string object, but not an instance of a subtype of the string type. New in version 2.2.

PyObject* PyString_FromString(const char *v)

Return value: **New reference.**

Return a new string object with the value `v` on success, and `NULL` on failure. The parameter `v` must not be `NULL`; it will not be checked.

PyObject* PyString_FromStringAndSize(const char *v, int len)

Return value: **New reference.**

Return a new string object with the value `v` and length `len` on success, and `NULL` on failure. If `v` is `NULL`, the contents of the string are uninitialized.

PyObject* PyString_FromFormat(const char *format, ...)

Return value: **New reference.**

Take a C `printf()`-style `format` string and a variable number of arguments, calculate the size of the resulting Python string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the `format`

string. The following format characters are allowed:

Format Characters	Type	Comment
%%	<i>n/a</i>	The literal % character.
%C	int	A single character, represented as an C int.
%d	int	Exactly equivalent to <code>printf("%d")</code> .
%ld	long	Exactly equivalent to <code>printf("%ld")</code> .
%i	int	Exactly equivalent to <code>printf("%i")</code> .
%X	int	Exactly equivalent to <code>printf("%X")</code> .
%S	char*	A null-terminated C character array.
%p	void*	The hex representation of a C pointer. Mostly equivalent to <code>printf("%p")</code> except that it is guaranteed to start with the literal <code>0x</code> regardless of what the platform's <code>printf</code> yields.

PyObject* **PyString_FromFormatV**(const char **format*, va_list *vargs*)

Return value: **New reference.**

Identical to `PyString_FromFormat()` except that it takes exactly two arguments.

int **PyString_Size**(PyObject **string*)

Return the length of the string in string object *string*.

int **PyString_GET_SIZE**(PyObject **string*)

Macro form of `PyString_Size()` but without error checking.

char* **PyString_AsString**(PyObject **string*)

Return a NUL-terminated representation of the contents of *string*. The pointer refers to the internal buffer of *string*, not a copy. The data must not be modified in any way, unless the string was just created using `PyString_FromStringAndSize(NULL, size)`. It must not be deallocated. If *string* is a Unicode object, this function computes the default encoding of *string* and operates on that. If *string* is not a string object at all, `PyString_AsString()` returns NULL and raises `TypeError`.

char* **PyString_AS_STRING**(PyObject *string)

Macro form of `PyString_AsString()` but without error checking. Only string objects are supported; no Unicode objects should be passed.

int **PyString_AsStringAndSize**(PyObject *obj, char **buffer, int *length)

Return a NUL-terminated representation of the contents of the object *obj* through the output variables *buffer* and *length*.

The function accepts both string and Unicode objects as input. For Unicode objects it returns the default encoded version of the object. If *length* is NULL, the resulting buffer may not contain NUL characters; if it does, the function returns -1 and a `TypeError` is raised.

The buffer refers to an internal string buffer of *obj*, not a copy. The data must not be modified in any way, unless the string was just created using `PyString_FromStringAndSize(NULL, size)`. It must not be deallocated. If *string* is a Unicode object, this function computes the default encoding of *string* and operates on that. If *string* is not a string object at all, `PyString_AsStringAndSize()` returns -1 and raises `TypeError`.

void **PyString_Concat**(PyObject **string, PyObject *newpart)

Create a new string object in **string* containing the contents of *newpart* appended to *string*; the caller will own the new reference. The reference to the old value of *string* will be stolen. If the new string cannot be created, the old reference to *string* will still be discarded and the value of **string* will be set to NULL; the appropriate exception will be set.

void **PyString_ConcatAndDel**(PyObject **string, PyObject *newpart)

Create a new string object in **string* containing the contents of *newpart* appended to *string*. This version decrements the reference count of *newpart*.

int **_PyString_Resize**(PyObject **string, int newsize)

A way to resize a string object even though it is "immutable". Only use this to build up a brand new string object; don't use this if the string may already be known in other parts of the code. It is an error to call this function if the refcount on the input string object is not one. Pass the address of an existing string object as an lvalue (it may be written into), and the new size desired.

On success, **string* holds the resized string object and 0 is returned; the address in **string* may differ from its input value. If the reallocation fails, the original string object at **string* is deallocated, **string* is set to NULL, a memory exception is set, and -1 is returned.

PyObject* **PyString_Format**(PyObject **format*, PyObject **args*)

Return value: **New reference.**

Return a new string object from *format* and *args*. Analogous to *format % args*. The *args* argument must be a tuple.

void **PyString_InternInPlace**(PyObject ***string*)

Intern the argument **string* in place. The argument must be the address of a pointer variable pointing to a Python string object. If there is an existing interned string that is the same as **string*, it sets **string* to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves **string* alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject* **PyString_InternFromString**(const char **v*)

Return value: **New reference.**

A combination of `PyString_FromString()` and `PyString_InternInPlace()`, returning either a new string object that has been interned, or a new ("owned") reference to an earlier interned string object with the same value.

PyObject* **PyString_Decode**(const char **s*, int *size*, const char **encoding*, const char **errors*)

Return value: **New reference.**

Create an object by decoding *size* bytes of the encoded buffer *s* using the codec registered for *encoding*. *encoding* and *errors* have the same meaning as the parameters of the same name in the `unicode()` built-in function. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject **str*, const char

PyObject* **PyString_AsDecodedObject**(**encoding*, const char **errors*)

Return value: **New reference.**

Decode a string object by passing it to the codec registered for *encoding* and return the result as Python object. *encoding* and *errors* have the same meaning as the parameters of the same name in the string `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyString_Encode**(const char **s*, int *size*, const char **encoding*, const char **errors*)

Return value: **New reference.**

Encode the `char` buffer of the given size by passing it to the codec registered for *encoding* and return a Python object. *encoding* and *errors* have the same meaning as the parameters of the same name in the string `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyString_AsEncodedObject**(PyObject **str*, const char **encoding*, const char **errors*)

Return value: **New reference.**

Encode a string object using the codec registered for *encoding* and return the result as Python object. *encoding* and *errors* have the same meaning as the parameters of the same name in the string `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

7.3.2 Unicode Objects

These are the basic Unicode object types used for the Unicode implementation in Python:

Py_UNICODE

This type represents the storage type which is used by Python internally as basis for holding Unicode ordinals. Python's default builds use a 16-bit type for `Py_UNICODE` and store Unicode values internally as UCS2. It is also possible to build a UCS4 version of Python (most recent Linux distributions come with UCS4 builds of Python). These builds then use a 32-bit type for `Py_UNICODE` and store Unicode data internally as UCS4. On platforms where `wchar_t` is available and compatible with the chosen Python Unicode build variant, `Py_UNICODE` is a typedef alias for `wchar_t` to enhance native platform compatibility. On all other platforms, `Py_UNICODE` is a typedef alias for either `unsigned short` (UCS2) or `unsigned long` (UCS4).

Note that UCS2 and UCS4 Python builds are not binary compatible. Please keep this in mind when writing extensions or interfaces.

PyUnicodeObject

This subtype of `PyObject` represents a Python Unicode object.

PyTypeObject PyUnicode_Type

This instance of `PyTypeObject` represents the Python Unicode type.

The following APIs are really C macros and can be used to do fast checks and to access internal read-only data of Unicode objects:

```
int PyUnicode_Check( PyObject *o)
```

Return true if the object `o` is a Unicode object or an instance of a Unicode subtype. Changed in version 2.2: Allowed subtypes to be accepted.

```
int PyUnicode_CheckExact( PyObject *o)
```

Return true if the object `o` is a Unicode object, but not an instance of a subtype. New in version 2.2.

int **PyUnicode_GET_SIZE**(PyObject *o)

Return the size of the object. *o* has to be a `PyUnicodeObject` (not checked).

int **PyUnicode_GET_DATA_SIZE**(PyObject *o)

Return the size of the object's internal buffer in bytes. *o* has to be a `PyUnicodeObject` (not checked).

Py_UNICODE* **PyUnicode_AS_UNICODE**(PyObject *o)

Return a pointer to the internal `Py_UNICODE` buffer of the object. *o* has to be a `PyUnicodeObject` (not checked).

const char* **PyUnicode_AS_DATA**(PyObject *o)

Return a pointer to the internal buffer of the object. *o* has to be a `PyUnicodeObject` (not checked).

Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

int **Py_UNICODE_ISSPACE**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a whitespace character.

int **Py_UNICODE_ISLOWER**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a lowercase character.

int **Py_UNICODE_ISUPPER**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is an uppercase character.

int **Py_UNICODE_ISTITLE**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a titlecase character.

int **Py_UNICODE_ISLINEBREAK**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a linebreak character.

int **Py_UNICODE_ISDECIMAL**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a decimal character.

int **Py_UNICODE_ISDIGIT**(Py_UNICODE *ch*)
Return 1 or 0 depending on whether *ch* is a digit character.

int **Py_UNICODE_ISNUMERIC**(Py_UNICODE *ch*)
Return 1 or 0 depending on whether *ch* is a numeric character.

int **Py_UNICODE_ISALPHA**(Py_UNICODE *ch*)
Return 1 or 0 depending on whether *ch* is an alphabetic character.

int **Py_UNICODE_ISALNUM**(Py_UNICODE *ch*)
Return 1 or 0 depending on whether *ch* is an alphanumeric character.

These APIs can be used for fast direct character conversions:

Py_UNICODE **Py_UNICODE_TOLOWER**(Py_UNICODE *ch*)
Return the character *ch* converted to lower case.

Py_UNICODE **Py_UNICODE_TOUPPER**(Py_UNICODE *ch*)
Return the character *ch* converted to upper case.

Py_UNICODE **Py_UNICODE_TOTITLE**(Py_UNICODE *ch*)
Return the character *ch* converted to title case.

int **Py_UNICODE_TODECIMAL**(Py_UNICODE *ch*)
Return the character *ch* converted to a decimal positive integer. Return -1 if this is not possible. This macro does not raise exceptions.

int **Py_UNICODE_TODIGIT**(Py_UNICODE *ch*)
Return the character *ch* converted to a single digit integer. Return -1 if this is not possible. This macro does not raise exceptions.

double **Py_UNICODE_TONUMERIC**(Py_UNICODE *ch*)
Return the character *ch* converted to a (positive) double. Return -1.0 if this is not possible. This macro does not raise exceptions.

To create Unicode objects and access their basic sequence properties, use these APIs:

PyObject* **PyUnicode_FromUnicode**(const Py_UNICODE **u*, int *size*)

*Return value: **New reference.***

Create a Unicode Object from the Py_UNICODE buffer *u* of the given size. *u* may be NULL which causes the contents to be undefined. It is the user's responsibility to fill in the needed data. The buffer is copied into the new object. If the buffer is not NULL, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when *u* is NULL.

Py_UNICODE* **PyUnicode_AsUnicode**(PyObject **unicode*)

Return a read-only pointer to the Unicode object's internal Py_UNICODE buffer, NULL if *unicode* is not a Unicode object.

int **PyUnicode_GetSize**(PyObject **unicode*)

Return the length of the Unicode object.

PyObject* **PyUnicode_FromEncodedObject**(PyObject **obj*, const char **encoding*, const char **errors*)

*Return value: **New reference.***

Coerce an encoded object *obj* to an Unicode object and return a reference with incremented refcount.

Coercion is done in the following way:

1. Unicode objects are passed back as-is with incremented refcount.
Note: These cannot be decoded; passing a non-NULL value for encoding will result in a `TypeError`.
2. String and other char buffer compatible objects are decoded according to the given encoding and using the error handling defined by errors. Both can be NULL to have the interface use the default values (see the next section for details).
3. All other objects cause an exception.

The API returns NULL if there was an error. The caller is responsible for decref'ing the returned objects.

PyObject* **PyUnicode_FromObject**(PyObject *obj)

Return value: **New reference.**

Shortcut for `PyUnicode_FromEncodedObject(obj, NULL, "strict")` which is used throughout the interpreter whenever coercion to Unicode is needed.

If the platform supports `wchar_t` and provides a header file `wchar.h`, Python can interface directly to this type using the following functions. Support is optimized if Python's own `Py_UNICODE` type is identical to the system's `wchar_t`.

PyObject* **PyUnicode_FromWideChar**(const wchar_t *w, int size)

Return value: **New reference.**

Create a Unicode object from the `wchar_t` buffer `w` of the given size. Return NULL on failure.

int **PyUnicode_AsWideChar**(PyUnicodeObject *unicode, wchar_t *w, int size)

Copy the Unicode object contents into the `wchar_t` buffer `w`. At most `size` `wchar_t` characters are copied (excluding a possibly trailing 0-termination character). Return the number of `wchar_t` characters copied or -1 in case of an error. Note that the resulting `wchar_t` string may or may not be 0-terminated. It is the responsibility of the caller to make sure that the `wchar_t` string is 0-terminated in case this is required by the application.

7.3.3 Buffer Objects

Python objects implemented in C can export a group of functions called the "buffer interface." These functions can be used by an object to expose its data in a raw, byte-oriented format. Clients of the object can use the buffer interface to access the object data directly, without needing to copy it first.

Two examples of objects that support the buffer interface are strings and arrays. The string object exposes the character contents in the buffer interface's byte-oriented form. An array can also expose its contents, but it should be noted that array elements may be multi-byte values.

An example user of the buffer interface is the file object's `write()` method. Any object that can export a series of bytes through the buffer interface can be written to a file. There are a number of format codes to `PyArg_ParseTuple()` that operate against an object's buffer interface, returning data from the target object.

More information on the buffer interface is provided in the section "Buffer Object Structures" (section [10.7](#)), under the description for `PyBufferProcs`.

A "buffer object" is defined in the `bufferobject.h` header (included by `Python.h`). These objects look very similar to string objects at the Python programming level: they support slicing, indexing, concatenation, and some other standard string operations. However, their data can come from one of two sources: from a block of memory, or from another object which exports the buffer interface.

Buffer objects are useful as a way to expose the data from another object's buffer interface to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

PyBufferObject

This subtype of `PyObject` represents a buffer object.

PyObject **PyBuffer_Type**

The instance of PyObject which represents the Python buffer type; it is the same object as `types.BufferType` in the Python layer..

int **Py_END_OF_BUFFER**

This constant may be passed as the *size* parameter to `PyBuffer_FromObject()` or `PyBuffer_FromReadWriteObject()`. It indicates that the new `PyObject` should refer to *base* object from the specified *offset* to the end of its exported buffer. Using this enables the caller to avoid querying the *base* object for its length.

int **PyBuffer_Check**(PyObject *p)

Return true if the argument has type `PyBuffer_Type`.

PyObject* **PyBuffer_FromObject**(PyObject *base, int offset, int size)

Return value: **New reference.**

Return a new read-only buffer object. This raises `TypeError` if *base* doesn't support the read-only buffer protocol or doesn't provide exactly one buffer segment, or it raises `ValueError` if *offset* is less than zero. The buffer will hold a reference to the *base* object, and the buffer's contents will refer to the *base* object's buffer interface, starting as position *offset* and extending for *size* bytes. If *size* is `Py_END_OF_BUFFER`, then the new buffer's contents extend to the length of the *base* object's exported buffer data.

PyObject* **PyBuffer_FromReadWriteObject**(PyObject *base, int offset, int size)

Return value: **New reference.**

Return a new writable buffer object. Parameters and exceptions are similar to those for `PyBuffer_FromObject()`. If the *base* object does not export the writable buffer protocol, then `TypeError` is raised.

PyObject* **PyBuffer_FromMemory**(void *ptr, int size)

Return value: **New reference.**

Return a new read-only buffer object that reads from a specified location in memory, with a specified size. The caller is responsible for ensuring that the memory buffer, passed in as *ptr*, is not deallocated while the returned buffer

object exists. Raises `ValueError` if `size` is less than zero. Note that `Py_END_OF_BUFFER` may *not* be passed for the `size` parameter; `ValueError` will be raised in that case.

`PyObject*` **`PyBuffer_FromReadWriteMemory`**(`void *ptr`, `int size`)

Return value: ***New reference.***

Similar to `PyBuffer_FromMemory`(), but the returned buffer is writable.

`PyObject*` **`PyBuffer_New`**(`int size`)

Return value: ***New reference.***

Return a new writable buffer object that maintains its own memory buffer of `size` bytes. `ValueError` is returned if `size` is not zero or positive. Note that the memory buffer (as returned by `PyObject_AsWriteBuffer`()) is not specifically aligned.

7.3.4 Tuple Objects

PyTupleObject

This subtype of `PyObject` represents a Python tuple object.

`PyTypeObject` **PyTuple_Type**

This instance of `PyTypeObject` represents the Python tuple type; it is the same object as `types.TupleType` in the Python layer..

`int` **PyTuple_Check**(`PyObject *p`)

Return true if `p` is a tuple object or an instance of a subtype of the tuple type. Changed in version 2.2: Allowed subtypes to be accepted.

`int` **PyTuple_CheckExact**(`PyObject *p`)

Return true if `p` is a tuple object, but not an instance of a subtype of the tuple type. New in version 2.2.

`PyObject*` **PyTuple_New**(`int len`)

Return value: **New reference.**

Return a new tuple object of size `len`, or `NULL` on failure.

`PyObject*` **PyTuple_Pack**(`int n, ...`)

Return value: **New reference.**

Return a new tuple object of size `n`, or `NULL` on failure. The tuple values are initialized to the subsequent `n` C arguments pointing to Python objects. "`PyTuple_Pack(2, a, b)`" is equivalent to "`Py_BuildValue("(OO)", a, b)`". New in version 2.4.

`int` **PyTuple_Size**(`PyObject *p`)

Take a pointer to a tuple object, and return the size of that tuple.

`int` **PyTuple_GET_SIZE**(`PyObject *p`)

Return the size of the tuple `p`, which must be non-`NULL` and point to a tuple; no error checking is performed.

`PyObject*` **PyTuple_GetItem**(`PyObject *p, int pos`)

Return value: **Borrowed reference.**

Return the object at position *pos* in the tuple pointed to by *p*. If *pos* is out of bounds, return NULL and sets an `IndexError` exception.

`PyObject*` **PyTuple_GET_ITEM**(`PyObject *`*p*, `int` *pos*)

Return value: **Borrowed reference.**

Like `PyTuple_GetItem()`, but does no checking of its arguments.

`PyObject*` **PyTuple_GetSlice**(`PyObject *`*p*, `int` *low*, `int` *high*)

Return value: **New reference.**

Take a slice of the tuple pointed to by *p* from *low* to *high* and return it as a new tuple.

`int` **PyTuple_SetItem**(`PyObject *`*p*, `int` *pos*, `PyObject *`*o*)

Insert a reference to object *o* at position *pos* of the tuple pointed to by *p*.

Return `0` on success. **Note:** This function "steals" a reference to *o*.

`void` **PyTuple_SET_ITEM**(`PyObject *`*p*, `int` *pos*, `PyObject *`*o*)

Like `PyTuple_SetItem()`, but does no error checking, and should *only* be used to fill in brand new tuples. **Note:** This function "steals" a reference to *o*.

`int` **_PyTuple_Resize**(`PyObject **`*p*, `int` *newsize*)

Can be used to resize a tuple. *newsize* will be the new length of the tuple. Because tuples are *supposed* to be immutable, this should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns `0` on success. Client code should never assume that the resulting value of **p* will be the same as before calling this function. If the object referenced by **p* is replaced, the original **p* is destroyed. On failure, returns `-1` and sets **p* to NULL, and raises `MemoryError` or `SystemError`. Changed in version 2.2: Removed unused third parameter, *last_is_sticky*.

7.3.5 List Objects

PyListObject

This subtype of `PyObject` represents a Python list object.

PyObject PyList_Type

This instance of `PyObject` represents the Python list type. This is the same object as `types.ListType`.

int PyList_Check(PyObject *p)

Return true if `p` is a list object or an instance of a subtype of the list type. Changed in version 2.2: Allowed subtypes to be accepted.

int PyList_CheckExact(PyObject *p)

Return true if `p` is a list object, but not an instance of a subtype of the list type. New in version 2.2.

PyObject* PyList_New(int len)

Return value: **New reference.**

Return a new list of length `len` on success, or `NULL` on failure. **Note:** If `length` is greater than zero, the returned list object's items are set to `NULL`. Thus you cannot use abstract API functions such as `PySequence_SetItem()` or expose the object to Python code before setting all items to a real object with `PyList_SetItem()`.

int PyList_Size(PyObject *list)

Return the length of the list object in `list`; this is equivalent to "`len(list)`" on a list object.

int PyList_GET_SIZE(PyObject *list)

Macro form of `PyList_Size()` without error checking.

PyObject* PyList_GetItem(PyObject *list, int index)

Return value: **Borrowed reference.**

Return the object at position `pos` in the list pointed to by `p`. The position must be positive, indexing from the end of the list is not supported. If `pos` is

out of bounds, return NULL and set an `IndexError` exception.

`PyObject*` **PyList_GET_ITEM**(`PyObject *list`, `int i`)

Return value: **Borrowed reference.**

Macro form of `PyList_GetItem()` without error checking.

`int` **PyList_SetItem**(`PyObject *list`, `int index`, `PyObject *item`)

Set the item at index `index` in list to `item`. Return `0` on success or `-1` on failure. **Note:** This function ``steals" a reference to `item` and discards a reference to an item already in the list at the affected position.

`void` **PyList_SET_ITEM**(`PyObject *list`, `int i`, `PyObject *o`)

Macro form of `PyList_SetItem()` without error checking. This is normally only used to fill in new lists where there is no previous content.

Note: This function ``steals" a reference to `item`, and, unlike `PyList_SetItem()`, does *not* discard a reference to any item that it being replaced; any reference in `list` at position `i` will be leaked.

`int` **PyList_Insert**(`PyObject *list`, `int index`, `PyObject *item`)

Insert the item `item` into list `list` in front of index `index`. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.insert(index, item)`.

`int` **PyList_Append**(`PyObject *list`, `PyObject *item`)

Append the object `item` at the end of list `list`. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.append(item)`.

`PyObject*` **PyList_GetSlice**(`PyObject *list`, `int low`, `int high`)

Return value: **New reference.**

Return a list of the objects in `list` containing the objects *between* `low` and `high`. Return NULL and set an exception if unsuccessful. Analogous to `list[low:high]`.

`int` **PyList_SetSlice**(`PyObject *list`, `int low`, `int high`, `PyObject *itemlist`)

Set the slice of `list` between `low` and `high` to the contents of `itemlist`. Analogous to `list[low:high] = itemlist`. The `itemlist` may be NULL,

indicating the assignment of an empty list (slice deletion). Return 0 on success, -1 on failure.

int **PyList_Sort**(PyObject *list)

Sort the items of *list* in place. Return 0 on success, -1 on failure. This is equivalent to "*list.sort()*".

int **PyList_Reverse**(PyObject *list)

Reverse the items of *list* in place. Return 0 on success, -1 on failure. This is the equivalent of "*list.reverse()*".

PyObject* **PyList_AsTuple**(PyObject *list)

Return value: *New reference.*

Return a new tuple object containing the contents of *list*; equivalent to "*tuple(list)*".

7.4.1 Dictionary Objects

PyDictObject

This subtype of `PyObject` represents a Python dictionary object.

`PyObject` **PyDict_Type**

This instance of `PyObject` represents the Python dictionary type. This is exposed to Python programs as `types.DictType` and `types.DictionaryType`.

`int` **PyDict_Check**(`PyObject *p`)

Return true if `p` is a dict object or an instance of a subtype of the dict type. Changed in version 2.2: Allowed subtypes to be accepted.

`int` **PyDict_CheckExact**(`PyObject *p`)

Return true if `p` is a dict object, but not an instance of a subtype of the dict type. New in version 2.4.

`PyObject*` **PyDict_New**()

Return value: **New reference.**

Return a new empty dictionary, or `NULL` on failure.

`PyObject*` **PyDictProxy_New**(`PyObject *dict`)

Return value: **New reference.**

Return a proxy object for a mapping which enforces read-only behavior. This is normally used to create a proxy to prevent modification of the dictionary for non-dynamic class types. New in version 2.2.

`void` **PyDict_Clear**(`PyObject *p`)

Empty an existing dictionary of all key-value pairs.

`int` **PyDict_Contains**(`PyObject *p`, `PyObject *key`)

Determine if dictionary `p` contains `key`. If an item in `p` matches `key`, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `"key in p"`. New in version 2.4.

PyObject* **PyDict_Copy**(PyObject *p)

*Return value: **New reference.***

Return a new dictionary that contains the same key-value pairs as *p*. New in version 1.6.

int **PyDict_SetItem**(PyObject *p, PyObject *key, PyObject *val)

Insert *value* into the dictionary *p* with a key of *key*. *key* must be hashable; if it isn't, `TypeError` will be raised. Return 0 on success or -1 on failure.

int **PyDict_SetItemString**(PyObject *p, char *key, PyObject *val)

Insert *value* into the dictionary *p* using *key* as a key. *key* should be a `char *`. The key object is created using `PyString_FromString(key)`. Return 0 on success or -1 on failure.

int **PyDict_DelItem**(PyObject *p, PyObject *key)

Remove the entry in dictionary *p* with key *key*. *key* must be hashable; if it isn't, `TypeError` is raised. Return 0 on success or -1 on failure.

int **PyDict_DelItemString**(PyObject *p, char *key)

Remove the entry in dictionary *p* which has a key specified by the string *key*. Return 0 on success or -1 on failure.

PyObject* **PyDict_GetItem**(PyObject *p, PyObject *key)

*Return value: **Borrowed reference.***

Return the object from dictionary *p* which has a key *key*. Return `NULL` if the key *key* is not present, but *without* setting an exception.

PyObject* **PyDict_GetItemString**(PyObject *p, char *key)

*Return value: **Borrowed reference.***

This is the same as `PyDict_GetItem()`, but *key* is specified as a `char *`, rather than a `PyObject *`.

PyObject* **PyDict_Items**(PyObject *p)

*Return value: **New reference.***

Return a `PyListObject` containing all the items from the dictionary, as in the dictionary method `items()` (see the [Python Library Reference](#)).

PyObject* **PyDict_Keys**(PyObject *p)

*Return value: **New reference.***

Return a `PyListObject` containing all the keys from the dictionary, as in the dictionary method `keys()` (see the [Python Library Reference](#)).

PyObject* **PyDict_Values**(PyObject *p)

*Return value: **New reference.***

Return a `PyListObject` containing all the values from the dictionary `p`, as in the dictionary method `values()` (see the [Python Library Reference](#)).

int **PyDict_Size**(PyObject *p)

Return the number of items in the dictionary. This is equivalent to "`len(p)`" on a dictionary.

int **PyDict_Next**(PyObject *p, int *ppos, PyObject **pkey, PyObject **pvalue)

Iterate over all key-value pairs in the dictionary `p`. The `int` referred to by `ppos` must be initialized to `0` prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters `pkey` and `pvalue` should either point to `PyObject *` variables that will be filled in with each key and value, respectively, or may be `NULL`. Any references returned through them are borrowed. `ppos` should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```
PyObject *key, *value;
int pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    /* do something interesting with the values... */
    ...
}
```

The dictionary `p` should not be mutated during iteration. It is safe (since Python 2.1) to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```

PyObject *key, *value;
int pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    int i = PyInt_AS_LONG(value) + 1;
    PyObject *o = PyInt_FromLong(i);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}

```

int **PyDict_Merge**(PyObject *a, PyObject *b, int *override*)

Iterate over mapping object *b* adding key-value pairs to dictionary *a*. *b* may be a dictionary, or any object supporting `PyMapping_Keys()` and `PyObject_GetItem()`. If *override* is true, existing pairs in *a* will be replaced if a matching key is found in *b*, otherwise pairs will only be added if there is not a matching key in *a*. Return 0 on success or -1 if an exception was raised. New in version 2.2.

int **PyDict_Update**(PyObject *a, PyObject *b)

This is the same as `PyDict_Merge(a, b, 1)` in C, or `a.update(b)` in Python. Return 0 on success or -1 if an exception was raised. New in version 2.2.

int **PyDict_MergeFromSeq2**(PyObject *a, PyObject *seq2, int *override*)

Update or merge into dictionary *a*, from the key-value pairs in *seq2*. *seq2* must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if *override* is true, else the first wins. Return 0 on success or -1 if an exception was raised. Equivalent Python (except for the return value):

```

def PyDict_MergeFromSeq2(a, seq2, override):
    for key, value in seq2:
        if override or key not in a:
            a[key] = value

```

New in version 2.2.

Previous: [7.5 Other Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.2 Instance Objects](#)

7.5.1 File Objects

Python's built-in file objects are implemented entirely on the `FILE*` support from the C standard library. This is an implementation detail and may change in future releases of Python.

PyFileObject

This subtype of `PyObject` represents a Python file object.

`PyTypeObject` **PyFile_Type**

This instance of `PyTypeObject` represents the Python file type. This is exposed to Python programs as `types.FileType`.

`int` **PyFile_Check**(`PyObject *p`)

Return true if its argument is a `PyFileObject` or a subtype of `PyFileObject`. Changed in version 2.2: Allowed subtypes to be accepted.

`int` **PyFile_CheckExact**(`PyObject *p`)

Return true if its argument is a `PyFileObject`, but not a subtype of `PyFileObject`. New in version 2.2.

`PyObject*` **PyFile_FromString**(`char *filename`, `char *mode`)

Return value: **New reference.**

On success, return a new file object that is opened on the file given by *filename*, with a file mode given by *mode*, where *mode* has the same semantics as the standard C routine `fopen()`. On failure, return `NULL`.

`PyObject*` **PyFile_FromFile**(`FILE *fp`, `char *name`, `char *mode`, `int (*close)(FILE*)`)

Return value: **New reference.**

Create a new `PyFileObject` from the already-open standard C file pointer, *fp*. The function *close* will be called when the file should be closed. Return `NULL` on failure.

`FILE*` **PyFile_AsFile**(`PyFileObject *p`)

Return the file object associated with *p* as a FILE*.

PyObject* **PyFile_GetLine**(PyObject **p*, int *n*)

Return value: **New reference**.

Equivalent to *p.readline*([*n*]), this function reads one line from the object *p*. *p* may be a file object or any object with a *readline*() method. If *n* is 0, exactly one line is read, regardless of the length of the line. If *n* is greater than 0, no more than *n* bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If *n* is less than 0, however, one line is read regardless of length, but **EOFError** is raised if the end of the file is reached immediately.

PyObject* **PyFile_Name**(PyObject **p*)

Return value: **Borrowed reference**.

Return the name of the file specified by *p* as a string object.

void **PyFile_SetBufSize**(PyFileObject **p*, int *n*)

Available on systems with *setvbuf*() only. This should only be called immediately after file object creation.

int **PyFile_Encoding**(PyFileObject **p*, char **enc*)

Set the file's encoding for Unicode output to *enc*. Return 1 on success and 0 on failure. New in version 2.3.

int **PyFile_SoftSpace**(PyObject **p*, int *newflag*)

This function exists for internal use by the interpreter. Set the *softspace* attribute of *p* to *newflag* and return the previous value. *p* does not have to be a file object for this function to work properly; any object is supported (though its only interesting if the *softspace* attribute can be set). This function clears any errors, and will return 0 as the previous value if the attribute either does not exist or if there were errors in retrieving it. There is no way to detect errors from this function, but doing so should not be needed.

int **PyFile_WriteObject**(PyObject **obj*, PyFileObject **p*, int *flags*)

Write object *obj* to file object *p*. The only supported flag for *flags* is

`Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`. Return `0` on success or `-1` on failure; the appropriate exception will be set.

int **PyFile_WriteString**(const char *s, PyFileObject *p)

Write string `s` to file object `p`. Return `0` on success or `-1` on failure; the appropriate exception will be set.

Previous: [7.5 Other Objects](#) Up: [7.5 Other Objects](#) Next: [7.5.2 Instance Objects](#)

Previous: [7.5.1 File Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.3 Method Objects](#)

7.5.2 Instance Objects

There are very few functions specific to instance objects.

PyObject **PyInstance_Type**

Type object for class instances.

int **PyInstance_Check**(PyObject *obj)

Return true if *obj* is an instance.

PyObject* **PyInstance_New**(PyObject *class, PyObject *arg, PyObject *kw)

Return value: **New reference.**

Create a new instance of a specific class. The parameters *arg* and *kw* are used as the positional and keyword parameters to the object's constructor.

PyObject* **PyInstance_NewRaw**(PyObject *class, PyObject *dict)

Return value: **New reference.**

Create a new instance of a specific class without calling it's constructor. *class* is the class of new object. The *dict* parameter will be used as the object's `__dict__`; if NULL, a new dictionary will be created for the instance.

Previous: [7.5.2 Instance Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.4 Module Objects](#)

7.5.3 Method Objects

There are some useful functions that are useful for working with method objects.

PyObject **PyMethod_Type**

This instance of `PyObject` represents the Python method type. This is exposed to Python programs as `types.MethodType`.

int **PyMethod_Check**(PyObject *o)

Return true if *o* is a method object (has type `PyMethod_Type`). The parameter must not be `NULL`.

PyObject* **PyMethod_New**(PyObject *func, PyObject *self, PyObject *class)

Return value: **New reference.**

Return a new method object, with *func* being any callable object; this is the function that will be called when the method is called. If this method should be bound to an instance, *self* should be the instance and *class* should be the class of *self*, otherwise *self* should be `NULL` and *class* should be the class which provides the unbound method..

PyObject* **PyMethod_Class**(PyObject *meth)

Return value: **Borrowed reference.**

Return the class object from which the method *meth* was created; if this was created from an instance, it will be the class of the instance.

PyObject* **PyMethod_GET_CLASS**(PyObject *meth)

Return value: **Borrowed reference.**

Macro version of `PyMethod_Class()` which avoids error checking.

PyObject* **PyMethod_Function**(PyObject *meth)

Return value: **Borrowed reference.**

Return the function object associated with the method *meth*.

PyObject* **PyMethod_GET_FUNCTION**(PyObject *meth)

Return value: **Borrowed reference.**

Macro version of `PyMethod_Function()` which avoids error checking.

PyObject* **PyMethod_Self**(PyObject *meth)

*Return value: **Borrowed reference.***

Return the instance associated with the method *meth* if it is bound, otherwise return NULL.

PyObject* **PyMethod_GET_SELF**(PyObject *meth)

*Return value: **Borrowed reference.***

Macro version of `PyMethod_Self()` which avoids error checking.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.5.3 Method Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.5 Iterator Objects](#)

7.5.4 Module Objects

There are only a few functions special to module objects.

PyObject **PyModule_Type**

This instance of `PyObject` represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

int **PyModule_Check**(PyObject *p)

Return true if *p* is a module object, or a subtype of a module object. Changed in version 2.2: Allowed subtypes to be accepted.

int **PyModule_CheckExact**(PyObject *p)

Return true if *p* is a module object, but not a subtype of `PyModule_Type`. New in version 2.2.

PyObject* **PyModule_New**(char *name)

Return value: **New reference.**

Return a new module object with the `__name__` attribute set to *name*. Only the module's `__doc__` and `__name__` attributes are filled in; the caller is responsible for providing a `__file__` attribute.

PyObject* **PyModule_GetDict**(PyObject *module)

Return value: **Borrowed reference.**

Return the dictionary object that implements *module*'s namespace; this object is the same as the `__dict__` attribute of the module object. This function never fails. It is recommended extensions use other `PyModule_*()` and `PyObject_*()` functions rather than directly manipulate a module's `__dict__`.

char* **PyModule_GetName**(PyObject *module)

Return *module*'s `__name__` value. If the module does not provide one, or if it is not a string, `SystemError` is raised and `NULL` is returned.

char* **PyModule_GetFilename**(PyObject *module)

Return the name of the file from which *module* was loaded using *module*'s

`__file__` attribute. If this is not defined, or if it is not a string, raise `SystemError` and return `NULL`.

int **PyModule_AddObject**(PyObject **module*, char **name*, PyObject **value*)

Add an object to *module* as *name*. This is a convenience function which can be used from the module's initialization function. This steals a reference to *value*. Return `-1` on error, `0` on success. New in version 2.0.

int **PyModule_AddIntConstant**(PyObject **module*, char **name*, long *value*)

Add an integer constant to *module* as *name*. This convenience function can be used from the module's initialization function. Return `-1` on error, `0` on success. New in version 2.0.

int **PyModule_AddStringConstant**(PyObject **module*, char **name*, char **value*)

Add a string constant to *module* as *name*. This convenience function can be used from the module's initialization function. The string *value* must be null-terminated. Return `-1` on error, `0` on success. New in version 2.0.

Previous: [7.5.4 Module Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.6 Descriptor Objects](#)

7.5.5 Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the `__getitem__()` method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

PyObject **PySeqIter_Type**

Type object for iterator objects returned by `PySeqIter_New()` and the one-argument form of the `iter()` built-in function for built-in sequence types. New in version 2.2.

int **PySeqIter_Check**(op)

Return true if the type of *op* is `PySeqIter_Type`. New in version 2.2.

PyObject* **PySeqIter_New**(PyObject *seq)

Return value: **New reference.**

Return an iterator that works with a general sequence object, *seq*. The iteration ends when the sequence raises `IndexError` for the subscripting operation. New in version 2.2.

PyObject **PyCallIter_Type**

Type object for iterator objects returned by `PyCallIter_New()` and the two-argument form of the `iter()` built-in function. New in version 2.2.

int **PyCallIter_Check**(op)

Return true if the type of *op* is `PyCallIter_Type`. New in version 2.2.

PyObject* **PyCallIter_New**(PyObject *callable, PyObject *sentinel)

Return value: **New reference.**

Return a new iterator. The first parameter, *callable*, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When *callable* returns a value equal to *sentinel*, the iteration will be terminated. New in version 2.2.

7.5.6 Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

PyTypeObject **PyProperty_Type**

The type object for the built-in descriptor types. New in version 2.2.

PyObject* **PyDescr_NewGetSet**(PyTypeObject *type, PyGetSetDef *getset)

*Return value: **New reference.***

New in version 2.2.

PyObject* **PyDescr_NewMember**(PyTypeObject *type, PyMemberDef *meth)

*Return value: **New reference.***

New in version 2.2.

PyObject* **PyDescr_NewMethod**(PyTypeObject *type, PyMethodDef *meth)

*Return value: **New reference.***

New in version 2.2.

PyObject* **PyDescr_NewWrapper**(PyTypeObject *type, struct wrapperbase *wrapper, void *wrapped)

*Return value: **New reference.***

New in version 2.2.

PyObject* **PyDescr_NewClassMethod**(PyTypeObject *type, PyMethodDef *method)

*Return value: **New reference.***

New in version 2.3.

int **PyDescr_IsData**(PyObject *descr)

Return true if the descriptor objects *descr* describes a data attribute, or false if it describes a method. *descr* must be a descriptor object; there is no error

checking. New in version 2.2.

PyObject* **PyWrapper_New**(PyObject *, PyObject *)

*Return value: **New reference.***

New in version 2.2.

Previous: [7.5.5 Iterator Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.7 Slice Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.5.6 Descriptor Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.8 Weak Reference Objects](#)

7.5.7 Slice Objects

PyObject **PySlice_Type**

The type object for slice objects. This is the same as `types.SliceType`.

int **PySlice_Check**(PyObject **ob*)

Return true if *ob* is a slice object; *ob* must not be NULL.

PyObject* **PySlice_New**(PyObject **start*, PyObject **stop*, PyObject **step*)

Return value: *New reference*.

Return a new slice object with the given values. The *start*, *stop*, and *step* parameters are used as the values of the slice object attributes of the same names. Any of the values may be NULL, in which case the None will be used for the corresponding attribute. Return NULL if the new object could not be allocated.

int **PySlice_GetIndices**(PySliceObject **slice*, int *length*, int **start*, int **stop*, int **step*)

Retrieve the start, stop and step indices from the slice object *slice*, assuming a sequence of length *length*. Treats indices greater than *length* as errors.

Returns 0 on success and -1 on error with no exception set (unless one of the indices was not None and failed to be converted to an integer, in which case -1 is returned with an exception set).

You probably do not want to use this function. If you want to use slice objects in versions of Python prior to 2.3, you would probably do well to incorporate the source of `PySlice_GetIndicesEX`, suitably renamed, in the source of your extension.

int **PySlice_GetIndicesEX**(PySliceObject **slice*, int *length*, int **start*, int **stop*, int **step*, int **slicelength*)

Usable replacement for `PySlice_GetIndices`. Retrieve the start, stop, and step indices from the slice object *slice* assuming a sequence of length *length*, and store the length of the slice in *slicelength*. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

New in version 2.3.

Previous: [7.5.6 Descriptor Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.8 Weak Reference Objects](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [7.5.7 Slice Objects](#) Up: [7.5 Other Objects](#) Next: [7.5.9 CObjects](#)

7.5.8 Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

int **PyWeakref_Check**(ob)

Return true if *ob* is either a reference or proxy object. New in version 2.2.

int **PyWeakref_CheckRef**(ob)

Return true if *ob* is a reference object. New in version 2.2.

int **PyWeakref_CheckProxy**(ob)

Return true if *ob* is a proxy object. New in version 2.2.

PyObject* **PyWeakref_NewRef**(PyObject *ob, PyObject *callback)

Return value: *New reference.*

Return a weak reference object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly-referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise `TypeError`. New in version 2.2.

PyObject* **PyWeakref_NewProxy**(PyObject *ob, PyObject *callback)

Return value: *New reference.*

Return a weak reference proxy object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly-referencable object, or if *callback* is not callable, `None`, or `NULL`, this will

return NULL and raise `TypeError`. New in version 2.2.

`PyObject*` **PyWeakref_GetObject**(`PyObject *ref`)

Return value: **Borrowed reference.**

Return the referenced object from a weak reference, *ref*. If the referent is no longer live, returns `None`. New in version 2.2.

`PyObject*` **PyWeakref_GET_OBJECT**(`PyObject *ref`)

Return value: **Borrowed reference.**

Similar to `PyWeakref_GetObject ()`, but implemented as a macro that does no error checking. New in version 2.2.

Previous: [7.5.7 Slice Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.9 CObjects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.5.8 Weak Reference Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [7.5.10 Cell Objects](#)

7.5.9 CObjects

Refer to *Extending and Embedding the Python Interpreter*, section 1.12, "Providing a C API for an Extension Module," for more information on using these objects.

PyObject

This subtype of `PyObject` represents an opaque value, useful for C extension modules who need to pass an opaque value (as a `void*` pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

`int PyObject_Check(PyObject *p)`

Return true if its argument is a `PyObject`.

`PyObject* PyObject_FromVoidPtr(void* cobj, void (*destr)(void *))`

Return value: *New reference.*

Create a `PyObject` from the `void *cobj`. The `destr` function will be called when the object is reclaimed, unless it is `NULL`.

`PyObject* PyObject_FromVoidPtrAndDesc(void* cobj, void* desc, void (*destr)(void *, void *))`

Return value: *New reference.*

Create a `PyObject` from the `void *cobj`. The `destr` function will be called when the object is reclaimed. The `desc` argument can be used to pass extra callback data for the destructor function.

`void* PyObject_AsVoidPtr(PyObject* self)`

Return the object `void *` that the `PyObject self` was created with.

`void* PyObject_GetDesc(PyObject* self)`

Return the description `void *` that the `PyObject self` was created with.

int **PyObject_SetVoidPtr**(PyObject* *self*, void* *cobj*)

Set the void pointer inside *self* to *cobj*. The **PyObject** must not have an associated destructor. Return true on success, false on failure.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.5.9 CObjects](#) Up: [7.5 Other Objects](#) Next: [7.5.11 Generator Objects](#)

7.5.10 Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

PyObject

The C structure used for cell objects.

PyObject **PyCell_Type**

The type object corresponding to cell objects

int **PyCell_Check**(PyObject)

Return true if *ob* is a cell object; *ob* must not be NULL.

PyObject* **PyCell_New**(PyObject **ob*)

Return value: **New reference.**

Create and return a new cell object containing the value *ob*. The parameter may be NULL.

PyObject* **PyCell_Get**(PyObject **cell*)

Return value: **New reference.**

Return the contents of the cell *cell*.

PyObject* **PyCell_GET**(PyObject **cell*)

Return value: **Borrowed reference.**

Return the contents of the cell *cell*, but without checking that *cell* is non-NULL and a cell object.

int **PyCell_Set**(PyObject **cell*, PyObject **value*)

Set the contents of the cell object *cell* to *value*. This releases the reference

to any current content of the cell. *value* may be NULL. *cell* must be non-NULL; if it is not a cell object, -1 will be returned. On success, 0 will be returned.

void **PyCell_SET**(PyObject **cell*, PyObject **value*)

Sets the value of the cell object *cell* to *value*. No reference counts are adjusted, and no checks are made for safety; *cell* must be non-NULL and must be a cell object.

7.5.11 Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling `PyGen_New`.

PyGenObject

The C structure used for generator objects.

PyTypeObject **PyGen_Type**

The type object corresponding to generator objects

int **PyGen_Check**(ob)

Return true if *ob* is a generator object; *ob* must not be NULL.

int **PyGen_CheckExact**(ob)

Return true if *ob*'s type is *PyGen_Type* is a generator object; *ob* must not be NULL.

PyObject* **PyGen_New**(PyFrameObject **frame*)

Return value: *New reference*.

Create and return a new generator object based on the *frame* object. A reference to *frame* is stolen by this function. The parameter must not be NULL.

Previous: [7.5.11 Generator Objects](#) **Up:** [7.5 Other Objects](#) **Next:** [8. Initialization, Finalization, and](#)

7.5.12 DateTime Objects

Various date and time objects are supplied by the `datetime` module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not include by `Python.h`), and macro `PyDateTime_IMPORT()` must be invoked. The macro arranges to put a pointer to a C structure in a static variable `PyDateTimeAPI`, which is used by the following macros.

Type-check macros:

`int PyDate_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateType` or a subtype of `PyDateTime_DateType`. *ob* must not be `NULL`. New in version 2.4.

`int PyDate_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateType`. *ob* must not be `NULL`. New in version 2.4.

`int PyDateTime_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateTimeType` or a subtype of `PyDateTime_DateTimeType`. *ob* must not be `NULL`. New in version 2.4.

`int PyDateTime_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateTimeType`. *ob* must not be `NULL`. New in version 2.4.

`int PyTime_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_TimeType` or a subtype of `PyDateTime_TimeType`. *ob* must not be `NULL`. New in version 2.4.

`int PyTime_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_TimeType`. *ob* must not be `NULL`. New in version 2.4.

int **PyDelta_Check**(PyObject *ob)
Return true if *ob* is of type `PyDateTime_DeltaType` or a subtype of `PyDateTime_DeltaType`. *ob* must not be NULL. New in version 2.4.

int **PyDelta_CheckExact**(PyObject *ob)
Return true if *ob* is of type `PyDateTime_DeltaType`. *ob* must not be NULL. New in version 2.4.

int **PyTZInfo_Check**(PyObject *ob)
Return true if *ob* is of type `PyDateTime_TZInfoType` or a subtype of `PyDateTime_TZInfoType`. *ob* must not be NULL. New in version 2.4.

int **PyTZInfo_CheckExact**(PyObject *ob)
Return true if *ob* is of type `PyDateTime_TZInfoType`. *ob* must not be NULL. New in version 2.4.

Macros to create objects:

PyObject* **PyDate_FromDate**(int year, int month, int day)
Return value: *New reference*.
Return a `datetime.date` object with the specified year, month and day.
New in version 2.4.

PyObject* **PyDateTime_FromDateAndTime**(int year, int month, int day,
int hour, int minute, int second, int usecond)

Return value: *New reference*.
Return a `datetime.datetime` object with the specified year, month, day, hour, minute, second and microsecond. New in version 2.4.

PyObject* **PyTime_FromTime**(int hour, int minute, int second, int usecond)
Return value: *New reference*.
Return a `datetime.time` object with the specified hour, minute, second and microsecond. New in version 2.4.

PyObject* **PyDelta_FromDSU**(int days, int seconds, int useconds)
Return value: *New reference*.

Return a `datetime.timedelta` object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of microseconds and seconds lie in the ranges documented for `datetime.timedelta` objects. New in version 2.4.

Macros to extract fields from date objects. The argument must be an instance of `PyDateTime_Date`, including subclasses (such as `PyDateTime_DateTime`). The argument must not be `NULL`, and the type is not checked:

int **PyDateTime_GET_YEAR**(`PyDateTime_Date *o`)

Return the year, as a positive int. New in version 2.4.

int **PyDateTime_GET_MONTH**(`PyDateTime_Date *o`)

Return the month, as an int from 1 through 12. New in version 2.4.

int **PyDateTime_GET_DAY**(`PyDateTime_Date *o`)

Return the day, as an int from 1 through 31. New in version 2.4.

Macros to extract fields from datetime objects. The argument must be an instance of `PyDateTime_DateTime`, including subclasses. The argument must not be `NULL`, and the type is not checked:

int **PyDateTime_DATE_GET_HOUR**(`PyDateTime_DateTime *o`)

Return the hour, as an int from 0 through 23. New in version 2.4.

int **PyDateTime_DATE_GET_MINUTE**(`PyDateTime_DateTime *o`)

Return the minute, as an int from 0 through 59. New in version 2.4.

int **PyDateTime_DATE_GET_SECOND**(`PyDateTime_DateTime *o`)

Return the second, as an int from 0 through 59. New in version 2.4.

int **PyDateTime_DATE_GET_MICROSECOND**(`PyDateTime_DateTime *o`)

Return the microsecond, as an int from 0 through 999999. New in version 2.4.

Macros to extract fields from time objects. The argument must be an instance of `PyDateTime_Time`, including subclasses. The argument must not be `NULL`,

and the type is not checked:

int **PyDateTime_TIME_GET_HOUR**(PyDateTime_Time *o)

Return the hour, as an int from 0 through 23. New in version 2.4.

int **PyDateTime_TIME_GET_MINUTE**(PyDateTime_Time *o)

Return the minute, as an int from 0 through 59. New in version 2.4.

int **PyDateTime_TIME_GET_SECOND**(PyDateTime_Time *o)

Return the second, as an int from 0 through 59. New in version 2.4.

int **PyDateTime_TIME_GET_MICROSECOND**(PyDateTime_Time *o)

Return the microsecond, as an int from 0 through 999999. New in version 2.4.

Macros for the convenience of modules implementing the DB API:

PyObject* **PyDateTime_FromTimestamp**(PyObject *args)

Return value: **New reference.**

Create and return a new `datetime.datetime` object given an argument tuple suitable for passing to `datetime.datetime.fromtimestamp()`. New in version 2.4.

PyObject* **PyDate_FromTimestamp**(PyObject *args)

Return value: **New reference.**

Create and return a new `datetime.date` object given an argument tuple suitable for passing to `datetime.date.fromtimestamp()`. New in version 2.4.

Previous: [7.5.12 DateTime Objects](#) **Up:** [Python/C API Reference Manual](#) **Next:**
[8.1 Thread State and](#)

8. Initialization, Finalization, and Threads

void **Py_Initialize()**

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; with the exception of `Py_SetProgramName()`, `PyEval_InitThreads()`, `PyEval_ReleaseLock()`, and `PyEval_AcquireLock()`. This initializes the table of loaded modules (`sys.modules`), and creates the fundamental modules `__builtin__`, `__main__` and `sys`. It also initializes the module search path (`sys.path`). It does not set `sys.argv`; use `PySys_SetArgv()` for that. This is a no-op when called for a second time (without calling `Py_Finalize()` first). There is no return value; it is a fatal error if the initialization fails.

void **Py_InitializeEx**(int *initsigs*)

This function works like `Py_Initialize()` if *initsigs* is 1. If *initsigs* is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded. New in version 2.4.

int **Py_IsInitialized()**

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After `Py_Finalize()` is called, this returns false until `Py_Initialize()` is called again.

void **Py_Finalize()**

Undo all initializations made by `Py_Initialize()` and subsequent use of Python/C API functions, and destroy all sub-interpreters (see `Py_NewInterpreter()` below) that were created and not yet destroyed since the last call to `Py_Initialize()`. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling `Py_Initialize()` again first). There is no return value; errors during finalization are ignored.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

Bugs and caveats: The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()` methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls `Py_Initialize()` and `Py_Finalize()` more than once.

`PyThreadState*` **`Py_NewInterpreter()`**

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules `__builtin__`, `__main__` and `sys`. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying `FILE` structures in the C library).

The return value points to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, `NULL` is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still

held when it returns; however, unlike most other Python/C API functions, there needn't be a current thread state on entry.)

Extension modules are shared between (sub-)interpreters as follows: the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_Finalize()` and `Py_Initialize()`; in that case, the extension's `inittmodule` function is called again.

Bugs and caveats: Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect -- for example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when the extension makes use of (static) global variables, or when the extension manipulates its module's dictionary after its initialization. It is possible to insert objects created in one sub-interpreter into a namespace of another sub-interpreter; this should be done with great care to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules. (XXX This is a hard-to-fix bug that will be addressed in a future release.)

void **Py_EndInterpreter**(PyThreadState **tstate*)

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) `Py_Finalize()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

void **Py_SetProgramName**(char **name*)

This function should be called before `Py_Initialize()` is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the `main()` function of the program. This is used by `Py_GetPath()` and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is `'python'`. The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

`char* Py_GetProgramName()`

Return the program name set with `Py_SetProgramName()`, or the default. The returned string points into static storage; the caller should not modify its value.

`char* Py_GetPrefix()`

Return the *prefix* for installed platform-independent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName()` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the prefix variable in the top-level Makefile and the `--prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.prefix`. It is only useful on UNIX. See also the next function.

`char* Py_GetExecPrefix()`

Return the *exec-prefix* for installed platform-dependent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName()` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the exec-prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the `exec_prefix` variable in the top-level Makefile and the `--exec-prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.exec_prefix`. It is only useful on UNIX.

Background: The exec-prefix differs from the prefix when platform

dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-UNIX operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the **mount** or **automount** programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each platform.

`char* Py_GetProgramFullPath()`

Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by `Py_SetProgramName()` above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

`char* Py_GetPath()`

Return the default module search path; this is computed from the program name (set by `Py_SetProgramName()` above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is `:"` on UNIX and Mac OS X, `;"` on Windows. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as the list `sys.path`, which may be modified to change the future search path for loaded modules.

`const char* Py_GetVersion()`

Return the version of this Python interpreter. This is a string that looks something like

```
"1.5 (#67, Dec 31 1997, 22:34:28) [GCC 2.7.2.2]"
```

The first word (up to the first space character) is the current Python version; the first three characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

const char* **Py_GetPlatform()**

Return the platform identifier for the current platform. On UNIX, this is formed from the "official" name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is 'sunos5'. On Mac OS X, it is 'darwin'. On Windows, it is 'win'. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

const char* **Py_GetCopyright()**

Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch  
Centrum, Amsterdam'
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.copyright`.

const char* **Py_GetCompiler()**

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

```
"[GCC 2.7.2.2]"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

const char* **Py_GetBuildInfo**()

Return information about the sequence number and build date and time of the current Python interpreter instance, for example

```
"#67, Aug 1 1997, 22:34:28"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

int **PySys_SetArgv**(int *argc*, char ***argv*)

Set `sys.argv` based on *argc* and *argv*. These parameters are similar to those passed to the program's `main()` function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in *argv* can be an empty string. If this function fails to initialize `sys.argv`, a fatal condition is signalled using `Py_FatalError()`.

8.1 Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread safe. In order to support multi-threaded Python programs, there's a global lock that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the global interpreter lock may operate on Python objects or call Python/C API functions. In order to support multi-threaded Python programs, the interpreter regularly releases and reacquires the lock -- by default, every 100 bytecode instructions (this can be changed with `sys.setcheckinterval()`). The lock is also released and reacquired around potentially blocking I/O operations like reading or writing a file, so that other threads can run while the thread that requests the I/O is waiting for the I/O operation to complete.

The Python interpreter needs to keep some bookkeeping information separate per thread -- for this it uses a data structure called `PyThreadState`. There's one global variable, however: the pointer to the current `PyThreadState` structure. While most thread packages have a way to store "per-thread global data," Python's internal platform independent thread abstraction doesn't support this yet. Therefore, the current thread state must be manipulated explicitly.

This is easy enough in most cases. Most code manipulating the global interpreter lock has the following simple structure:

```
Save the thread state in a local variable.  
Release the interpreter lock.  
...Do some blocking I/O operation...  
Reacquire the interpreter lock.  
Restore the thread state from the local variable.
```

This is so common that a pair of macros exists to simplify it:

```
Py_BEGIN_ALLOW_THREADS
...Do some blocking I/O operation...
Py_END_ALLOW_THREADS
```

The `Py_BEGIN_ALLOW_THREADS` macro opens a new block and declares a hidden local variable; the `Py_END_ALLOW_THREADS` macro closes the block. Another advantage of using these two macros is that when Python is compiled without thread support, they are defined empty, thus saving the thread state and lock manipulations.

When thread support is enabled, the block above expands to the following code:

```
PyThreadState *_save;

_save = PyEval_SaveThread();
...Do some blocking I/O operation...
PyEval_RestoreThread(_save);
```

Using even lower level primitives, we can get roughly the same effect as follows:

```
PyThreadState *_save;

_save = PyThreadState_Swap(NULL);
PyEval_ReleaseLock();
...Do some blocking I/O operation...
PyEval_AcquireLock();
PyThreadState_Swap(_save);
```

There are some subtle differences; in particular, `PyEval_RestoreThread()` saves and restores the value of the global variable `errno`, since the lock manipulation does not guarantee that `errno` is left alone. Also, when thread support is disabled, `PyEval_SaveThread()` and `PyEval_RestoreThread()` don't manipulate the lock; in this case, `PyEval_ReleaseLock()` and `PyEval_AcquireLock()` are not available. This is done so that dynamically loaded extensions compiled with thread support enabled can be loaded by an interpreter that was compiled with disabled thread support.

The global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global

variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.

Why am I going on with so much detail about this? Because when threads are created from C, they don't have the global interpreter lock, nor is there a thread state data structure for them. Such threads must bootstrap themselves into existence, by first creating a thread state data structure, then acquiring the lock, and finally storing their thread state pointer, before they can start using the Python/C API. When they are done, they should reset the thread state pointer, release the lock, and finally free their thread state data structure.

Beginning with version 2.3, threads can now take advantage of the `PyGILState_*()` functions to do all of the above automatically. The typical idiom for calling into Python from a C thread is now:

```
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();

/* Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result */

/* Release the thread. No Python API allowed beyond this point.
PyGILState_Release(gstate);
```

Note that the `PyGILState_*()` functions assume there is only one global interpreter (created automatically by `Py_Initialize()`). Python still supports the creation of additional interpreters (using `Py_NewInterpreter()`), but mixing multiple interpreters and the `PyGILState_*()` API is unsupported.

PyInterpreterState

This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

PyThreadState

This data structure represents the state of a single thread. The only public data member is `PyInterpreterState *interp`, which points to this thread's interpreter state.

void **PyEval_InitThreads()**

Initialize and acquire the global interpreter lock. It should be called in the main thread before creating a second thread or engaging in any other thread operations such as `PyEval_ReleaseLock()` or `PyEval_ReleaseThread(tstate)`. It is not needed before calling `PyEval_SaveThread()` or `PyEval_RestoreThread()`.

This is a no-op when called for a second time. It is safe to call this function before calling `Py_Initialize()`.

When only the main thread exists, no lock operations are needed. This is a common situation (most Python programs do not use threads), and the lock operations slow the interpreter down a bit. Therefore, the lock is not created initially. This situation is equivalent to having acquired the lock: when there is only a single thread, all object accesses are safe. Therefore, when this function initializes the lock, it also acquires it. Before the Python `thread` module creates a new thread, knowing that either it has the lock or the lock hasn't been created yet, it calls `PyEval_InitThreads()`. When this call returns, it is guaranteed that the lock has been created and that the calling thread has acquired it.

It is **not** safe to call this function when it is unknown which thread (if any) currently has the global interpreter lock.

This function is not available when thread support is disabled at compile time.

int **PyEval_ThreadsInitialized()**

Returns a non-zero value if `PyEval_InitThreads()` has been called. This function can be called without holding the lock, and therefore can be used to avoid calls to the locking API when running single-threaded. This function is not available when thread support is disabled at compile time. New in version 2.4.

void **PyEval_AcquireLock**()

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues. This function is not available when thread support is disabled at compile time.

void **PyEval_ReleaseLock**()

Release the global interpreter lock. The lock must have been created earlier. This function is not available when thread support is disabled at compile time.

void **PyEval_AcquireThread**(PyThreadState **tstate*)

Acquire the global interpreter lock and set the current thread state to *tstate*, which should not be NULL. The lock must have been created earlier. If this thread already has the lock, deadlock ensues. This function is not available when thread support is disabled at compile time.

void **PyEval_ReleaseThread**(PyThreadState **tstate*)

Reset the current thread state to NULL and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The *tstate* argument, which must not be NULL, is only used to check that it represents the current thread state -- if it isn't, a fatal error is reported. This function is not available when thread support is disabled at compile time.

PyThreadState* **PyEval_SaveThread**()

Release the interpreter lock (if it has been created and thread support is enabled) and reset the thread state to NULL, returning the previous thread state (which is not NULL). If the lock has been created, the current thread must have acquired it. (This function is available even when thread support is disabled at compile time.)

void **PyEval_RestoreThread**(PyThreadState **tstate*)

Acquire the interpreter lock (if it has been created and thread support is enabled) and set the thread state to *tstate*, which must not be NULL. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues. (This function is available even when thread support is disabled at compile time.)

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

Py_BEGIN_ALLOW_THREADS

This macro expands to "{ PyThreadState *_save; _save = PyEval_SaveThread();". Note that it contains an opening brace; it must be matched with a following Py_END_ALLOW_THREADS macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

Py_END_ALLOW_THREADS

This macro expands to "PyEval_RestoreThread(_save); }". Note that it contains a closing brace; it must be matched with an earlier Py_BEGIN_ALLOW_THREADS macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

Py_BLOCK_THREADS

This macro expands to "PyEval_RestoreThread(_save);": it is equivalent to Py_END_ALLOW_THREADS without the closing brace. It is a no-op when thread support is disabled at compile time.

Py_UNBLOCK_THREADS

This macro expands to "_save = PyEval_SaveThread();": it is equivalent to Py_BEGIN_ALLOW_THREADS without the opening brace and variable declaration. It is a no-op when thread support is disabled at compile time.

All of the following functions are only available when thread support is enabled at compile time, and must be called only when the interpreter lock has been created.

PyInterpreterState* PyInterpreterState_New()

Create a new interpreter state object. The interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void PyInterpreterState_Clear(PyInterpreterState *interp)

Reset all information in an interpreter state object. The interpreter lock must be held.

void **PyInterpreterState_Delete**(PyInterpreterState *interp)

Destroy an interpreter state object. The interpreter lock need not be held. The interpreter state must have been reset with a previous call to `PyInterpreterState_Clear()`.

PyThreadState* **PyThreadState_New**(PyInterpreterState *interp)

Create a new thread state object belonging to the given interpreter object. The interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void **PyThreadState_Clear**(PyThreadState *tstate)

Reset all information in a thread state object. The interpreter lock must be held.

void **PyThreadState_Delete**(PyThreadState *tstate)

Destroy a thread state object. The interpreter lock need not be held. The thread state must have been reset with a previous call to `PyThreadState_Clear()`.

PyThreadState* **PyThreadState_Get**()

Return the current thread state. The interpreter lock must be held. When the current thread state is NULL, this issues a fatal error (so that the caller needn't check for NULL).

PyThreadState* **PyThreadState_Swap**(PyThreadState *tstate)

Swap the current thread state with the thread state given by the argument `tstate`, which may be NULL. The interpreter lock must be held.

PyObject* **PyThreadState_GetDict**()

Return value: **Borrowed reference.**

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns NULL, no exception has been raised and the caller should assume no current thread state is available. Changed in version 2.3: Previously this could only be called when a current thread is active, and NULL meant that an exception was raised.

int **PyThreadState_SetAsyncExc**(long *id*, PyObject **exc*)

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; if it returns a number greater than one, you're in trouble, and you should call it again with *exc* set to NULL to revert the effect. This raises no exceptions. New in version 2.3.

PyGILState_STATE **PyGILState_Ensure**()

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of its thread lock. This may be called as many times as desired by a thread as long as each call is matched with a call to `PyGILState_Release()`. In general, other thread-related APIs may be used between `PyGILState_Ensure()` and `PyGILState_Release()` calls as long as the thread state is restored to its previous state before the `Release()`. For example, normal usage of the `Py_BEGIN_ALLOW_THREADS` and `Py_END_ALLOW_THREADS` macros is acceptable.

The return value is an opaque "handle" to the thread state when `PyGILState_Acquire()` was called, and must be passed to `PyGILState_Release()` to ensure Python is left in the same state. Even though recursive calls are allowed, these handles *cannot* be shared - each unique call to `PyGILState_Ensure` must save the handle for its call to `PyGILState_Release`.

When the function returns, the current thread will hold the GIL. Failure is a fatal error. New in version 2.3.

void **PyGILState_Release**(PyGILState_STATE)

Release any resources previously acquired. After this call, Python's state will be the same as it was prior to the corresponding `PyGILState_Ensure` call (but generally this state will be unknown to the caller, hence the use of the GILState API.)

Every call to `PyGILState_Ensure()` must be matched by a call to `PyGILState_Release()` on the same thread. New in version 2.3.

8.2 Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

Starting with Python 2.2, the implementation of this facility was substantially revised, and an interface from C was added. This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as *obj*, *frame* is the frame object to which the event pertains, *what* is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, or `PyTrace_C_RETURN`, and *arg* depends on the value of *what*:

Value of <i>what</i>	Meaning of <i>arg</i>
<code>PyTrace_CALL</code>	Always NULL.
<code>PyTrace_EXCEPTION</code>	Exception information as returned by <code>sys.exc_info()</code> .
<code>PyTrace_LINE</code>	Always NULL.
<code>PyTrace_RETURN</code>	Value being returned to the caller.
<code>PyTrace_C_CALL</code>	Name of function being called.
<code>PyTrace_C_EXCEPTION</code>	Always NULL.
<code>PyTrace_C_RETURN</code>	Always NULL.

int **PyTrace_CALL**

The value of the *what* parameter to a `Py_tracefunc` function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

int **PyTrace_EXCEPTION**

The value of the *what* parameter to a `Py_tracefunc` function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

int **PyTrace_LINE**

The value passed as the *what* parameter to a trace function (but not a profiling function) when a line-number event is being reported.

int **PyTrace_RETURN**

The value for the *what* parameter to `Py_tracefunc` functions when a call is returning without propagating an exception.

int **PyTrace_C_CALL**

The value for the *what* parameter to `Py_tracefunc` functions when a C function is about to be called.

int **PyTrace_C_EXCEPTION**

The value for the *what* parameter to `Py_tracefunc` functions when a C function has thrown an exception.

int **PyTrace_C_RETURN**

The value for the *what* parameter to `Py_tracefunc` functions when a C function has returned.

void **PyEval_SetProfile**(`Py_tracefunc func`, `PyObject *obj`)

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or `NULL`. If the profile function needs to maintain state, using a different value for *obj* for each

thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except the line-number events.

void **PyEval_SetTrace**(Py_tracefunc *func*, PyObject **obj*)

Set the tracing function to *func*. This is similar to `PyEval_SetProfile()`, except the tracing function does receive line-number events.

8.3 Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

PyInterpreterState* **PyInterpreterState_Head**()

Return the interpreter state object at the head of the list of all such objects. New in version 2.2.

PyInterpreterState* **PyInterpreterState_Next**(PyInterpreterState **interp*)

Return the next interpreter state object after *interp* from the list of all such objects. New in version 2.2.

PyThreadState * **PyInterpreterState_ThreadHead**(PyInterpreterState **interp*)

Return the a pointer to the first PyThreadState object in the list of threads associated with the interpreter *interp*. New in version 2.2.

PyThreadState* **PyThreadState_Next**(PyThreadState **tstate*)

Return the next thread state object after *tstate* from the list of all such objects belonging to the same PyInterpreterState object. New in version 2.2.

Previous: [9. Memory Management](#) **Up:** [9. Memory Management](#) **Next:** [9.2 Memory Interface](#)

9.1 Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if she regularly manipulates object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: `malloc()`, `calloc()`, `realloc()` and `free()`. This will result in mixed calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
```

```
    return PyErr_NoMemory();
    ...Do some I/O operation involving buf...
    res = PyString_FromString(buf);
    free(buf); /* malloc'ed */
    return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the string object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to *inform* the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly-specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

Previous: [9.1 Overview](#) Up: [9. Memory Management](#) Next: [9.3 Examples](#)

9.2 Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap:

void* PyMem_Malloc(size_t *n*)

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

void* PyMem_Realloc(void **p*, size_t *n*)

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes. If *p* is `NULL`, the call is equivalent to `PyMem_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`. Unless *p* is `NULL`, it must have been returned by a previous call to `PyMem_Malloc()` or `PyMem_Realloc()`.

void PyMem_Free(void **p*)

Frees the memory block pointed to by *p*, which must have been returned by a previous call to `PyMem_Malloc()` or `PyMem_Realloc()`. Otherwise, or if `PyMem_Free(p)` has been called before, undefined behavior occurs. If *p* is `NULL`, no operation is performed.

The following type-oriented macros are provided for convenience. Note that *TYPE* refers to any C type.

TYPE* PyMem_New(TYPE, size_t *n*)

Same as `PyMem_Malloc()`, but allocates ($n * \text{sizeof}(TYPE)$) bytes of memory. Returns a pointer cast to `TYPE*`. The memory will not have been initialized in any way.

TYPE* PyMem_Resize(void **p*, TYPE, size_t *n*)

Same as `PyMem_Realloc()`, but the memory block is resized to $(n * \text{sizeof}(TYPE))$ bytes. Returns a pointer cast to `TYPE*`.

void **PyMem_Del**(void **p*)

Same as `PyMem_Free()`.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

`PyMem_MALLOC()`, `PyMem_REALLOC()`, `PyMem_FREE()`.

`PyMem_NEW()`, `PyMem_RESIZE()`, `PyMem_DEL()`.

Previous: [9.2 Memory Interface](#) **Up:** [9. Memory Management](#) **Next:** [10. Object Implementation Support](#)

9.3 Examples

Here is the example from section [9.1](#), rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3); /* Wrong -- should be PyMem_Free() */
free(buf2);      /* Right -- allocated via malloc() */
free(buf1);      /* Fatal -- should be PyMem_Del() */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with

`PyObject_New()`, `PyObject_NewVar()` and `PyObject_Del()`, or with their corresponding macros `PyObject_NEW()`, `PyObject_NEW_VAR()` and `PyObject_DEL()`.

These will be explained in the next chapter on defining and implementing new object types in C.

10.1 Allocating Objects on the Heap

PyObject* **_PyObject_New**(PyTypeObject *type)

Return value: *New reference.*

PyVarObject* **_PyObject_NewVar**(PyTypeObject *type, int size)

Return value: *New reference.*

void **_PyObject_Del**(PyObject *op)

PyObject* **PyObject_Init**(PyObject *op, PyTypeObject *type)

Return value: *Borrowed reference.*

Initialize a newly-allocated object *op* with its type and initial reference. Returns the initialized object. If *type* indicates that the object participates in the cyclic garbage detector, it is added to the detector's set of observed objects. Other fields of the object are not affected.

PyVarObject* **PyObject_InitVar**(PyVarObject *op, PyTypeObject *type, int size)

This does everything `PyObject_Init()` does, and also initializes the length information for a variable-size object.

*TYPE** **PyObject_New**(*TYPE*, PyTypeObject *type)

Return value: *New reference.*

Allocate a new Python object using the C structure type *TYPE* and the Python type object *type*. Fields not defined by the Python object header are not initialized; the object's reference count will be one. The size of the memory allocation is determined from the `tp_basicsize` field of the type object.

*TYPE** **PyObject_NewVar**(*TYPE*, PyTypeObject *type, int size)

Return value: *New reference.*

Allocate a new Python object using the C structure type *TYPE* and the Python type object *type*. Fields not defined by the Python object header are not initialized. The allocated memory allows for the *TYPE* structure plus

size fields of the size given by the `tp_itemsize` field of `type`. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

void **PyObject_Del**(PyObject *op)

Releases memory allocated to an object using `PyObject_New()` or `PyObject_NewVar()`. This is normally called from the `tp_dealloc` handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

*TYPE** **PyObject_NEW**(*TYPE*, PyTypeObject *type)

Return value: **New reference.**

Macro version of `PyObject_New()`, to gain performance at the expense of safety. This does not check `type` for a `NULL` value.

*TYPE** **PyObject_NEW_VAR**(*TYPE*, PyTypeObject *type, int size)

Return value: **New reference.**

Macro version of `PyObject_NewVar()`, to gain performance at the expense of safety. This does not check `type` for a `NULL` value.

void **PyObject_DEL**(PyObject *op)

Macro version of `PyObject_Del()`.

PyObject* **Py_InitModule**(char *name, PyMethodDef *methods)

Return value: **Borrowed reference.**

Create a new module object based on a name and table of functions, returning the new module object.

Changed in version 2.3: Older versions of Python did not support `NULL` as the value for the `methods` argument.

PyObject* **Py_InitModule3**(char *name, PyMethodDef *methods, char *doc)

Return value: **Borrowed reference.**

Create a new module object based on a name and table of functions,

returning the new module object. If *doc* is non-NULL, it will be used to define the docstring for the module.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the *methods* argument.

PyObject* **Py_InitModule4**(char **name*, PyMethodDef **methods*, char **doc*, PyObject **self*, int *apiver*)

Return value: **Borrowed reference.**

Create a new module object based on a name and table of functions, returning the new module object. If *doc* is non-NULL, it will be used to define the docstring for the module. If *self* is non-NULL, it will be passed to the functions of the module as their (otherwise NULL) first parameter. (This was added as an experimental feature, and there are no known uses in the current version of Python.) For *apiver*, the only value which should be passed is defined by the constant PYTHON_API_VERSION.

Note: Most uses of this function should probably be using the `Py_InitModule3()` instead; only use this if you are sure you need it.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the *methods* argument.

DL_IMPORT

PyObject **_Py_NoneStruct**

Object which is visible in Python as `None`. This should only be accessed using the `Py_None` macro, which evaluates to a pointer to this object.

Previous: [10. Object Implementation Support](#) **Up:** [10. Object Implementation Support](#) **Next:** [10.2 Common Object Structures](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

Previous: [10.1 Allocating Objects on](#) **Up:** [10. Object Implementation Support](#)
Next: [10.3 Type Objects](#)

10.2 Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the `PyObject` and `PyVarObject` types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

PyObject

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal ``release" build, it contains only the objects reference count and a pointer to the corresponding type object. It corresponds to the fields defined by the expansion of the `PyObject_HEAD` macro.

PyVarObject

This is an extension of `PyObject` that adds the `ob_size` field. This is only used for objects that have some notion of *length*. This type does not often appear in the Python/C API. It corresponds to the fields defined by the expansion of the `PyObject_VAR_HEAD` macro.

These macros are used in the definition of `PyObject` and `PyVarObject`:

PyObject_HEAD

This is a macro which expands to the declarations of the fields of the `PyObject` type; it is used when declaring new types which represent objects without a varying length. The specific fields it expands to depend on the definition of `Py_TRACE_REFS`. By default, that macro is not defined, and `PyObject_HEAD` expands to:

```
int ob_refcnt;  
PyTypeObject *ob_type;
```

When `Py_TRACE_REFS` is defined, it expands to:

```
PyObject *_ob_next, *_ob_prev;
```

```
int ob_refcnt;
PyTypeObject *ob_type;
```

PyObject_VAR_HEAD

This is a macro which expands to the declarations of the fields of the `PyVarObject` type; it is used when declaring new types which represent objects with a length that varies from instance to instance. This macro always expands to:

```
PyObject_HEAD
int ob_size;
```

Note that `PyObject_HEAD` is part of the expansion, and that its own expansion varies depending on the definition of `Py_TRACE_REFS`.

PyObject_HEAD_INIT

PyCFunction

Type of the functions used to implement most Python callables in C. Functions of this type take two `PyObject *` parameters and return one such value. If the return value is `NULL`, an exception shall have been set. If not `NULL`, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

PyMethodDef

Structure used to describe a method of an extension type. This structure has four fields:

Field	C Type	Meaning
<code>m1_name</code>	<code>char *</code>	name of the method
<code>m1_meth</code>	<code>PyCFunction</code>	pointer to the C implementation
<code>m1_flags</code>	<code>int</code>	flag bits indicating how the call should be constructed
<code>m1_doc</code>	<code>char *</code>	points to the contents of the docstring

The `m1_meth` is a C function pointer. The functions may be of different types, but they always return `PyObject *`. If the function is not of the `PyCFunction`, the compiler will require a cast in the method table. Even though `PyCFunction` defines the first parameter as `PyObject *`, it is common that the method implementation uses a the specific C type of the *self*

object.

The `m1_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention. Of the calling convention flags, only `METH_VARARGS` and `METH_KEYWORDS` can be combined (but note that `METH_KEYWORDS` alone is equivalent to `METH_VARARGS | METH_KEYWORDS`). Any of the calling convention flags can be combined with a binding flag.

METH_VARARGS

This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject *` values. The first one is the *self* object for methods; for module functions, it has the value given to `Py_InitModule4()` (or `NULL` if `Py_InitModule()` was used). The second parameter (often called *args*) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple()` or `PyArg_UnpackTuple`.

METH_KEYWORDS

Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: *self*, *args*, and a dictionary of all the keyword arguments. The flag is typically combined with `METH_VARARGS`, and the parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

METH_NOARGS

Methods without parameters don't need to check whether arguments are given if they are listed with the `METH_NOARGS` flag. They need to be of type `PyCFunction`. When used with object methods, the first parameter is typically named `self` and will hold a reference to the object instance. In all cases the second parameter will be `NULL`.

METH_O

Methods with a single object argument can be listed with the `METH_O` flag, instead of invoking `PyArg_ParseTuple()` with a "O" argument. They have the type `PyCFunction`, with the *self* parameter, and a `PyObject *` parameter representing the single argument.

METH_OLDARGS

This calling convention is deprecated. The method must be of type `PyCFunction`. The second argument is `NULL` if no arguments are given, a single object if exactly one argument is given, and a tuple of objects if more than one argument is given. There is no way for a function using this convention to distinguish between a call with multiple arguments and a call with a tuple as the only argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

METH_CLASS

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the `classmethod()` built-in function. New in version 2.3.

METH_STATIC

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the `staticmethod()` built-in function. New in version 2.3.

One other constant controls whether a method is loaded in place of another definition with the same method name.

METH_COEXIST

The method will be loaded in place of existing definitions. Without `METH_COEXIST`, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a `sq_contains` slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding `PyCFunction` with the same name. With the flag defined, the `PyCFunction` will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to `PyCFunctions` are optimized more than wrapper object calls. New in version 2.4.

`PyMethodDef table[], PyObject *ob, char`

PyObject* **Py_FindMethod**(*name)

*Return value: **New reference.***

Return a bound method object for an extension type implemented in C. This can be useful in the implementation of a `tp_getattro` or `tp_getattr` handler that does not use the `PyObject_GenericGetAttr()` function.

10.3 Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*` or `PyType_*` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

Typedefs: `unaryfunc`, `binaryfunc`, `ternaryfunc`, `inquiry`, `coercion`, `intargfunc`, `intintargfunc`, `intobjargproc`, `intintobjargproc`, `objobjargproc`, `destructor`, `freefunc`, `printfunc`, `getattrfunc`, `getattrofunc`, `setattrfunc`, `setattrofunc`, `cmpfunc`, `reprfunc`, `hashfunc`

The structure definition for `PyTypeObject` can be found in `Include/object.h`. For convenience of reference, this repeats the definition found there:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>" */
    int tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    printfunc tp_print;
    getattrfunc tp_getattr;
    setattrfunc tp_setattr;
    cmpfunc tp_compare;
    reprfunc tp_repr;

    /* Method suites for standard classes */

    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;
```

```

/* More standard operations (here for binary compatibility) */

hashfunc tp_hash;
ternaryfunc tp_call;
reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */
long tp_flags;

char *tp_doc; /* Documentation string */

/* Assigned meaning in release 2.0 */
/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* Assigned meaning in release 2.1 */
/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Added in release 2.2 */
/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;

PyObject *tp_subclasses;  
PyObject *tp_weaklist;  
  
} PyTypeObject;
```

Download as text (original file name: `typestruct.h`).

The type object structure extends the `PyVarObject` structure. The `ob_size` field is used for dynamic types (created by `type_new()`, usually called from a class statement). Note that `PyType_Type` (the metatype) initializes `tp_itemsize`, which means that its instances (i.e. type objects) *must* have the `ob_size` field.

`PyObject* _ob_next`

`PyObject* _ob_prev`

These fields are only present when the macro `Py_TRACE_REFS` is defined. Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain `NULL`. For dynamically allocated objects, these two fields are used to link the object into a doubly-linked list of *all* live objects on the heap. This could be used for various debugging purposes; currently the only use is to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

These fields are not inherited by subtypes.

`int ob_refcnt`

This is the type object's reference count, initialized to `1` by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose `ob_type` points back to the type) do *not* count as references. But for dynamically allocated type objects, the instances *do* count as references.

This field is not inherited by subtypes.

`PyTypeObject* ob_type`

This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable

extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. `PyType_Ready()` checks if `ob_type` is `NULL`, and if so, initializes it: in Python 2.2, it is set to `&PyType_Type`; in Python 2.2.1 and later it is initialized to the `ob_type` field of the base class. `PyType_Ready()` will not change this field if it is non-zero.

In Python 2.2, this field is not inherited by subtypes. In 2.2.1, and in 2.3 and beyond, it is inherited by subtypes.

int **ob_size**

For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.

This field is not inherited by subtypes.

char* **tp_name**

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named `T` defined in module `M` in subpackage `Q` in package `P` should have the `tp_name` initializer `"P.Q.M.T"`.

For dynamically allocated type objects, this should just be the type name, and the module name explicitly stored in the type dict as the value for key `'__module__'`.

For statically allocated type objects, the `tp_name` field should contain a dot. Everything before the last dot is made accessible as the `__module__` attribute, and everything after the last dot is made accessible as the

`__name__` attribute.

If no dot is present, the entire `tp_name` field is made accessible as the `__name__` attribute, and the `__module__` attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle.

This field is not inherited by subtypes.

int **`tp_basicsize`**

int **`tp_itemsize`**

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero `tp_itemsize` field, types with variable-length instances have a non-zero `tp_itemsize` field. For a type with fixed-length instances, all instances have the same size, given in `tp_basicsize`.

For a type with variable-length instances, the instances must have an `ob_size` field, and the instance size is `tp_basicsize` plus N times `tp_itemsize`, where N is the "length" of the object. The value of N is typically stored in the instance's `ob_size` field. There are exceptions: for example, long ints use a negative `ob_size` to indicate a negative number, and N is `abs(ob_size)` there. Also, the presence of an `ob_size` field in the instance layout doesn't mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful `ob_size` field).

The basic size includes the fields in the instance declared by the macro `PyObject_HEAD` or `PyObject_VAR_HEAD` (whichever is used to declare the instance struct) and this in turn includes the `_ob_prev` and `_ob_next` fields if they are present. This means that the only correct way to get an initializer for the `tp_basicsize` is to use the `sizeof` operator on the struct used to declare the instance layout. The basic size does not include the GC header size (this is new in Python 2.2; in 2.1 and 2.0, the GC header size was included in `tp_basicsize`).

These fields are inherited separately by subtypes. If the base type has a non-zero `tp_itemsize`, it is generally not safe to set `tp_itemsize` to a

different non-zero value in a subtype (though this depends on the implementation of the base type).

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of `tp_basicsize`. Example: suppose a type implements an array of `double`. `tp_itemsize` is `sizeof(double)`. It is the programmer's responsibility that `tp_basicsize` is a multiple of `sizeof(double)` (assuming this is the alignment requirement for `double`).

destructor **tp_dealloc**

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`).

The destructor function is called by the `Py_DECREF()` and `Py_XDECREF()` macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and finally (as its last action) call the type's `tp_free` function. If the type is not subtypable (doesn't have the `Py_TPFLAGS_BASETYPE` flag bit set), it is permissible to call the object deallocator directly instead of via `tp_free`. The object deallocator should be the one used to allocate the instance; this is normally `PyObject_Deal()` if the instance was allocated using `PyObject_New()` or `PyObject_VarNew()`, or `PyObject_GC_Deal()` if the instance was allocated using `PyObject_GC_New()` or `PyObject_GC_VarNew()`.

This field is inherited by subtypes.

printfunc **tp_print**

An optional pointer to the instance print function.

The print function is only called when the instance is printed to a *real* file; when it is printed to a pseudo-file (like a `StringIO` instance), the instance's `tp_repr` or `tp_str` function is called to convert it to a string. These are also called when the type's `tp_print` field is `NULL`. A type

should never implement `tp_print` in a way that produces different output than `tp_repr` or `tp_str` would.

The print function is called with the same signature as `PyObject_Print(): int tp_print(PyObject *self, FILE *file, int flags)`. The *self* argument is the instance to be printed. The *file* argument is the stdio file to which it is to be printed. The *flags* argument is composed of flag bits. The only flag bit currently defined is `Py_PRINT_RAW`. When the `Py_PRINT_RAW` flag bit is set, the instance should be printed the same way as `tp_str` would format it; when the `Py_PRINT_RAW` flag bit is clear, the instance should be printed the same way as `tp_repr` would format it. It should return `-1` and set an exception condition when an error occurred during the comparison.

It is possible that the `tp_print` field will be deprecated. In any case, it is recommended not to define `tp_print`, but instead to rely on `tp_repr` and `tp_str` for printing.

This field is inherited by subtypes.

getattrfunc **tp_getattr**

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_GetAttrString()`.

This field is inherited by subtypes together with `tp_getattro`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

setattrfunc **tp_setattr**

An optional pointer to the set-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_SetAttrString()`.

This field is inherited by subtypes together with `tp_setattro`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both NULL.

cmpfunc **tp_compare**

An optional pointer to the three-way comparison function.

The signature is the same as for `PyObject_Compare()`. The function should return `1` if *self* greater than *other*, `0` if *self* is equal to *other*, and `-1` if *self* less than *other*. It should return `-1` and set an exception condition when an error occurred during the comparison.

This field is inherited by subtypes together with `tp_richcompare` and `tp_hash`: a subtypes inherits all three of `tp_compare`, `tp_richcompare`, and `tp_hash` when the subtype's `tp_compare`, `tp_richcompare`, and `tp_hash` are all NULL.

reprfunc **tp_repr**

An optional pointer to a function that implements the built-in function `repr()`.

The signature is the same as for `PyObject_Repr()`; it must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with "<" and ending with ">" from which both the type and the value of the object can be deduced.

When this field is not set, a string of the form "<%s object at %p>" is returned, where %S is replaced by the type name, and %p by the object's memory address.

This field is inherited by subtypes.

PyNumberMethods *tp_as_number;

XXX

PySequenceMethods *tp_as_sequence;

XXX

PyMappingMethods *tp_as_mapping;

XXX

hashfunc **tp_hash**

An optional pointer to a function that implements the built-in function `hash()`.

The signature is the same as for `PyObject_Hash()`; it must return a C long. The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

When this field is not set, two possibilities exist: if the `tp_compare` and `tp_richcompare` fields are both `NULL`, a default hash value based on the object's address is returned; otherwise, a `TypeError` is raised.

This field is inherited by subtypes together with `tp_richcompare` and `tp_compare`: a subtype inherits all three of `tp_compare`, `tp_richcompare`, and `tp_hash`, when the subtype's `tp_compare`, `tp_richcompare` and `tp_hash` are all `NULL`.

ternaryfunc **tp_call**

An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`.

This field is inherited by subtypes.

reprfunc **tp_str**

An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()` will call this handler.)

The signature is the same as for `PyObject_Str()`; it must return a string or a Unicode object. This function should return a "friendly" string

representation of the object, as this is the representation that will be used by the print statement.

When this field is not set, `PyObject_Repr()` is called to return a string representation.

This field is inherited by subtypes.

getattrofunc **tp_getattro**

An optional pointer to the get-attribute function.

The signature is the same as for `PyObject_GetAttr()`. It is usually convenient to set this field to `PyObject_GenericGetAttr()`, which implements the normal way of looking for object attributes.

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both NULL.

setattrofunc **tp_setattro**

An optional pointer to the set-attribute function.

The signature is the same as for `PyObject_SetAttr()`. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both NULL.

PyBufferProcs* **tp_as_buffer**

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in "Buffer Object Structures" (section [10.7](#)).

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

long **tp_flags**

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or NULL value instead.

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist (as indicated by the `Py_TPFLAGS_HAVE_RICHCOMPARE` flag bit) and have NULL values.

The following bit masks are currently defined; these can be or-ed together using the `|` operator to form the value of the `tp_flags` field. The macro `PyType_HasFeature()` takes a type and a flags value, `tp` and `f`, and checks whether `tp->tp_flags & f` is non-zero.

Py_TPFLAGS_HAVE_GETCHARBUFFER

If this bit is set, the `PyBufferProcs` struct referenced by `tp_as_buffer` has the `bf_getcharbuffer` field.

Py_TPFLAGS_HAVE_SEQUENCE_IN

If this bit is set, the `PySequenceMethods` struct referenced by `tp_as_sequence` has the `sq_contains` field.

Py_TPFLAGS_GC

This bit is obsolete. The bit it used to name is no longer in use. The symbol is now defined as zero.

Py_TPFLAGS_HAVE_INPLACEOPS

If this bit is set, the `PySequenceMethods` struct referenced by

`tp_as_sequence` and the `PyNumberMethods` structure referenced by `tp_as_number` contain the fields for in-place operators. In particular, this means that the `PyNumberMethods` structure has the fields `nb_inplace_add`, `nb_inplace_subtract`, `nb_inplace_multiply`, `nb_inplace_divide`, `nb_inplace_remainder`, `nb_inplace_power`, `nb_inplace_lshift`, `nb_inplace_rshift`, `nb_inplace_and`, `nb_inplace_xor`, and `nb_inplace_or`; and the `PySequenceMethods` struct has the fields `sq_inplace_concat` and `sq_inplace_repeat`.

Py_TPFLAGS_CHECKTYPES

If this bit is set, the binary and ternary operations in the `PyNumberMethods` structure referenced by `tp_as_number` accept arguments of arbitrary object types, and do their own type conversions if needed. If this bit is clear, those operations require that all arguments have the current type as their type, and the caller is supposed to perform a coercion operation first. This applies to `nb_add`, `nb_subtract`, `nb_multiply`, `nb_divide`, `nb_remainder`, `nb_divmod`, `nb_power`, `nb_lshift`, `nb_rshift`, `nb_and`, `nb_xor`, and `nb_or`.

Py_TPFLAGS_HAVE_RICHCOMPARE

If this bit is set, the type object has the `tp_richcompare` field, as well as the `tp_traverse` and the `tp_clear` fields.

Py_TPFLAGS_HAVE_WEAKREFS

If this bit is set, the `tp_weaklistoffset` field is defined. Instances of a type are weakly referenceable if the type's `tp_weaklistoffset` field has a value greater than zero.

Py_TPFLAGS_HAVE_ITER

If this bit is set, the type object has the `tp_iter` and `tp_iternext` fields.

Py_TPFLAGS_HAVE_CLASS

If this bit is set, the type object has several new fields defined starting in Python 2.2: `tp_methods`, `tp_members`, `tp_getset`,

`tp_base`, `tp_dict`, `tp_descr_get`, `tp_descr_set`,
`tp_dictoffset`, `tp_init`, `tp_alloc`, `tp_new`, `tp_free`,
`tp_is_gc`, `tp_bases`, `tp_mro`, `tp_cache`, `tp_subclasses`,
and `tp_weaklist`.

Py_TPFLAGS_HEAPTYPE

This bit is set when the type object itself is allocated on the heap. In this case, the `ob_type` field of its instances is considered a reference to the type, and the type object is INCREMENT'ed when a new instance is created, and DECREMENT'ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's `ob_type` gets INCREMENT'ed or DECREMENT'ed).

Py_TPFLAGS_BASETYPE

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a "final" class in Java).

Py_TPFLAGS_READY

This bit is set when the type object has been fully initialized by `PyType_Ready()`.

Py_TPFLAGS_READYING

This bit is set while `PyType_Ready()` is in the process of initializing the type object.

Py_TPFLAGS_HAVE_GC

This bit is set when the object supports garbage collection. If this bit is set, instances must be created using `PyObject_GC_New()` and destroyed using `PyObject_GC_Del()`. More information in section XXX about garbage collection. This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object; but those fields also exist when `Py_TPFLAGS_HAVE_GC` is clear but `Py_TPFLAGS_HAVE_RICHCOMPARE` is set.

Py_TPFLAGS_DEFAULT

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits:

Py_TPFLAGS_HAVE_GETCHARBUFFER,
Py_TPFLAGS_HAVE_SEQUENCE_IN,
Py_TPFLAGS_HAVE_INPLACEOPS,
Py_TPFLAGS_HAVE_RICHCOMPARE,
Py_TPFLAGS_HAVE_WEAKREFS, Py_TPFLAGS_HAVE_ITER,
and Py_TPFLAGS_HAVE_CLASS.

char* **tp_doc**

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.

This field is *not* inherited by subtypes.

The following three fields only exist if the `Py_TPFLAGS_HAVE_RICHCOMPARE` flag bit is set.

traverseproc **tp_traverse**

An optional pointer to a traversal function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. More information in section [10.9](#) about garbage collection.

This field is inherited by subtypes together with `tp_clear` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype *and* the subtype has the `Py_TPFLAGS_HAVE_RICHCOMPARE` flag bit set.

inquiry **tp_clear**

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. More information in section [10.9](#) about garbage collection.

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype *and* the subtype has the `Py_TPFLAGS_HAVE_RICHCOMPARE` flag bit set.

richcmpfunc **tp_richcompare**

An optional pointer to the rich comparison function.

The signature is the same as for `PyObject_RichCompare()`. The function should return `1` if the requested comparison returns true, `0` if it returns false. It should return `-1` and set an exception condition when an error occurred during the comparison.

This field is inherited by subtypes together with `tp_compare` and `tp_hash`: a subtype inherits all three of `tp_compare`, `tp_richcompare`, and `tp_hash`, when the subtype's `tp_compare`, `tp_richcompare`, and `tp_hash` are all `NULL`.

The following constants are defined to be used as the third argument for `tp_richcompare` and for `PyObject_RichCompare()`:

Constant	Comparison
<code>Py_LT</code>	<code><</code>
<code>Py_LE</code>	<code><=</code>
<code>Py_EQ</code>	<code>==</code>
<code>Py_NE</code>	<code>!=</code>
<code>Py_GT</code>	<code>></code>
<code>Py_GE</code>	<code>>=</code>

The next field only exists if the `Py_TPFLAGS_HAVE_WEAKREFS` flag bit is set.

long **tp_weaklistoffset**

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by `PyObject_ClearWeakRefs()` and the `PyWeakref_*()` functions. The instance structure needs to include a field of type `PyObject*` which is initialized to `NULL`.

Do not confuse this field with `tp_weaklist`; that is the list head for weak references to the type object itself.

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via `tp_weaklistoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the `tp_weaklistoffset` of that slot's offset.

When a type's `__slots__` declaration contains a slot named `__weakref__`, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's `tp_weaklistoffset`.

When a type's `__slots__` declaration does not contain a slot named `__weakref__`, the type inherits its `tp_weaklistoffset` from its base type.

The next two fields only exist if the `Py_TPFLAGS_HAVE_CLASS` flag bit is set.

getiterfunc **tp_iter**

An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function, and classic instances always have this function, even if they don't define an `__iter__()` method).

This function has the same signature as `PyObject_GetIter()`.

This field is inherited by subtypes.

iternextfunc **tp_iternext**

An optional pointer to a function that returns the next item in an iterator, or raises `StopIteration` when the iterator is exhausted. Its presence normally signals that the instances of this type are iterators (although classic instances always have this function, even if they don't define a `next()` method).

Iterator types should also define the `tp_iter` function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as `PyIter_Next()`.

This field is inherited by subtypes.

The next fields, up to and including `tp_weaklist`, only exist if the `Py_TPFLAGS_HAVE_CLASS` flag bit is set.

struct PyMethodDef* **tp_methods**

An optional pointer to a static NULL-terminated array of `PyMethodDef` structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a method descriptor.

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct PyMemberDef* **tp_members**

An optional pointer to a static NULL-terminated array of `PyMemberDef` structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a member descriptor.

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct PyGetSetDef* **tp_getset**

An optional pointer to a static NULL-terminated array of `PyGetSetDef` structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

Docs for PyGetSetDef (XXX belong elsewhere):

```
typedef PyObject *(*getter)(PyObject *, void *);
typedef int (*setter)(PyObject *, PyObject *, void *);

typedef struct PyGetSetDef {
    char *name; /* attribute name */
    getter get; /* C function to get the attribute */
    setter set; /* C function to set the attribute */
    char *doc; /* optional doc string */
    void *closure; /* optional additional data for getter and setter */
} PyGetSetDef;
```

PyTypeObject* **tp_base**

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

This field is not inherited by subtypes (obviously), but it defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type object).

PyObject* **tp_dict**

The type's dictionary is stored here by `PyType_Ready()`.

This field should normally be initialized to `NULL` before `PyType_Ready` is called; it may also be initialized to a dictionary containing initial attributes for the type. Once `PyType_Ready()` has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like `__add__()`).

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

descrgetfunc **tp_descr_get**

An optional pointer to a "descriptor get" function.

XXX blah, blah.

This field is inherited by subtypes.

descrsetfunc **tp_descr_set**

An optional pointer to a "descriptor set" function.

XXX blah, blah.

This field is inherited by subtypes.

long **tp_dictoffset**

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by `PyObject_GenericGetAttr()`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the *end* of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of `str` or `tuple`. Note that the `tp_basicsize` field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, `tp_dictoffset` should be set to -4 to indicate that the dictionary is at the very end of the structure.

The real dictionary offset in an instance can be computed from a negative `tp_dictoffset` as follows:

```
dictoffset = tp_basicsize + abs(ob_size)*tp_itemsize + tp_dicto:  
if dictoffset is not aligned on sizeof(void*):  
    round up to sizeof(void*)
```

where `tp_basicsize`, `tp_itemsize` and `tp_dictoffset` are taken from the type object, and `ob_size` is taken from the instance. The absolute value is taken because long ints use the sign of `ob_size` to store the sign of the number. (There's never a need to do this calculation yourself; it is done for you by `_PyObject_GetDictPtr()`.)

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a difference offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the `tp_dictoffset` is set to that slot's offset.

When a type defined by a class statement has a `__slots__` declaration, the type inherits its `tp_dictoffset` from its base type.

(Adding a slot named `__dict__` to the `__slots__` declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like `__weakref__` though.)

initproc **tp_init**

An optional pointer to an instance initialization function.

This function corresponds to the `__init__()` method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is

```
int tp_init(PyObject *self, PyObject *args, PyObject *kwds)
```

The `self` argument is the instance to be initialized; the `args` and `kwds` arguments represent positional and keyword arguments of the call to `__init__()`.

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called. (VERSION NOTE: described here is

what is implemented in Python 2.2.1 and later. In Python 2.2, the `tp_init` of the type of the object returned by `tp_new` was always called, if not `NULL`.)

This field is inherited by subtypes.

allocfunc **tp_alloc**

An optional pointer to an instance allocation function.

The function signature is

```
PyObject *tp_alloc(PyTypeObject *self, int nitems)
```

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with `ob_refcnt` set to 1 and `ob_type` set to the type argument. If the type's `tp_itemsize` is non-zero, the object's `ob_size` field should be initialized to *nitems* and the length of the allocated memory block should be `tp_basicsize + nitems*tp_itemsize`, rounded up to a multiple of `sizeof(void*)`; otherwise, *nitems* is not used and the length of the block should be `tp_basicsize`.

Do not use this function to do any other instance initialization, not even to allocate additional memory; that should be done by `tp_new`.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is always set to `PyType_GenericAlloc()`, to force a standard heap allocation strategy. That is also the recommended value for statically defined types.

newfunc **tp_new**

An optional pointer to an instance creation function.

If this function is `NULL` for a particular type, that type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

The function signature is

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *args, PyObject
```

The *subtype* argument is the type of the object being created; the *args* and *kwds* arguments represent positional and keyword arguments of the call to the type. Note that *subtype* doesn't have to equal the type whose `tp_new` function is called; it may be a subtype of that type (but not an unrelated type).

The `tp_new` function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the `tp_init` handler. A good rule of thumb is that for immutable types, all initialization should take place in `tp_new`, while for mutable types, most initialization should be deferred to `tp_init`.

This field is inherited by subtypes, except it is not inherited by static types whose `tp_base` is `NULL` or `&PyBaseObject_Type`. The latter exception is a precaution so that old extension types don't become callable simply by being linked with Python 2.2.

destructor **tp_free**

An optional pointer to an instance deallocation function.

The signature of this function has changed slightly: in Python 2.2 and 2.2.1, its signature is `destructor`:

```
void tp_free(PyObject *)
```

In Python 2.3 and beyond, its signature is `freefunc`:

```
void tp_free(void *)
```

The only initializer that is compatible with both versions is `_PyObject_De1`, whose definition has suitably adapted in Python 2.3.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is set to a deallocator suitable to match `PyType_GenericAlloc()` and the value of the `Py_TPFLAGS_HAVE_GC` flag bit.

inquiry **tp_is_gc**

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is

```
int tp_is_gc(PyObject *self)
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

This field is inherited by subtypes. (VERSION NOTE: in Python 2.2, it was not inherited. It is inherited in 2.2.1 and later versions.)

PyObject* **tp_bases**

Tuple of base types.

This is set for types created by a class statement. It should be `NULL` for statically defined types.

This field is not inherited.

PyObject* **tp_mro**

Tuple containing the expanded set of base types, starting with the type itself and ending with `object`, in Method Resolution Order.

This field is not inherited; it is calculated fresh by `PyType_Ready()`.

PyObject* **tp_cache**

Unused. Not inherited. Internal use only.

PyObject* **tp_subclasses**

List of weak references to subclasses. Not inherited. Internal use only.

PyObject* **tp_weaklist**

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

The remaining fields are only defined if the feature test macro `COUNT_ALLOCS` is defined, and are for internal use only. They are documented here for completeness. None of these fields are inherited by subtypes.

int **tp_allocs**

Number of allocations.

int **tp_frees**

Number of frees.

int **tp_maxalloc**

Maximum simultaneously allocated objects.

PyTypeObject* **tp_next**

Pointer to the next type object with a non-zero `tp_allocs` field.

Also, note that, in a garbage collected Python, `tp_dealloc` may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which `tp_dealloc` is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called `tp_dealloc` will not violate any assumptions of the library.

10.7 Buffer Object Structures

The buffer interface exports a model where an object can expose its internal data as a set of chunks of data, where each chunk is specified as a pointer/length pair. These chunks are called *segments* and are presumed to be non-contiguous in memory.

If an object does not export the buffer interface, then its `tp_as_buffer` member in the `PyTypeObject` structure should be `NULL`. Otherwise, the `tp_as_buffer` will point to a `PyBufferProcs` structure.

Note: It is very important that your `PyTypeObject` structure uses `Py_TPFLAGS_DEFAULT` for the value of the `tp_flags` member rather than `0`. This tells the Python runtime that your `PyBufferProcs` structure contains the `bf_getcharbuffer` slot. Older versions of Python did not have this member, so a new Python interpreter using an old extension needs to be able to test for its presence before using it.

PyBufferProcs

Structure used to hold the function pointers which define an implementation of the buffer protocol.

The first slot is `bf_getreadbuffer`, of type `getreadbufferproc`. If this slot is `NULL`, then the object does not support reading from the internal data. This is non-sensical, so implementors should fill this in, but callers should test that the slot contains a non-`NULL` value.

The next slot is `bf_getwritebuffer` having type `getwritebufferproc`. This slot may be `NULL` if the object does not allow writing into its returned buffers.

The third slot is `bf_getsegcount`, with type `getsegcountproc`. This slot must not be `NULL` and is used to inform the caller how many segments the object contains. Simple objects such as `PyString_Type` and `PyBuffer_Type` objects contain a single segment.

The last slot is `bf_getcharbuffer`, of type `getcharbufferproc`.

This slot will only be present if the `Py_TPFLAGS_HAVE_GETCHARBUFFER` flag is present in the `tp_flags` field of the object's `PyTypeObject`. Before using this slot, the caller should test whether it is present by using the `PyType_HasFeature()` function. If the flag is present, `bf_getcharbuffer` may be `NULL`, indicating that the object's contents cannot be used as *8-bit characters*. The slot function may also raise an error if the object's contents cannot be interpreted as 8-bit characters. For example, if the object is an array which is configured to hold floating point values, an exception may be raised if a caller attempts to use `bf_getcharbuffer` to fetch a sequence of 8-bit characters. This notion of exporting the internal buffers as ```text"` is used to distinguish between objects that are binary in nature, and those which have character-based content.

Note: The current policy seems to state that these characters may be multi-byte characters. This implies that a buffer size of *N* does not mean there are *N* characters present.

Py_TPFLAGS_HAVE_GETCHARBUFFER

Flag bit set in the type structure to indicate that the `bf_getcharbuffer` slot is known. This being set does not indicate that the object supports the buffer interface or that the `bf_getcharbuffer` slot is non-`NULL`.

int (*getreadbufferproc) (PyObject *self, int segment, void **ptrptr)

Return a pointer to a readable segment of the buffer in `*ptrptr`. This function is allowed to raise an exception, in which case it must return `-1`. The *segment* which is specified must be zero or positive, and strictly less than the number of segments returned by the `bf_getsegcount` slot function. On success, it returns the length of the segment, and sets `*ptrptr` to a pointer to that memory.

int (*getwritebufferproc) (PyObject *self, int segment, void **ptrptr)

Return a pointer to a writable memory buffer in `*ptrptr`, and the length of that segment as the function return value. The memory buffer must correspond to buffer segment *segment*. Must return `-1` and set an exception on error. `TypeError` should be raised if the object only supports read-

only buffers, and `SystemError` should be raised when *segment* specifies a segment that doesn't exist.

`int (*getsegcountproc) (PyObject *self, int *lenp)`

Return the number of memory segments which comprise the buffer. If *lenp* is not `NULL`, the implementation must report the sum of the sizes (in bytes) of all segments in **lenp*. The function cannot fail.

`int (*getcharbufferproc) (PyObject *self, int segment, const char **ptrptr)`

Return the size of the segment *segment* that *ptrptr* is set to. **ptrptr* is set to the memory buffer. Returns `-1` on error.

10.9 Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

An example showing the use of these interfaces can be found in ["Supporting the Cycle Collector"](#) in ["Extending and Embedding the Python Interpreter"](#).

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

Py_TPFLAGS_HAVE_GC

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New()` or `PyObject_GC_VarNew()`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

*TYPE** **PyObject_GC_New**(*TYPE*, *PyTypeObject *type*)

Analogous to `PyObject_New()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

*TYPE** **PyObject_GC_NewVar**(*TYPE*, *PyTypeObject *type*, *int size*)

Analogous to `PyObject_NewVar()` but for container objects with the

Py_TPFLAGS_HAVE_GC flag set.

PyObject * **PyObject_GC_Resize**(PyObject **op*, int)

Resize an object allocated by `PyObject_NewVar()`. Returns the resized object or NULL on failure.

void **PyObject_GC_Track**(PyObject **op*)

Adds the object *op* to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

void **_PyObject_GC_TRACK**(PyObject **op*)

A macro version of `PyObject_GC_Track()`. It should not be used for extension modules.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.
2. The object's memory must be deallocated using `PyObject_GC_Del()`.

void **PyObject_GC_Del**(PyObject **op*)

Releases memory allocated to an object using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

void **PyObject_GC_UnTrack**(PyObject **op*)

Remove the object *op* from the set of container objects tracked by the collector. Note that `PyObject_GC_Track()` can be called again on this object to add it back to the set of tracked objects. The deallocator (`tp_dealloc` handler) should call this for the object before any of the fields used by the `tp_traverse` handler become invalid.

void **_PyObject_GC_UNTRACK**(PyObject **op*)

A macro version of `PyObject_GC_UnTrack()`. It should not be used

for extension modules.

The `tp_traverse` handler accepts a function parameter of this type:

int (*visitproc)(PyObject *object, void *arg)

Type of the visitor function passed to the `tp_traverse` handler. The function should be called with an object to traverse as *object* and the third parameter to the `tp_traverse` handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it's not expected that users will need to write their own visitor functions.

The `tp_traverse` handler must have the following type:

int (*traverseproc)(PyObject *self, visitproc visit, void *arg)

Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a NULL object argument. If *visit* returns a non-zero value that value should be returned immediately.

To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly *visit* and *arg*:

void Py_VISIT(PyObject *o)

Call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

New in version 2.4.

The `tp_clear` handler must be of the `inquiry` type, or NULL if the object is immutable.

`int (*inquiry)(PyObject *self)`

Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don't just call `Py_DECREF()` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.

A. Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python or its documentation.

Before submitting a report, you will be required to log into SourceForge; this will make it possible for the developers to contact you for additional information if needed. It is not possible to submit a bug report anonymously.

All bug reports should be submitted via the Python Bug Tracker on SourceForge (http://sourceforge.net/bugs/?group_id=5470). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the left side of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker (http://sourceforge.net/bugs/?group_id=5470). Select the "Submit a Bug" link at the top of the page to open the bug reporting form.

The submission form has a number of fields. The only fields that are required are the "Summary" and "Details" fields. For the summary, enter a *very* short description of the problem; less than ten words is good. In the Details field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include the version of Python you used, whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

The only other field that you may want to set is the "Category" field, which allows you to place the bug report into a broad category (such as "Documentation" or "Library").

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

B.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <http://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <http://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <http://www.zope.com/>). In 2001, the Python Software Foundation (PSF, see <http://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <http://www.opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL compatible?
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes

2.4.4	2.4.3	2006	PSF	yes
2.5	2.4	2006	PSF	yes

Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

B.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.4.4

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.4.4 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.4.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.4.4 alone or in any derivative version prepared by Licensee.
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.4.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.4.4.
4. PSF is making Python 2.4.4 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.4.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS

OF PYTHON 2.4.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.4.4, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 2.4.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION

1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.
3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT

LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at <http://www.pythonlabs.com/logos.html> may be used according to the permissions granted on that web page.
7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to

reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: <http://hdl.handle.net/1895.22/1013>."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.
4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. This License Agreement shall be governed by the federal intellectual

property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

B.3.1 Mersenne Twister

The `_random` module includes code based on a download from <http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html>. The following are the verbatim comments from the original code:

```
A C-program for MT19937, with initialization improved 2002/1/26.  
Coded by Takuji Nishimura and Makoto Matsumoto.
```

```
Before using, initialize the state by using init_genrand(seed)  
or init_by_array(init_key, key_length).
```

```
Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura,  
All rights reserved.
```

```
Redistribution and use in source and binary forms, with or without  
modification, are permitted provided that the following conditions  
are met:
```

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in documentation and/or other materials provided with the distribut
3. The names of its contributors may not be used to endorse or prom products derived from this software without specific prior writt permission.

```
THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS  
"AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT  
LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FO  
A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT  
CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL  
EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO,  
PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR  
PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY

B.3.2 Sockets

The `socket` module uses the functions, `getaddrinfo`, and `getnameinfo`, which are coded in separate source files from the WIDE Project, <http://www.wide.ad.jp/about/index.html>.

Copyright (C) 1995, 1996, 1997, and 1998 WIDE Project.
All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
3. Neither the name of the project nor the names of its contributors may be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE PROJECT AND CONTRIBUTORS ``AS IS'' WITHOUT ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. IN NO EVENT SHALL THE PROJECT OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN CONNECTION WITH THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```

Modified by Jack Jansen, CWI, July 1995:

- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. The version is still 5 times faster, though.
- Arguments more compliant with python standard

Documenting Python

Fred L. Drake, Jr.

PythonLabs
Email: fdrake@acm.org

Release 2.4.4c1
11 October 2006

Abstract:

The Python language has a substantial body of documentation, much of it contributed by various authors. The markup used for the Python documentation is based on LaTeX and requires a significant set of macros written specifically for documenting Python. This document describes the macros introduced to support Python documentation and how they should be used to support a wide range of output formats.

This document describes the document classes and special markup used in the Python documentation. Authors may use this guide, in conjunction with the template files provided with the distribution, to create or maintain whole documents or sections.

If you're interested in contributing to Python's documentation, there's no need to learn LaTeX if you're not so inclined; plain text contributions are more than welcome as well.

1 Introduction

Python's documentation has long been considered to be good for a free programming language. There are a number of reasons for this, the most important being the early commitment of Python's creator, Guido van Rossum, to providing documentation on the language and its libraries, and the continuing involvement of the user community in providing assistance for creating and maintaining documentation.

The involvement of the community takes many forms, from authoring to bug reports to just plain complaining when the documentation could be more complete or easier to use. All of these forms of input from the community have proved useful during the time I've been involved in maintaining the documentation.

This document is aimed at authors and potential authors of documentation for Python. More specifically, it is for people contributing to the standard documentation and developing additional documents using the same tools as the standard documents. This guide will be less useful for authors using the Python documentation tools for topics other than Python, and less useful still for authors not using the tools at all.

The material in this guide is intended to assist authors using the Python documentation tools. It includes information on the source distribution of the standard documentation, a discussion of the document types, reference material on the markup defined in the document classes, a list of the external tools needed for processing documents, and reference material on the tools provided with the documentation resources. At the end, there is also a section discussing future directions for the Python documentation and where to turn for more information.

If your interest is in contributing to the Python documentation, but you don't have the time or inclination to learn LaTeX and the markup structures documented here, there's a welcoming place for you among the Python contributors as well. Any time you feel that you can clarify existing documentation or provide documentation that's missing, the existing documentation team will gladly work with you to integrate your text, dealing with the markup for you. Please don't let the material in this document stand

between the documentation and your desire to help out!

Documenting Python

2 Directory Structure

The source distribution for the standard Python documentation contains a large number of directories. While third-party documents do not need to be placed into this structure or need to be placed within a similar structure, it can be helpful to know where to look for examples and tools when developing new documents using the Python documentation tools. This section describes this directory structure.

The documentation sources are usually placed within the Python source distribution as the top-level directory `Doc/`, but are not dependent on the Python source distribution in any way.

The `Doc/` directory contains a few files and several subdirectories. The files are mostly self-explanatory, including a `README` and a `Makefile`. The directories fall into three categories:

Document Sources

The LaTeX sources for each document are placed in a separate directory. These directories are given short names which vaguely indicate the document in each:

Directory	Document Title
<code>api/</code>	<i>The Python/C API</i>
<code>dist/</code>	<i>Distributing Python Modules</i>
<code>doc/</code>	<i>Documenting Python</i>
<code>ext/</code>	<i>Extending and Embedding the Python Interpreter</i>
<code>inst/</code>	<i>Installing Python Modules</i>
<code>lib/</code>	<i>Python Library Reference</i>
<code>mac/</code>	<i>Macintosh Module Reference</i>
<code>ref/</code>	<i>Python Reference Manual</i>
<code>tut/</code>	<i>Python Tutorial</i>
<code>whatsnew/</code>	<i>What's New in Python 2.4</i>

Format-Specific Output

Most output formats have a directory which contains a `Makefile` which

controls the generation of that format and provides storage for the formatted documents. The only variations within this category are the Portable Document Format (PDF) and PostScript versions are placed in the directories `paper-a4/` and `paper-letter/` (this causes all the temporary files created by LaTeX to be kept in the same place for each paper size, where they can be more easily ignored).

Directory	Output Formats
<code>html/</code>	HTML output
<code>info/</code>	GNU info output
<code>isilo/</code>	iSilo documents (for Palm OS devices)
<code>paper-a4/</code>	PDF and PostScript, A4 paper
<code>paper-letter/</code>	PDF and PostScript, US-Letter paper

Supplemental Files

Some additional directories are used to store supplemental files used for the various processes. Directories are included for the shared LaTeX document classes, the LaTeX2HTML support, template files for various document components, and the scripts used to perform various steps in the formatting processes.

Directory	Contents
<code>commontex/</code>	Document content shared among documents
<code>perl/</code>	Support for LaTeX2HTML processing
<code>templates/</code>	Example files for source documents
<code>texinputs/</code>	Style implementation for LaTeX
<code>tools/</code>	Custom processing scripts

3 Style Guide

The Python documentation should follow the [Apple Publications Style Guide](#) wherever possible. This particular style guide was selected mostly because it seems reasonable and is easy to get online.

Topics which are not covered in the Apple's style guide will be discussed in this document if necessary.

Many special names are used in the Python documentation, including the names of operating systems, programming languages, standards bodies, and the like. Many of these were assigned LaTeX macros at some point in the distant past, and these macros lived on long past their usefulness. In the current markup, most of these entities are not assigned any special markup, but the preferred spellings are given here to aid authors in maintaining the consistency of presentation in the Python documentation.

Other terms and words deserve special mention as well; these conventions should be used to ensure consistency throughout the documentation:

CPU

For "central processing unit." Many style guides say this should be spelled out on the first use (and if you must use it, do so!). For the Python documentation, this abbreviation should be avoided since there's no reasonable way to predict which occurrence will be the first seen by the reader. It is better to use the word "processor" instead.

POSIX

The name assigned to a particular group of standards. This is always uppercase. Use the macro `\POSIX` to represent this name.

Python

The name of our favorite programming language is always capitalized.

Unicode

The name of a character set and matching encoding. This is always written capitalized.

UNIX

The name of the operating system developed at AT&T Bell Labs in the early 1970s. Use the macro `\UNIX` to use this name.

4 LaTeX Primer

This section is a brief introduction to LaTeX concepts and syntax, to provide authors enough information to author documents productively without having to become ``TeXnicians." This does not teach everything needed to know about writing LaTeX for Python documentation; many of the standard ``environments" are not described here (though you will learn how to mark something as an environment).

Perhaps the most important concept to keep in mind while marking up Python documentation is that while TeX is unstructured, LaTeX was designed as a layer on top of TeX which specifically supports structured markup. The Python-specific markup is intended to extend the structure provided by standard LaTeX document classes to support additional information specific to Python.

LaTeX documents contain two parts: the preamble and the body. The preamble is used to specify certain metadata about the document itself, such as the title, the list of authors, the date, and the *class* the document belongs to. Additional information used to control index generation and the use of bibliographic databases can also be placed in the preamble. For most authors, the preamble can be most easily created by copying it from an existing document and modifying a few key pieces of information.

The *class* of a document is used to place a document within a broad category of documents and set some fundamental formatting properties. For Python documentation, two classes are used: the `manual` class and the `howto` class. These classes also define the additional markup used to document Python concepts and structures. Specific information about these classes is provided in [section 5](#), ``Document Classes," below. The first thing in the preamble is the declaration of the document's class.

After the class declaration, a number of *macros* are used to provide further information about the document and setup any additional markup that is needed. No output is generated from the preamble; it is an error to include free text in the preamble because it would cause output.

The document body follows the preamble. This contains all the printed

components of the document marked up structurally. Generic LaTeX structures include hierarchical sections, numbered and bulleted lists, and special structures for the document abstract and indexes.

Subsections

- [4.1 Syntax](#)
- [4.2 Hierarchical Structure](#)
- [4.3 Common Environments](#)

Previous: [3 Style Guide](#) Up: [Documenting Python](#) Next: [4.1 Syntax](#)

See [About this document...](#) for information on suggesting changes.*

Previous: [4 LaTeX Primer](#) Up: [4 LaTeX Primer](#) Next: [4.2 Hierarchical Structure](#)

4.1 Syntax

There are some things that an author of Python documentation needs to know about LaTeX syntax.

A *comment* is started by the ``percent" character ("%") and continues through the end of the line and all leading whitespace on the following line. This is a little different from any programming language I know of, so an example is in order:

```
This is text.% comment
  This is more text. % another comment
Still more text.
```

The first non-comment character following the first comment is the letter "T" on the second line; the leading whitespace on that line is consumed as part of the first comment. This means that there is no space between the first and second sentences, so the period and letter "T" will be directly adjacent in the typeset document.

Note also that though the first non-comment character after the second comment is the letter "S", there is whitespace preceding the comment, so the two sentences are separated as expected.

A *group* is an enclosure for a collection of text and commands which encloses the formatting context and constrains the scope of any changes to that context made by commands within the group. Groups can be nested hierarchically. The formatting context includes the font and the definition of additional macros (or overrides of macros defined in outer groups). Syntactically, groups are enclosed in braces:

```
{text in a group}
```

An alternate syntax for a group using brackets, [. . .], is used by macros and environment constructors which take optional parameters; brackets do not normally hold syntactic significance. A degenerate group, containing only one atomic bit of content, does not need to have an explicit group, unless it is required to avoid ambiguity. Since Python tends toward the explicit, groups are also made explicit in the documentation markup.

Groups are used only sparingly in the Python documentation, except for their use in marking parameters to macros and environments.

A *macro* is usually a simple construct which is identified by name and can take some number of parameters. In normal LaTeX usage, one of these can be optional. The markup is introduced using the backslash character ("`\`"), and the name is given by alphabetic characters (no digits, hyphens, or underscores). Required parameters should be marked as a group, and optional parameters should be marked using the alternate syntax for a group.

For example, a macro which takes a single parameter would appear like this:

```
\name{parameter}
```

A macro which takes an optional parameter would be typed like this when the optional parameter is given:

```
\name[optional]
```

If both optional and required parameters are to be required, it looks like this:

```
\name[optional]{required}
```

A macro name may be followed by a space or newline; a space between the macro name and any parameters will be consumed, but this usage is not practiced in the Python documentation. Such a space is still consumed if there are no parameters to the macro, in which case inserting an empty group (`{}`) or explicit word space ("`\` ") immediately after the macro name helps to avoid running the expansion of the macro into the following text. Macros which take no parameters but which should not be followed by a word space do not need special treatment if the following character in the document source is not a name character (such as punctuation).

Each line of this example shows an appropriate way to write text which includes a macro which takes no parameters:

```
This \UNIX{} is followed by a space.  
This \UNIX\ is also followed by a space.  
\UNIX, followed by a comma, needs no additional markup.
```

An *environment* is a larger construct than a macro, and can be used for things with more content than would conveniently fit in a macro parameter. They are

primarily used when formatting parameters need to be changed before and after a large chunk of content, but the content itself needs to be highly flexible. Code samples are presented using an environment, and descriptions of functions, methods, and classes are also marked using environments.

Since the content of an environment is free-form and can consist of several paragraphs, they are actually marked using a pair of macros: `\begin` and `\end`. These macros both take the name of the environment as a parameter. An example is the environment used to mark the abstract of a document:

```
\begin{abstract}
  This is the text of the abstract. It concisely explains what
  information is found in the document.

  It can consist of multiple paragraphs.
\end{abstract}
```

An environment can also have required and optional parameters of its own. These follow the parameter of the `\begin` macro. This example shows an environment which takes a single required parameter:

```
\begin{datadesc}{controlnames}
  A 33-element string array that contains the \ASCII{} mnemonics for
  the thirty-two \ASCII{} control characters from 0 (NUL) to 0x1f
  (US), in order, plus the mnemonic \samp{SP} for the space character.
\end{datadesc}
```

There are a number of less-used marks in LaTeX which are used to enter characters which are not found in ASCII or which are considered special, or *active* in TeX or LaTeX. Given that these are often used adjacent to other characters, the markup required to produce the proper character may need to be followed by a space or an empty group, or the markup can be enclosed in a group. Some which are found in Python documentation are:

Character	Markup
^	<code>\textasciicircum</code>
~	<code>\textasciitilde</code>
>	<code>\textgreater</code>
<	<code>\textless</code>
ç	<code>\c c</code>
ö	<code>\"o</code>

Previous: [4.1 Syntax](#) Up: [4 LaTeX Primer](#) Next: [4.3 Common Environments](#)

4.2 Hierarchical Structure

LaTeX expects documents to be arranged in a conventional, hierarchical way, with chapters, sections, sub-sections, appendixes, and the like. These are marked using macros rather than environments, probably because the end of a section can be safely inferred when a section of equal or higher level starts.

There are six "levels" of sectioning in the document classes used for Python documentation, and the deepest two levels¹ are not used. The levels are:

Level	Macro Name	Notes
1	<code>\chapter</code>	(1)
2	<code>\section</code>	
3	<code>\subsection</code>	
4	<code>\subsubsection</code>	
5	<code>\paragraph</code>	(2)
6	<code>\subparagraph</code>	

Notes:

- (1)
Only used for the `manual` documents, as described in section [5](#), "Document Classes."
- (2)
Not the same as a paragraph of text; nobody seems to use this.

Footnotes

... levels¹

The deepest levels have the highest numbers in the table.

4.3 Common Environments

LaTeX provides a variety of environments even without the additional markup provided by the Python-specific document classes introduced in the next section. The following environments are provided as part of standard LaTeX and are being used in the standard Python documentation; descriptions will be added here as time allows.

```
abstract
alltt
description
displaymath
document
enumerate
figure
flushleft
itemize
list
math
quotation
quote
sloppypar
verbatim
```

Previous: [4.3 Common Environments](#) **Up:** [Documenting Python](#) **Next:** [6 Special Markup Constructs](#)

5 Document Classes

Two LaTeX document classes are defined specifically for use with the Python documentation. The `manual` class is for large documents which are sectioned into chapters, and the `howto` class is for smaller documents.

The `manual` documents are larger and are used for most of the standard documents. This document class is based on the standard LaTeX `report` class and is formatted very much like a long technical report. The [Python Reference Manual](#) is a good example of a `manual` document, and the [Python Library Reference](#) is a large example.

The `howto` documents are shorter, and don't have the large structure of the `manual` documents. This class is based on the standard LaTeX `article` class and is formatted somewhat like the Linux Documentation Project's ``HOWTO'' series as done originally using the LinuxDoc software. The original intent for the document class was that it serve a similar role as the LDP's HOWTO series, but the applicability of the class turns out to be somewhat broader. This class is used for ``how-to'' documents (this document is an example) and for shorter reference manuals for small, fairly cohesive module libraries. Examples of the later use include [Using Kerberos from Python](#), which contains reference material for an extension package. These documents are roughly equivalent to a single chapter from a larger work.

6 Special Markup Constructs

The Python document classes define a lot of new environments and macros. This section contains the reference material for these facilities. Documentation for ``standard" LaTeX constructs is not included here, though they are used in the Python documentation.

Subsections

- [6.1 Markup for the Preamble](#)
- [6.2 Meta-information Markup](#)
- [6.3 Information Units](#)
- [6.4 Showing Code Examples](#)
- [6.5 Inline Markup](#)
- [6.6 Miscellaneous Text Markup](#)
- [6.7 Module-specific Markup](#)
- [6.8 Library-level Markup](#)
- [6.9 Table Markup](#)
- [6.10 Reference List Markup](#)
- [6.11 Index-generating Markup](#)
- [6.12 Grammar Production Displays](#)
- [6.13 Graphical Interface Components](#)

Previous: [6 Special Markup Constructs](#) **Up:** [6 Special Markup Constructs](#)
Next: [6.2 Meta-information Markup](#)

6.1 Markup for the Preamble

`\release {ver}`

Set the version number for the software described in the document.

`\setshortversion {sver}`

Specify the ``short" version number of the documented software to be *sver*.

Previous: [6 Special Markup Constructs](#) Up: [6 Special Markup Constructs](#)

Next: [6.2 Meta-information Markup](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

Previous: [6.1 Markup for the Information Units](#) Up: [6 Special Markup Constructs](#) Next: [6.3](#)

6.2 Meta-information Markup

`\sectionauthor {author}{email}`

Identifies the author of the current section. *author* should be the author's name such that it can be used for presentation (though it isn't), and *email* should be the author's email address. The domain name portion of the address should be lower case.

No presentation is generated from this markup, but it is used to help keep track of contributions.

Next: [6.4 Showing Code Examples](#)

6.3 Information Units

XXX Explain terminology, or come up with something more ``lay."

There are a number of environments used to describe specific features provided by modules. Each environment requires parameters needed to provide basic information about what is being described, and the environment content should be the description. Most of these environments make entries in the general index (if one is being produced for the document); if no index entry is desired, non-indexing variants are available for many of these environments. The environments have names of the form *featuredesc*, and the non-indexing variants are named *featuredescni*. The available variants are explicitly included in the list below.

For each of these environments, the first parameter, *name*, provides the name by which the feature is accessed.

Environments which describe features of objects within a module, such as object methods or data attributes, allow an optional *type name* parameter. When the feature is an attribute of class instances, *type name* only needs to be given if the class was not the most recently described class in the module; the *name* value from the most recent `\classdesc` is implied. For features of built-in or extension types, the *type name* value should always be provided. Another special case includes methods and members of general ``protocols," such as the formatter and writer protocols described for the `formatter` module: these may be documented without any specific implementation classes, and will always require the *type name* parameter to be provided.

```
\begin{cfuncdesc} {type}{name}{args}  
\end{cfuncdesc}
```

Environment used to described a C function. The *type* should be specified as a `typedef` name, `struct tag`, or the name of a primitive type. If it is a pointer type, the trailing asterisk should not be preceded by a space. *name* should be the name of the function (or function-like pre-processor macro), and *args* should give the types and names of the parameters. The names need to be given so they may be used in the description.

```
\begin{cmemberdesc} {container}{type}{name}
\end{cmemberdesc}
```

Description for a structure member. *container* should be the `typedef` name, if there is one, otherwise it should be "`struct tag`". The type of the member should be given as *type*, and the name should be given as *name*. The text of the description should include the range of values allowed, how the value should be interpreted, and whether the value can be changed. References to structure members in text should use the `\member` macro.

```
\begin{csimplemacrodesc} {name}
\end{csimplemacrodesc}
```

Documentation for a "simple" macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include `PyObject_HEAD` and `Py_BEGIN_ALLOW_THREADS`.

```
\begin{ctypedesc} [tag]{name}
\end{ctypedesc}
```

Environment used to describe a C type. The *name* parameter should be the `typedef` name. If the type is defined as a `struct` without a `typedef`, *name* should have the form `struct tag`. *name* will be added to the index unless *tag* is provided, in which case *tag* will be used instead. *tag* should not be used for a `typedef` name.

```
\begin{cvardesc} {type}{name}
\end{cvardesc}
```

Description of a global C variable. *type* should be the `typedef` name, `struct tag`, or the name of a primitive type. If variable has a pointer type, the trailing asterisk should *not* be preceded by a space.

```
\begin{datadesc} {name}
\end{datadesc}
```

This environment is used to document global data in a module, including both variables and values used as "defined constants." Class and object attributes are not documented using this environment.

```
\begin{datadescni} {name}
\end{datadescni}
```

Like `\datadesc`, but without creating any index entries.

```
\begin{excclassdesc} {name}{constructor parameters}  
\end{excclassdesc}
```

Describe an exception defined by a class. *constructor parameters* should not include the *self* parameter or the parentheses used in the call syntax. To describe an exception class without describing the parameters to its constructor, use the `\excdesc` environment.

```
\begin{excdesc} {name}  
\end{excdesc}
```

Describe an exception. In the case of class exceptions, the constructor parameters are not described; use `\excclassdesc` to describe an exception class and its constructor.

```
\begin{funcdesc} {name}{parameters}  
\end{funcdesc}
```

Describe a module-level function. *parameters* should not include the parentheses used in the call syntax. Object methods are not documented using this environment. Bound object methods placed in the module namespace as part of the public interface of the module are documented using this, as they are equivalent to normal functions for most purposes.

The description should include information about the parameters required and how they are used (especially whether mutable objects passed as parameters are modified), side effects, and possible exceptions. A small example may be provided.

```
\begin{funcdescni} {name}{parameters}  
\end{funcdescni}
```

Like `\funcdesc`, but without creating any index entries.

```
\begin{classdesc} {name}{constructor parameters}  
\end{classdesc}
```

Describe a class and its constructor. *constructor parameters* should not include the *self* parameter or the parentheses used in the call syntax.

```
\begin{classdesc*} {name}  
\end{classdesc*}
```

Describe a class without describing the constructor. This can be used to describe classes that are merely containers for attributes or which should never be instantiated or subclassed by user code.

```
\begin{memberdesc} [type name] {name}  
\end{memberdesc}
```

Describe an object data attribute. The description should include information about the type of the data to be expected and whether it may be changed directly.

```
\begin{memberdescni} [type name] {name}  
\end{memberdescni}
```

Like `\memberdesc`, but without creating any index entries.

```
\begin{methoddesc} [type name] {name} {parameters}  
\end{methoddesc}
```

Describe an object method. *parameters* should not include the *self* parameter or the parentheses used in the call syntax. The description should include similar information to that described for `\funcdesc`.

```
\begin{methoddescni} [type name] {name} {parameters}  
\end{methoddescni}
```

Like `\methoddesc`, but without creating any index entries.

Previous: [6.3 Information Units](#) **Up:** [6 Special Markup Constructs](#) **Next:** [6.5
Inline Markup](#)

6.4 Showing Code Examples

Examples of Python source code or interactive sessions are represented as `\verbatim` environments. This environment is a standard part of LaTeX. It is important to only use spaces for indentation in code examples since TeX drops tabs instead of converting them to spaces.

Representing an interactive session requires including the prompts and output along with the Python code. No special markup is required for interactive sessions. After the last line of input or output presented, there should not be an ```unused"` primary prompt; this is an example of what *not* to do:

```
>>> 1 + 1
2
>>>
```

Within the `\verbatim` environment, characters special to LaTeX do not need to be specially marked in any way. The entire example will be presented in a monospaced font; no attempt at ```pretty-printing"` is made, as the environment must work for non-Python code and non-code displays. There should be no blank lines at the top or bottom of any `\verbatim` display.

Longer displays of verbatim text may be included by storing the example text in an external file containing only plain text. The file may be included using the standard `\verbatiminput` macro; this macro takes a single argument naming the file containing the text. For example, to include the Python source file `example.py`, use:

```
\verbatiminput{example.py}
```

Use of `\verbatiminput` allows easier use of special editing modes for the included file. The file should be placed in the same directory as the LaTeX files for the document.

The Python Documentation Special Interest Group has discussed a number of approaches to creating pretty-printed code displays and interactive sessions; see the Doc-SIG area on the Python Web site for more information on this topic.

See [About this document...](#) for information on suggesting changes.*

Previous: [6.4 Showing Code Examples](#) **Up:** [6 Special Markup Constructs](#)
Next: [6.6 Miscellaneous Text Markup](#)

6.5 Inline Markup

The macros described in this section are used to mark just about anything interesting in the document text. They may be used in headings (though anything involving hyperlinks should be avoided there) as well as in the body text.

\bfcode *{text}*

Like `\code`, but also makes the font bold-face.

\cdata *{name}*

The name of a C-language variable.

\cfunction *{name}*

The name of a C-language function. *name* should include the function name and the trailing parentheses.

\character *{char}*

A character when discussing the character rather than a one-byte string value. The character will be typeset as with `\samp`.

\citetitle [*url*] *{title}*

A title for a referenced publication. If *url* is specified, the title will be made into a hyperlink when formatted as HTML.

\class *{name}*

A class name; a dotted name may be used.

\code *{text}*

A short code fragment or literal constant value. Typically, it should not include any spaces since no quotation marks are added.

\constant *{name}*

The name of a "defined" constant. This may be a C-language `#define` or a Python variable that is not intended to be changed.

\csimplemacro *{name}*

The name of a "simple" macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described

as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include `PyObject_HEAD` and `Py_BEGIN_ALLOW_THREADS`.

\ctype {*name*}

The name of a C `typedef` or structure. For structures defined without a `typedef`, use `\ctype{struct struct_tag}` to make it clear that the `struct` is required.

\deprecated {*version*} {*what to do*}

Declare whatever is being described as being deprecated starting with release *version*. The text given as *what to do* should recommend something to use instead. It should be complete sentences. The entire deprecation notice will be presented as a separate paragraph; it should either precede or succeed the description of the deprecated feature.

\dfn {*term*}

Mark the defining instance of *term* in the text. (No index entries are generated.)

\e

Produces a backslash. This is convenient in `\code`, `\file`, and similar macros, and the `\alltt` environment, and is only defined there. To create a backslash in ordinary text (such as the contents of the `\citetitle` macro), use the standard `\textbackslash` macro.

\email {*address*}

An email address. Note that this is *not* hyperlinked in any of the possible output formats. The domain name portion of the address should be lower case.

\emph {*text*}

Emphasized text; this will be presented in an italic font.

\envvar {*name*}

An environment variable. Index entries are generated.

\exception {*name*}

The name of an exception. A dotted name may be used.

\file *{file or dir}*

The name of a file or directory. In the PDF and PostScript outputs, single quotes and a font change are used to indicate the file name, but no quotes are used in the HTML output. **Warning:** The `\file` macro cannot be used in the content of a section title due to processing limitations.

\filenq *{file or dir}*

Like `\file`, but single quotes are never used. This can be used in conjunction with tables if a column will only contain file or directory names. **Warning:** The `\filenq` macro cannot be used in the content of a section title due to processing limitations.

\function *{name}*

The name of a Python function; dotted names may be used.

\infinity

The symbol for mathematical infinity: ∞ . Some Web browsers are not able to render the HTML representation of this symbol properly, but support is growing.

\kbd *{key sequence}*

Mark a sequence of keystrokes. What form *key sequence* takes may depend on platform- or application-specific conventions. When there are no relevant conventions, the names of modifier keys should be spelled out, to improve accessibility for new users and non-native speakers. For example, an **xemacs** key sequence may be marked like `\kbd{C-x C-f}`, but without reference to a specific application or platform, the same sequence should be marked as `\kbd{Control-x Control-f}`.

\keyword *{name}*

The name of a keyword in a programming language.

\mailheader *{name}*

The name of an [RFC 822](#)-style mail header. This markup does not imply that the header is being used in an email message, but can be used to refer to any header of the same ``style." This is also used for headers defined by the various MIME specifications. The header name should be entered in the same way it would normally be found in practice, with the camel-casing conventions being preferred where there is more than one common usage.

The colon which follows the name of the header should not be included. For example: `\mailheader{Content-Type}`.

\makevar *{name}*

The name of a **make** variable.

\manpage *{name}* *{section}*

A reference to a UNIX manual page.

\member *{name}*

The name of a data attribute of an object.

\method *{name}*

The name of a method of an object. *name* should include the method name and the trailing parentheses. A dotted name may be used.

\mimetype *{name}*

The name of a MIME type, or a component of a MIME type (the major or minor portion, taken alone).

\module *{name}*

The name of a module; a dotted name may be used. This should also be used for package names.

\newsgroup *{name}*

The name of a Usenet newsgroup.

\note *{text}*

An especially important bit of information about an API that a user should be aware of when using whatever bit of API the note pertains to. This should be the last thing in the paragraph as the end of the note is not visually marked in any way. The content of *text* should be written in complete sentences and include all appropriate punctuation.

\pep *{number}*

A reference to a Python Enhancement Proposal. This generates appropriate index entries. The text "PEP *number*" is generated; in the HTML output, this text is a hyperlink to an online copy of the specified PEP.

\plusminus

The symbol for indicating a value that may take a positive or negative value of a specified magnitude, typically represented by a plus sign placed over a minus sign. For example: `\plusminus 3%`.

\program {*name*}

The name of an executable program. This may differ from the file name for the executable for some platforms. In particular, the `.exe` (or other) extension should be omitted for Windows programs.

\programopt {*option*}

A command-line option to an executable program. Use this only for "short" options, and include the leading hyphen.

\longprogramopt {*option*}

A long command-line option to an executable program. This should only be used for long option names which will be prefixed by two hyphens; the hyphens should not be provided as part of *option*.

\refmodule [*key*] {*name*}

Like `\module`, but create a hyperlink to the documentation for the named module. Note that the corresponding `\declaremodule` must be in the same document. If the `\declaremodule` defines a module key different from the module name, it must also be provided as *key* to the `\refmodule` macro.

\regexp {*string*}

Mark a regular expression.

\rfc {*number*}

A reference to an Internet Request for Comments. This generates appropriate index entries. The text "RFC *number*" is generated; in the HTML output, this text is a hyperlink to an online copy of the specified RFC.

\samp {*text*}

A short code sample, but possibly longer than would be given using `\code`. Since quotation marks are added, spaces are acceptable.

\shortversion

The `\short` version number of the documented software, as specified using the `\setshortversion` macro in the preamble. For Python, the short version number for a release is the first three characters of the `sys.version` value. For example, versions 2.0b1 and 2.0.1 both have a short version of 2.0. This may not apply for all packages; if `\setshortversion` is not used, this produces an empty expansion. See also the `\version` macro.

\strong {text}

Strongly emphasized text; this will be presented using a bold font.

\uink {text}{url}

A hypertext link with a target specified by a URL, but for which the link text should not be the title of the resource. For resources being referenced by name, use the `\citetitle` macro. Not all formatted versions support arbitrary hypertext links. Note that many characters are special to LaTeX and this macro does not always do the right thing. In particular, the tilde character ("`~`") is mis-handled; encoding it as a hex-sequence does work, use `"%7e"` in place of the tilde character.

\url {url}

A URL (or URN). The URL will be presented as text. In the HTML and PDF formatted versions, the URL will also be a hyperlink. This can be used when referring to external resources without specific titles; references to resources which have titles should be marked using the `\citetitle` macro. See the comments about special characters in the description of the `\uink` macro for special considerations.

\var {name}

The name of a variable or formal parameter in running text.

\version

The version number of the described software, as specified using `\release` in the preamble. See also the `\shortversion` macro.

\warning {text}

An important bit of information about an API that a user should be very aware of when using whatever bit of API the warning pertains to. This

should be the last thing in the paragraph as the end of the warning is not visually marked in any way. The content of *text* should be written in complete sentences and include all appropriate punctuation. This differs from `\note` in that it is recommended over `\note` for information regarding security.

The following two macros are used to describe information that's associated with changes from one release to another. For features which are described by a single paragraph, these are typically added as separate source lines at the end of the paragraph. When adding these to features described by multiple paragraphs, they are usually collected in a single separate paragraph after the description. When both `\versionadded` and `\versionchanged` are used, `\versionadded` should come first; the versions should be listed in chronological order. Both of these should come before availability statements. The location should be selected so the explanation makes sense and may vary as needed.

`\versionadded` [*explanation*] {*version*}

The version of Python which added the described feature to the library or C API. *explanation* should be a *brief* explanation of the change consisting of a capitalized sentence fragment; a period will be appended by the formatting process. When this applies to an entire module, it should be placed at the top of the module section before any prose.

`\versionchanged` [*explanation*] {*version*}

The version of Python in which the named feature was changed in some way (new parameters, changed side effects, etc.). *explanation* should be a *brief* explanation of the change consisting of a capitalized sentence fragment; a period will be appended by the formatting process. This should not generally be applied to modules.

Previous: [6.4 Showing Code Examples](#) Up: [6 Special Markup Constructs](#)

Next: [6.6 Miscellaneous Text Markup](#)

Previous: [6.5 Inline Markup](#) **Up:** [6 Special Markup Constructs](#) **Next:** [6.7 Module-specific Markup](#)

6.6 Miscellaneous Text Markup

In addition to the inline markup, some additional ``block" markup is defined to make it easier to bring attention to various bits of text. The markup described here serves this purpose, and is intended to be used when marking one or more paragraphs or other block constructs (such as `\verbatim` environments).

```
\begin{notice} [type]  
\end{notice}
```

Label some paragraphs as being worthy of additional attention from the reader. What sort of attention is warranted can be indicated by specifying the *type* of the notice. The only values defined for *type* are `note` and `warning`; these are equivalent in intent to the inline markup of the same name. If *type* is omitted, `note` is used. Additional values may be defined in the future.

Previous: [6.5 Inline Markup](#) Up: [6 Special Markup Constructs](#) Next: [6.7 Module-specific Markup](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [6.6 Miscellaneous Text Markup](#) **Up:** [6 Special Markup Constructs](#)
Next: [6.8 Library-level Markup](#)

6.7 Module-specific Markup

The markup described in this section is used to provide information about a module being documented. Each module should be documented in its own `\section`. A typical use of this markup appears at the top of that section and might look like this:

```
\section{\module{spam} ---
        Access to the SPAM facility}

\declaremodule{extension}{spam}
  \platform{Unix}
\modulesynopsis{Access to the SPAM facility of \UNIX.}
\moduleauthor{Jane Doe}{jane.doe@frobnitz.org}
```

Python packages -- collections of modules that can be described as a unit -- are documented using the same markup as modules. The name for a module in a package should be typed in "fully qualified" form (it should include the package name). For example, a module "foo" in package "bar" should be marked as `\module{bar . foo}`, and the beginning of the reference section would appear as:

```
\section{\module{bar.foo} ---
        Module from the \module{bar} package}

\declaremodule{extension}{bar.foo}
\modulesynopsis{Nifty module from the \module{bar} package.}
\moduleauthor{Jane Doe}{jane.doe@frobnitz.org}
```

Note that the name of a package is also marked using `\module`.

\declaremodule [*key*] {*type*} {*name*}

Requires two parameters: module type ("standard", "builtin", "extension", or ""), and the module name. An optional parameter should be given as the basis for the module's "key" used for linking to or referencing the section. The "key" should only be given if the module's name contains any underscores, and should be the name with the underscores stripped. Note that the *type* parameter must be one of the values listed above or an error will be printed. For modules which are contained in packages, the fully-qualified name should be given as *name* parameter. This should be the first thing after the `\section` used to

introduce the module.

\platform {*specifier*}

Specifies the portability of the module. *specifier* is a comma-separated list of keys that specify what platforms the module is available on. The keys are short identifiers; examples that are in use include "IRIX", "Mac", "Windows", and "Unix". It is important to use a key which has already been used when applicable. This is used to provide annotations in the Module Index and the HTML and GNU info output.

\modulesynopsis {*text*}

The *text* is a short, "one line" description of the module that can be used as part of the chapter introduction. This must be placed after `\declaremodule`. The synopsis is used in building the contents of the table inserted as the `\localmodule` table. No text is produced at the point of the markup.

\moduleauthor {*name*} {*email*}

This macro is used to encode information about who authored a module. This is currently not used to generate output, but can be used to help determine the origin of the module.

Previous: [6.7 Module-specific Markup](#) **Up:** [6 Special Markup Constructs](#) **Next:** [6.9 Table Markup](#)

6.8 Library-level Markup

This markup is used when describing a selection of modules. For example, the [Macintosh Library Modules](#) document uses this to help provide an overview of the modules in the collection, and many chapters in the [Python Library Reference](#) use it for the same purpose.

`\localmoduleable`

If a `.syn` file exists for the current chapter (or for the entire document in `howto` documents), a `\synopsistable` is created with the contents loaded from the `.syn` file.

Previous: [6.7 Module-specific Markup](#) Up: [6 Special Markup Constructs](#) Next:
[6.9 Table Markup](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [6.8 Library-level Markup](#) **Up:** [6 Special Markup Constructs](#) **Next:**
[6.10 Reference List Markup](#)

6.9 Table Markup

There are three general-purpose table environments defined which should be used whenever possible. These environments are defined to provide tables of specific widths and some convenience for formatting. These environments are not meant to be general replacements for the standard LaTeX table environments, but can be used for an advantage when the documents are processed using the tools for Python documentation processing. In particular, the generated HTML looks good! There is also an advantage for the eventual conversion of the documentation to XML (see section [9](#), "Future Directions").

Each environment is named `\tablecols`, where *cols* is the number of columns in the table specified in lower-case Roman numerals. Within each of these environments, an additional macro, `\linecols`, is defined, where *cols* matches the *cols* value of the corresponding table environment. These are supported for *cols* values of `ii`, `iii`, and `iv`. These environments are all built on top of the `\tabular` environment. Variants based on the `\longtable` environment are also provided.

Note that all tables in the standard Python documentation use vertical lines between columns, and this must be specified in the markup for each table. A general border around the outside of the table is not used, but would be the responsibility of the processor; the document markup should not include an exterior border.

The `\longtable`-based variants of the table environments are formatted with extra space before and after, so should only be used on tables which are long enough that splitting over multiple pages is reasonable; tables with fewer than twenty rows should never be marked using the long flavors of the table environments. The header row is repeated across the top of each part of the table.

```
\begin{tableii} {colspec} {col1font} {heading1} {heading2}  
\end{tableii}
```

Create a two-column table using the LaTeX column specifier *colspec*. The column specifier should indicate vertical bars between columns as appropriate for the specific table, but should not specify vertical bars on the outside of the table (that is considered a stylesheet issue). The *col1font*

parameter is used as a stylistic treatment of the first column of the table: the first column is presented as `\col1font{column1}`. To avoid treating the first column specially, `col1font` may be "texttrm". The column headings are taken from the values `heading1` and `heading2`.

```
\begin{longtableii} ...  
\end{longtableii}
```

Like `\tableii`, but produces a table which may be broken across page boundaries. The parameters are the same as for `\tableii`.

```
\lineii {column1}{column2}
```

Create a single table row within a `\tableii` or `\longtableii` environment. The text for the first column will be generated by applying the macro named by the `col1font` value when the `\tableii` was opened.

```
\begin{tableiii} {colspec}{col1font}{heading1}{heading2}  
{heading3}  
\end{tableiii}
```

Like the `\tableii` environment, but with a third column. The heading for the third column is given by `heading3`.

```
\begin{longtableiii} ...  
\end{longtableiii}
```

Like `\tableiii`, but produces a table which may be broken across page boundaries. The parameters are the same as for `\tableiii`.

```
\lineiii {column1}{column2}{column3}
```

Like the `\lineii` macro, but with a third column. The text for the third column is given by `column3`.

```
\begin{tableiv} {colspec}{col1font}{heading1}{heading2}  
{heading3}{heading4}  
\end{tableiv}
```

Like the `\tableiii` environment, but with a fourth column. The heading for the fourth column is given by `heading4`.

```
\begin{longtableiv} ...  
\end{longtableiv}
```

Like `\tableiv`, but produces a table which may be broken across page

boundaries. The parameters are the same as for `\tableiv`.

`\lineiv` *{column1}{column2}{column3}{column4}*

Like the `\lineiii` macro, but with a fourth column. The text for the fourth column is given by *column4*.

`\begin{tablev}` *{colspec}{col1font}{heading1}{heading2}{heading3}{heading4}{heading5}*

`\end{tablev}`

Like the `\tableiv` environment, but with a fifth column. The heading for the fifth column is given by *heading5*.

`\begin{longtablev}` ...

`\end{longtablev}`

Like `\tablev`, but produces a table which may be broken across page boundaries. The parameters are the same as for `\tablev`.

`\linev` *{column1}{column2}{column3}{column4}{column5}*

Like the `\lineiv` macro, but with a fifth column. The text for the fifth column is given by *column5*.

An additional table-like environment is `\synopsistable`. The table generated by this environment contains two columns, and each row is defined by an alternate definition of `\modulesynopsis`. This environment is not normally used by authors, but is created by the `\localmoduletable` macro.

Here is a small example of a table given in the documentation for the `warnings` module; markup inside the table cells is minimal so the markup for the table itself is readily discernable. Here is the markup for the table:

```
\begin{tableii}{l|l}{exception}{Class}{Description}
  \lineii{Warning}
    {This is the base class of all warning category classes. I
     is a subclass of \exception{Exception}.}
  \lineii{UserWarning}
    {The default category for \function{warn()}.}
  \lineii{DeprecationWarning}
    {Base category for warnings about deprecated features.}
  \lineii{SyntaxWarning}
    {Base category for warnings about dubious syntactic
     features.}
  \lineii{RuntimeWarning}
```

```

        {Base category for warnings about dubious runtime features.
\lineii{FutureWarning}
        {Base category for warnings about constructs that will chan
        semantically in the future.}
\end{tableii}

```

Here is the resulting table:

Class	Description
Warning	This is the base class of all warning category classes. It is a subclass of <code>Exception</code> .
UserWarning	The default category for <code>warn()</code> .
DeprecationWarning	Base category for warnings about deprecated features.
SyntaxWarning	Base category for warnings about dubious syntactic features.
RuntimeWarning	Base category for warnings about dubious runtime features.

Note that the class names are implicitly marked using the `\exception` macro, since that is given as the `col1font` value for the `\tableii` environment. To create a table using different markup for the first column, use `texttrm` for the `col1font` value and mark each entry individually.

To add a horizontal line between vertical sections of a table, use the standard `\hline` macro between the rows which should be separated:

```

\begin{tableii}{1|1}{constant}{Language}{Audience}
\lineii{APL}{Masochists.}
\lineii{BASIC}{First-time programmers on PC hardware.}
\lineii{C}{\UNIX{}} \&\ Linux kernel developers.}
\hline
\lineii{Python}{Everyone!}
\end{tableii}

```

Note that not all presentation formats are capable of displaying a horizontal rule in this position. This is how the table looks in the format you're reading now:

Language	Audience
APL	Masochists.
C	UNIX & Linux kernel developers.

JavaScript	Web developers.
Python	Everyone!

6.10 Reference List Markup

Many sections include a list of references to module documentation or external documents. These lists are created using the `\seealso` or `\seealso*` environments. These environments define some additional macros to support creating reference entries in a reasonable manner.

The `\seealso` environment is typically placed in a section just before any subsections. This is done to ensure that reference links related to the section are not hidden in a subsection in the hypertext renditions of the documentation. For the HTML output, it is shown as a "side bar," boxed off from the main flow of the text. The `\seealso*` environment is different in that it should be used when a list of references is being presented as part of the primary content; it is not specially set off from the text.

```
\begin{seealso}  
\end{seealso}
```

This environment creates a "See also:" heading and defines the markup used to describe individual references.

```
\begin{seealso*}  
\end{seealso*}
```

This environment is used to create a list of references which form part of the main content. It is not given a special header and is not set off from the main flow of the text. It provides the same additional markup used to describe individual references.

For each of the following macros, *why* should be one or more complete sentences, starting with a capital letter (unless it starts with an identifier, which should not be modified), and ending with the appropriate punctuation.

These macros are only defined within the content of the `\seealso` and `\seealso*` environments.

```
\seelink {url} {linktext} {why}
```

References to specific on-line resources should be given using the `\seelink` macro if they don't have a meaningful title but there is some short description of what's at the end of the link. Online documents which

have identifiable titles should be referenced using the `\seetitle` macro, using the optional parameter to that macro to provide the URL.

\seemodule [*key*] {*name*} {*why*}

Refer to another module. *why* should be a brief explanation of why the reference may be interesting. The module name is given in *name*, with the link key given in *key* if necessary. In the HTML and PDF conversions, the module name will be a hyperlink to the referred-to module. **Note:** The module must be documented in the same document (the corresponding `\declaremodule` is required).

\seepep {*number*} {*title*} {*why*}

Refer to an Python Enhancement Proposal (PEP). *number* should be the official number assigned by the PEP Editor, *title* should be the human-readable title of the PEP as found in the official copy of the document, and *why* should explain what's interesting about the PEP. This should be used to refer the reader to PEPs which specify interfaces or language features relevant to the material in the annotated section of the documentation.

\seerfc {*number*} {*title*} {*why*}

Refer to an IETF Request for Comments (RFC). Otherwise very similar to `\seepep`. This should be used to refer the reader to PEPs which specify protocols or data formats relevant to the material in the annotated section of the documentation.

\seetext {*text*}

Add arbitrary text *text* to the "See also:" list. This can be used to refer to off-line materials or on-line materials using the `\url` macro. This should consist of one or more complete sentences.

\seetitle [*url*] {*title*} {*why*}

Add a reference to an external document named *title*. If *url* is given, the title is made a hyperlink in the HTML version of the documentation, and displayed below the title in the typeset versions of the documentation.

\seeur1 {*url*} {*why*}

References to specific on-line resources should be given using the `\seeur1` macro if they don't have a meaningful title. Online documents which have identifiable titles should be referenced using the `\seetitle`

macro, using the optional parameter to that macro to provide the URL.

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [6.10 Reference List Markup](#) **Up:** [6 Special Markup Constructs](#) **Next:**
[6.12 Grammar Production Displays](#)

6.11 Index-generating Markup

Effective index generation for technical documents can be very difficult, especially for someone familiar with the topic but not the creation of indexes. Much of the difficulty arises in the area of terminology: including the terms an expert would use for a concept is not sufficient. Coming up with the terms that a novice would look up is fairly difficult for an author who, typically, is an expert in the area she is writing on.

The truly difficult aspects of index generation are not areas with which the documentation tools can help. However, ease of producing the index once content decisions are made is within the scope of the tools. Markup is provided which the processing software is able to use to generate a variety of kinds of index entry with minimal effort. Additionally, many of the environments described in section [6.3](#), "Information Units," will generate appropriate entries into the general and module indexes.

The following macro can be used to control the generation of index data, and should be used in the document preamble:

`\makemodindex`

This should be used in the document preamble if a "Module Index" is desired for a document containing reference material on many modules. This causes a data file `libjobname.idx` to be created from the `\declaremodule` macros. This file can be processed by the **`makeindex`** program to generate a file which can be `\input` into the document at the desired location of the module index.

There are a number of macros that are useful for adding index entries for particular concepts, many of which are specific to programming languages or even Python.

`\bifuncindex` {*name*}

Add an index entry referring to a built-in function named *name*; parentheses should not be included after *name*.

`\exindex` {*exception*}

Add a reference to an exception named *exception*. The exception should be

class-based.

\kwindex {*keyword*}

Add a reference to a language keyword (not a keyword parameter in a function or method call).

\obindex {*object type*}

Add an index entry for a built-in object type.

\opindex {*operator*}

Add a reference to an operator, such as "+".

\refmodindex [*key*] {*module*}

Add an index entry for module *module*; if *module* contains an underscore, the optional parameter *key* should be provided as the same string with underscores removed. An index entry ``*module* (module)" will be generated. This is intended for use with non-standard modules implemented in Python.

\refexmodindex [*key*] {*module*}

As for `\refmodindex`, but the index entry will be ``*module* (extension module)." This is intended for use with non-standard modules not implemented in Python.

\refbimodindex [*key*] {*module*}

As for `\refmodindex`, but the index entry will be ``*module* (built-in module)." This is intended for use with standard modules not implemented in Python.

\refstmodindex [*key*] {*module*}

As for `\refmodindex`, but the index entry will be ``*module* (standard module)." This is intended for use with standard modules implemented in Python.

\stindex {*statement*}

Add an index entry for a statement type, such as `print` or `try/finally`.

XXX Need better examples of difference from `\kwindex`.

Additional macros are provided which are useful for conveniently creating general index entries which should appear at many places in the index by rotating a list of words. These are simple macros that simply use `\index` to build some number of index entries. Index entries build using these macros contain both primary and secondary text.

`\indexii` `{word1}{word2}`

Build two index entries. This is exactly equivalent to using `\index{word1!word2}` and `\index{word2!word1}`.

`\indexiii` `{word1}{word2}{word3}`

Build three index entries. This is exactly equivalent to using `\index{word1!word2 word3}`, `\index{word2!word3, word1}`, and `\index{word3!word1 word2}`.

`\indexiv` `{word1}{word2}{word3}{word4}`

Build four index entries. This is exactly equivalent to using `\index{word1!word2 word3 word4}`, `\index{word2!word3 word4, word1}`, `\index{word3!word4, word1 word2}`, and `\index{word4!word1 word2 word3}`.

Previous: [6.11 Index-generating Markup](#) **Up:** [6 Special Markup Constructs](#)
Next: [6.13 Graphical Interface Components](#)

6.12 Grammar Production Displays

Special markup is available for displaying the productions of a formal grammar. The markup is simple and does not attempt to model all aspects of BNF (or any derived forms), but provides enough to allow context-free grammars to be displayed in a way that causes uses of a symbol to be rendered as hyperlinks to the definition of the symbol. There is one environment and a pair of macros:

```
\begin{productionlist} [language]  
\end{productionlist}
```

This environment is used to enclose a group of productions. The two macros are only defined within this environment. If a document describes more than one language, the optional parameter *language* should be used to distinguish productions between languages. The value of the parameter should be a short name that can be used as part of a filename; colons or other characters that can't be used in filename across platforms should be included.

```
\production {name}{definition}
```

A production rule in the grammar. The rule defines the symbol *name* to be *definition*. *name* should not contain any markup, and the use of hyphens in a document which supports more than one grammar is undefined. *definition* may contain `\token` macros and any additional content needed to describe the grammatical model of *symbol*. Only one `\production` may be used to define a symbol -- multiple definitions are not allowed.

```
\token {name}
```

The name of a symbol defined by a `\production` macro, used in the *definition* of a symbol. Where possible, this will be rendered as a hyperlink to the definition of the symbol *name*.

Note that the entire grammar does not need to be defined in a single `\productionlist` environment; any number of groupings may be used to describe the grammar. Every use of the `\token` must correspond to a `\production`.

The following is an example taken from the [Python Reference Manual](#):

```
\begin{productionlist}
  \production{identifier}
    {(\token{letter}|"_" ) (\token{letter} | \token{digit} |
  \production{letter}
    {\token{lowercase} | \token{uppercase}}}
  \production{lowercase}
    {"a"... "z"}
  \production{uppercase}
    {"A"... "Z"}
  \production{digit}
    {"0"... "9"}
\end{productionlist}
```

[Constructs](#) **Next:** [7 Processing Tools](#)

6.13 Graphical Interface Components

The components of graphical interfaces will be assigned markup, but most of the specifics have not been determined.

`\gui label` *{label}*

Labels presented as part of an interactive user interface should be marked using `\gui label`. This includes labels from text-based interfaces such as those created using `curses` or other text-based libraries. Any label used in the interface should be marked with this macro, including button labels, window titles, field names, menu and menu selection names, and even values in selection lists.

`\menuselection` *{menupath}*

Menu selections should be marked using a combination of `\menuselection` and `\sub`. This macro is used to mark a complete sequence of menu selections, including selecting submenus and choosing a specific operation, or any subsequence of such a sequence. The names of individual selections should be separated by occurrences of `\sub`.

For example, to mark the selection "Start > Programs", use this markup:

```
\menuselection{Start \sub Programs}
```

When including a selection that includes some trailing indicator, such as the ellipsis some operating systems use to indicate that the command opens a dialog, the indicator should be omitted from the selection name.

Individual selection names within the `\menuselection` should not be marked using `\gui label` since that's implied by using `\menuselection`.

`\sub`

Separator for menu selections that include multiple levels. This macro is only defined within the context of the `\menuselection` macro.

See [About this document...](#) for information on suggesting changes.*

Previous: [7 Processing Tools](#) **Up:** [7 Processing Tools](#) **Next:** [7.2 Internal Tools](#)

7.1 External Tools

Many tools are needed to be able to process the Python documentation if all supported formats are required. This section lists the tools used and when each is required. Consult the `Doc/README` file to see if there are specific version requirements for any of these.

dvips

This program is a typical part of TeX installations. It is used to generate PostScript from the "device independent" `.dvi` files. It is needed for the conversion to PostScript.

emacs

Emacs is the kitchen sink of programmers' editors, and a damn fine kitchen sink it is. It also comes with some of the processing needed to support the proper menu structures for Texinfo documents when an info conversion is desired. This is needed for the info conversion. Using **xemacs** instead of FSF **emacs** may lead to instability in the conversion, but that's because nobody seems to maintain the Emacs Texinfo code in a portable manner.

latex

LaTeX is a large and extensible macro package by Leslie Lamport, based on TeX, a world-class typesetter by Donald Knuth. It is used for the conversion to PostScript, and is needed for the HTML conversion as well (LaTeX2HTML requires one of the intermediate files it creates).

latex2html

Probably the longest Perl script anyone ever attempted to maintain. This converts LaTeX documents to HTML documents, and does a pretty reasonable job. It is required for the conversions to HTML and GNU info.

lynx

This is a text-mode Web browser which includes an HTML-to-plain text conversion. This is used to convert `howto` documents to text.

make

Just about any version should work for the standard documents, but GNU **make** is required for the experimental processes in `Doc/tools/sgmlconv/`,

at least while they're experimental. This is not required for running the **mkhowto** script.

makeindex

This is a standard program for converting LaTeX index data to a formatted index; it should be included with all LaTeX installations. It is needed for the PDF and PostScript conversions.

makeinfo

GNU **makeinfo** is used to convert Texinfo documents to GNU info files. Since Texinfo is used as an intermediate format in the info conversion, this program is needed in that conversion.

pdflatex

pdfTeX is a relatively new variant of TeX, and is used to generate the PDF version of the manuals. It is typically installed as part of most of the large TeX distributions. **pdflatex** is pdfTeX using the LaTeX format.

perl

Perl is required for LaTeX2HTML and one of the scripts used to post-process LaTeX2HTML output, as well as the HTML-to-Texinfo conversion. This is required for the HTML and GNU info conversions.

python

Python is used for many of the scripts in the `Doc/tools/` directory; it is required for all conversions. This shouldn't be a problem if you're interested in writing documentation for Python!

Previous: [7.1 External Tools](#) **Up:** [7 Processing Tools](#) **Next:** [7.3 Working on Cygwin](#)

7.2 Internal Tools

This section describes the various scripts that are used to implement various stages of document processing or to orchestrate entire build sequences. Most of these tools are only useful in the context of building the standard documentation, but some are more general.

mkhowto

This is the primary script used to format third-party documents. It contains all the logic needed to ``get it right." The proper way to use this script is to make a symbolic link to it or run it in place; the actual script file must be stored as part of the documentation source tree, though it may be used to format documents outside the tree. Use **mkhowto --help** for a list of command line options.

mkhowto can be used for both `howto` and `manual` class documents. It is usually a good idea to always use the latest version of this tool rather than a version from an older source release of Python. It can be used to generate DVI, HTML, PDF, PostScript, and plain text documents. The GNU info and iSilo formats will be supported by this script in some future version.

Use the **--help** option on this script's command line to get a summary of options for this script.

XXX Need more here.

Previous: [7.2 Internal Tools](#) **Up:** [7 Processing Tools](#) **Next:** [8 Including Graphics](#)

7.3 Working on Cygwin

Installing the required tools under Cygwin under Cygwin can be a little tedious. Most of the required packages can be installed using Cygwin's graphical installer, while netpbm and LaTeX2HTML must be installed from source.

Start with a reasonably modern version of Cygwin. If you haven't upgraded for a few years, now would be a good time.

Using the Cygwin installer, make sure your Cygwin installation includes Perl, Python, and the TeX packages. Perl and Python are located under the Interpreters heading. The TeX packages are located under the Text heading, and are named `tetex-*`. To ensure that all required packages are available, install every `tetex` package, except `tetex-x11`. (There may be a more minimal set, but I've not spent time trying to minimize the installation.)

The netpbm package is used by LaTeX2HTML, and *must* be installed before LaTeX2HTML can be successfully installed, even though its features will not be used for most Python documentation. References to download locations are located in the [netpbm README](#). Install from the latest stable source distribution according to the instructions. (Note that binary packages of netpbm are sometimes available, but these may not work correctly with LaTeX2HTML.)

LaTeX2HTML can be installed from the source archive, but only after munging one of the files in the distribution. Download the source archive from the LaTeX2HTML website <http://www.latex2html.org/> (or one of the many alternate sites) and unpack it to a build directory. In the top level of this build directory there will be a file named `L2hos.pm`. Open `L2hos.pm` in an editor, and near the bottom of the file replace the text `^O` with the text `'unix'`. Proceed using this command to build and install the software:

```
% ./configure && make install
```

You should now be able to build at least the DVI, HTML, PDF, and PostScript versions of the formatted documentation.

8 Including Graphics

The standard documentation included with Python makes no use of diagrams or images; this is intentional. The outside tools used to format the documentation have not always been suited to working with graphics. As the tools have evolved and been improved by their maintainers, support for graphics has improved.

The internal tools, starting with the **mkhowto** script, do not provide any direct support for graphics. However, **mkhowto** will not interfere with graphics support in the external tools.

Experience using graphics together with these tools and the `howto` and `manual` document classes is not extensive, but has been known to work. The basic approach is this:

1. Create the image or graphic using your favorite application.
2. Convert the image to a format supported by the conversion to your desired output format. If you want to generate HTML or PostScript, you can convert the image or graphic to encapsulated PostScript (a `.eps` file); LaTeX2HTML can convert that to a `.gif` file; it may be possible to provide a `.gif` file directly. If you want to generate PDF, you need to provide an "encapsulated" PDF file. This can be generated from encapsulated PostScript using the **epstopdf** tool provided with the TeX distribution on Linux and UNIX.
3. In your document, add this line to "import" the general graphics support package `graphicx`:

```
\usepackage{graphicx}
```

4. Where you want to include your graphic or image, include markup similar to this:

```
\begin{figure}  
  \centering  
  \includegraphics[width=5in]{myimage}  
  \caption{Description of my image}  
\end{figure}
```

In particular, note for the `\includegraphics` macro that no file extension is provided. If you're only interested in one target format, you can include the extension of the appropriate input file, but to allow support for multiple formats, omitting the extension makes life easier.

5. Run **mkhowto** normally.

If you're working on systems which support some sort of **make** facility, you can use that to ensure the intermediate graphic formats are kept up to date. This example shows a **Makefile** used to format a document containing a diagram created using the **dia** application:

```
default: pdf
all:      html pdf ps

html:     mydoc/mydoc.html
pdf:      mydoc.pdf
ps:       mydoc.ps

mydoc/mydoc.html: mydoc.tex mygraphic.eps
                mkhowto --html $<

mydoc.pdf:  mydoc.tex mygraphic.pdf
            mkhowto --pdf $<

mydoc.ps:   mydoc.tex mygraphic.eps
            mkhowto --postscript $<

.SUFFIXES: .dia .eps .pdf

.dia.eps:
            dia --nosplash --export $@ $<

.eps.pdf:
            epstopdf $<
```

Previous: [8 Including Graphics](#) **Up:** [Documenting Python](#) **Next:** [9.1 Structured Documentation](#)

9 Future Directions

The history of the Python documentation is full of changes, most of which have been fairly small and evolutionary. There has been a great deal of discussion about making large changes in the markup languages and tools used to process the documentation. This section deals with the nature of the changes and what appears to be the most likely path of future development.

Subsections

- [9.1 Structured Documentation](#)
- [9.2 Discussion Forums](#)

Previous: [9 Future Directions](#) **Up:** [9 Future Directions](#) **Next:** [9.2 Discussion Forums](#)

9.1 Structured Documentation

Most of the small changes to the LaTeX markup have been made with an eye to divorcing the markup from the presentation, making both a bit more maintainable. Over the course of 1998, a large number of changes were made with exactly this in mind; previously, changes had been made but in a less systematic manner and with more concern for not needing to update the existing content. The result has been a highly structured and semantically loaded markup language implemented in LaTeX. With almost no basic TeX or LaTeX markup in use, however, the markup syntax is about the only evidence of LaTeX in the actual document sources.

One side effect of this is that while we've been able to use standard ``engines'' for manipulating the documents, such as LaTeX and LaTeX2HTML, most of the actual transformations have been created specifically for Python. The LaTeX document classes and LaTeX2HTML support are both complete implementations of the specific markup designed for these documents.

Combining highly customized markup with the somewhat esoteric systems used to process the documents leads us to ask some questions: Can we do this more easily? and, Can we do this better? After a great deal of discussion with the community, we have determined that actively pursuing modern structured documentation systems is worth some investment of time.

There appear to be two real contenders in this arena: the Standard General Markup Language (SGML), and the Extensible Markup Language (XML). Both of these standards have advantages and disadvantages, and many advantages are shared.

SGML offers advantages which may appeal most to authors, especially those using ordinary text editors. There are also additional abilities to define content models. A number of high-quality tools with demonstrated maturity are available, but most are not free; for those which are, portability issues remain a problem.

The advantages of XML include the availability of a large number of evolving tools. Unfortunately, many of the associated standards are still evolving, and the tools will have to follow along. This means that developing a robust tool set that

uses more than the basic XML 1.0 recommendation is not possible in the short term. The promised availability of a wide variety of high-quality tools which support some of the most important related standards is not immediate. Many tools are likely to be free, and the portability issues of those which are, are not expected to be significant.

It turns out that converting to an XML or SGML system holds promise for translators as well; how much can be done to ease the burden on translators remains to be seen, and may have some impact on the schema and specific technologies used.

XXX Eventual migration to XML.

The documentation will be moved to XML in the future, and tools are being written which will convert the documentation from the current format to something close to a finished version, to the extent that the desired information is already present in the documentation. Some XSLT stylesheets have been started for presenting a preliminary XML version as HTML, but the results are fairly rough.

The timeframe for the conversion is not clear since there doesn't seem to be much time available to work on this, but the apparent benefits are growing more substantial at a moderately rapid pace.

Installing Python Modules

Greg Ward

Python Software Foundation Email: distutils-sig@python.org

Release 2.4.4c1
11 October 2006

Abstract:

This document describes the Python Distribution Utilities ("Distutils") from the end-user's point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.

1 Introduction

Although Python's extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don't need to know Python to read this document; there will be some brief forays into using Python's interactive mode to explore your installation, but that's it. If you're looking for information on how to distribute your own Python modules so that others may use them, see the [Distributing Python Modules](#) manual.

1.1 Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm - - install` it if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything--you might not even need to read any instructions (although it's always a good idea to do so anyways).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

1.2 The new standard: Distutils

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running

```
python setup.py install
```

If all these things are true, then you already know how to build and install the modules you've just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don't really need this manual. Or rather, the above command is everything you need to get out of this manual.

Installing Python Modules

Previous: [1 Introduction](#) Up: [Installing Python Modules](#) Next: [3 Alternate Installation](#)

Subsections

- [2.1 Platform variations](#)
 - [2.2 Splitting the job up](#)
 - [2.3 How building works](#)
 - [2.4 How installation works](#)
-

2 Standard Build and Install

As described in section [1.2](#), building and installing a module distribution using the Distutils is usually one simple command:

```
python setup.py install
```

On UNIX, you'd run this command from a shell prompt; on Windows, you have to open a command prompt window ("DOS box") and do it there; on Mac OS X, you open a Terminal window to get a shell prompt.

2.1 Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution `foo-1.0.tar.gz` onto a UNIX system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -      # unpacks into directory foo-
cd foo-1.0
python setup.py install
```

On Windows, you'd probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as **unzip** or **pkunzip**) to unpack the archive. Then, open a command prompt window ("DOS box"), and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```

2.2 Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally--especially useful if you want to customize the build process, or if things are going wrong--you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users--for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```
python setup.py build
python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which--in this case--quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the 'net, but it's very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you'll run lots of individual Distutils commands on their own.

2.3 How building works

As implied above, the `build` command is responsible for putting the files to install into a *build directory*. By default, this is `build` under the distribution root; if you're excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the `--build-base` option. For example:

```
python setup.py build --build-base=/tmp/pybuild/foo-1.0
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section [5](#).) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
               temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for "pure module distributions"--that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.plat` directory holds temporary files generated by the compile/link process that don't actually get installed. In either case, the `lib` (or `lib.plat`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.

2.4 How installation works

After the `build` command runs (whether you run it explicitly, or the `install` command does it for you), the work of the `install` command is relatively simple: all it has to do is copy everything under `build/lib` (or `build/lib.plat`) to your chosen installation directory.

If you don't choose an installation directory--i.e., if you just run `setup.py install`--then the `install` command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On UNIX (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions ("non-pure"):

Platform	Standard installation location	Default value	Notes
UNIX (pure)	<i>prefix</i> /lib/python2.4/site-packages	/usr/local/lib/python2.4/site-packages	(1)
UNIX (non-pure)	<i>exec-prefix</i> /lib/python2.4/site-packages	/usr/local/lib/python2.4/site-packages	(1)
Windows	<i>prefix</i>	C:\Python	(2)

Notes:

(1)

Most Linux distributions include Python as a standard part of the system, so *prefix* and *exec-prefix* are usually both `/usr` on Linux. If you build Python yourself on Linux (or any UNIX-like system), the default *prefix* and *exec-prefix* are `/usr/local`.

(2)

The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.

prefix and *exec-prefix* stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under UNIX and Mac OS X. You can find out

what your Python installation uses for *prefix* and *exec-prefix* by running Python in interactive mode and typing a few simple commands. Under UNIX, just type `python` at the shell prompt. Under Windows, choose **Start > Programs > Python 2.4 > Python (command line)**. Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my *prefix* and *exec-prefix*:

```
Python 2.4 (#26, Aug 7 2004, 17:19:02)
Type "help", "copyright", "credits" or "license" for more informatio
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

If you don't want to install modules to the standard location, or if you don't have permission to write there, then you need to read about alternate installations in section [3](#). If you want to customize your installation directories more heavily, see section [4](#) on custom installations.

Installing Python Modules

Previous: [1 Introduction](#) Up: [Installing Python Modules](#) Next: [3 Alternate Installation](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Subsections

- [3.1 Alternate installation: the home scheme](#)
 - [3.2 Alternate installation: UNIX \(the prefix scheme\)](#)
 - [3.3 Alternate installation: Windows \(the prefix scheme\)](#)
-

3 Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a UNIX system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils `install` command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the `install` command picks a set of directories (called an *installation scheme*) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

3.1 Alternate installation: the home scheme

The idea behind the "home scheme" is that you build and maintain a personal stash of Python modules. This scheme's name is derived from the idea of a "home" directory on UNIX, since it's not unusual for a UNIX user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system they're installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the `--home` option. On UNIX, lazy typists can just type a tilde (`~`); the `install` command will expand this to your home directory:

```
python setup.py install --home=~
```

The `--home` option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

Type of file	Installation Directory	Override option
pure module distribution	<i>home/lib/python</i>	<code>--install-purelib</code>
non-pure module distribution	<i>home/lib/python</i>	<code>--install-platlib</code>
scripts	<i>home/bin</i>	<code>--install-scripts</code>
data	<i>home/share</i>	<code>--install-data</code>

Changed in version 2.4: The `--home` option used to be supported only on UNIX.

3.2 Alternate installation: UNIX (the prefix scheme)

The "prefix scheme" is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is--that's why the "home scheme" comes first. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of "the system" rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in `/usr/local/lib/python2.X` rather than `/usr/lib/python2.X`. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.X`, but those modules would have to be installed to, say, `/mnt/@server/export/lib/python2.X`. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@server/export
```

In either case, the `--prefix` option defines the installation base, and the `--exec-prefix` option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If `--exec-prefix` is not supplied, it defaults to `--prefix`. Files are installed as follows:

Type of file	Installation Directory	Override option
pure module distribution	<i>prefix</i> /lib/python2.X/site-packages	<code>--install-purelib</code>
non-pure module distribution	<i>exec-prefix</i> /lib/python2.X/site-packages	<code>--install-platlib</code>

scripts	<i>prefix/bin</i>	--install-scripts
data	<i>prefix/share</i>	--install-data

There is no requirement that **--prefix** or **--exec-prefix** actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard UNIX installation uses the prefix scheme, but with **--prefix** and **--exec-prefix** supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix scheme, but every time you run `python setup.py install` without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your **--prefix** and **--exec-prefix** don't even point to an alternate Python installation, this is immaterial.)

3.3 Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under UNIX, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows. Files are installed as follows:

Type of file	Installation Directory	Override option
pure module distribution	<i>prefix</i>	<code>--install-purelib</code>
non-pure module distribution	<i>prefix</i>	<code>--install-platlib</code>
scripts	<i>prefix</i> \Scripts	<code>--install-scripts</code>
data	<i>prefix</i> \Data	<code>--install-data</code>

Installing Python Modules

Previous: [2 Standard Build and](#) Up: [Installing Python Modules](#) Next: [4 Custom Installation](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [3 Alternate Installation](#) Up: [Installing Python Modules](#) Next: [5 Distutils Configuration Files](#)

Subsections

- [4.1 Modifying Python's Search Path](#)
-

4 Custom Installation

Sometimes, the alternate installation schemes described in section [3](#) just don't do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you're creating a *custom installation scheme*.

You probably noticed the column of "override options" in the tables describing the alternate installation schemes above. Those options are how you define a custom installation scheme. These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same--they only differ when you use the UNIX "prefix scheme" and supply different **--prefix** and **--exec-prefix** options.)

For example, say you're installing a module distribution to your home directory under UNIX--but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the **--install-scripts** option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another UNIX example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the **--install-scripts** option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the "prefix scheme," where the prefix is whatever your Python interpreter was installed with-- `/usr/local/python` in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of *prefix*, rather than right in *prefix* itself. This is almost as easy as customizing the script installation directory--you just have to remember

that there are two types of modules to worry about, pure modules and non-pure modules (i.e., modules from a non-pure distribution). For example:

```
python setup.py install --install-purelib=Site --install-platlib=Site
```

The specified installation directories are relative to *prefix*. Of course, you also have to ensure that these directories are in Python's module search path, such as by putting a *.pth* file in *prefix*. See section [4.1](#) to find out how to modify Python's search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under *python* in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~ \
    --install-purelib=python/lib \
    --install-platlib=python/lib.$PLAT \
    --install-scripts=python/scripts
    --install-data=python/data
```

or, equivalently,

```
python setup.py install --home=~ /python \
    --install-purelib=lib \
    --install-platlib='lib.$PLAT' \
    --install-scripts=scripts
    --install-data=data
```

\$PLAT is not (necessarily) an environment variable--it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section [5](#)):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
```

```
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are *not* equivalent if you supply a different installation base directory when you run the setup script. For example,

```
python setup.py --install-base=/tmp
```

would install pure modules to */tmp/python/lib* in the first case, and to */tmp/lib* in the second case. (For the second case, you probably want to supply an installation base of */tmp/python*.)

You probably noticed the use of `$HOME` and `$PLAT` in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as `$PLAT`. (And of course, on systems that don't have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section [5](#) for details.

4.1 Modifying Python's Search Path

When the Python interpreter executes an `import` statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the `SYS` module and printing the value of `sys.path`.

```
$ python
Python 2.2 (#11, Oct  3 2002, 13:31:27)
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type ``help'', ``copyright'', ``credits'' or ``license'' for more in
>>> import sys
>>> sys.path
['', '/usr/local/lib/python2.3', '/usr/local/lib/python2.3/plat-linu
'/usr/local/lib/python2.3/lib-tk', '/usr/local/lib/python2.3/lib-dy
'/usr/local/lib/python2.3/site-packages']
>>>
```

The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `.../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `.../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. Any directories added to the search path will be scanned in turn for `.pth` files. See [site module documentation](#) for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```
import sys
sys.path.append('/www/python/')
```

However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You'd have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. `PYTHONHOME` sets an alternate value for the prefix of the Python installation. For example, if `PYTHONHOME` is set to `"/www/python"`, the search path will be set to `['', '/www/python/lib/python2.2/', '/www/python/lib/python2.3/plat-linux2', ...]`.

The `PYTHONPATH` variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if `PYTHONPATH` is set to `"/www/python:/opt/py"`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the `site` module removes paths that don't exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.

 - [5.2 Syntax of config files](#)
-

5 Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from ``earlier'' files are overridden by ``later'' files.

5.1 Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On UNIX and Mac OS X, the three configuration files (in the order they are processed) are:

Type of file	Location and filename	Notes
system	<i>prefix/lib/pythonver/distutils/distutils.cfg</i>	(1)
personal	<code>\$HOME/.pydistutils.cfg</code>	(2)
local	<code>setup.cfg</code>	(3)

And on Windows, the configuration files are:

Type of file	Location and filename	Notes
system	<i>prefix\Lib\distutils\distutils.cfg</i>	(4)
personal	<code>%HOME%\pydistutils.cfg</code>	(5)
local	<code>setup.cfg</code>	(3)

Notes:

(1)

Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on UNIX, this is as shown. For Python 1.5.2, the Distutils will normally be installed to *prefix/lib/python1.5/site-packages/distutils*, so the system configuration file should be put there under Python 1.5.2.

(2)

On UNIX, if the HOME environment variable is not defined, the user's home directory will be determined with the `getpwuid()` function from the standard `pwd` module.

(3)

I.e., in the current directory (usually the location of the setup script).

(4)

(See also note (1).) Under Python 1.6 and later, Python's default "installation prefix" is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the

default prefix was C:\Program Files\Python, and the Distutils were not part of the standard library--so the system configuration file would be C:\Program Files\Python\distutils\distutils.cfg in a standard Python 1.5.2 installation under Windows.

(5)

On Windows, if the HOME environment variable is not defined, no personal configuration file will be found or used. (In other words, the Distutils make no attempt to guess your home directory on Windows.)

5.2 Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a `global` section for global options that affect every command. Each section consists of one option per line, specified as `option=value`.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default `build base` directory and make the `build*` commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the `build` command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the `--help` option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using **--help** without a command:

```
python setup.py --help
```

See also the "Reference" section of the "Distributing Python Modules" manual.

Installing Python Modules

 - [6.2 Using non-Microsoft compilers on Windows](#)
 - [6.2.1 Borland C++](#)
 - [6.2.2 GNU C / Cygwin / MinGW](#)
-

6 Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

6.1 Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn't been tested on your platform, or if you're trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `Setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let's examine each of the fields in turn.

- *module* is the name of the extension module to be built, and should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.
- *sourcefile* is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.C` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- *cpparg* is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.
- *library* is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the `Setup` file and running `python setup.py build`. For example, if the module defined by the line

```
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you'll have to supply multiple `-Xcompiler` options; for example, to pass `-x c++` the `Setup` file would have to contain `-Xcompiler -x -Xcompiler c++`.

Compiler flags can also be supplied through setting the `CFLAGS` environment variable. If set, the contents of `CFLAGS` will be added to the compiler flags specified in the `Setup` file.

6.2 Using non-Microsoft compilers on Windows

6.2.1 Borland C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5.

First you have to know that Borland's object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python's library `python24.lib` into the Borland format. You can do this as follows:

```
coff2omf python24.lib python24_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python24.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (`zlib`,...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn't find such a special library it uses the default name (`foo.lib`).¹

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section [5](#).)

Information about the free C++ compiler from Borland, including links to the download pages.

[Creating Python Extensions Using Borland's Free Compiler](#)

Document describing how to use Borland's free command-line C++ compiler to build Python.

6.2.2 GNU C / Cygwin / MinGW

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions.²For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

These compilers require some special libraries. This task is more complex than for Borland's C++, because there is no program to convert the library.

First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at <http://starship.python.net/crew/kernr/mingw32/Notes.html>, see at PExports 0.42h there.)

```
pexports python24.dll >python24.def
```

Then you can create from these information an import library for gcc.

```
dlltool --dllname python24.dll --def python24.def --output-lib libpy
```

The resulting library has to be placed in the same directory as `python24.lib`. (Should be the `libs` directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

To let Distutils compile your extension with Cygwin you now have to type

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode³ or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider to write it in your personal or system-wide configuration file for Distutils (see section 5.)

Abstract:

This document describes the Python Distribution Utilities ("Distutils") from the module developer's point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

Previous: [1. An Introduction to](#) Up: [1. An Introduction to](#) Next: [1.2 A Simple Example](#)

1.1 Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (`setup.py` by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [1.1 Concepts & Terminology](#) **Up:** [1. An Introduction to General Python terminology](#) **Next:** [1.3](#)

1.2 A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called `foo`, contained in a file `foo.py`, then your setup script can be as simple as this:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
      )
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see [section 2](#) for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run:

```
python setup.py sdist
```

which will create an archive file (e.g., tarball on UNIX, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

1.3 General Python terminology

If you're reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module

the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module

a module written in Python and contained in a single `.py` file (and possibly associated `.pyc` and/or `.pyo` files). Sometimes referred to as a "pure module."

extension module

a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (`.SO`) file for Python extensions on UNIX, a DLL (given the `.pyd` extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package

a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file `__init__.py`.

root package

the root of the hierarchy of packages. (This isn't really a package, since it doesn't have an `__init__.py` file. But we have to call it something.) The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in `sys.path`

contributes modules to the root package.

Distributing Python Modules

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [1.3 General Python terminology](#) **Up:** [1. An Introduction to Writing the Setup](#) **Next:** [2.](#)

1.4 Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution

a collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are Numeric Python, PyXML, PIL (the Python Imaging Library), or mxBase. (This would be called a *package*, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution

a module distribution that contains only pure Python modules and packages. Sometimes referred to as a "pure distribution."

non-pure module distribution

a module distribution that contains at least one extension module. Sometimes referred to as a "non-pure distribution."

distribution root

the top-level directory of your source tree (or source distribution); the directory where `setup.py` exists. Generally `setup.py` will be run from this directory.

Previous: [1.4 Distutils-specific terminology](#) **Up:** [Distributing Python Modules](#)
Next: [2.1 Listing whole packages](#)

2. Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section [1.2](#) above, the setup script consists mainly of a call to `setup()`, and most information supplied to the Distutils by the module developer is supplied as keyword arguments to `setup()`.

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='http://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
      )
```

There are only two differences between this and the trivial one-file distribution presented in section [1.2](#): more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section [2.7](#).

Note that any pathnames (files or directories) supplied in the setup script should be written using the UNIX convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is

appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated. (Mac OS 9 programmers should keep in mind that the *absence* of a leading slash indicates a relative path, the opposite of the Mac OS convention with colons.)

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```

Next: [2.1 Listing whole packages](#)

See [About this document..](#) for information on suggesting changes.

Previous: [2. Writing the Setup individual modules](#) **Up:** [2. Writing the Setup](#) **Next:** [2.2 Listing](#)

2.1 Listing whole packages

The `packages` option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the `packages` list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package `distutils` is found in the directory `distutils` relative to the distribution root. Thus, when you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyways.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the `package_dir` option to tell the Distutils about your convention. For example, say you keep all Python source under `lib`, so that modules in the ``root package" (i.e., not in any package at all) are in `lib`, modules in the `foo` package are in `lib/foo`, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file `lib/foo/__init__.py` exists.

Another possible convention is to put the `foo` package right in `lib`, the `foo.bar` package in `lib/bar`, etc. This would be written in the setup script as

```
package_dir = {'foo': 'lib'}
```

A *package*: `dir` entry in the `package_dir` dictionary implicitly applies to all packages below *package*, so the `foo.bar` case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although `package_dir` applies recursively, you must explicitly list all packages in `packages`: the Distutils will *not* recursively scan your source tree looking for

any directory with an `__init__.py` file.)

Distributing Python Modules

Previous: [2.1 Listing whole packages](#) **Up:** [2. Writing the Setup](#) **Next:** [2.3 Describing extension modules](#)

2.2 Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages--especially the case of a single module that goes in the ``root package" (i.e., no package at all). This simplest case was shown in section [1.2](#); here is a slightly more involved example:

```
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the ``root" package, the other in the `pkg` package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.

Distributing Python Modules

2.3 Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it's not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to `setup()`, the `ext_modules` option. `ext_modules` is just a list of `Extension` instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called `foo` and implemented by `foo.c`. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```
Extension('foo', ['foo.c'])
```

The `Extension` class can be imported from `distutils.core` along with `setup()`. Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
      )
```

The `Extension` class (actually, the underlying extension-building machinery implemented by the `build_ext` command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.

2.3.1 Extension names and packages

The first argument to the `Extension` constructor is always the name of the extension, including any package names. For example,

```
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the `pkg` package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python's namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to `setup()`. For example,

```
setup(...
    ext_package='pkg',
    ext_modules=[Extension('foo', ['foo.c']),
                 Extension('subpkg.bar', ['bar.c'])],
)
```

will compile `foo.c` to the extension `pkg.foo`, and `bar.c` to `pkg.subpkg.bar`.

2.3.2 Extension source files

The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish C++ source files: `.cc` and `.cpp` seem to be recognized by both UNIX and Windows compilers.)

However, you can also include SWIG interface (`.i`) files in the list; the `build_ext` command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

**** SWIG support is rough around the edges and largely untested; especially SWIG support for C++ extensions! Explain in more detail here when the interface firms up. ****

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (`.mc`) files and resource definition (`.rc`) files for Visual C++. These will be compiled to binary resource (`.res`) files and linked into the executable.

2.3.3 Preprocessor options

Three optional arguments to `Extension` will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

```
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on UNIX systems with X11R6 installed to `/usr`, you can get away with

```
Extension('foo', ['foo.c'], include_dirs=['/usr/include/X11'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_header` command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory--`/usr/local/include/python1.5` in this case--is always included in the search path when building Python extensions, the best approach is to write C code like

```
#include <Numerical/arrayobject.h>
```

If you must put the Numerical include directory right into your header search path, though, you can find that directory using the Distutils [distutils.sysconfig](#) module:

```
from distutils.sysconfig import get_python_inc
incdir = os.path.join(get_python_inc(plat_specific=1), 'Numerical')
```

```
setup(...,
      Extension(..., include_dirs=[incdir]),
      )
```

Even though this is quite portable--it will work on any Python installation, regardless of platform--it's probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of (`name`, `value`) tuples, where `name` is the name of the macro to define (a string) and `value` is its value: either a string or `None`. (Defining a macro `F00` to `None` is the equivalent of a bare `#define F00` in your C source: with most compilers, this sets `F00` to the string `1`.) `undef_macros` is just a list of macros to undefine.

For example:

```
Extension(...,
          define_macros=[('NDEBUG', '1'),
                        ('HAVE_STRFTIME', None)],
          undef_macros=['HAVE_F00', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_F00
#undef HAVE_BAR
```

2.3.4 Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and `runtime_library_dirs` is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```
Extension(...,
           libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in `library_dirs`:

```
Extension(...,
           library_dirs=['/usr/X11R6/lib'],
           libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

**** Should mention clib libraries here or somewhere else! ****

2.3.5 Other options

There are still some other options which can be used to handle special cases.

The `extra_objects` option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

`extra_compile_args` and `extra_link_args` can be used to specify additional command line options for the respective compiler and linker command lines.

`export_symbols` is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add `__initmodule` to the list of exported symbols.

See [About this document...](#) for information on suggesting changes.

Previous: [2.3 Describing extension modules](#) **Up:** [2. Writing the Setup](#) **Next:** [2.5 Installing Package Data](#)

2.4 Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don't require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word `python`, the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `--executable` (or `-e`) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```
setup(...
    scripts=['scripts/xmlproc_parse', 'scripts/xmlproc_val']
)
```

Previous: [2.4 Installing Scripts](#) **Up:** [2. Writing the Setup](#) **Next:** [2.6 Installing Additional Files](#)

2.5 Installing Package Data

Often, additional files need to be installed into a package. These files are often data that's closely related to the package's implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```
setup.py
src/
  mypkg/
    __init__.py
    module.py
    data/
      tables.dat
      spoons.dat
      forks.dat
```

The corresponding call to `setup()` might be:

```
setup(...,
      packages=['mypkg'],
      package_dir={'mypkg': 'src/mypkg'},
      package_data={'mypkg': ['data/*.dat']},
      )
```

New in version 2.4.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [2.5 Installing Package Data](#) **Up:** [2. Writing the Setup](#) **Next:** [2.7 Additional meta-data](#)

2.6 Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn't fit in the previous categories.

`data_files` specifies a sequence of (*directory*, *files*) pairs in the following way:

```
setup(...
    data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                ('config', ['cfg/data.cfg']),
                ('/etc/init.d', ['init-script'])]
)
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each (*directory*, *files*) pair in the sequence specifies the installation directory and the files to install there. If *directory* is a relative path, it is interpreted relative to the installation prefix (Python's `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in *files* is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from *files* is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the `install` command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.

Previous: [2.6 Installing Additional Files](#) **Up:** [2. Writing the Setup](#) **Next:** [2.8 Debugging the setup](#)

2.7 Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

Meta-Data	Description	Value	Notes
name	name of the package	short string	(1)
version	version of this release	short string	(1)(2)
author	package author's name	short string	(3)
author_email	email address of the package author	email address	(3)
maintainer	package maintainer's name	short string	(3)
maintainer_email	email address of the package maintainer	email address	(3)
url	home page for the package	URL	(1)
description	short, summary description of the package	short string	
long_description	longer description of the package	long string	
download_url	location where the package may be downloaded	URL	(4)
classifiers	a list of classifiers	list of strings	(4)

Notes:

- (1) These fields are required.
- (2) It is recommended that versions take the form *major.minor[.patch[.sub]]*.
- (3)

Either the author or the maintainer must be identified.

(4)

These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the [PyPI website](#).

'short string'

A single line of text, not more than 200 characters.

'long string'

Multiple lines of plain text in reStructuredText format (see <http://docutils.sf.net/>).

'list of strings'

See below.

None of the string values may be Unicode.

Encoding the version information is an art in itself. Python packages generally adhere to the version format *major.minor[.patch][sub]*. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are "a1,a2,...,aN" (for alpha releases, where functionality and API may change), "b1,b2,...,bN" (for beta releases, which only fix bugs) and "pr1,pr2,...,prN" (for final pre-release release testing). Some examples:

0.1.0

the first, experimental release of a package

1.0.1a2

the second alpha release of the first patch version of 1.0

classifiers are specified in a python list:

```
setup(...
    classifiers=[
        'Development Status :: 4 - Beta',
        'Environment :: Console',
        'Environment :: Web Environment',
        'Intended Audience :: End Users/Desktop',
        'Intended Audience :: Developers',
```

```
'Intended Audience :: System Administrators',
'License :: OSI Approved :: Python Software Foundation Lic
'Operating System :: MacOS :: MacOS X',
'Operating System :: Microsoft :: Windows',
'Operating System :: POSIX',
'Programming Language :: Python',
'Topic :: Communications :: Email',
'Topic :: Office/Business',
'Topic :: Software Development :: Bug Tracking',
],
)
```

If you wish to include classifiers in your `setup.py` file and also wish to remain backwards-compatible with Python releases prior to 2.2.3, then you can include the following code fragment in your `setup.py` before the `setup()` call.

```
# patch distutils if it can't cope with the "classifiers" or
# "download_url" keywords
from sys import version
if version < '2.2.3':
    from distutils.dist import DistributionMetadata
    DistributionMetadata.classifiers = None
    DistributionMetadata.download_url = None
```

2.8 Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the `DISTUTILS_DEBUG` environment variable can be set to anything except an empty string, and distutils will now print detailed information what it is doing, and prints the full traceback in case an exception occurs.

Previous: [2.8 Debugging the setup](#) **Up:** [Distributing Python Modules](#) **Next:** [4. Creating a Source](#)

3. Writing the Setup Configuration File

Often, it's not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user's system, in order to proceed. As long as that information is fairly simple--a list of directories to search for C header files or libraries, for example--then providing a configuration file, `setup.cfg`, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script--which, ideally, would be opaque to installers^{3.1}--and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, `setup.cfg` (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in `setup.py` by editing `setup.cfg`
- you can provide non-standard defaults for options that are not easily set in `setup.py`
- installers can override anything in `setup.cfg` using the command-line options to `setup.py`

The basic syntax of the configuration file is simple:

```
[command]
option=value
...
```

where *command* is one of the Distutils commands (e.g. `build_py`, `install`), and *option* is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a `"#"` character until the end of the line. Long option values can be split across

multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal **--help** option, e.g.

```
> python setup.py --help build_ext
[...]
Options for 'build_ext' command:
  --build-lib (-b)      directory for compiled extension modules
  --build-temp (-t)     directory for temporary files (build by-product)
  --inplace (-i)        ignore build-lib and put compiled extensions
                        source directory alongside your pure Python modules
  --include-dirs (-I)   list of directories to search for header files
  --define (-D)         C preprocessor macros to define
  --undef (-U)          C preprocessor macros to undefine
[...]

```

Note that an option spelled **--foo-bar** on the command-line is spelled `foo_bar` in configuration files.

For example, say you want your extensions to be built "in-place"--that is, you have an extension `pkg.ext`, and you want the compiled extension file (`ext.so` on UNIX, say) to be put in the same source directory as your pure Python modules `pkg.mod1` and `pkg.mod2`. You can always use the **--inplace** option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the `build_ext` command explicitly, and remember to provide **--inplace**. An easier way is to "set and forget" this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify `build_ext`. If you include `setup.cfg` in your source distribution, it will also affect end-user builds--which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don't change from run to run; for example, `bdist_rpm` needs to know everything required to generate a ``spec" file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to `bdist_rpm`, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils' own `setup.cfg`:

```
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
            README.txt
            USAGE.txt
            doc/
            examples/
```

Note that the `doc_files` option is simply a whitespace-separated string split across multiple lines for readability.

See Also:

[Installing Python Modules](#)

More information on the configuration files is available in the manual for system administrators.

Footnotes

... installers^{3.1}

This ideal probably won't be achieved until auto-configuration is fully supported by the Distutils.

Creating a Source

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [3. Writing the Setup](#) **Up:** [Distributing Python Modules](#) **Next:** [4.1 Specifying the files](#)

4. Creating a Source Distribution

As shown in section [1.2](#), you use the `sdist` command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven't specified any `sdist` options in the setup script or config file), `sdist` creates the archive of the default format for the current platform. The default format is a gzipped tar file (`.tar.gz`) on UNIX, and ZIP file on Windows.

You can specify as many formats as you like using the `--formats` option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

Format	Description	Notes
zip	zip file (.zip)	(1),(3)
gztar	gzipped tar file (.tar.gz)	(2),(4)
bztar	bzip2'ed tar file (.tar.bz2)	(4)
ztar	compressed tar file (.tar.Z)	(4)
tar	tar file (.tar)	(4)

Notes:

- (1) default on Windows
- (2) default on UNIX
- (3) requires either external **zip** utility or `zipfile` module (part of the standard Python library since Python 1.6)
- (4) requires external utilities: **tar** and possibly one of **gzip**, **bzip2**, or **compress**

Distributing Python Modules

Previous: [3. Writing the Setup](#) Up: [Distributing Python Modules](#) Next: [4.1 Specifying the files](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [4. Creating a Source](#) **Up:** [4. Creating a Source](#) **Next:** [4.2 Manifest-related options](#)

4.1 Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the `sdist` command puts a minimal default set into the source distribution:

- all Python source files implied by the `py_modules` and `packages` options
- all C source files mentioned in the `ext_modules` or `libraries` options (****getting C library sources currently broken--no `get_source_files()` method in `build_clib.py!`** **)
- scripts identified by the `scripts` option
- anything that looks like a test script: `test/test*.py` (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- `README.txt` (or `README`), `setup.py` (or whatever you called your setup script), and `setup.cfg`

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a *manifest template*, called `MANIFEST.in` by default. The manifest template is just a list of instructions for how to generate your manifest file, `MANIFEST`, which is the exact list of files to include in your source distribution. The `sdist` command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do supply your own `MANIFEST`, you must specify everything: the default set of files described above does not apply in this case.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching *.txt, all files anywhere under the `examples` directory matching *.txt or *.py, and exclude all directories matching `examples/sample?/build`. All of this is done *after* the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the **--no-defaults** option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section [9.2](#).

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils ``build" tree (default build/)
- all files in directories named `RCS`, `CVS` or `.svn`

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the **--no-defaults** option, and you can disable the standard exclude set with **--no-prune**.

Following the Distutils' own manifest template, let's trace how the `sdist` command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the `distutils` and `distutils/command` subdirectories (because packages corresponding to those two directories were mentioned in the `packages` option in the setup script--see section [2](#))
2. include `README.txt`, `setup.py`, and `setup.cfg` (standard files)
3. include `test/test*.py` (standard files)
4. include *.txt in the distribution root (this will find `README.txt` a second time, but such redundancies are weeded out later)
5. include anything matching *.txt or *.py in the sub-tree under `examples`,
6. exclude all files in the sub-trees starting at directories matching `examples/sample?/build`--this may exclude files included by the previous two steps, so it's important that the `prune` command in the manifest template comes after the `recursive-include` command
7. exclude the entire `build` tree, and any `RCS`, `CVS` and `.svn` directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.

Previous: [4. Creating a Source](#) **Up:** [4. Creating a Source](#) **Next:** [4.2 Manifest-related options](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [4.1 Specifying the files](#) **Up:** [4. Creating a Source](#) **Next:** [5. Creating Built Distributions](#)

4.2 Manifest-related options

The normal course of operations for the `sdist` command is as follows:

- if the manifest file, MANIFEST doesn't exist, read MANIFEST.in and create the manifest
- if neither MANIFEST nor MANIFEST.in exist, create a manifest with just the default file set
- if either MANIFEST.in or the setup script (`setup.py`) are more recent than MANIFEST, recreate MANIFEST by reading MANIFEST.in
- use the list of files now in MANIFEST (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use the **--no-defaults** and **--no-prune** to disable the standard `include` and `exclude` sets.

Second, you might want to force the manifest to be regenerated--for example, if you have added or removed files or directories that match an existing pattern in the manifest template, you should regenerate the manifest:

```
python setup.py sdist --force-manifest
```

Or, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

--manifest-only implies **--force-manifest**. **-o** is a shortcut for **--manifest-only**, and **-f** for **--force-manifest**.

Previous: [4.2 Manifest-related options](#) **Up:** [Distributing Python Modules](#) **Next:**
[5.1 Creating dumb built](#)

5. Creating Built Distributions

A "built distribution" is what you're probably used to thinking of either as a "binary package" or an "installer" (depending on your background). It's not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don't call it a package, because that word is already spoken for in Python. (And "installer" is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it's a binary RPM; for Windows users, it's an executable installer; for Debian-based Linux users, it's a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty--writing code and creating source distributions--while an intermediary species called *packagers* springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer "out there" somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the bdist command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:

```
python setup.py bdist
```

then the Distutils builds my module distribution (the Distutils itself in this case), does a "fake" installation (also in the build directory), and creates the default type of built distribution for my platform. The default format for built distributions is a "dumb" tar file on UNIX, and a simple executable installer on Windows. (That tar file is considered "dumb" because it has to be unpacked in a specific location to work.)

Thus, the above command on a UNIX system creates `Distutils-1.0.plat.tar.gz`; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run `python setup.py install`. (The "right place" is either the root of the filesystem or Python's *prefix* directory, depending on the options given to the `bdist_dumb` command; the default is to make dumb distributions relative to *prefix*.)

Obviously, for pure Python distributions, this isn't any simpler than just running `python setup.py install`--but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating "smart" built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn't include any extensions.

The `bdist` command has a `--formats` option, similar to the `sdist` command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a UNIX system, create `Distutils-1.0.plat.zip`--again, this archive would be unpacked from the root directory to install the Distutils.

The available formats for built distributions are:

Format	Description	Notes
<code>gztar</code>	gzipped tar file (.tar.gz)	(1),(3)
<code>ztar</code>	compressed tar file (.tar.Z)	(3)
<code>tar</code>	tar file (.tar)	(3)
<code>zip</code>	zip file (.zip)	(4)
<code>rpm</code>	RPM	(5)
<code>pkgtool</code>	Solaris pkgtool	
<code>sdux</code>	HP-UX swinstall	
<code>rpm</code>	RPM	(5)
<code>wininst</code>	self-extracting ZIP file for Windows	(2),(4)

Notes:

- (1) default on UNIX
- (2) default on Windows **** to-do! ****
- (3) requires external utilities: **tar** and possibly one of **gzip**, **bzip2**, or **compress**
- (4) requires either external **zip** utility or `zipfile` module (part of the standard Python library since Python 1.6)
- (5) requires external **rpm** utility, version 3.0.4 or better (use `rpm --version` to find out which version you have)

You don't have to use the `bdist` command with the `--formats` option; you can also use the command that directly implements the format you're interested in. Some of these `bdist` "sub-commands" actually generate several similar formats; for instance, the `bdist_dumb` command generates all the "dumb" archive formats (`tar`, `ztar`, `gztar`, and `zip`), and `bdist_rpm` generates both binary and source RPMs. The `bdist` sub-commands, and the formats generated by each, are:

Command	Formats
<code>bdist_dumb</code>	<code>tar</code> , <code>ztar</code> , <code>gztar</code> , <code>zip</code>
<code>bdist_rpm</code>	<code>rpm</code> , <code>srpm</code>
<code>bdist_wininst</code>	<code>wininst</code>

The following sections give details on the individual `bdist_*` commands.

5.2 Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the `bdist_rpm` command:

```
python setup.py bdist_rpm
```

or the `bdist` command with the `--format` option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple `bdist_*` commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.org>" \  
bdist_wininst --target_version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the `bdist_rpm` command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:

RPM .spec file option or section	Distutils setup script option
Name	name
Summary (in preamble)	description
Version	version
Vendor	author and author_email, or & maintainer and maintainer_email

Copyright	licence
Url	url
%description (section)	long_description

Additionally, there are many options in .spec files that don't have corresponding options in the setup script. Most of these are handled through options to the `bdist_rpm` command as follows:

RPM .spec file option or section	bdist_rpm option	default value
Release	release	``1"
Group	group	``Development/Libraries"
Vendor	vendor	(see above)
Packager	packager	(none)
Provides	provides	(none)
Requires	requires	(none)
Conflicts	conflicts	(none)
Obsoletes	obsoletes	(none)
Distribution	distribution_name	(none)
BuildRequires	build_requires	(none)
Icon	icon	(none)

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it's usually best to put them in the setup configuration file, `setup.cfg`--see section [3](#). If you distribute or package many Python module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (`~/pydistutils.cfg`).

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a .spec file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the .spec file)
2. create the source RPM
3. create the ``binary" RPM (which may or may not contain binary code, depending on whether your module distribution contains Python

extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the **--spec-only** option to make `bdist_rpm` just create the `.spec` file and exit; in this case, the `.spec` file will be written to the "distribution directory"--normally `dist/`, but customizable with the **--dist-dir** option. (Normally, the `.spec` file winds up deep in the "build tree," in a temporary directory created by `bdist_rpm`.)

5.3 Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

```
python setup.py bdist_wininst
```

or the `bdist` command with the **--formats** option:

```
python setup.py bdist --formats=wininst
```

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like `foo-1.0.win32.exe`. These installers can even be created on UNIX or Mac OS platforms.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form `foo-1.0.win32-py2.0.exe`. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into bytecode after installation on the target system in normal and optimizing mode. If you don't want this to happen for some reason, you can run the `bdist_wininst` command with the **--no-target-compile** and/or the **--no-target-optimize** option.

By default the installer will display the cool "Python Powered" logo when it is run, but you can also supply your own bitmap which must be a Windows `.bmp` file with the **--bitmap** option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the **--title** option.

The installer file will be written to the ``distribution directory" -- normally dist/, but customizable with the **--dist-dir** option.

5.3.1 The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified which the **--install-script** option. The basename of the script must be specified, and the script filename must also be listed in the `scripts` argument to the `setup` function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to **-install**, and again at uninstallation time before the files are removed with `argv[1]` set to **-remove**.

The installation script runs embedded in the windows installer, every output (`sys.stdout`, `sys.stderr`) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

directory_created(*path*)

file_created(*path*)

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register *path* with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

get_special_folder_path(*csidl_string*)

This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. *csidl_string* must be one of the following strings:

```
"CSIDL_APPDATA"
```

```
"CSIDL_COMMON_STARTMENU"  
"CSIDL_STARTMENU"
```

```
"CSIDL_COMMON_DESKTOPDIRECTORY"  
"CSIDL_DESKTOPDIRECTORY"
```

```
"CSIDL_COMMON_STARTUP"  
"CSIDL_STARTUP"
```

"CSIDL_COMMON_PROGRAMS"

"CSIDL_PROGRAMS"

"CSIDL_FONTS"

If the folder cannot be retrieved, `OSError` is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the `SHGetSpecialFolderPath()` function.

create_shortcut(*target*, *description*, *filename*[, *arguments*[, *workdir*[, *iconpath*[, *iconindex*]]]])

This function creates a shortcut. *target* is the path to the program to be started by the shortcut. *description* is the description of the shortcut. *filename* is the title of the shortcut that the user will see. *arguments* specifies the command line arguments, if any. *workdir* is the working directory for the program. *iconpath* is the file containing the icon for the shortcut, and *iconindex* is the index of the icon in the file *iconpath*. Again, for details consult the Microsoft documentation for the `IShellLink` interface.

Distributing Python Modules

Next: [7. Examples](#)

6. Registering with the Package Index

The Python Package Index (PyPI) holds meta-data describing distributions packaged with distutils. The distutils command `register` is used to submit your distribution's meta-data to the index. It is invoked as follows:

```
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either:
 1. use your existing login,
 2. register as a new user,
 3. have the server generate a new password for you (and email it to
 4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.

Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and `register` will then submit your meta-data to the index.

You may submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you may submit it again and the index will be updated.

PyPI holds a record for each (name, version) combination submitted. The first user to submit information for a given name is designated the Owner of that name. They may submit changes through the `register` command or through the web interface. They may also designate other users as Owners or Maintainers.

Maintainers may edit the package information, but not designate other Owners or Maintainers.

By default PyPI will list all versions of a given package. To hide certain versions, the Hidden property should be set to yes. This must be edited through the web interface.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7. Examples](#) Up: [7. Examples](#) Next: [7.2 Pure Python distribution](#)

7.1 Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, `foo.py` in this example:

```
<root>/
    setup.py
    foo.py
```

(In all diagrams in this section, `<root>` will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
    )
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules `foo` and `bar`, your setup might look like this:

```
<root>/
    setup.py
    foo.py
    bar.py
```

and the setup script might be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
```

```
py_modules=['foo', 'bar'],  
)
```

You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.

Previous: [7. Examples](#) Up: [7. Examples](#) Next: [7.2 Pure Python distribution](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.1 Pure Python distribution](#) **Up:** [7. Examples](#) **Next:** [7.3 Single extension module](#)

7.2 Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an `__init__.py` file).

The setup script from the last example could also be written as

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=[''],
      )
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
  setup.py
  src/
    foo.py
    bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'': 'src'},
      packages=[''],
      )
```

More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the `foo` and `bar` modules belong in package `foobar`, one way to layout your source tree is

```

<root>/
  setup.py
  foobar/
    __init__.py
    foo.py
    bar.py

```

This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```

from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar'],
      )

```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the `foobar` package:

```

<root>/
  setup.py
  src/
    __init__.py
    foo.py
    bar.py

```

an appropriate setup script would be

```

from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
      )

```

Or, you might put modules from your main package right in the distribution root:

```

<root>/
  setup.py
  __init__.py
  foo.py
  bar.py

```

in which case your setup script would be

```

from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},

```

```
packages=[ 'foobar' ],
)
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does *not* scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```
<root>/
  setup.py
  foobar/
    __init__.py
    foo.py
    bar.py
    subfoo/
      __init__.py
      blah.py
```

then the corresponding setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar', 'foobar.subfoo'],
)
```

(Again, the empty string in `package_dir` stands for the current directory.)

Distributing Python Modules

Previous: [7.1 Pure Python distribution](#) Up: [7. Examples](#) Next: [7.3 Single extension module](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [7.2 Pure Python distribution](#) **Up:** [7. Examples](#) **Next:** [8. Extending Distutils](#)

7.3 Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```
<root>/
    setup.py
    foo.c
```

If the `foo` extension belongs in the root package, the setup script for this could be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
    )
```

If the extension actually belongs in a package, say `foopkg`, then

With exactly the same source tree layout, this extension can be put in the `foopkg` package simply by changing the name of the extension:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foopkg.foo', ['foo.c'])],
    )
```

Previous: [7.3 Single extension module](#) **Up:** [Distributing Python Modules](#) **Next:**
[8.1 Integrating new commands](#)

8. Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within `setup.py` scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to `.py` files as a convenience.

Most distutils command implementations are subclasses of the `Command` class from [distutils.cmd](#). New commands may directly inherit from `Command`, while replacements often derive from `Command` indirectly, directly subclassing the command they are replacing. Commands are required to derive from `Command`.

Previous: [8. Extending Distutils](#) **Up:** [8. Extending Distutils](#) **Next:** [9. Command Reference](#)

8.1 Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your `setup.py` script, and cause the `distutils.core.setup()` function use them:

```
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

    # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
      ...)
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing `setup.py` scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration option, `command_packages` (command-line option `--command-packages`), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils options, this can be specified on the command line or in a configuration file. This option can only be set in the `[global]` section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the `distutils.command` package. When `setup.py` is run with the option `--command-packages distcmds,buildcmds`, however, the packages `distutils.command`, `distcmds`, and `buildcmds` will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command `bdist_openpkg` could be implemented by the class `distcmds.bdist_openpkg.bdist_openpkg` or `buildcmds.bdist_openpkg.bdist_openpkg`.

9.2 Creating a source distribution: the `sdist` command

**** fragment moved down from above: needs context! ****

The manifest template commands are:

Command	Description
<code>include pat1 pat2 ...</code>	include all files matching any of the listed patterns
<code>exclude pat1 pat2 ...</code>	exclude all files matching any of the listed patterns
<code>recursive-include dir pat1 pat2 ...</code>	include all files under <i>dir</i> matching any of the listed patterns
<code>recursive-exclude dir pat1 pat2 ...</code>	exclude all files under <i>dir</i> matching any of the listed patterns
<code>global-include pat1 pat2 ...</code>	include all files anywhere in the source tree matching & any of the listed patterns
<code>global-exclude pat1 pat2 ...</code>	exclude all files anywhere in the source tree matching & any of the listed patterns
<code>prune dir</code>	exclude all files under <i>dir</i>
<code>graft dir</code>	include all files under <i>dir</i>

The patterns here are UNIX-style "glob" patterns: * matches any sequence of regular filename characters, ? matches any single regular filename character, and [range] matches any of the characters in range (e.g., a-z, a-zA-Z, a-f0-9_.). The definition of "regular filename character" is platform-specific: on UNIX it is anything except slash; on Windows anything except backslash or colon; on Mac OS 9 anything except colon.

**** Windows support not there yet ****

[distutils.compiler](#)

10.1 `distutils.core` -- Core Distutils functionality

The `distutils.core` module is the only module that needs to be installed to use the Distutils. It provides the `setup()` (which is called from the setup script). Indirectly provides the `distutils.dist.Distribution` and `distutils.cmd.Command` class.

setup(*arguments*)

The basic do-everything function that does most everything you could ever ask for from a Distutils method. See XXXXX

The setup function takes a large number of arguments. These are laid out in the following table.

argument name	value	type
name	The name of the package	a string
version	The version number of the package	See distutils.version
description	A single line describing the package	a string
long_description	Longer description of the package	a string
author	The name of the package author	a string
author_email	The email address of the package author	a string
maintainer	The name of the	a string

	current maintainer, if different from the author	
maintainer_email	The email address of the current maintainer, if different from the author	
url	A URL for the package (homepage)	a URL
download_url	A URL to download the package	a URL
packages	A list of Python packages that distutils will manipulate	a list of strings
py_modules	A list of Python modules that distutils will manipulate	a list of strings
scripts	A list of standalone script files to be built and installed	a list of strings
ext_modules	A list of Python extensions to be built	A list of instances of <code>distutils.</code>
classifiers	A list of categories for the package	The list of available categorizations http://cheeseshop.python.org/py
distclass	the <code>Distribution</code> class to use	A subclass of <code>distutils.core</code>

<code>script_name</code>	The name of the <code>setup.py</code> script - defaults to <code>sys.argv[0]</code>	a string
<code>script_args</code>	Arguments to supply to the <code>setup</code> script	a list of strings
<code>options</code>	default options for the <code>setup</code> script	a string
<code>license</code>	The license for the package	
<code>keywords</code>	Descriptive meta-data. See PEP 314	
<code>platforms</code>		
<code>cmdclass</code>	A mapping of command names to <code>Command</code> subclasses	a dictionary

`run_setup(script_name[, script_args=None, stop_after= 'run '])`

Run a `setup` script in a somewhat controlled environment, and return the `distutils.dist.Distribution` instance that drives things. This is useful if you need to find out the distribution meta-data (passed as keyword args from `script` to `setup()`), or the contents of the config files or command-line.

`script_name` is a file that will be run with `execfile()` `sys.argv[0]` will be replaced with `script` for the duration of the call. `script_args` is a list of strings; if supplied, `sys.argv[1:]` will be replaced by `script_args` for the duration of the call.

`stop_after` tells `setup()` when to stop processing; possible values:

value	description
<code>init</code>	Stop after the <code>Distribution</code> instance has been created

	and populated with the keyword arguments to <code>setup()</code>
config	Stop after config files have been parsed (and their data stored in the <code>Distribution</code> instance)
commandline	Stop after the command-line (<code>sys.argv[1:]</code> or <code>script_args</code>) have been parsed (and the data stored in the <code>Distribution</code> instance.)
run	Stop after all commands have been run (the same as if <code>setup()</code> had been called in the usual way). This is the default value.

In addition, the `distutils.core` module exposed a number of classes that live elsewhere.

- Extension from `distutils.extension`
- Command from `distutils.cmd`
- `Distribution` from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.

class Extension

The `Extension` class describes a single C or C++-extension module in a setup script. It accepts the following keyword arguments in its constructor

argument name	value	type
name	the full name of the extension, including any packages -- ie. <i>not</i> a filename or pathname, but Python dotted name	string
sources	list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the <code>build_ext</code>	string

	command as source for a Python extension.	
include_dirs	list of directories to search for C/C++ header files (in UNIX form for portability)	string
define_macros	list of macros to define; each macro is defined using a 2-tuple, where 'value' is either the string to define it to or <code>NONE</code> to define it without a particular value (equivalent of <code>#define FOO</code> in source or <code>-DFOO</code> on UNIX C compiler command line)	(string,string) tuple or (name,None)
undef_macros	list of macros to undefine explicitly	string
library_dirs	list of directories to search for C/C++ libraries at link time	string
libraries	list of library names (not filenames or paths) to link against	string
runtime_library_dirs	list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)	string
extra_objects	list of extra files to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)	string
extra_compile_args	any extra platform- and compiler-specific information to use when compiling the source files in 'sources'. For platforms and compilers where a command line makes sense, this is typically a list of command-line arguments, but for other platforms it could be anything.	string

extra_link_args	any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for 'extra_compile_args'.	string
export_symbols	list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: <code>init + extension_name</code> .	string
depends	list of files that the extension depends on	string
language	extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided.	string

class Distribution

A `Distribution` describes how to build, install and package up a Python software package.

See the `setup()` function for a list of keyword arguments accepted by the `Distribution` constructor. `setup()` creates a `Distribution` instance.

class Command

A `Command` class (or rather, an instance of one of its subclasses) implement a single `distutils` command.

Previous: [10.1 distutils.core](#) Up: [10. API Reference](#) Next: [10.3 distutils.unixccompiler](#)

10.2 `distutils.ccompiler` -- CCompiler base class

This module provides the abstract base class for the `CCompiler` classes. A `CCompiler` instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler -- macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

gen_lib_options(*compiler, library_dirs, runtime_library_dirs, libraries*)

Generate linker options for searching library directories and linking with specific libraries. *libraries* and *library_dirs* are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

gen_preprocess_options(*macros, include_dirs*)

Generate C pre-processor options (**-D**, **-U**, **-I**) as used by at least two types of compilers: the typical UNIX compiler and Visual C++. *macros* is the usual thing, a list of 1- or 2-tuples, where (*name*,) means undefine (**-U**) macro *name*, and (*name*, *value*) means define (**-D**) macro *name* to *value*. *include_dirs* is just a list of directory names to be added to the header file search path (**-I**). Returns a list of command-line options suitable for either UNIX compilers or Visual C++.

get_default_compiler(*osname, platform*)

Determine the default compiler to use for the given platform.

osname should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and *platform* the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

new_compiler(*plat=None, compiler=None, verbose=0, dry_run=0, force=0*)

Factory function to generate an instance of some `CCompiler` subclass for the supplied platform/compiler combination. *plat* defaults to `os.name` (eg. `'posix'`, `'nt'`), and *compiler* defaults to the default compiler for that platform. Currently only `'posix'` and `'nt'` are supported, and the default compilers are "traditional UNIX interface" (`UnixCCompiler` class) and Visual C++ (`MSVCCompiler` class). Note that it's perfectly possible to ask for a UNIX compiler object under Windows, and a Microsoft compiler object under UNIX--if you supply a value for *compiler*, *plat* is ignored.

show_compilers()

Print list of available compilers (used by the `--help-compiler` options to `build`, `build_ext`, `build_clib`).

class CCompiler([*verbose=0, dry_run=0, force=0*])

The abstract base class `CCompiler` defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps -- include directories, macros to define, libraries to link against, etc. -- are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the `Compiler` object. Flags are *verbose* (show verbose output), *dry_run* (don't actually execute the steps) and *force* (rebuild everything, regardless of dependencies). All of these flags default to `0` (off). Note that you probably don't want to instantiate `CCompiler` or one of its subclasses directly - use the `distutils.CCompiler.new_compiler()` factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

add_include_dir(*dir*)

Add *dir* to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to `add_include_dir()`.

set_include_dirs(*dirs*)

Set the list of directories that will be searched to *dirs* (a list of strings). Overrides any preceding calls to `add_include_dir()`; subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of standard include directories that the compiler may search by default.

add_library(*libname*)

Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to `add_library()` and/or `set_libraries()`. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

set_libraries(*libnames*)

Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

add_library_dir(*dir*)

Add *dir* to the list of directories that will be searched for libraries specified to `add_library()` and `set_libraries()`. The linker will be instructed to search for libraries in the order they are supplied

to `add_library_dir()` and/or `set_library_dirs()`.

set_library_dirs(*dirs*)

Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the linker may search by default.

add_runtime_library_dir(*dir*)

Add *dir* to the list of directories that will be searched for shared libraries at runtime.

set_runtime_library_dirs(*dirs*)

Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

define_macro(*name*[, *value=None*])

Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used (XXX true? does ANSI say anything about this?)

undefine_macro(*name*)

Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by `define_macro()` and undefined by `undefine_macro()` the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to `compile()`), then that takes precedence.

add_link_object(*object*)

Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of "resource compilers") to be included in every link driven by this compiler object.

set_link_objects(*objects*)

Set the list of object files (or analogues) to be included in every link to *objects*. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU **autoconf**.

detect_language(*sources*)

Detect the language of a given file, or list of files. Uses the instance attributes `language_map` (a dictionary), and `language_order` (a list) to do the job.

find_library_file(*dirs*, *lib* [, *debug*=0])

Search the specified list of directories for a static or shared library file *lib* and return the full path to that file. If *debug* is true, look for a debugging version (if that makes sense on the current platform). Return `NONE` if *lib* wasn't found in any of the specified directories.

has_function(*funcname* [, *includes*=None, *include_dirs*=None, *libraries*=None, *library_dirs*=None])

Return a boolean indicating whether *funcname* is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

library_dir_option(*dir*)

Return the compiler option to add *dir* to the list of directories searched for libraries.

library_option(*lib*)

Return the compiler option to add *lib* to the list of libraries linked into the shared library or executable.

runtime_library_dir_option(*dir*)

Return the compiler option to add *dir* to the list of directories searched for runtime libraries.

set_executables(*args*)**

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the 'executables' class attribute), but most will have:

attribute	description
compiler	the C/C++ compiler
linker_so	linker used to create shared objects and libraries
linker_exe	linker used to create binary executables
archiver	static library creator

On platforms with a command-line (UNIX, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how UNIX shells operate: words are delimited by spaces, but quotes and backslashes can override this. See `distutils.util.split_quoted()`.)

The following methods invoke stages in the build process.

compile(*sources* [, *output_dir=None*, *macros=None*,
include_dirs=None, *debug=0*, *extra_preargs=None*,
extra_postargs=None, *depends=None*])

Compile one or more source files. Generates object files (e.g. transforms a .C file to a .O file.)

sources must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. `MSVCCompiler` can handle resource files in *sources*). Return a list of object filenames, one per source filename in *sources*. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If *output_dir* is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a UNIX implementation); if *output_dir* is *build*, then it

would compile to build/foo/bar.o.

macros, if given, must be a list of macro definitions. A macro definition is either a (*name*, *value*) 2-tuple or a (*name*,) 1-tuple. The former defines a macro; if the value is `NONE`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

include_dirs, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

debug is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

extra_preargs and *extra_postargs* are implementation-dependent. On platforms that have the notion of a command-line (e.g. UNIX, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn't cut the mustard.

depends, if given, is a list of filenames that all targets depend on. If a source file is older than any file in *depends*, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises `CompileError` on failure.

create_static_lib(*objects*, *output_libname*[, *output_dir*=`NONE`,
debug=`0`, *target_lang*=`NONE`])

Link a bunch of stuff together to create a static library file. The ``bunch of stuff'' consists of the list of object files supplied as *objects*, the extra object files supplied to `add_link_object()` and/or `set_link_objects()`, the libraries supplied to `add_library()` and/or `set_libraries()`, and the libraries supplied as *libraries* (if any).

output_libname should be a library name, not a filename; the filename

will be inferred from the library name. *output_dir* is the directory where the library file will be put. XXX defaults to what?

debug is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the compile step where this matters: the *debug* flag is included here just for consistency).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises `LibError` on failure.

```
link(target_desc, objects, output_filename [, output_dir=None,  
libraries=None, library_dirs=None, runtime_library_dirs=None,  
export_symbols=None, debug=0, extra_preargs=None,  
extra_postargs=None, build_temp=None, target_lang=None])
```

Link a bunch of stuff together to create an executable or shared library file.

The "bunch of stuff" consists of the list of object files supplied as *objects*. *output_filename* should be a filename. If *output_dir* is supplied, *output_filename* is relative to it (i.e. *output_filename* can provide directory components if needed).

libraries is a list of libraries to link against. These are library names, not filenames, since they're translated into filenames in a platform-specific way (eg. *foo* becomes *libfoo.a* on UNIX and *foo.lib* on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

library_dirs, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to `add_library_dir()` and/or `set_library_dirs()`.

runtime_library_dirs is a list of directories that will be embedded into the shared library and used to search for other shared libraries that **it** depends on at run-time. (This may only be relevant on UNIX.)

export_symbols is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

debug is as for `compile()` and `create_static_lib()`, with the slight distinction that it actually matters on most platforms (as opposed to `create_static_lib()`, which includes a *debug* flag mostly for form's sake).

extra_preargs and *extra_postargs* are as for `compile()` (except of course that they supply command-line arguments for the particular linker being used).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises `LinkError` on failure.

```
link_executable(objects, output_progname[, output_dir=None,  
                libraries=None, library_dirs=None,  
                runtime_library_dirs=None, debug=0,  
                extra_preargs=None, extra_postargs=None,  
                target_lang=None])
```

Link an executable. *output_progname* is the name of the file executable, while *objects* are a list of object filenames to link in. Other arguments are as for the `link` method.

```
link_shared_lib(objects, output_libname[, output_dir=None,  
                libraries=None, library_dirs=None,  
                runtime_library_dirs=None,  
                export_symbols=None, debug=0,  
                extra_preargs=None, extra_postargs=None,  
                build_temp=None, target_lang=None])
```

Link a shared library. *output_libname* is the name of the output library, while *objects* is a list of object filenames to link in. Other arguments are as for the `link` method.

objects, *output_filename*[, *output_dir=None*,
libraries=None, *library_dirs=None*,
link_shared_object(*runtime_library_dirs=None*,
export_symbols=None, *debug=0*,
extra_preargs=None, *extra_postargs=None*,
build_temp=None, *target_lang=None*)]

Link a shared object. *output_filename* is the name of the shared object that will be created, while *objects* is a list of object filenames to link in. Other arguments are as for the `link` method.

source[, *output_file=None*, *macros=None*,
preprocess(*include_dirs=None*, *extra_preargs=None*,
extra_postargs=None)]

Preprocess a single C/C++ source file, named in *source*. Output will be written to file named *output_file*, or *stdout* if *output_file* not supplied. *macros* is a list of macro definitions as for `compile()`, which will augment the macros set with `define_macro()` and `undefine_macro()`. *include_dirs* is a list of directory names that will be added to the default list, in the same way as `add_include_dir()`.

Raises `PreprocessError` on failure.

The following utility methods are defined by the `CCompiler` class, for use by the various concrete subclasses.

executable_filename(*basename*[, *strip_dir=0*, *output_dir=''*])

Returns the filename of the executable for the given *basename*. Typically for non-Windows platforms this is the same as the *basename*, while Windows will get a `.exe` added.

library_filename(*libname*[, *lib_type='static'*, *strip_dir=0*,
output_dir=''])

Returns the filename for the given library name on the current platform. On UNIX a library with *lib_type* of `'static'` will typically be of the form `liblibname.a`, while a *lib_type* of `'dynamic'` will be of the form `liblibname.so`.

object_filenames(*source_filenames*[, *strip_dir=0*, *output_dir= ''*])

Returns the name of the object files for the given source files.
source_filenames should be a list of filenames.

shared_object_filename(*basename*[, *strip_dir=0*,
output_dir= ''])

Returns the name of a shared object file for the given file name
basename.

execute(*func*, *args*[, *msg=None*, *level=1*])

Invokes `distutils.util.execute()` This method invokes a Python function *func* with the given arguments *args*, after logging and taking into account the *dry_run* flag. XXX see also.

spawn(*cmd*)

Invokes `distutils.util.spawn()`. This invokes an external process to run the given command. XXX see also.

mkpath(*name*[, *mode=511*])

Invokes `distutils.dir_util.mkpath()`. This creates a directory and any missing ancestor directories. XXX see also.

move_file(*src*, *dst*)

Invokes `distutils.file_util.move_file()`. Renames *src* to *dst*. XXX see also.

announce(*msg*[, *level=1*])

Write a message using `distutils.log.debug()`. XXX see also.

warn(*msg*)

Write a warning message *msg* to standard error.

debug_print(*msg*)

If the *debug* flag is set on this `CCompiler` instance, print *msg* to standard output, otherwise do nothing.

Distributing Python Modules

Previous: [10.2 distutils.compiler](#) Up: [10. API Reference](#) Next: [10.4 distutils.msvccompiler](#)

10.3 `distutils.unixccompiler` -- Unix C Compiler

This module provides the `UnixCCompiler` class, a subclass of `CCompiler` that handles the typical UNIX-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-llib`
- library search directories specified with `-Ldir`
- compile handled by `cc` (or similar) executable with `-c` option: compiles `.C` to `.O`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc -shared`

Previous: [10.2 `distutils.ccompiler`](#) Up: [10. API Reference](#) Next: [10.4 `distutils.msvccompiler`](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

10.9 distutils.archive_util -- Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

make_archive(*base_name*, *format*[, *root_dir=None*, *base_dir=None*,
verbose=0, *dry_run=0*])

Create an archive file (eg. zip or tar). *base_name* is the name of the file to create, minus any format-specific extension; *format* is the archive format: one of zip, tar, ztar, or gztar. *root_dir* is a directory that will be the root directory of the archive; ie. we typically `chdir` into *root_dir* before creating the archive. *base_dir* is the directory where we start archiving from; ie. *base_dir* will be the common prefix of all files and directories in the archive. *root_dir* and *base_dir* both default to the current directory. Returns the name of the archive file.

Warning: This should be changed to support bz2 files

make_tarball(*base_name*, *base_dir*[, *compress='gzip'*, *verbose=0*,
dry_run=0])

Create an (optional compressed) archive as a tar file from all files in and under *base_dir*. *compress* must be 'gzip' (the default), 'compress', 'bzip2', or None. Both **tar** and the compression utility named by *compress* must be on the default program search path, so this is probably UNIX-specific. The output tar file will be named *base_dir.tar*, possibly plus the appropriate compression extension (.gz, .bz2 or .Z). Return the output filename.

Warning: This should be replaced with calls to the `tarfile` module.

make_zipfile(*base_name*, *base_dir*[, *verbose=0*, *dry_run=0*])

Create a zip file from all files in and under *base_dir*. The output zip file will be named *base_dir* + .zip. Uses either the `zipfile` Python module (if

available) or the InfoZIP zip utility (if installed and found on the default search path). If neither tool is available, raises `DistutilsExecError`. Returns the name of the output zip file.

10.10 `distutils.dep_util` -- Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

`newer(source, target)`

Return true if *source* exists and is more recently modified than *target*, or if *source* exists and *target* doesn't. Return false if both exist and *target* is the same age or newer than *source*. Raise `DistutilsFileError` if *source* does not exist.

`newer_pairwise(sources, targets)`

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (*sources*, *targets*) where source is newer than target, according to the semantics of `newer()`

`newer_group(sources, target[, missing= 'error'])`

Return true if *target* is out-of-date with respect to any file listed in *sources*. In other words, if *target* exists and is newer than every file in *sources*, return false; otherwise return true. *missing* controls what we do when a source file is missing; the default ('error') is to blow up with an `OSError` from inside `os.stat()`; if it is 'ignore', we silently drop any missing source files; if it is 'newer', any missing source files make us assume that *target* is out-of-date (this is handy in "dry-run" mode: it'll make you pretend to carry out commands that wouldn't work because inputs are missing, but that doesn't matter because you're not actually going to run the commands).

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

Previous: [10.10 distutils.dep_util](#) **Up:** [10. API Reference](#) **Next:** [10.12 distutils.file_util](#)

10.11 `distutils.dir_util` -- Directory tree operations

This module provides functions for operating on directories and trees of directories.

mkpath(*name*[, *mode*=0777, *verbose*=0, *dry_run*=0])

Create a directory and any missing ancestor directories. If the directory already exists (or if *name* is the empty string, which means the current directory, which of course exists), then do nothing. Raise `DistutilsFileError` if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If *verbose* is true, print a one-line summary of each `mkdir` to `stdout`. Return the list of directories actually created.

create_tree(*base_dir*, *files*[, *mode*=0777, *verbose*=0, *dry_run*=0])

Create all the empty directories under *base_dir* needed to put *files* there. *base_dir* is just the name of a directory which doesn't necessarily exist yet; *files* is a list of filenames to be interpreted relative to *base_dir*. *base_dir* + the directory portion of every file in *files* will be created if it doesn't already exist. *mode*, *verbose* and *dry_run* flags are as for `mkpath()`.

copy_tree(*src*, *dst*[*preserve_mode*=1, *preserve_times*=1,
preserve_symlinks=0, *update*=0, *verbose*=0, *dry_run*=0])

Copy an entire directory tree *src* to a new location *dst*. Both *src* and *dst* must be directory names. If *src* is not a directory, raise `DistutilsFileError`. If *dst* does not exist, it is created with `mkpath()`. The end result of the copy is that every file in *src* is copied to *dst*, and directories under *src* are recursively copied to *dst*. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by *update* or *dry_run*: it is simply the list of all files under *src*, with the names changed to be under *dst*.

preserve_mode and *preserve_times* are the same as for `copy_file` in [distutils.file_util](#); note that they only apply to regular files, not to directories. If *preserve_symlinks* is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. *update* and *verbose* are the same as for `copy_file()`.

remove_tree(*directory*[*verbose*=0, *dry_run*=0])

Recursively remove *directory* and all files and directories underneath it. Any errors are ignored (apart from being reported to `sys.stdout` if *verbose* is true).

**** Some of this could be replaced with the shutil module? ****

10.12 distutils.file_util -- Single file operations

This module contains some utility functions for operating on individual files.

copy_file(*src*, *dst*[*preserve_mode=1*, *preserve_times=1*, *update=0*,
link=None, *verbose=0*, *dry_run=0*])

Copy file *src* to *dst*. If *dst* is a directory, then *src* is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If *preserve_mode* is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If *preserve_times* is true (the default), the last-modified and last-access times are copied as well. If *update* is true, *src* will only be copied if *dst* does not exist, or if *dst* does exist but is older than *src*.

link allows you to make hard links (using `os.link`) or symbolic links (using `os.symlink`) instead of copying: set it to 'hard' or 'sym'; if it is `None` (the default), files are copied. Don't set *link* on systems that don't support it: `copy_file()` doesn't check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple "(*dest_name*, *copied*)": *dest_name* is the actual name of the output file, and *copied* is true if the file was copied (or would have been copied, if *dry_run* true).

move_file(*src*, *dst*[*verbose*, *dry_run*])

Move file *src* to *dst*. If *dst* is a directory, the file will be moved into it with the same name; otherwise, *src* is just renamed to *dst*. Returns the new full name of the file. **Warning:** Handles cross-device moves on Unix using `copy_file()`. What about other systems???

write_file(*filename*, *contents*)

Create a file called *filename* and write *contents* (a sequence of strings without line terminators) to it.

10.13 `distutils.util` -- Miscellaneous other utility functions

This module contains other assorted bits and pieces that don't fit into any other utility module.

`get_platform()`

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by `'os.uname()'`), although the exact information included depends on the OS; eg. for IRIX the architecture isn't particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn't particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`
- `irix-5.3`
- `irix64-6.2`

For non-POSIX platforms, currently just returns `sys.platform`.

`convert_path(pathname)`

Return `'pathname'` as a name that will work on the native filesystem, i.e. split it on `'/'` and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises `ValueError` on non-UNIX-ish systems if `pathname` either starts or ends with a slash.

`change_root(new_root, pathname)`

Return `pathname` with `new_root` prepended. If `pathname` is relative, this is

equivalent to `os.path.join(new_root, pathname)` Otherwise, it requires making *pathname* relative and then joining the two, which is tricky on DOS/Windows.

check_environ()

Ensure that `os.environ` has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- HOME - user's home directory (UNIX only)
- PLAT - description of the current platform, including hardware and OS (see `get_platform()`)

subst_vars(s, local_vars)

Perform shell/Perl-style variable substitution on *s*. Every occurrence of `$` followed by a name is considered a variable, and variable is substituted by the value found in the *local_vars* dictionary, or in `os.environ` if it's not in *local_vars*. `os.environ` is first checked/augmented to guarantee that it contains certain values: see `check_environ()`. Raise `ValueError` for any variables not found in either *local_vars* or `os.environ`.

Note that this is not a fully-fledged string interpolation function. A valid `$variable` can consist only of upper and lower case letters, numbers and an underscore. No `{ }` or style quoting is available.

grok_environment_error(exc[, prefix=teX2html_deferred''error: ''])

Generate a useful error message from an `EnvironmentError` (`IOError` or `OSError`) exception object. Handles Python 1.5.1 and later styles, and does what it can to deal with exception objects that don't have a filename (which happens when the error is due to a two-file operation, such as `rename()` or `link()`). Returns the error message as a string prefixed with *prefix*.

split_quoted(s)

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and

double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

execute(*func*, *args*[, *msg=None*, *verbose=0*, *dry_run=0*])

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the *dry_run* flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the "external action" being performed), and an optional message to print.

strtobool(*val*)

Convert a string representation of truth to true (1) or false (0).

True values are y, yes, t, true, on and 1; false values are n, no, f, false, off and 0. Raises `ValueError` if *val* is anything else.

byte_compile(*py_files*[, *optimize=0*, *force=0*, *prefix=None*,
base_dir=None, *verbose=1*, *dry_run=0*, *direct=None*])

Byte-compile a collection of Python source files to either `.pyc` or `.pyo` files in the same directory. *py_files* is a list of files to compile; any files that don't end in `.py` are silently skipped. *optimize* must be one of the following:

- 0 - don't optimize (generate `.pyc`)
- 1 - normal optimization (like "python -O")
- 2 - extra optimization (like "python -OO")

If *force* is true, all files are recompiled regardless of timestamps.

The source filename encoded in each bytecode file defaults to the filenames listed in *py_files*; you can modify these with *prefix* and *basedir*. *prefix* is a string that will be stripped off of each source filename, and *base_dir* is a directory name that will be prepended (after *prefix* is stripped). You can supply either or both (or neither) of *prefix* and *base_dir*, as you wish.

If *dry_run* is true, doesn't actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard `py_compile` module, or indirectly by writing a temporary script and executing it. Normally, you should let `byte_compile()` figure out to use direct compilation or not (see the source for details). The *direct* flag is used by the script generated in indirect mode; unless you know what you're doing, leave it set to `None`.

`rfc822_escape()` (*header*)

Return a version of *header* escaped for inclusion in an [RFC 822](#) header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.

10.18 `distutils.fancy_getopt` -- Wrapper around the standard `getopt` module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have "negative aliases" -- eg. if `--quiet` is the "negative alias" of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

**** Should be replaced with `optik` (which is also now known as `optparse` in Python 2.3 and later). ****

`fancy_getopt`(*options*, *negative_opt*, *object*, *args*)

Wrapper function. *options* is a list of "(long_option, short_option, help_string)" 3-tuples as described in the constructor for `FancyGetopt`. *negative_opt* should be a dictionary mapping option names to option names, both the key and value should be in the *options* list. *object* is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). *args* is the argument list. Will use `sys.argv[1:]` if you pass `None` as *args*.

`wrap_text`(*text*, *width*)

Wraps *text* to less than *width* wide.

Warning: Should be replaced with `textwrap` (which is available in Python 2.3 and later).

`class FancyGetopt`([*option_table=None*])

The `option_table` is a list of 3-tuples: "(`long_option`, `short_option`, `help_string`)"

If an option takes an argument, its `long_option` should have '=' appended; `short_option` should just be a single character, no ':' in any case. `short_option` should be `None` if a `long_option` doesn't have a corresponding `short_option`. All option tuples must have long options.

The `FancyGetopt` class provides the following methods:

getopt([args=None, object=None])

Parse command-line options in `args`. Store as attributes on `object`.

If `args` is `None` or not supplied, uses `sys.argv[1:]`. If `object` is `None` or not supplied, creates a new `OptionDummy` instance, stores option values there, and returns a tuple "(`args`, `object`)". If `object` is supplied, it is modified in place and `getopt()` just returns `args`; in both cases, the returned `args` is a modified copy of the passed-in `args` list, which is left untouched.

get_option_order()

Returns the list of "(`option`, `value`)" tuples processed by the previous run of `getopt()`. Raises `RuntimeError` if `getopt()` hasn't been called yet.

generate_help([header=None])

Generate help text (a list of strings, one per suggested line of output) from the option table for this `FancyGetopt` object.

If supplied, prints the supplied `header` at the top of the help.

10.22 `distutils.sysconfig` -- System configuration information

The `distutils.sysconfig` module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the Makefile and configuration header that are installed with Python on UNIX systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the `distutils` package.

PREFIX

The result of `os.path.normpath(sys.prefix)`.

EXEC_PREFIX

The result of `os.path.normpath(sys.exec_prefix)`.

get_config_var(*name*)

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

get_config_vars(...)

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, `NONE` will be included for that variable.

get_config_h_filename()

Return the full path name of the configuration header. For UNIX, this will be the header generated by the **configure** script; for other platforms the header will have been supplied directly by the Python source distribution. The file

is a platform-specific text file.

get_makefile_filename()

Return the full path name of the **Makefile** used to build Python. For UNIX, this will be a file generated by the **configure** script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

get_python_inc([plat_specific[, prefix]])

Return the directory for either the general or platform-dependent C include files. If *plat_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of **PREFIX**, or as the exec-prefix instead of **EXEC_PREFIX** if *plat_specific* is true.

get_python_lib([plat_specific[, standard_lib[, prefix]])

Return the directory for either the general or platform-dependent library installation. If *plat_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of **PREFIX**, or as the exec-prefix instead of **EXEC_PREFIX** if *plat_specific* is true. If *standard_lib* is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the **distutils** package.

customize_compiler(compiler)

Do any platform-specific customization of a **distutils.ccompiler.CCompiler** instance.

This function is only needed on UNIX at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across UNIX flavors and is stored in Python's **Makefile**. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from

Python's own build procedures.

set_python_build()

Inform the `distutils.sysconfig` module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.

10.23 `distutils.text_file` -- The `TextFile` class

This module provides the `TextFile` class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

class `TextFile`([*filename*=None, *file*=None, ****options**])

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as `#` is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

`TextFile` instances are create with either *filename*, *file*, or both. `RuntimeError` is raised if both are `None`. *filename* should be a string, and *file* a file object (or something that provides `readline()` and `close()` methods). It is recommended that you supply at least *filename*, so that `TextFile` can include it in warning messages. If *file* is not supplied, `TextFile` creates its own using the `open()` built-in function.

The options are all boolean, and affect the values returned by `readline()`

option name	description	default
	strip from <code>"#"</code> to end-of-line, as well as any whitespace leading up to the <code>"#"</code> --unless it is escaped by a backslash	true

	strip leading whitespace from each line before returning it	false
	strip trailing whitespace (including line terminator!) from each line before returning it.	true
	skip lines that are empty <i>after</i> stripping comments and whitespace. (If both <code>lstrip_ws</code> and <code>rstrip_ws</code> are false, then some lines may consist of solely whitespace: these will <i>not</i> be skipped, even if <code>skip_blanks</code> is true.)	true
	if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.	false
	strip leading whitespace from lines that are joined to their predecessor; only matters if " <code>join_lines</code> and not <code>lstrip_ws</code> ")	false

Note that since `rstrip_ws` can strip the trailing newline, the semantics of `readline()` must differ from those of the builtin file object's `readline()` method! In particular, `readline()` returns `None` for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if `rstrip_ws` is true but `skip_blanks` is not.

open(*filename*)

Open a new file *filename*. This overrides any *file* or *filename* constructor arguments.

close()

Close the current file and forget everything we know about it (including the filename and the current line number).

warn(*msg*[,*line*=None])

Print (to `stderr`) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as `"lines 3-5"`. If *line* is supplied, it overrides the current line

number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

readline()

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been ``unread" with `unreadline()`). If the `join_lines` option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling `warn()` after `readline()` emits a warning about the physical line(s) just read. Returns `None` on end-of-file, since the empty string can occur if `rstrip_ws` is true but `strip_blanks` is not.

readlines()

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

unreadline(*line*)

Push *line* (a string) onto an internal buffer that will be checked by future `readline()` calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are ``unread" with `unreadline` are not subsequently re-cleansed (whitespace stripped, or whatever) when read with `readline`. If multiple calls are made to `unreadline` before a call to `readline`, the lines will be returned most in most recent first order.

10.25 `distutils.cmd` -- Abstract base class for Distutils commands

This module supplies the abstract base class `Command`.

class `Command`(*dist*)

Abstract base class for defining command classes, the ``worker bees" of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called *options*. The options are declared in `initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed -- hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument *dist*, a `Distribution` instance.

10.45

`distutils.command.register --` Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in [PEP 301](#).

Distributing Python Modules

[Module Index](#)

10.46 Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you'd copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it's implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `Command` must define the following methods.

`initialize_options()` (S)

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

`finalize_options()`

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to code option dependencies: if *foo* depends on *bar*, then it is safe to set *foo* from *bar* as long as *foo* still has the same value it was assigned in `initialize_options()`.

`run()`

A command's raison d'etre: carry out the action it exists to perform, controlled by the options initialized in `initialize_options()`,

customized by other commands, the setup script, the command-line, and config files, and finalized in `finalize_options()`. All terminal output and filesystem interaction should be done by `run()`.

`sub_commands` formalizes the notion of a "family" of commands, eg. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines `sub_commands` as a class attribute; it's a list of 2-tuples "(`command_name`, `predicate`)", with `command_name` a string and `predicate` an unbound method, a string or None. `predicate` is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (Eg. we `install_headers` is only applicable if we have any C header files to install.) If `predicate` is None, that command is always applicable.

`sub_commands` is usually defined at the *end* of a class, because predicates can be unbound methods, so they must already have been defined. The canonical example is the `install` command.

This article explains the new features in Python 2.4, released in December 2004.

Python 2.4 is a medium-sized release. It doesn't introduce as many changes as the radical Python 2.2, but introduces more features than the conservative 2.3 release. The most significant new language features are function decorators and generator expressions; most other changes are to the standard library.

According to the CVS change logs, there were 481 patches applied and 502 bugs fixed between Python 2.3 and 2.4. Both figures are likely to be underestimates.

This article doesn't attempt to provide a complete specification of every single new feature, but instead provides a brief introduction to each feature. For full details, you should refer to the documentation for Python 2.4, such as the [Python](#)

[Library Reference](#) and the [Python Reference Manual](#). Often you will be referred to the PEP for a particular new feature for explanations of the implementation and design rationale.

Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the [Python Bug Tracker](#) at [SourceForge](#). If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, [comp.lang.python](#), or the [Python mailing list](#) (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.

Abstract:

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python's elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, <http://www.python.org/>, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see the [Python Library](#)

[Reference](#) document. The [Python Reference Manual](#) gives a more formal definition of the language. To write extensions in C or C++, read [Extending and Embedding the Python Interpreter](#) and [Python/C API Reference](#). There are also several books covering Python in depth.

This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python's most noteworthy features, and will give you a good idea of the language's flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in the [Python Library Reference](#).

Python Tutorial, 11 October 2006, Release 2.4.4c1

This document was generated using the [LaTeX2HTML](#) translator.

[LaTeX2HTML](#) is Copyright © 1993, 1994, 1995, 1996, 1997, [Nikos Drakos](#), Computer Based Learning Unit, University of Leeds, and Copyright © 1997, 1998, [Ross Moore](#), Mathematics Department, Macquarie University, Sydney.

The application of [LaTeX2HTML](#) to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.

Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the [Python Bug Tracker](#) at [SourceForge](#). If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, [comp.lang.python](#), or the [Python mailing list](#) (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

2.3.6.1 String Methods

These are the string methods which both 8-bit strings and Unicode objects support:

capitalize()

Return a copy of the string with only its first character capitalized.

For 8-bit strings, this method is locale-dependent.

center(*width*[, *fillchar*])

Return centered in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). Changed in version 2.4: Support for the *fillchar* argument.

count(*sub*[, *start*[, *end*]])

Return the number of occurrences of substring *sub* in string S [*start*:*end*]. Optional arguments *start* and *end* are interpreted as in slice notation.

decode([*encoding*[, *errors*]])

Decodes the string using the codec registered for *encoding*. *encoding* defaults to the default string encoding. *errors* may be given to set a different error handling scheme. The default is 'strict', meaning that encoding errors raise `UnicodeError`. Other possible values are 'ignore', 'replace' and any other name registered via `codecs.register_error`, see section [4.9.1](#). New in version 2.2. Changed in version 2.3: Support for other error handling schemes added.

encode([*encoding*[,*errors*]])

Return an encoded version of the string. Default encoding is the current default string encoding. *errors* may be given to set a different error handling scheme. The default for *errors* is 'strict', meaning that encoding errors raise a `UnicodeError`. Other possible values are

'ignore', 'replace', 'xmlcharrefreplace', 'backslashreplace' and any other name registered via `codecs.register_error`, see section [4.9.1](#). For a list of possible encodings, see section [4.9.2](#). New in version 2.0. Changed in version 2.3: Support for 'xmlcharrefreplace' and 'backslashreplace' and other error handling schemes added.

endswith(*suffix*[, *start*[, *end*]])

Return `True` if the string ends with the specified *suffix*, otherwise return `False`. With optional *start*, test beginning at that position. With optional *end*, stop comparing at that position.

expandtabs([*tabsize*])

Return a copy of the string where all tab characters are expanded using spaces. If *tabsize* is not given, a tab size of 8 characters is assumed.

find(*sub*[, *start*[, *end*]])

Return the lowest index in the string where substring *sub* is found, such that *sub* is contained in the range [*start*, *end*]. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` if *sub* is not found.

index(*sub*[, *start*[, *end*]])

Like `find()`, but raise `ValueError` when the substring is not found.

isalnum()

Return true if all characters in the string are alphanumeric and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

isalpha()

Return true if all characters in the string are alphabetic and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

isdigit()

Return true if all characters in the string are digits and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

islower()

Return true if all cased characters in the string are lowercase and there is at least one cased character, false otherwise.

For 8-bit strings, this method is locale-dependent.

isspace()

Return true if there are only whitespace characters in the string and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

istitle()

Return true if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. Return false otherwise.

For 8-bit strings, this method is locale-dependent.

isupper()

Return true if all cased characters in the string are uppercase and there is at least one cased character, false otherwise.

For 8-bit strings, this method is locale-dependent.

join(*seq*)

Return a string which is the concatenation of the strings in the sequence *seq*. The separator between elements is the string providing this method.

ljust(*width*[, *fillchar*])

Return the string left justified in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). The original string is

returned if *width* is less than `len(s)`. Changed in version 2.4: Support for the *fillchar* argument.

lower()

Return a copy of the string converted to lowercase.

For 8-bit strings, this method is locale-dependent.

lstrip([chars])

Return a copy of the string with leading characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `NONE`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a prefix; rather, all combinations of its values are stripped:

```
>>> '  spacious  '.lstrip()
'spacious  '
>>> 'www.example.com'.lstrip('cmowz.')
'example.com'
```

Changed in version 2.2.2: Support for the *chars* argument.

replace(old, new[, count])

Return a copy of the string with all occurrences of substring *old* replaced by *new*. If the optional argument *count* is given, only the first *count* occurrences are replaced.

rfind(sub [,start [,end]])

Return the highest index in the string where substring *sub* is found, such that *sub* is contained within `s[start,end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` on failure.

rindex(sub[, start[, end]])

Like `rfind()` but raises `ValueError` when the substring *sub* is not found.

rjust(width[, fillchar])

Return the string right justified in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). The original string is

returned if *width* is less than `len(s)`. Changed in version 2.4: Support for the *fillchar* argument.

rsplit([*sep* [,*maxsplit*]])

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done, the *rightmost* ones. If *sep* is not specified or `None`, any whitespace string is a separator. Except for splitting from the right, `rsplit()` behaves like `split()` which is described in detail below. New in version 2.4.

rstrip([*chars*])

Return a copy of the string with trailing characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a suffix; rather, all combinations of its values are stripped:

```
>>> '  spacious  '.rstrip()
'  spacious'
>>> 'mississippi'.rstrip('ipz')
'mississ'
```

Changed in version 2.2.2: Support for the *chars* argument.

split([*sep* [,*maxsplit*]])

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done. (thus, the list will have at most *maxsplit*+1 elements). If *maxsplit* is not specified, then there is no limit on the number of splits (all possible splits are made). Consecutive delimiters are not grouped together and are deemed to delimit empty strings (for example, `"'1,,2'.split(',')"` returns `"['1', '', '2']"`). The *sep* argument may consist of multiple characters (for example, `"'1,2,3'.split(',')"` returns `"['1', '2', '3']"`). Splitting an empty string with a specified separator returns `"['']"`.

If *sep* is not specified or is `None`, a different splitting algorithm is applied. First, whitespace characters (spaces, tabs, newlines, returns, and formfeeds) are stripped from both ends. Then, words are separated by arbitrary length strings of whitespace characters. Consecutive whitespace delimiters are

treated as a single delimiter ("`'1 2 3'.split()`" returns "`['1', '2', '3']`"). Splitting an empty string or a string consisting of just whitespace returns an empty list.

splitlines([*keepends*])

Return a list of the lines in the string, breaking at line boundaries. Line breaks are not included in the resulting list unless *keepends* is given and true.

startswith(*prefix*[, *start*[, *end*]])

Return `True` if string starts with the *prefix*, otherwise return `False`. With optional *start*, test string beginning at that position. With optional *end*, stop comparing string at that position.

strip([*chars*])

Return a copy of the string with the leading and trailing characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `NONE`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a prefix or suffix; rather, all combinations of its values are stripped:

```
>>> '  spacious  '.strip()
'spacious'
>>> 'www.example.com'.strip('cmowz.')
'example'
```

Changed in version 2.2.2: Support for the *chars* argument.

swapcase()

Return a copy of the string with uppercase characters converted to lowercase and vice versa.

For 8-bit strings, this method is locale-dependent.

title()

Return a titlecased version of the string: words start with uppercase characters, all remaining cased characters are lowercase.

For 8-bit strings, this method is locale-dependent.

translate(*table*[, *deletechars*])

Return a copy of the string where all characters occurring in the optional argument *deletechars* are removed, and the remaining characters have been mapped through the given translation table, which must be a string of length 256.

For Unicode objects, the `translate()` method does not accept the optional *deletechars* argument. Instead, it returns a copy of the *s* where all characters have been mapped through the given translation table which must be a mapping of Unicode ordinals to Unicode ordinals, Unicode strings or `None`. Unmapped characters are left untouched. Characters mapped to `None` are deleted. Note, a more flexible approach is to create a custom character mapping codec using the [codecs](#) module (see `encodings.cp1251` for an example).

upper()

Return a copy of the string converted to uppercase.

For 8-bit strings, this method is locale-dependent.

zfill(*width*)

Return the numeric string left filled with zeros in a string of length *width*. The original string is returned if *width* is less than `len(s)`. New in version 2.2.2.

2.3.6.2 String Formatting Operations

String and Unicode objects have one unique built-in operation: the % operator (modulo). This is also known as the string *formatting* or *interpolation* operator. Given *format* % *values* (where *format* is a string or Unicode object), % conversion specifications in *format* are replaced with zero or more elements of *values*. The effect is similar to the using `printf()` in the C language. If *format* is a Unicode object, or if any of the objects being converted using the %s conversion are Unicode objects, the result will also be a Unicode object.

If *format* requires a single argument, *values* may be a single non-tuple object. [2.8](#) Otherwise, *values* must be a tuple with exactly the number of items specified by the format string, or a single mapping object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The "%" character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, (*somename*)).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an "*" (asterisk), the actual width is read from the next element of the tuple in *values*, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a "." (dot) followed by the precision. If specified as "*" (an asterisk), the actual width is read from the next element of the tuple in *values*, and the value to convert comes after the precision.
6. Length modifier (optional).
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the string *must* include a parenthesised mapping key into that dictionary inserted immediately after the "%" character. The mapping key selects the value to be formatted from the mapping. For example:

```
>>> print '%(language)s has %(#)03d quote types.' % \
        {'language': "Python", "#": 2}
Python has 002 quote types.
```

In this case no * specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:

Flag	Meaning
#	The value conversion will use the "alternate form" (where defined below).
0	The conversion will be zero padded for numeric values.
-	The converted value is left adjusted (overrides the "0" conversion if both are given).
(a space)	A blank should be left before a positive number (or empty string) produced by a signed conversion.
+	A sign character ("+" or "-") will precede the conversion (overrides a "space" flag).

A length modifier (h, l, or L) may be present, but is ignored as it is not necessary for Python.

The conversion types are:

Conversion	Meaning	Notes
d	Signed integer decimal.	
i	Signed integer decimal.	
o	Unsigned octal.	(1)
u	Unsigned decimal.	
x	Unsigned hexadecimal (lowercase).	(2)
X	Unsigned hexadecimal (uppercase).	(2)
e	Floating point exponential format (lowercase).	
E	Floating point exponential format (uppercase).	
f	Floating point decimal format.	
F	Floating point decimal format.	
g	Same as "e" if exponent is greater than -4 or less than	

	precision, "f" otherwise.	
G	Same as "E" if exponent is greater than -4 or less than precision, "F" otherwise.	
c	Single character (accepts integer or single character string).	
r	String (converts any python object using <code>repr()</code>).	(3)
s	String (converts any python object using <code>str()</code>).	(4)
%	No argument is converted, results in a "%" character in the result.	

Notes:

(1)

The alternate form causes a leading zero ("0") to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

(2)

The alternate form causes a leading '0x' or '0X' (depending on whether the "x" or "X" format was used) to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

(3)

The %r conversion was added in Python 2.0.

(4)

If the object or format provided is a `unicode` string, the resulting string will also be `unicode`.

Since Python strings have an explicit length, %S conversions do not assume that '\0' is the end of the string.

For safety reasons, floating point precisions are clipped to 50; %f conversions for numbers whose absolute value is over 1e25 are replaced by %g conversions. [2.9](#) All other errors raise exceptions.

Additional string operations are defined in standard modules [string](#) and [re](#).

Footnotes

... object.[2.8](#)

To format only a tuple you should therefore provide a singleton tuple whose only element is the tuple to be formatted.

... conversions.[2.9](#)

These numbers are fairly arbitrary. They are intended to avoid printing endless strings of meaningless digits without hampering correct use and without having to know the exact precision of floating point values on a particular machine.

Abstract:

Python is an extensible, interpreted, object-oriented programming language. It supports a wide range of applications, from simple text processing scripts to interactive Web browsers.

While the [Python Reference Manual](#) describes the exact syntax and semantics of the language, it does not describe the standard library that is distributed with the language, and which greatly enhances its immediate usability. This library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs.

This library reference manual documents Python's standard library, as well as many optional library modules (which may or may not be available, depending on whether the underlying platform supports them and on the configuration choices made at compile time). It also documents the standard types of the language and its built-in functions and exceptions, many of which are not or incompletely documented in the Reference Manual.

This manual assumes basic knowledge about the Python language. For an

informal introduction to Python, see the [Python Tutorial](#); the [Python Reference Manual](#) remains the highest authority on syntactic and semantic questions. Finally, the manual entitled [Extending and Embedding the Python Interpreter](#) describes how to add new extensions to Python and how to embed it in other applications.

About this document ...

Python Library Reference, 11 October 2006, Release 2.4.4c1

This document was generated using the [LaTeX2HTML](#) translator.

[LaTeX2HTML](#) is Copyright © 1993, 1994, 1995, 1996, 1997, [Nikos Drakos](#), Computer Based Learning Unit, University of Leeds, and Copyright © 1997, 1998, [Ross Moore](#), Mathematics Department, Macquarie University, Sydney.

The application of [LaTeX2HTML](#) to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.

Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the [Python Bug Tracker](#) at [SourceForge](#). If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, [comp.lang.python](#), or the [Python mailing list](#) (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.

2.3.4.1 Bit-string Operations on Integer Types

Plain and long integer types support additional operations that make sense only for bit-strings. Negative numbers are treated as their 2's complement value (for long integers, this assumes a sufficiently large number of bits that no overflow occurs during the operation).

The priorities of the binary bit-wise operations are all lower than the numeric operations and higher than the comparisons; the unary operation "~" has the same priority as the other unary numeric operations ("+" and "-").

This table lists the bit-string operations sorted in ascending priority (operations in the same box have the same priority):

Operation	Result	Notes
$x \mid y$	bitwise <i>or</i> of x and y	
$x \wedge y$	bitwise <i>exclusive or</i> of x and y	
$x \& y$	bitwise <i>and</i> of x and y	
$x \ll n$	x shifted left by n bits	(1), (2)
$x \gg n$	x shifted right by n bits	(1), (3)
$\sim x$	the bits of x inverted	

Notes:

- (1) Negative shift counts are illegal and cause a `ValueError` to be raised.
 - (2) A left shift by n bits is equivalent to multiplication by `pow(2, n)` without overflow check.
 - (3) A right shift by n bits is equivalent to division by `pow(2, n)` without overflow check.
-
-

Next: [2.3.6.4 Mutable Sequence Types](#)

2.3.6.3 xrange Type

The `xrange` type is an immutable sequence which is commonly used for looping. The advantage of the `xrange` type is that an `xrange` object will always take the same amount of memory, no matter the size of the range it represents. There are no consistent performance advantages.

`XRange` objects have very little behavior: they only support indexing, iteration, and the `len()` function.

Next: [2.3.6.4 Mutable Sequence Types](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

2.3.6.4 Mutable Sequence Types

List objects support additional operations that allow in-place modification of the object. Other mutable sequence types (when added to the language) should also support these operations. Strings and tuples are immutable sequence types: such objects cannot be modified once created. The following operations are defined on mutable sequence types (where x is an arbitrary object):

Operation	Result	Notes
<code>s[i] = x</code>	item i of s is replaced by x	
<code>s[i:j] = t</code>	slice of s from i to j is replaced by t	
<code>del s[i:j]</code>	same as <code>s[i:j] = []</code>	
<code>s[i:j:k] = t</code>	the elements of <code>s[i:j:k]</code> are replaced by those of t	(1)
<code>del s[i:j:k]</code>	removes the elements of <code>s[i:j:k]</code> from the list	
<code>s.append(x)</code>	same as <code>s[len(s):len(s)] = [x]</code>	(2)
<code>s.extend(x)</code>	same as <code>s[len(s):len(s)] = x</code>	(3)
<code>s.count(x)</code>	return number of i 's for which <code>s[i] == x</code>	
<code>s.index(x[, i[, j]])</code>	return smallest k such that <code>s[k] == x</code> and $i \leq k < j$	(4)
<code>s.insert(i, x)</code>	same as <code>s[i:i] = [x]</code>	(5)
<code>s.pop([i])</code>	same as <code>x = s[i]; del s[i]; return x</code>	(6)
<code>s.remove(x)</code>	same as <code>del s[s.index(x)]</code>	(4)
<code>s.reverse()</code>	reverses the items of s in place	(7)
<code>s.sort([cmp[, key[, reverse]])</code>	sort the items of s in place	(7), (8), (9), (10)

Notes:

- (1) *t* must have the same length as the slice it is replacing.
- (2) The C implementation of Python has historically accepted multiple parameters and implicitly joined them into a tuple; this no longer works in Python 2.0. Use of this misfeature has been deprecated since Python 1.4.
- (3) *x* can be any iterable object.
- (4) Raises `ValueError` when *x* is not found in *s*. When a negative index is passed as the second or third parameter to the `index()` method, the list length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices. Changed in version 2.3: Previously, `index()` didn't have arguments for specifying start and stop positions.
- (5) When a negative index is passed as the first parameter to the `insert()` method, the list length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices. Changed in version 2.3: Previously, all negative indices were truncated to zero.
- (6) The `pop()` method is only supported by the list and array types. The optional argument *i* defaults to `-1`, so that by default the last item is removed and returned.
- (7) The `sort()` and `reverse()` methods modify the list in place for economy of space when sorting or reversing a large list. To remind you that they operate by side effect, they don't return the sorted or reversed list.
- (8) The `sort()` method takes optional arguments for controlling the comparisons.

cmp specifies a custom comparison function of two arguments (list items)

which should return a negative, zero or positive number depending on whether the first argument is considered smaller than, equal to, or larger than the second argument: "`cmp=lambda x,y: cmp(x.lower(), y.lower())`"

`key` specifies a function of one argument that is used to extract a comparison key from each list element: "`key=str.lower`"

`reverse` is a boolean value. If set to `True`, then the list elements are sorted as if each comparison were reversed.

In general, the `key` and `reverse` conversion processes are much faster than specifying an equivalent `cmp` function. This is because `cmp` is called multiple times for each list element while `key` and `reverse` touch each element only once.

Changed in version 2.3: Support for `NONE` as an equivalent to omitting `cmp` was added.

Changed in version 2.4: Support for `key` and `reverse` was added.

(9)

Starting with Python 2.3, the `sort()` method is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal -- this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).

(10)

While a list is being sorted, the effect of attempting to mutate, or even inspect, the list is undefined. The C implementation of Python 2.3 and newer makes the list appear empty for the duration, and raises `ValueError` if it can detect that the list has been mutated during a sort.

2.3.10.1 Modules

The only special operation on a module is attribute access: `m.name`, where `m` is a module and `name` accesses a name defined in `m`'s symbol table. Module attributes can be assigned to. (Note that the `import` statement is not, strictly speaking, an operation on a module object; `import foo` does not require a module object named `foo` to exist, rather it requires an (external) *definition* for a module named `foo` somewhere.)

A special member of every module is `__dict__`. This is the dictionary containing the module's symbol table. Modifying this dictionary will actually change the module's symbol table, but direct assignment to the `__dict__` attribute is not possible (you can write `m.__dict__['a'] = 1`, which defines `m.a` to be 1, but you can't write `m.__dict__ = {}`). Modifying `__dict__` directly is not recommended.

Modules built into the interpreter are written like this: `<module 'sys' (built-in)>`. If loaded from a file, they are written as `<module 'os' from '/usr/local/lib/python2.4/os.pyc'>`.

2.3.10.3 Functions

Function objects are created by function definitions. The only operation on a function object is to call it: *func(argument-list)*.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

See the [Python Reference Manual](#) for more information.

See [About this document...](#) for information on suggesting changes.

2.3.10.4 Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as `append()` on lists) and class instance methods. Built-in methods are described with the types that support them.

The implementation adds two special read-only attributes to class instance methods: `m.im_self` is the object on which the method operates, and `m.im_func` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.im_func(m.im_self, arg-1, arg-2, ..., arg-n)`.

Class instance methods are either *bound* or *unbound*, referring to whether the method was accessed through an instance or a class, respectively. When a method is unbound, its `im_self` attribute will be `None` and if called, an explicit `self` object must be passed as the first argument. In this case, `self` must be an instance of the unbound method's class (or a subclass of that class), otherwise a `TypeError` is raised.

Like function objects, methods objects support getting arbitrary attributes. However, since method attributes are actually stored on the underlying function object (`meth.im_func`), setting method attributes on either bound or unbound methods is disallowed. Attempting to set a method attribute results in a `TypeError` being raised. In order to set a method attribute, you need to explicitly set it on the underlying function object:

```
class C:
    def method(self):
        pass

c = C()
c.method.im_func.whoami = 'my name is c'
```

See the [Python Reference Manual](#) for more information.

Previous: [2.3.10.3 Functions](#) **Up:** [2.3.10 Other Built-in Types](#) **Next:** [2.3.10.5 Code Objects](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

Previous: [2.3.10.4 Methods](#) Up: [2.3.10 Other Built-in Types](#) Next: [2.3.10.6 Type Objects](#)

2.3.10.5 Code Objects

Code objects are used by the implementation to represent ``pseudo-compiled'' executable Python code such as a function body. They differ from function objects because they don't contain a reference to their global execution environment. Code objects are returned by the built-in `compile()` function and can be extracted from function objects through their `func_code` attribute.

A code object can be executed or evaluated by passing it (instead of a source string) to the `EXEC` statement or the built-in `eval()` function.

See the [Python Reference Manual](#) for more information.

Previous: [2.3.10.5 Code Objects](#) Up: [2.3.10 Other Built-in Types](#) Next:
[2.3.10.7 The Null Object](#)

2.3.10.6 Type Objects

Type objects represent the various object types. An object's type is accessed by the built-in function `type()`. There are no special operations on types. The standard module [types](#) defines names for all standard built-in types.

Types are written like this: `<type 'int'>`.

2.3.10.9 Boolean Values

Boolean values are the two constant objects `False` and `True`. They are used to represent truth values (although other values can also be considered false or true). In numeric contexts (for example when used as the argument to an arithmetic operator), they behave like the integers 0 and 1, respectively. The built-in function `bool()` can be used to cast any value to a Boolean, if the value can be interpreted as a truth value (see section Truth Value Testing above).

They are written as `False` and `True`, respectively.

3.14.5.1 Pickling and unpickling normal class instances

When a pickled class instance is unpickled, its `__init__()` method is normally *not* invoked. If it is desirable that the `__init__()` method be called on unpickling, an old-style class can define a method `__getinitargs__()`, which should return a *tuple* containing the arguments to be passed to the class constructor (i.e. `__init__()`). The `__getinitargs__()` method is called at pickle time; the tuple it returns is incorporated in the pickle for the instance.

New-style types can provide a `__getnewargs__()` method that is used for protocol 2. Implementing this method is needed if the type establishes some internal invariants when the instance is created, or if the memory allocation is affected by the values passed to the `__new__()` method for the type (as it is for tuples and strings). Instances of a new-style type `C` are created using

```
obj = C.__new__(C, *args)
```

where `args` is the result of calling `__getnewargs__()` on the original object; if there is no `__getnewargs__()`, an empty tuple is assumed.

Classes can further influence how their instances are pickled; if the class defines the method `__getstate__()`, it is called and the return state is pickled as the contents for the instance, instead of the contents of the instance's dictionary. If there is no `__getstate__()` method, the instance's `__dict__` is pickled.

Upon unpickling, if the class also defines the method `__setstate__()`, it is called with the unpickled state.^{[3.6](#)} If there is no `__setstate__()` method, the pickled state must be a dictionary and its items are assigned to the new instance's dictionary. If a class defines both `__getstate__()` and `__setstate__()`, the state object needn't be a dictionary and these methods can do what they want.^{[3.7](#)}

Warning: For new-style classes, if `__getstate__()`

returns a false value, the `__setstate__()` method will not be called.

Footnotes

... state. [3.6](#)

These methods can also be used to implement copying class instances.

... want. [3.7](#)

This protocol is also used by the shallow and deep copying operations defined in the [copy](#) module.

[3.14.5.2 Pickling and unpickling](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

3.14.5.2 Pickling and unpickling extension types

When the `Pickler` encounters an object of a type it knows nothing about -- such as an extension type -- it looks in two places for a hint of how to pickle it. One alternative is for the object to implement a `__reduce__()` method. If provided, at pickling time `__reduce__()` will be called with no arguments, and it must return either a string or a tuple.

If a string is returned, it names a global variable whose contents are pickled as normal. The string returned by `__reduce__` should be the object's local name relative to its module; the pickle module searches the module namespace to determine the object's module.

When a tuple is returned, it must be between two and five elements long. Optional elements can either be omitted, or `NONE` can be provided as their value. The semantics of each element are:

- A callable object that will be called to create the initial version of the object. The next element of the tuple will provide arguments for this callable, and later elements provide additional state information that will subsequently be used to fully reconstruct the pickled data.

In the unpickling environment this object must be either a class, a callable registered as a "safe constructor" (see below), or it must have an attribute `__safe_for_unpickling__` with a true value. Otherwise, an `UnpicklingError` will be raised in the unpickling environment. Note that as usual, the callable itself is pickled by name.

- A tuple of arguments for the callable object, or `None`.
Deprecated since release 2.3. If this item is `None`, then instead of calling the callable directly, its `__basicnew__()` method is called without arguments; this method should also return the unpickled object. Providing `None` is deprecated, however; return a tuple of arguments instead.
- Optionally, the object's state, which will be passed to the object's

`__setstate__()` method as described in section [3.14.5](#). If the object has no `__setstate__()` method, then, as above, the value must be a dictionary and it will be added to the object's `__dict__`.

- Optionally, an iterator (and not a sequence) yielding successive list items. These list items will be pickled, and appended to the object using either `obj.append(item)` or `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as they have `append()` and `extend()` methods with the appropriate signature. (Whether `append()` or `extend()` is used depends on which pickle protocol version is used as well as the number of items to append, so both must be supported.)
- Optionally, an iterator (not a sequence) yielding successive dictionary items, which should be tuples of the form `(key, value)`. These items will be pickled and stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they implement `__setitem__`.

It is sometimes useful to know the protocol version when implementing `__reduce__`. This can be done by implementing a method named `__reduce_ex__` instead of `__reduce__`. `__reduce_ex__`, when it exists, is called in preference over `__reduce__` (you may still provide `__reduce__` for backwards compatibility). The `__reduce_ex__` method will be called with a single integer argument, the protocol version.

The `object` class implements both `__reduce__` and `__reduce_ex__`; however, if a subclass overrides `__reduce__` but not `__reduce_ex__`, the `__reduce_ex__` implementation detects this and calls `__reduce__`.

An alternative to implementing a `__reduce__()` method on the object to be pickled, is to register the callable with the [copy_reg](#) module. This module provides a way for programs to register "reduction functions" and constructors for user-defined types. Reduction functions have the same semantics and interface as the `__reduce__()` method described above, except that they are called with a single argument, the object to be pickled.

The registered constructor is deemed a "safe constructor" for purposes of unpickling as described above.

3.14.5.3 Pickling and unpickling external objects

For the benefit of object persistence, the `pickle` module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a ``persistent id'', which is just an arbitrary string of printable ASCII characters. The resolution of such names is not defined by the `pickle` module; it will delegate this resolution to user defined functions on the pickler and unpickler. [3.8](#)

To define external persistent id resolution, you need to set the `persistent_id` attribute of the pickler object and the `persistent_load` attribute of the unpickler object.

To pickle objects that have an external persistent id, the pickler must have a custom `persistent_id()` method that takes an object as an argument and returns either `None` or the persistent id for that object. When `None` is returned, the pickler simply pickles the object as normal. When a persistent id string is returned, the pickler will pickle that string, along with a marker so that the unpickler will recognize the string as a persistent id.

To unpickle external objects, the unpickler must have a custom `persistent_load()` function that takes a persistent id string and returns the referenced object.

Here's a silly example that *might* shed more light:

```
import pickle
from cStringIO import StringIO

src = StringIO()
p = pickle.Pickler(src)

def persistent_id(obj):
    if hasattr(obj, 'x'):
        return 'the value %d' % obj.x
    else:
        return None

p.persistent_id = persistent_id
```

```

class Integer:
    def __init__(self, x):
        self.x = x
    def __str__(self):
        return 'My name is integer %d' % self.x

i = Integer(7)
print i
p.dump(i)

datastream = src.getvalue()
print repr(datastream)
dst = StringIO(datastream)

up = pickle.Unpickler(dst)

class FancyInteger(Integer):
    def __str__(self):
        return 'I am the integer %d' % self.x

def persistent_load(persid):
    if persid.startswith('the value '):
        value = int(persid.split()[2])
        return FancyInteger(value)
    else:
        raise pickle.UnpicklingError, 'Invalid persistent id'

up.persistent_load = persistent_load

j = up.load()
print j

```

In the `cPickle` module, the unpickler's `persistent_load` attribute can also be set to a Python list, in which case, when the unpickler reaches a persistent id, the persistent id string will simply be appended to this list. This functionality exists so that a pickle data stream can be "sniffed" for object references without actually instantiating all the objects in a pickle. [3.9](#) Setting `persistent_load` to a list is usually used in conjunction with the `noload()` method on the Unpickler.

Footnotes

... unpickler. [3.8](#)

The actual mechanism for associating these user defined functions is

slightly different for `pickle` and `cPickle`. The description given here works the same for both implementations. Users of the `pickle` module could also use subclassing to effect the same results, overriding the `persistent_id()` and `persistent_load()` methods in the derived classes.

... [pickle.3.9](#)

We'll leave you with the image of Guido and Jim sitting around sniffing pickles in their living rooms.

4.9.1.1 Codec Objects

The Codec class defines these methods which also define the function interfaces of the stateless encoder and decoder:

encode(*input*[, *errors*])

Encodes the object *input* and returns a tuple (output object, length consumed). While codecs are not restricted to use with Unicode, in a Unicode context, encoding converts a Unicode object to a plain string using a particular character set encoding (e.g., `cp1252` or `iso-8859-1`).

errors defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the `Codec` instance. Use `StreamCodec` for codecs which have to keep state in order to make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

decode(*input*[, *errors*])

Decodes the object *input* and returns a tuple (output object, length consumed). In a Unicode context, decoding converts a plain string encoded using a particular character set encoding to a Unicode object.

input must be an object which provides the `bf_getreadbuf` buffer slot. Python strings, buffer objects and memory mapped files are examples of objects providing this slot.

errors defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the `Codec` instance. Use `StreamCodec` for codecs which have to keep state in order to make

encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The `StreamWriter` and `StreamReader` classes provide generic working interfaces which can be used to implement new encodings submodules very easily. See `encodings.utf_8` for an example of how this is done.

Python Library Reference

Previous: [4.9.1 Codec Base Classes](#) Up: [4.9.1 Codec Base Classes](#) Next:
[4.9.1.2 StreamWriter Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

4.9.1.2 StreamWriter Objects

The `StreamWriter` class is a subclass of `Codec` and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

class StreamWriter(*stream*[, *errors*])

Constructor for a `StreamWriter` instance.

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

stream must be a file-like object open for writing (binary) data.

The `StreamWriter` may implement different error handling schemes by providing the *errors* keyword argument. These parameters are predefined:

- 'strict' Raise `ValueError` (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamWriter` object.

The set of allowed values for the *errors* argument can be extended with `register_error()`.

write(*object*)

Writes the object's contents encoded to the stream.

writelines() (*list*)

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).

reset()

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state, that allows appending of new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the `StreamWriter` must also inherit all other methods and attributes from the underlying stream.

Previous: 4.9.1.1 Codec Objects	Up: 4.9.1 Codec Base Classes	Next: 4.9.1.3 StreamReader Objects		

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

4.9.1.3 StreamReader Objects

The `StreamReader` class is a subclass of `Codec` and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

class `StreamReader`(*stream*[, *errors*])

Constructor for a `StreamReader` instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

stream must be a file-like object open for reading binary data.

The `StreamReader` may implement different error handling schemes by providing the *errors* keyword argument. These parameters are defined:

- 'strict' Raise `ValueError` (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamReader` object.

The set of allowed values for the *errors* argument can be extended with `register_error()`.

`read`([*size*[, *chars*, [*firstline*]])

Decodes data from the stream and returns the resulting object.

chars indicates the number of characters to read from the stream. `read()` will never return more than *chars* characters, but it might return less, if there are not enough characters available.

size indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. *size* is intended to prevent having to decode huge files in one step.

firstline indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given *size*, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

Changed in version 2.4: *chars* argument added. Changed in version 2.4.2: *firstline* argument added.

readline([size[, keepends]])

Read one line from the input stream and return the decoded data.

size, if given, is passed as *size* argument to the stream's `readline()` method.

If *keepends* is false line-endings will be stripped from the lines returned.

Changed in version 2.4: *keepends* argument added.

readlines([sizehint[, keepends]])

Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if *keepends* is true.

sizehint, if given, is passed as the *size* argument to the stream's `read()` method.

reset()

Resets the codec buffers used for keeping state.

Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the `StreamReader` must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.

Previous: [4.9.1.2 StreamWriter Objects](#) Up: [4.9.1 Codec Base Classes](#) Next: [4.9.1.4 StreamReaderWriter Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

4.9.1.4 StreamReaderWriter Objects

The `StreamReaderWriter` allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

class `StreamReaderWriter`(*stream, Reader, Writer, errors*)

Creates a `StreamReaderWriter` instance. *stream* must be a file-like object. *Reader* and *Writer* must be factory functions or classes providing the `StreamReader` and `StreamWriter` interface resp. Error handling is done in the same way as defined for the stream readers and writers.

`StreamReaderWriter` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.

4.9.1.5 StreamRecoder Objects

The `StreamRecoder` provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

class `StreamRecoder`(*stream*, *encode*, *decode*, *Reader*, *Writer*, *errors*)

Creates a `StreamRecoder` instance which implements a two-way conversion: *encode* and *decode* work on the frontend (the input to `read()` and output of `write()`) while *Reader* and *Writer* work on the backend (reading and writing to the stream).

You can use these objects to do transparent direct recordings from e.g. Latin-1 to UTF-8 and back.

stream must be a file-like object.

encode, *decode* must adhere to the `Codec` interface. *Reader*, *Writer* must be factory functions or classes providing objects of the `StreamReader` and `StreamWriter` interface respectively.

encode and *decode* are needed for the frontend translation, *Reader* and *Writer* for the backend translation. The intermediate format used is determined by the two sets of codecs, e.g. the Unicode codecs will use Unicode as the intermediate encoding.

Error handling is done in the same way as defined for the stream readers and writers.

`StreamRecoder` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.

Previous: [5.2.3 How It Works](#) Up: [5.2.3 How It Works](#) Next: [5.2.3.2 How are Docstring](#)

5.2.3.1 Which Docstrings Are Examined?

The module docstring, and all function, class and method docstrings are searched. Objects imported into the module are not searched.

In addition, if `M.__test__` exists and "is true", it must be a dict, and each entry maps a (string) name to a function object, class object, or string. Function and class object docstrings found from `M.__test__` are searched, and strings are treated as if they were docstrings. In output, a key `K` in `M.__test__` appears with name

`<name of M>.__test__.K`

Any classes found are recursively searched similarly, to test docstrings in their contained methods and nested classes.

Changed in version 2.4: A "private name" concept is deprecated and no longer documented.

Previous: [5.2.3 How It Works](#) Up: [5.2.3 How It Works](#) Next: [5.2.3.2 How are Docstring](#)

5.2.3.2 How are Docstring Examples Recognized?

In most cases a copy-and-paste of an interactive console session works fine, but doctest isn't trying to do an exact emulation of any specific Python shell. All hard tab characters are expanded to spaces, using 8-column tab stops. If you don't believe tabs should mean that, too bad: don't use hard tabs, or write your own `DocTestParser` class.

Changed in version 2.4: Expanding tabs to spaces is new; previous versions tried to preserve hard tabs, with confusing results.

```
>>> # comments are ignored
>>> x = 12
>>> x
12
>>> if x == 13:
...     print "yes"
... else:
...     print "no"
...     print "NO"
...     print "NO!!!"
...
no
NO
NO!!!
>>>
```

Any expected output must immediately follow the final '`>>>`' or '`...`' line containing the code, and the expected output (if any) extends to the next '`>>>`' or all-whitespace line.

The fine print:

- Expected output cannot contain an all-whitespace line, since such a line is taken to signal the end of expected output. If expected output does contain a blank line, put `<BLANKLINE>` in your doctest example each place a blank line is expected. Changed in version 2.4: `<BLANKLINE>` was added; there was no way to use expected output containing empty lines in previous versions.

- Output to stdout is captured, but not output to stderr (exception tracebacks are captured via a different means).
- If you continue a line via backslashing in an interactive session, or for any other reason use a backslash, you should use a raw docstring, which will preserve your backslashes exactly as you type them:

```
>>> def f(x):
...     r'''Backslashes in a raw docstring: m\n'''
>>> print f.__doc__
Backslashes in a raw docstring: m\n
```

Otherwise, the backslash will be interpreted as part of the string. For example, the "\n" above would be interpreted as a newline character. Alternatively, you can double each backslash in the doctest version (and not use a raw string):

```
>>> def f(x):
...     '''Backslashes in a raw docstring: m\\n'''
>>> print f.__doc__
Backslashes in a raw docstring: m\n
```

- The starting column doesn't matter:

```
>>> assert "Easy!"
>>> import math
>>> math.floor(1.9)
1.0
```

and as many leading whitespace characters are stripped from the expected output as appeared in the initial '>>>' line that started the example.

Previous: [5.2.3.2 How are Docstring](#) Up: [5.2.3 How It Works](#) Next: [5.2.3.4 What About Exceptions?](#)

5.2.3.3 What's the Execution Context?

By default, each time `doctest` finds a docstring to test, it uses a *shallow copy* of `M`'s globals, so that running tests doesn't change the module's real globals, and so that one test in `M` can't leave behind crumbs that accidentally allow another test to work. This means examples can freely use any names defined at top-level in `M`, and names defined earlier in the docstring being run. Examples cannot see names defined in other docstrings.

You can force use of your own dict as the execution context by passing `globs=your_dict` to `testmod()` or `testfile()` instead.

Previous: [5.2.3.2 How are Docstring](#) Up: [5.2.3 How It Works](#) Next: [5.2.3.4 What About Exceptions?](#)

5.2.3.4 What About Exceptions?

No problem, provided that the traceback is the only output produced by the example: just paste in the traceback.^{5.1} Since tracebacks contain details that are likely to change rapidly (for example, exact file paths and line numbers), this is one case where doctest works hard to be flexible in what it accepts.

Simple example:

```
>>> [1, 2, 3].remove(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: list.remove(x): x not in list
```

That doctest succeeds if `ValueError` is raised, with the `"list.remove(x): x not in list"` detail as shown.

The expected output for an exception must start with a traceback header, which may be either of the following two lines, indented the same as the first line of the example:

```
Traceback (most recent call last):
Traceback (innermost last):
```

The traceback header is followed by an optional traceback stack, whose contents are ignored by doctest. The traceback stack is typically omitted, or copied verbatim from an interactive session.

The traceback stack is followed by the most interesting part: the line(s) containing the exception type and detail. This is usually the last line of a traceback, but can extend across multiple lines if the exception has a multi-line detail:

```
>>> raise ValueError('multi\n    line\ndetail')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: multi
    line
detail
```

The last three lines (starting with `ValueError`) are compared against the exception's type and detail, and the rest are ignored.

Best practice is to omit the traceback stack, unless it adds significant documentation value to the example. So the last example is probably better as:

```
>>> raise ValueError('multi\n    line\ndetail')
Traceback (most recent call last):
...
ValueError: multi
    line
detail
```

Note that tracebacks are treated very specially. In particular, in the rewritten example, the use of ". . ." is independent of doctest's `ELLIPSIS` option. The ellipsis in that example could be left out, or could just as well be three (or three hundred) commas or digits, or an indented transcript of a Monty Python skit.

Some details you should read once, but won't need to remember:

- Doctest can't guess whether your expected output came from an exception traceback or from ordinary printing. So, e.g., an example that expects "ValueError: 42 is prime" will pass whether `ValueError` is actually raised or if the example merely prints that traceback text. In practice, ordinary output rarely begins with a traceback header line, so this doesn't create real problems.
- Each line of the traceback stack (if present) must be indented further than the first line of the example, *or* start with a non-alphanumeric character. The first line following the traceback header indented the same and starting with an alphanumeric is taken to be the start of the exception detail. Of course this does the right thing for genuine tracebacks.
- When the `IGNORE_EXCEPTION_DETAIL` doctest option is specified, everything following the leftmost colon is ignored.
- The interactive shell omits the traceback header line for some `SyntaxErrors`. But doctest uses the traceback header line to distinguish exceptions from non-exceptions. So in the rare case where you need to test a `SyntaxError` that omits the traceback header, you will need to manually add the traceback header line to your test example.

- For some `SyntaxErrors`, Python displays the character position of the syntax error, using a `^` marker:

```
>>> 1 1
      File "<stdin>", line 1
        1 1
          ^
SyntaxError: invalid syntax
```

Since the lines showing the position of the error come before the exception type and detail, they are not checked by doctest. For example, the following test would pass, even though it puts the `^` marker in the wrong location:

```
>>> 1 1
Traceback (most recent call last):
  File "<stdin>", line 1
    1 1
      ^
SyntaxError: invalid syntax
```

Changed in version 2.4: The ability to handle a multi-line exception detail, and the `IGNORE_EXCEPTION_DETAIL` doctest option, were added.

Footnotes

... [traceback.5.1](#)

Examples containing both expected output and an exception are not supported. Trying to guess where one ends and the other begins is too error-prone, and that also makes for a confusing test.

5.2.3.5 Option Flags and Directives

A number of option flags control various aspects of doctest's behavior. Symbolic names for the flags are supplied as module constants, which can be or'ed together and passed to various functions. The names can also be used in doctest directives (see below).

The first group of options define test semantics, controlling aspects of how doctest decides whether actual output matches an example's expected output:

DONT_ACCEPT_TRUE_FOR_1

By default, if an expected output block contains just `1`, an actual output block containing just `1` or just `True` is considered to be a match, and similarly for `0` versus `False`. When `DONT_ACCEPT_TRUE_FOR_1` is specified, neither substitution is allowed. The default behavior caters to that Python changed the return type of many functions from integer to boolean; doctests expecting "little integer" output still work in these cases. This option will probably go away, but not for several years.

DONT_ACCEPT_BLANKLINE

By default, if an expected output block contains a line containing only the string `<BLANKLINE>`, then that line will match a blank line in the actual output. Because a genuinely blank line delimits the expected output, this is the only way to communicate that a blank line is expected. When `DONT_ACCEPT_BLANKLINE` is specified, this substitution is not allowed.

NORMALIZE_WHITESPACE

When specified, all sequences of whitespace (blanks and newlines) are treated as equal. Any sequence of whitespace within the expected output will match any sequence of whitespace within the actual output. By default, whitespace must match exactly. `NORMALIZE_WHITESPACE` is especially useful when a line of expected output is very long, and you want to wrap it across multiple lines in your source.

ELLIPSIS

When specified, an ellipsis marker (. . .) in the expected output can match any substring in the actual output. This includes substrings that span line boundaries, and empty substrings, so it's best to keep usage of this simple. Complicated uses can lead to the same kinds of "oops, it matched too much!" surprises that `.*` is prone to in regular expressions.

IGNORE_EXCEPTION_DETAIL

When specified, an example that expects an exception passes if an exception of the expected type is raised, even if the exception detail does not match. For example, an example expecting "ValueError: 42" will pass if the actual exception raised is "ValueError: 3*14", but will fail, e.g., if `TypeError` is raised.

Note that a similar effect can be obtained using `ELLIPSIS`, and `IGNORE_EXCEPTION_DETAIL` may go away when Python releases prior to 2.4 become uninteresting. Until then, `IGNORE_EXCEPTION_DETAIL` is the only clear way to write a doctest that doesn't care about the exception detail yet continues to pass under Python releases prior to 2.4 (doctest directives appear to be comments to them). For example,

```
>>> (1, 2)[3] = 'moo' #doctest: +IGNORE_EXCEPTION_DETAIL
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object doesn't support item assignment
```

passes under Python 2.4 and Python 2.3. The detail changed in 2.4, to say "does not" instead of "doesn't".

COMPARISON_FLAGS

A bitmask or'ing together all the comparison flags above.

The second group of options controls how test failures are reported:

REPORT_UDIFF

When specified, failures that involve multi-line expected and actual outputs are displayed using a unified diff.

REPORT_CDIF

When specified, failures that involve multi-line expected and actual outputs will be displayed using a context diff.

REPORT_NDIFF

When specified, differences are computed by `diff.lib.Differ`, using the same algorithm as the popular `ndiff.py` utility. This is the only method that marks differences within lines as well as across lines. For example, if a line of expected output contains digit `1` where actual output contains letter `l`, a line is inserted with a caret marking the mismatching column positions.

REPORT_ONLY_FIRST_FAILURE

When specified, display the first failing example in each doctest, but suppress output for all remaining examples. This will prevent doctest from reporting correct examples that break because of earlier failures; but it might also hide incorrect examples that fail independently of the first failure. When `REPORT_ONLY_FIRST_FAILURE` is specified, the remaining examples are still run, and still count towards the total number of failures reported; only the output is suppressed.

REPORTING_FLAGS

A bitmask or'ing together all the reporting flags above.

"Doctest directives" may be used to modify the option flags for individual examples. Doctest directives are expressed as a special Python comment following an example's source code:

```
directive ::= "#" "doctest:"  
           directive options  
directive_options ::= directive option (","  
           directive option)*  
directive_option ::= on or off  
           directive option name  
on_or_off ::= "+" | "-"  
directive_option_name ::= "DONT_ACCEPT_BLANKLINE"  
           |  
           "NORMALIZE_WHITESPACE"  
           | ...
```

[Download entire grammar as text.](#)

Whitespace is not allowed between the `+` or `-` and the directive option name.

The directive option name can be any of the option flag names explained above.

An example's doctest directives modify doctest's behavior for that single example. Use + to enable the named behavior, or - to disable it.

For example, this test passes:

```
>>> print range(20) #doctest: +NORMALIZE_WHITESPACE
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9,
10, 11, 12, 13, 14, 15, 16, 17, 18, 19]
```

Without the directive it would fail, both because the actual output doesn't have two blanks before the single-digit list elements, and because the actual output is on a single line. This test also passes, and also requires a directive to do so:

```
>>> print range(20) # doctest:+ELLIPSIS
[0, 1, ..., 18, 19]
```

Multiple directives can be used on a single physical line, separated by commas:

```
>>> print range(20) # doctest: +ELLIPSIS, +NORMALIZE_WHITESPACE
[0, 1, ..., 18, 19]
```

If multiple directive comments are used for a single example, then they are combined:

```
>>> print range(20) # doctest: +ELLIPSIS
... # doctest: +NORMALIZE_WHITESPACE
[0, 1, ..., 18, 19]
```

As the previous example shows, you can add ". . ." lines to your example containing only directives. This can be useful when an example is too long for a directive to comfortably fit on the same line:

```
>>> print range(5) + range(10,20) + range(30,40) + range(50,60)
... # doctest: +ELLIPSIS
[0, ..., 4, 10, ..., 19, 30, ..., 39, 50, ..., 59]
```

Note that since all options are disabled by default, and directives apply only to the example they appear in, enabling options (via + in a directive) is usually the only meaningful choice. However, option flags can also be passed to functions that run doctests, establishing different defaults. In such cases, disabling an option via - in a directive can be useful.

Changed in version 2.4: Constants `DONT_ACCEPT_BLANKLINE`, `NORMALIZE_WHITESPACE`, `ELLIPSIS`, `IGNORE_EXCEPTION_DETAIL`, `REPORT_UDIFF`, `REPORT_CDIF`, `REPORT_NDIFF`, `REPORT_ONLY_FIRST_FAILURE`, `COMPARISON_FLAGS` and `REPORTING_FLAGS` were added; by default `<BLANKLINE>` in expected output matches an empty line in actual output; and `doctest` directives were added.

There's also a way to register new option flag names, although this isn't useful unless you intend to extend [doctest](#) internals via subclassing:

register_optionflag(*name*)

Create a new option flag with a given name, and return the new flag's integer value. `register_optionflag()` can be used when subclassing `OutputChecker` or `DocTestRunner` to create new options that are supported by your subclasses. `register_optionflag` should always be called using the following idiom:

```
MY_FLAG = register_optionflag('MY_FLAG')
```

New in version 2.4.

Previous: [5.2.3.4 What About Exceptions?](#) Up: [5.2.3 How It Works](#) Next: [5.2.3.6 Warnings](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

5.2.3.6 Warnings

`doctest` is serious about requiring exact matches in expected output. If even a single character doesn't match, the test fails. This will probably surprise you a few times, as you learn exactly what Python does and doesn't guarantee about output. For example, when printing a dict, Python doesn't guarantee that the key-value pairs will be printed in any particular order, so a test like

```
>>> foo()
{"Hermione": "hippogryph", "Harry": "broomstick"}
```

is vulnerable! One workaround is to do

```
>>> foo() == {"Hermione": "hippogryph", "Harry": "broomstick"}
True
```

instead. Another is to do

```
>>> d = foo().items()
>>> d.sort()
>>> d
[('Harry', 'broomstick'), ('Hermione', 'hippogryph')]
```

There are others, but you get the idea.

Another bad idea is to print things that embed an object address, like

```
>>> id(1.0) # certain to fail some of the time
7948648
>>> class C: pass
>>> C() # the default repr() for instances embeds an address
<__main__.C instance at 0x00AC18F0>
```

The `ELLIPSIS` directive gives a nice approach for the last example:

```
>>> C() #doctest: +ELLIPSIS
<__main__.C instance at 0x...>
```

Floating-point numbers are also subject to small output variations across platforms, because Python defers to the platform C library for float formatting,

and C libraries vary widely in quality here.

```
>>> 1./7 # risky
0.14285714285714285
>>> print 1./7 # safer
0.142857142857
>>> print round(1./7, 6) # much safer
0.142857
```

Numbers of the form $I/2.**J$ are safe across all platforms, and I often contrive doctest examples to produce numbers of that form:

```
>>> 3./4 # utterly safe
0.75
```

Simple fractions are also easier for people to understand, and that makes for better documentation.

5.2.6.1 DocTest Objects

class DocTest(*examples, globs, name, filename, lineno, docstring*)

A collection of doctest examples that should be run in a single namespace. The constructor arguments are used to initialize the member variables of the same names. New in version 2.4.

`DocTest` defines the following member variables. They are initialized by the constructor, and should not be modified directly.

examples

A list of `Example` objects encoding the individual interactive Python examples that should be run by this test.

globs

The namespace (aka globals) that the examples should be run in. This is a dictionary mapping names to values. Any changes to the namespace made by the examples (such as binding new variables) will be reflected in `globs` after the test is run.

name

A string name identifying the `DocTest`. Typically, this is the name of the object or file that the test was extracted from.

filename

The name of the file that this `DocTest` was extracted from; or `NONE` if the filename is unknown, or if the `DocTest` was not extracted from a file.

lineno

The line number within `filename` where this `DocTest` begins, or `NONE` if the line number is unavailable. This line number is zero-based with respect to the beginning of the file.

docstring

The string that the test was extracted from, or ``None`` if the string is

unavailable, or if the test was not extracted from a string.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

5.2.6.2 Example Objects

class Example(*source*, *want*[, *exc_msg*][, *lineno*][, *indent*][, *options*])

A single interactive example, consisting of a Python statement and its expected output. The constructor arguments are used to initialize the member variables of the same names. New in version 2.4.

`Example` defines the following member variables. They are initialized by the constructor, and should not be modified directly.

source

A string containing the example's source code. This source code consists of a single Python statement, and always ends with a newline; the constructor adds a newline when necessary.

want

The expected output from running the example's source code (either from stdout, or a traceback in case of exception). `want` ends with a newline unless no output is expected, in which case it's an empty string. The constructor adds a newline when necessary.

exc_msg

The exception message generated by the example, if the example is expected to generate an exception; or `NONE` if it is not expected to generate an exception. This exception message is compared against the return value of `traceback.format_exception_only()`. `exc_msg` ends with a newline unless it's `NONE`. The constructor adds a newline if needed.

lineno

The line number within the string containing this example where the example begins. This line number is zero-based with respect to the beginning of the containing string.

indent

The example's indentation in the containing string, i.e., the number of space

characters that precede the example's first prompt.

options

A dictionary mapping from option flags to `True` or `False`, which is used to override default options for this example. Any option flags not contained in this dictionary are left at their default value (as specified by the `DocTestRunner`'s `optionflags`). By default, no options are set.

Previous: 5.2.6.1 DocTest Objects Up: 5.2.6 Advanced API Next: 5.2.6.3 DocTestFinder objects						

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

5.2.6.3 DocTestFinder objects

class DocTestFinder([*verbose*][, *parser*][, *recurse*][, *exclude_empty*])

A processing class used to extract the `DOCTESTS` that are relevant to a given object, from its docstring and the docstrings of its contained objects. `DOCTESTS` can currently be extracted from the following object types: modules, functions, classes, methods, staticmethods, classmethods, and properties.

The optional argument *verbose* can be used to display the objects searched by the finder. It defaults to `False` (no output).

The optional argument *parser* specifies the `DocTestParser` object (or a drop-in replacement) that is used to extract doctests from docstrings.

If the optional argument *recurse* is false, then `DocTestFinder.find()` will only examine the given object, and not any contained objects.

If the optional argument *exclude_empty* is false, then `DocTestFinder.find()` will include tests for objects with empty docstrings.

New in version 2.4.

`DocTestFinder` defines the following method:

find(*obj*[, *name*][, *module*][, *globs*][, *extraglobs*])

Return a list of the `DOCTESTS` that are defined by *obj*'s docstring, or by any of its contained objects' docstrings.

The optional argument *name* specifies the object's name; this name will be used to construct names for the returned `DOCTESTS`. If *name* is not specified, then `obj.__name__` is used.

The optional parameter *module* is the module that contains the given object.

If the module is not specified or is `None`, then the test finder will attempt to automatically determine the correct module. The object's module is used:

- As a default namespace, if *globs* is not specified.
- To prevent the `DocTestFinder` from extracting `DocTests` from objects that are imported from other modules. (Contained objects with modules other than *module* are ignored.)
- To find the name of the file containing the object.
- To help find the line number of the object within its file.

If *module* is `False`, no attempt to find the module will be made. This is obscure, of use mostly in testing `doctest` itself: if *module* is `False`, or is `None` but cannot be found automatically, then all objects are considered to belong to the (non-existent) module, so all contained objects will (recursively) be searched for `doctests`.

The globals for each `DocTest` is formed by combining *globs* and *extraglobs* (bindings in *extraglobs* override bindings in *globs*). A new shallow copy of the globals dictionary is created for each `DocTest`. If *globs* is not specified, then it defaults to the module's `__dict__`, if specified, or `{}` otherwise. If *extraglobs* is not specified, then it defaults to `{}`.

Python Library Reference

Previous: [5.2.6.2 Example Objects](#) Up: [5.2.6 Advanced API](#) Next: [5.2.6.4 DocTestParser objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

5.2.6.4 DocTestParser objects

class DocTestParser()

A processing class used to extract interactive examples from a string, and use them to create a `DocTest` object. New in version 2.4.

`DocTestParser` defines the following methods:

`get_doctest(string, globs, name, filename, lineno)`

Extract all doctest examples from the given string, and collect them into a `DocTest` object.

globs, *name*, *filename*, and *lineno* are attributes for the new `DocTest` object. See the documentation for `DocTest` for more information.

`get_examples(string[, name])`

Extract all doctest examples from the given string, and return them as a list of `Example` objects. Line numbers are 0-based. The optional argument *name* is a name identifying this string, and is only used for error messages.

`parse(string[, name])`

Divide the given string into examples and intervening text, and return them as a list of alternating `Examples` and strings. Line numbers for the `Examples` are 0-based. The optional argument *name* is a name identifying this string, and is only used for error messages.

5.2.6.5 DocTestRunner objects

class DocTestRunner([*checker*][, *verbose*][, *optionflags*])

A processing class used to execute and verify the interactive examples in a DocTest.

The comparison between expected outputs and actual outputs is done by an `OutputChecker`. This comparison may be customized with a number of option flags; see section [5.2.3](#) for more information. If the option flags are insufficient, then the comparison may also be customized by passing a subclass of `OutputChecker` to the constructor.

The test runner's display output can be controlled in two ways. First, an output function can be passed to `TestRunner.run()`; this function will be called with strings that should be displayed. It defaults to `sys.stdout.write`. If capturing the output is not sufficient, then the display output can be also customized by subclassing `DocTestRunner`, and overriding the methods `report_start`, `report_success`, `report_unexpected_exception`, and `report_failure`.

The optional keyword argument *checker* specifies the `OutputChecker` object (or drop-in replacement) that should be used to compare the expected outputs to the actual outputs of doctest examples.

The optional keyword argument *verbose* controls the `DocTestRunner`'s verbosity. If *verbose* is `True`, then information is printed about each example, as it is run. If *verbose* is `False`, then only failures are printed. If *verbose* is unspecified, or `None`, then verbose output is used iff the command-line switch `-v` is used.

The optional keyword argument *optionflags* can be used to control how the test runner compares expected output to actual output, and how it displays failures. For more information, see section [5.2.3](#).

New in version 2.4.

DocTestParser defines the following methods:

report_start(*out*, *test*, *example*)

Report that the test runner is about to process the given example. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. *test* is the test containing *example*. *out* is the output function that was passed to DocTestRunner.run().

report_success(*out*, *test*, *example*, *got*)

Report that the given example ran successfully. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. *got* is the actual output from the example. *test* is the test containing *example*. *out* is the output function that was passed to DocTestRunner.run().

report_failure(*out*, *test*, *example*, *got*)

Report that the given example failed. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. *got* is the actual output from the example. *test* is the test containing *example*. *out* is the output function that was passed to DocTestRunner.run().

report_unexpected_exception(*out*, *test*, *example*, *exc_info*)

Report that the given example raised an unexpected exception. This method is provided to allow subclasses of DocTestRunner to customize their output; it should not be called directly.

example is the example about to be processed. *exc_info* is a tuple containing information about the unexpected exception (as returned by sys.exc_info()). *test* is the test containing *example*. *out* is the output function that was passed to DocTestRunner.run().

run(*test*[, *compileflags*][, *out*][, *clear_globs*])

Run the examples in *test* (a `DocTest` object), and display the results using the writer function *out*.

The examples are run in the namespace `test.globs`. If *clear_globs* is true (the default), then this namespace will be cleared after the test runs, to help with garbage collection. If you would like to examine the namespace after the test completes, then use *clear_globs=False*.

compileflags gives the set of flags that should be used by the Python compiler when running the examples. If not specified, then it will default to the set of future-import flags that apply to *globs*.

The output of each example is checked using the `DocTestRunner`'s output checker, and the results are formatted by the `DocTestRunner.report_*` methods.

summarize([*verbose*])

Print a summary of all the test cases that have been run by this `DocTestRunner`, and return a tuple "(*failure_count*, *test_count*)".

The optional *verbose* argument controls how detailed the summary is. If the verbosity is not specified, then the `DocTestRunner`'s verbosity is used.

Previous:	5.2.6.4 DocTestParser objects	Up:	5.2.6 Advanced API	Next:	5.2.6.6 OutputChecker objects

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

5.2.6.6 OutputChecker objects

class OutputChecker()

A class used to check the whether the actual output from a doctest example matches the expected output. `OutputChecker` defines two methods: `check_output`, which compares a given pair of outputs, and returns true if they match; and `output_difference`, which returns a string describing the differences between two outputs. New in version 2.4.

`OutputChecker` defines the following methods:

`check_output(want, got, optionflags)`

Return `True` iff the actual output from an example (*got*) matches the expected output (*want*). These strings are always considered to match if they are identical; but depending on what option flags the test runner is using, several non-exact match types are also possible. See section [5.2.3](#) for more information about option flags.

`output_difference(example, got, optionflags)`

Return a string describing the differences between the expected output for a given example (*example*) and the actual output (*got*). *optionflags* is the set of option flags used to compare *want* and *got*.

5.6.5.1 Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent 0.1 exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```
# Examples from Seminumerical Algorithms, Section 4.2.2.
>>> from decimal import *
>>> getcontext().prec = 8

>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7.5111')
>>> (u + v) + w
Decimal("9.5111111")
>>> u + (v + w)
Decimal("10")

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal("0.01")
>>> u * (v+w)
Decimal("0.0060000")
```

The `decimal` module makes it possible to restore the identities by expanding the precision sufficiently to avoid loss of significance:

```
>>> getcontext().prec = 20
>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7.5111')
>>> (u + v) + w
Decimal("9.51111111")
>>> u + (v + w)
Decimal("9.51111111")
>>>
>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal("0.0060000")
>>> u * (v+w)
```

```
Decimal("0.0060000")
```

[5.6.5.2 Special values](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

5.6.5.2 Special values

The number system for the `decimal` module provides special values including `NaN`, `sNaN`, `-Infinity`, `Infinity`, and two zeroes, `+0` and `-0`.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the `DivisionByZero` signal is not trapped. Likewise, when the `Overflow` signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return `NaN`, or if the `InvalidOperation` signal is trapped, raise an exception. For example, `0/0` returns `NaN` which means "not a number". This variety of `NaN` is quiet and, once created, will flow through other computations always resulting in another `NaN`. This behavior can be useful for a series of computations that occasionally have missing inputs -- it allows the calculation to proceed while flagging specific results as invalid.

A variant is `sNaN` which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.

In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation

returns a value equal to zero:

```
>>> 1 / Decimal('Infinity')
Decimal("0E-1000000026")
```

Next: [6.8.1.3 Security](#)

6.8.1.2 Exceptions

Exceptions raised in the child process, before the new program has started to execute, will be re-raised in the parent. Additionally, the exception object will have one extra attribute called `child_traceback`, which is a string containing traceback information from the child's point of view.

The most common exception raised is `OSError`. This occurs, for example, when trying to execute a non-existent file. Applications should prepare for `OSError` exceptions.

A `ValueError` will be raised if `Popen` is called with invalid arguments.

Next: [6.8.3.4 Replacing os.spawn*](#)

6.8.3.3 Replacing os.system()

```
sts = os.system("mycmd" + " myarg")  
==>  
p = Popen("mycmd" + " myarg", shell=True)  
sts = os.waitpid(p.pid, 0)
```

Notes:

- Calling the program through the shell is usually not required.
- It's easier to look at the `returncode` attribute than the exit status.

A more realistic example would look like this:

```
try:  
    retcode = call("mycmd" + " myarg", shell=True)  
    if retcode < 0:  
        print >>sys.stderr, "Child was terminated by signal", -retcode  
    else:  
        print >>sys.stderr, "Child returned", retcode  
except OSError, e:  
    print >>sys.stderr, "Execution failed:", e
```

pipe = os.popen(cmd, mode='w', bufsize)
==>
pipe = Popen(cmd, shell=True, bufsize=bufsize, stdin=PIPE).stdin

(child_stdin, child_stdout) = os.popen2(cmd, mode, bufsize)
==>
p = Popen(cmd, shell=True, bufsize=bufsize,
          stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdin, child_stdout) = (p.stdin, p.stdout)

(child_stdin,
 child_stdout,
 child_stderr) = os.popen3(cmd, mode, bufsize)
==>
p = Popen(cmd, shell=True, bufsize=bufsize,
          stdin=PIPE, stdout=PIPE, stderr=PIPE, close_fds=True)
(child_stdin,
 child_stdout,
 child_stderr) = (p.stdin, p.stdout, p.stderr)

(child_stdin, child_stdout_and_stderr) = os.popen4(cmd, mode, bufsiz
==>
p = Popen(cmd, shell=True, bufsize=bufsize,
          stdin=PIPE, stdout=PIPE, stderr=STDOUT, close_fds=True)
(child_stdin, child_stdout_and_stderr) = (p.stdin, p.stdout)
```

Previous: [6.8.3.4 Replacing os.spawn*](#) Up: [6.8.3 Replacing Older Functions](#)
Next: [6.8.3.6 Replacing popen2.*](#)

6.8.3.6 Replacing popen2.*

Note: If the cmd argument to popen2 functions is a string, the command is executed through /bin/sh. If it is a list, the command is directly executed.

```
(child_stdout, child_stdin) = popen2.popen2("somestring", bufsize, m
==>
p = Popen(["somestring"], shell=True, bufsize=bufsize,
          stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)

(child_stdout, child_stdin) = popen2.popen2(["mycmd", "myarg"], bufs
==>
p = Popen(["mycmd", "myarg"], bufsize=bufsize,
          stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

The popen2.Popen3 and popen2.Popen4 basically works as subprocess.Popen, except that:

- subprocess.Popen raises an exception if the execution fails
- the *capturestderr* argument is replaced with the *stderr* argument.
- stdin=PIPE and stdout=PIPE must be specified.
- popen2 closes all file descriptors by default, but you have to specify close_fds=True with subprocess.Popen.

6.21.1.1 Terminology

argument

a string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). UNIX shells also use the term `word`.

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read `argument` as `an element of sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`.

option

an argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional UNIX syntax is a hyphen (`-`) followed by a single letter, e.g. `-x` or `-F`. Also, traditional UNIX syntax allows multiple options to be merged into a single argument, e.g. `-x -F` is equivalent to `-xF`. The GNU project introduced `-` followed by a series of hyphen-separated words, e.g. `-file` or `-dry-run`. These are the only two option syntaxes provided by `optparse`.

Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. `-pf` (this is *not* the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. `-file` (this is technically equivalent to the previous syntax, but they aren't usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. `+f`, `+rgb`

- a slash followed by a letter, or a few letters, or a word, e.g. `"/f"`, `"/file"`

These option syntaxes are not supported by `optparse`, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you're exclusively targeting VMS, MS-DOS, and/or Windows.

option argument

an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With `optparse`, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-ffoo
--file=foo
```

Typically, a given option either takes an argument or it doesn't. Lots of people want an "optional option arguments" feature, meaning that some options will take an argument if they see it, and won't if they don't. This is somewhat controversial, because it makes parsing ambiguous: if `"-a"` takes an optional argument and `"-b"` is another option entirely, how do we interpret `"-ab"`? Because of this ambiguity, `optparse` does not support this feature.

positional argument

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

required option

an option that must be supplied on the command-line; note that the phrase "required option" is self-contradictory in English. `optparse` doesn't prevent you from implementing required options, but doesn't give you much help at it either. See `examples/required_1.py` and `examples/required_2.py` in the `optparse` source distribution for

two ways to implement required options with `optparse`.

For example, consider this hypothetical command-line:

```
prog -v --report /tmp/report.txt foo bar
```

"`-v`" and "`-report`" are both options. Assuming that `--report` takes one argument, "`/tmp/report.txt`" is an option argument. "`foo`" and "`bar`" are positional arguments.

			Python Library Reference	toc <small>CONTENTS</small>	m <small>MODULES</small>	i <small>INDEX</small>
Previous: 6.21.1 Background Up: 6.21.1 Background Next: 6.21.1.2 What are options						

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.1.2 What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn't clear, options are usually *optional*. A program should be able to run just fine with no options whatsoever. (Pick a random program from the UNIX or GNU toolsets. Can it run without any options at all and still make sense? The main exceptions are `find`, `tar`, and `dd`--all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have "required options". Think about it. If it's required, then it's *not optional*! If there is a piece of information that your program absolutely requires in order to run successfully, that's what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn't make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

See [About this document..](#) for information on suggesting changes.

6.21.1.3 What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in order to run successfully, it doesn't much matter *how* you get that information from the user--most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply--use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the "Preferences" dialog of a GUI, or command-line options--the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.

Previous: [6.21.2 Tutorial](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.2 The store action](#)

6.21.2.1 Understanding option actions

Actions tell `optparse` what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into `optparse`; adding new actions is an advanced topic covered in section , `Extending optparse`. Most actions tell `optparse` to store a value in some variable--for example, take a string from the command line and store it in an attribute of `options`.

If you don't specify an option action, `optparse` defaults to `store`.

Previous: [6.21.2 Tutorial](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.2 The store action](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

6.21.2.2 The store action

The most common option action is `store`, which tells `optparse` to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```
parser.add_option("-f", "--file",
                  action="store", type="string", dest="filename")
```

Now let's make up a fake command line and ask `optparse` to parse it:

```
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When `optparse` sees the option string `"-f"`, it consumes the next argument, `"foo.txt"`, and stores it in `options.filename`. So, after this call to `parse_args()`, `options.filename` is `"foo.txt"`.

Some other option types supported by `optparse` are `int` and `float`. Here's an option that expects an integer argument:

```
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly acceptable. Also, there's no explicit action, since the default is `store`.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since `"-n42"` (one argument) is equivalent to `"-n 42"` (two arguments), the code

```
(options, args) = parser.parse_args(["-n42"])
print options.num
```

will print `"42"`.

If you don't specify a type, `optparse` assumes `string`. Combined with the

fact that the default action is `store`, that means our first example can be a lot shorter:

```
parser.add_option("-f", "--file", dest="filename")
```

If you don't supply a destination, `optparse` figures out a sensible default from the option strings: if the first long option string is `"-foo-bar"`, then the default destination is `foo_bar`. If there are no long option strings, `optparse` looks at the first short option string: the default destination for `"-f"` is `f`.

`optparse` also includes built-in `long` and `complex` types. Adding types is covered in section , `Extending optparse`.

Previous: [6.21.2.1 Understanding option actions](#) **Up:** [6.21.2 Tutorial](#) **Next:** [6.21.2.3 Handling boolean \(flag\)](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.2.3 Handling boolean (flag) options

Flag options--set a variable to true or false when a particular option is seen--are quite common. `optparse` supports them with two separate actions, `store_true` and `store_false`. For example, you might have a `verbose` flag that is turned on with `"-v"` and off with `"-q"`:

```
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values--see below.)

When `optparse` encounters `"-v"` on the command line, it sets `options.verbose` to `True`; when it encounters `"-q"`, `options.verbose` is set to `False`.

Previous: [6.21.2.3 Handling boolean \(flag\)](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.5 Default values](#)

6.21.2.4 Other actions

Some other actions supported by `optparse` are:

store_const

store a constant value

append

append this option's argument to a list

count

increment a counter by one

callback

call a specified function

These are covered in section [6.21.3](#), Reference Guide and section [6.21.4](#), Option Callbacks.

Python Library Reference

CONTENTS MODULES INDEX

Previous: [6.21.2.3 Handling boolean \(flag\)](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.5 Default values](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.2.5 Default values

All of the above examples involve setting some variable (the ``destination'') when certain command-line options are seen. What happens if those options are never seen? Since we didn't supply any defaults, they are all set to `None`. This is usually fine, but sometimes you want more control. `optparse` lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want `optparse` to set `verbose` to `True` unless `"-q"` is seen, then we can do this:

```
parser.add_option("-v", action="store_true", dest="verbose", default
parser.add_option("-q", action="store_false", dest="verbose")
```

Since default values apply to the *destination* rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose", default
```

Consider this:

```
parser.add_option("-v", action="store_true", dest="verbose", default
parser.add_option("-q", action="store_false", dest="verbose", default
```

Again, the default value for `verbose` will be `True`: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the `set_defaults()` method of `OptionParser`, which you can call at any time before calling `parse_args()`:

```
parser.set_defaults(verbose=True)
parser.add_option(...)
(options, args) = parser.parse_args()
```

As before, the last value specified for a given option destination is the one that

counts. For clarity, try to use one method or the other of setting default values, not both.

Previous: 6.21.2.4 Other actions Up: 6.21.2 Tutorial Next: 6.21.2.6 Generating help						

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.2.6 Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here's an `OptionParser` populated with user-friendly (documented) options:

```
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parser.add_option("-v", "--verbose",
                  action="store_true", dest="verbose", default=True,
                  help="make lots of noise [default]")
parser.add_option("-q", "--quiet",
                  action="store_false", dest="verbose",
                  help="be vewwy quiet (I'm hunting wabbits)")
parser.add_option("-f", "--filename",
                  metavar="FILE", help="write output to FILE"),
parser.add_option("-m", "--mode",
                  default="intermediate",
                  help="interaction mode: novice, intermediate, "
                  "or expert [default: %default]")
```

If `optparse` encounters either `"-h"` or `"-help"` on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:

```
usage: <yourscrip> [options] arg1 arg2

options:
  -h, --help            show this help message and exit
  -v, --verbose         make lots of noise [default]
  -q, --quiet          be vewwy quiet (I'm hunting wabbits)
  -f FILE, --filename=FILE
                        write output to FILE
  -m MODE, --mode=MODE interaction mode: novice, intermediate, or
                        expert [default: intermediate]
```

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There's a lot going on here to help `optparse` generate the best possible help

message:

- the script defines its own usage message:

```
usage = "usage: %prog [options] arg1 arg2"
```

`optparse` expands "`%prog`" in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

If you don't supply a usage string, `optparse` uses a bland but sensible default: ``usage: %prog [options]'`, which is fine if your script doesn't take any positional arguments.

- every option defines a help string, and doesn't worry about line- wrapping--`optparse` takes care of wrapping lines and making the help output look good.
- options that take a value indicate this fact in their automatically-generated help message, e.g. for the ``mode'` option:

```
-m MODE, --mode=MODE
```

Here, ``MODE'` is called the meta-variable: it stands for the argument that the user is expected to supply to `-m/--mode`. By default, `optparse` converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that's not what you want--for example, the `--filename` option explicitly sets `metavar="FILE"`, resulting in this automatically-generated option description:

```
-f FILE, --filename=FILE
```

This is important for more than just saving space, though: the manually written help text uses the meta-variable ``FILE'` to clue the user in that there's a connection between the semi-formal syntax ``-f FILE'` and the informal semantic description ``write output to FILE'`. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

- options that have a default value can include `%default` in the help string--`optparse` will replace it with `str()` of the option's default value. If an

option has no default value (or the default value is None), %default expands to none.

Previous: 6.21.2.5 Default values Up: 6.21.2 Tutorial Next: 6.21.2.7 Printing a version						

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

Previous: [6.21.2.6 Generating help](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.8 How optparse handles](#)

6.21.2.7 Printing a version string

Similar to the brief usage string, `optparse` can also print a version string for your program. You have to supply the string as the `version` argument to `OptionParser`:

```
parser = OptionParser(usage="%prog [-f] [-q]", version="%prog 1.0")
```

Note that `"%prog"` is expanded just like it is in `usage`. Apart from that, `version` can contain anything you like. When you supply it, `optparse` automatically adds a `"-version"` option to your parser. If it encounters this option on the command line, it expands your `version` string (by replacing `"%prog"`), prints it to `stdout`, and exits.

For example, if your script is called `/usr/bin/foo`:

```
$ /usr/bin/foo --version
foo 1.0
```

CONTENTS MODULES INDEX

Previous: [6.21.2.6 Generating help](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.8 How optparse handles](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.2.8 How `optparse` handles errors

There are two broad classes of errors that `optparse` has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to `parser.add_option()`, e.g. invalid option strings, unknown option attributes, missing option attributes, etc. These are dealt with in the usual way: raise an exception (either `optparse.OptionError` or `TypeError`) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. `optparse` can automatically detect some user errors, such as bad option arguments (passing "`-n 4x`" where `-n` takes an integer argument), missing arguments ("`-n`" at the end of the command line, where `-n` takes an argument of any type). Also, you can call `parser.error()` to signal an application-defined error condition:

```
(options, args) = parser.parse_args()
[...]
```

```
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
```

In either case, `optparse` handles the error the same way: it prints the program's usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes "`4x`" to an option that takes an integer:

```
$ /usr/bin/foo -n 4x
usage: foo [options]

foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```
$ /usr/bin/foo -n
usage: foo [options]
```

```
foo: error: -n option requires an argument
```

`optparse`-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling `parser.error()` from your application code.

If `optparse`'s default error-handling behaviour does not suite your needs, you'll need to subclass `OptionParser` and override `exit()` and/or `error()`.

CONTENTS MODULES INDEX

Previous: [6.21.2.7 Printing a version](#) Up: [6.21.2 Tutorial](#) Next: [6.21.2.9 Putting it all](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

6.21.2.9 Putting it all together

Here's what optparse-based scripts usually look like:

```
from optparse import OptionParser
[...]
```

```
def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                    help="read data from FILENAME")
    parser.add_option("-v", "--verbose",
                    action="store_true", dest="verbose")
    parser.add_option("-q", "--quiet",
                    action="store_false", dest="verbose")
    [...]
    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print "reading %s..." % options.filename
    [...]
```

```
if __name__ == "__main__":
    main()
```

6.21.3.1 Creating the parser

The first step in using `optparse` is to create an `OptionParser` instance:

```
parser = OptionParser(...)
```

The `OptionParser` constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

usage (default: "%prog [options]")

The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

option_list (default: [])

A list of `Option` objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by `OptionParser` subclasses), but before any version or help options.

Deprecated; use `add_option()` after creating the parser instead.

option_class (default: `optparse.Option`)

Class to use when adding options to the parser in `add_option()`.

version (default: `None`)

A version string to print when the user supplies a version option. If you supply a true value for `version`, `optparse` automatically adds a version option with the single option string `"-version"`. The substring `"%prog"` is expanded the same as for `usage`.

conflict_handler (default: `"error"`)

Specifies what to do when options with conflicting option strings are added to the parser; see section [6.21.3](#), Conflicts between options.

description (default: `None`)

A paragraph of text giving a brief overview of your program. `optparse` reformats this paragraph to fit the current terminal width and prints it when

the user requests help (after `usage`, but before the list of options).

formatter (default: a new `IndentedHelpFormatter`)

An instance of `optparse.HelpFormatter` that will be used for printing help text. `optparse` provides two concrete classes for this purpose:

`IndentedHelpFormatter` and `TitledHelpFormatter`.

add_help_option (default: `True`)

If true, `optparse` will add a help option (with option strings "`-h`" and "`-help`") to the parser.

prog

The string to use when expanding "`%prog`" in `usage` and `version` instead of `os.path.basename(sys.argv[0])`.

Previous: [6.21.3 Reference Guide](#) Up: [6.21.3 Reference Guide](#) Next: [6.21.3.2 Populating the parser](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

6.21.3.2 Populating the parser

There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section [6.21.2](#), the tutorial. `add_option()` can be called in one of two ways:

- pass it an `Option` instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the `Option` constructor), and it will create the `Option` instance for you

The other alternative is to pass a list of pre-constructed `Option` instances to the `OptionParser` constructor, as in:

```
option_list = [  
    make_option("-f", "--filename",  
                action="store", type="string", dest="filename"),  
    make_option("-q", "--quiet",  
                action="store_false", dest="verbose"),  
]  
parser = OptionParser(option_list=option_list)
```

(`make_option()` is a factory function for creating `Option` instances; currently it is an alias for the `Option` constructor. A future version of `optparse` may split `Option` into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate `Option` directly.)

6.21.3.3 Defining options

Each `Option` instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.

The canonical way to create an `Option` instance is with the `add_option()` method of `OptionParser`:

```
parser.add_option(opt_str[, ...], attr=value, ...)
```

To define an option with only a short option string:

```
parser.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```
parser.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new `Option` object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an `OptionError` exception explaining your mistake.

An option's *action* determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

store

store this option's argument (default)

store_const

store a constant value

store_true

store a true value

store_false

store a false value

append

append this option's argument to a list

count

increment a counter by one

callback

call a specified function

help

print a usage message including all options and the documentation for them

(If you don't supply an action, the default is `store`. For this action, you may also supply `type` and `dest` option attributes; see below.)

As you can see, most actions involve storing or updating a value somewhere. `optparse` always creates a special object for this, conventionally called `options` (it happens to be an instance of `optparse.Values`). Option arguments (and various other values) are stored as attributes of this object, according to the `dest` (destination) option attribute.

For example, when you call

```
parser.parse_args()
```

one of the first things `optparse` does is create the `options` object:

```
options = Values()
```

If one of the options in this parser is defined with

```
parser.add_option("-f", "--file", action="store", type="string", des
```

and the command-line being parsed includes any of the following:

```
-ffoo  
-f foo  
--file=foo  
--file foo
```

then `optparse`, on seeing this option, will do the equivalent of

```
options.filename = "foo"
```

The `type` and `dest` option attributes are almost as important as `action`, but

action is the only one that makes sense for *all* options.

Previous: [6.21.3.2 Populating the parser](#) Up: [6.21.3 Reference Guide](#) Next:
[6.21.3.4 Standard option actions](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

6.21.3.4 Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`'s behaviour; a few have required attributes, which you must specify for any option using that action.

- `store` [relevant: `type`, `dest`, `nargs`, `choices`]

The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs > 1`, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a tuple. See the "Option types" section below.

If `choices` is supplied (a list or tuple of strings), the type defaults to `choice`.

If `type` is not supplied, it defaults to `string`.

If `dest` is not supplied, `optparse` derives a destination from the first long option string (e.g., "`-foo-bar`" implies `foo_bar`). If there are no long option strings, `optparse` derives a destination from the first short option string (e.g., "`-f`" implies `f`).

Example:

```
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

`optparse` will set

```
options.f = "foo.txt"
```

```
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- `store_const` [required: `const`; relevant: `dest`]

The value `const` is stored in `dest`.

Example:

```
parser.add_option("-q", "--quiet",
                  action="store_const", const=0, dest="verbose")
parser.add_option("-v", "--verbose",
                  action="store_const", const=1, dest="verbose")
parser.add_option("--noisy",
                  action="store_const", const=2, dest="verbose")
```

If "`--noisy`" is seen, `optparse` will set

```
options.verbose = 2
```

- `store_true` [relevant: `dest`]

A special case of `store_const` that stores a true value to `dest`.

- `store_false` [relevant: `dest`]

Like `store_true`, but stores a false value.

Example:

```
parser.add_option("--clobber", action="store_true", dest="clobber")
parser.add_option("--no-clobber", action="store_false", dest="clobber")
```

- `append` [relevant: `type`, `dest`, `nargs`, `choices`]

The option must be followed by an argument, which is appended to the list in `dest`. If no default value for `dest` is supplied, an empty list is automatically created when `optparse` first encounters this option on the command-line. If `nargs > 1`, multiple arguments are consumed, and a tuple of length `nargs` is appended to `dest`.

The defaults for `type` and `dest` are the same as for the `store` action.

Example:

```
parser.add_option("-t", "--tracks", action="append", type="int")
```

If `"-t3"` is seen on the command-line, `optparse` does the equivalent of:

```
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, `"-tracks=4"` is seen, it does:

```
options.tracks.append(int("4"))
```

- `count` [relevant: `dest`]

Increment the integer stored at `dest`. If no default value is supplied, `dest` is set to zero before being incremented the first time.

Example:

```
parser.add_option("-v", action="count", dest="verbosity")
```

The first time `"-v"` is seen on the command line, `optparse` does the equivalent of:

```
options.verbosity = 0
options.verbosity += 1
```

Every subsequent occurrence of `"-v"` results in

```
options.verbosity += 1
```

- `callback` [required: `callback`; relevant: `type`, `nargs`, `callback_args`, `callback_kwargs`]

Call the function specified by `callback`, which is called as

```
func(option, opt_str, value, parser, *args, **kwargs)
```

See section [6.21.4](#), Option Callbacks for more detail.

- `help`

Prints a complete help message for all the options in the current option parser. The help message is constructed from the `usage` string passed to `OptionParser`'s constructor and the `help` string passed to every option.

If no `help` string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value `optparse.SUPPRESS_HELP`.

`optparse` automatically adds a `help` option to all `OptionParsers`, so you do not normally need to create one.

Example:

```
from optparse import OptionParser, SUPPRESS_HELP

parser = OptionParser()
parser.add_option("-h", "--help", action="help"),
parser.add_option("-v", action="store_true", dest="verbose",
                  help="Be moderately verbose")
parser.add_option("--file", dest="filename",
                  help="Input file to read data from"),
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If `optparse` sees either `"-h"` or `"-help"` on the command line, it will print something like the following help message to `stdout` (assuming `sys.argv[0]` is `"foo.py"`):

```
usage: foo.py [options]

options:
  -h, --help          Show this help message and exit
  -v                  Be moderately verbose
  --file=FILENAME    Input file to read data from
```

After printing the help message, `optparse` terminates your process with `sys.exit(0)`.

- **version**

Prints the version number supplied to the `OptionParser` to `stdout` and exits. The version number is actually formatted and printed by the `print_version()` method of `OptionParser`. Generally only relevant if the `version` argument is supplied to the `OptionParser` constructor. As

with `help` options, you will rarely create `version` options, since `optparse` automatically adds them when needed.

Previous: [6.21.3.3 Defining options](#) Up: [6.21.3 Reference Guide](#) Next: [6.21.3.5 Option attributes](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

6.21.3.5 Option attributes

The following option attributes may be passed as keyword arguments to `parser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises `OptionError`.

- `action` (default: "store")

Determines `optparse`'s behaviour when this option is seen on the command line; the available options are documented above.

- `type` (default: "string")

The argument type expected by this option (e.g., "string" or "int"); the available option types are documented below.

- `dest` (default: derived from option strings)

If the option's action implies writing or modifying a value somewhere, this tells `optparse` where to write it: `dest` names an attribute of the `options` object that `optparse` builds as it parses the command line.

- `default` (deprecated)

The value to use for this option's destination if the option is not seen on the command line. Deprecated; use `parser.set_defaults()` instead.

- `nargs` (default: 1)

How many arguments of type `type` should be consumed when this option is seen. If > 1 , `optparse` will store a tuple of values to `dest`.

- `const`

For actions that store a constant value, the constant value to store.

- `choices`

For options of type `"choice"`, the list of strings the user may choose from.

- `callback`

For options with action `"callback"`, the callable to call when this option is seen. See section [6.21.4](#), Option Callbacks for detail on the arguments passed to `callable`.

- `callback_args`, `callback_kwargs`

Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.

- `help`

Help text to print for this option when listing all available options after the user supplies a `help` option (such as `"-help"`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `SUPPRESS_HELP`.

- `metavar` (default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section [6.21.2](#), the tutorial for an example.

6.21.3.6 Standard option types

`optparse` has six built-in option types: `string`, `int`, `long`, `choice`, `float` and `complex`. If you need to add new option types, see section , `Extending optparse`.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments are passed to `int()` to convert them to Python integers. If `int()` fails, so will `optparse`, although with a more useful error message. (Internally, `optparse` raises `OptionValueError`; `OptionParser` catches this exception higher up and terminates your program with a useful error message.)

Likewise, `float` arguments are passed to `float()` for conversion, `long` arguments to `long()`, and `complex` arguments to `complex()`. Apart from that, they are handled identically to integer arguments.

`choice` options are a subtype of `string` options. The `choices` option attribute (a sequence of strings) defines the set of allowed option arguments. `optparse.check_choice()` compares user-supplied option arguments against this master list and raises `OptionValueError` if an invalid string is given.

6.21.3.7 Parsing arguments

The whole point of creating and populating an `OptionParser` is to call its `parse_args()` method:

```
(options, args) = parser.parse_args(args=None, options=None)
```

where the input parameters are

args

the list of arguments to process (`sys.argv[1:]` by default)

options

object to store option arguments in (a new instance of `optparse.Values` by default)

and the return values are

options

the same object as was passed in as `options`, or the new `optparse.Values` instance created by `optparse`

args

the leftover positional arguments after all options have been processed

The most common usage is to supply neither keyword argument. If you supply a `values` object, it will be repeatedly modified with a `setattr()` call for every option argument written to an option destination, and finally returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the `OptionParser`'s `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional UNIX exit status for command-line errors).

6.21.3.8 Querying and manipulating

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

6.21.3.8 Querying and manipulating your option parser

Sometimes, it's useful to poke around your option parser and see what's there. `OptionParser` provides a couple of methods to help you out:

has_option(opt_str)

Return true if the `OptionParser` has an option with option string `opt_str` (e.g., `"-q"` or `"-verbose"`).

get_option(opt_str)

Returns the `Option` instance with the option string `opt_str`, or `None` if no options have that option string.

remove_option(opt_str)

If the `OptionParser` has an option corresponding to `opt_str`, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If `opt_str` does not occur in any option belonging to this `OptionParser`, raises `ValueError`.

6.21.3.9 Conflicts between options

If you're not careful, it's easy to define options with conflicting option strings:

```
parser.add_option("-n", "--dry-run", ...)
[...]
parser.add_option("-n", "--noisy", ...)
```

(This is particularly true if you've defined your own `OptionParser` subclass with some standard options.)

Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```
parser = OptionParser(..., conflict_handler=handler)
```

or with a separate call:

```
parser.set_conflict_handler(handler)
```

The available conflict handlers are:

error (default)

assume option conflicts are a programming error and raise `OptionConflictError`

resolve

resolve option conflicts intelligently (see below)

As an example, let's define an `OptionParser` that resolves conflicts intelligently and add conflicting options to it:

```
parser = OptionParser(conflict_handler="resolve")
parser.add_option("-n", "--dry-run", ..., help="do no harm")
parser.add_option("-n", "--noisy", ..., help="be noisy")
```

At this point, `optparse` detects that a previously-added option is already using the `"-n"` option string. Since `conflict_handler` is `"resolve"`, it

resolves the situation by removing "-n" from the earlier option's list of option strings. Now "-dry-run" is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```
options:
  --dry-run      do no harm
  [...]
  -n, --noisy   be noisy
```

It's possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, `optparse` removes that option completely, so it doesn't show up in help text or anywhere else. Carrying on with our existing `OptionParser`:

```
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original **-n/-dry-run** option is no longer accessible, so `optparse` removes it, leaving this help text:

```
options:
  [...]
  -n, --noisy   be noisy
  --dry-run     new dry-run option
```

Previous: [6.21.3.8 Querying and manipulating](#) Up: [6.21.3 Reference Guide](#)

Next: [6.21.3.10 Other methods](#)

6.21.3.10 Other methods

OptionParser supports several other public methods:

- `set_usage(usage)`

Set the usage string according to the rules described above for the `usage` constructor keyword argument. Passing `NONE` sets the default usage string; use `SUPPRESS_USAGE` to suppress a usage message.

- `enable_interspersed_args()`,
`disable_interspersed_args()`

Enable/disable positional arguments interspersed with options, similar to GNU `getopt` (enabled by default). For example, if "`-a`" and "`-b`" are both simple options that take no arguments, `optparse` normally accepts this syntax:

```
prog -a arg1 -b arg2
```

and treats it as equivalent to

```
prog -a -b arg1 arg2
```

To disable this feature, call `disable_interspersed_args()`. This restores traditional UNIX syntax, where option parsing stops with the first non-option argument.

- `set_defaults(dest=value, ...)`

Set default values for several option destinations at once. Using `set_defaults()` is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several `mode` options all set the same destination, any one of them can set the default, and the last one wins:

```
parser.add_option("--advanced", action="store_const",
```

```
        dest="mode", const="advanced",
        default="novice") # overridden below
parser.add_option("--novice", action="store_const",
        dest="mode", const="novice",
        default="advanced") # overrides above setting
```

To avoid this confusion, use `set_defaults()`:

```
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const",
        dest="mode", const="advanced")
parser.add_option("--novice", action="store_const",
        dest="mode", const="novice")
```

Previous: [6.21.3.9 Conflicts between options](#) **Up:** [6.21.3 Reference Guide](#)

Next: [6.21.4 Option Callbacks](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

6.21.4.1 Defining a callback option

As always, the easiest way to define a callback option is by using the `parser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```
parser.add_option("-c", action="callback", callback=my_callback)
```

`callback` is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments--the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this section.

`optparse` always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via `callback_args` and `callback_kwargs`. Thus, the minimal callback function signature is:

```
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

type

has its usual meaning: as with the `store` or `append` actions, it instructs `optparse` to consume one argument and convert it to `type`. Rather than storing the converted value(s) anywhere, though, `optparse` passes it to your callback function.

nargs

also has its usual meaning: if it is supplied and > 1 , `optparse` will consume `nargs` arguments, each of which must be convertible to `type`. It then passes a tuple of converted values to your callback.

callback_args

a tuple of extra positional arguments to pass to the callback

callback_kwargs

a dictionary of extra keyword arguments to pass to the callback

Previous: [6.21.4 Option Callbacks](#) Up: [6.21.4 Option Callbacks](#) Next: [6.21.4.2 How callbacks are](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

6.21.4.2 How callbacks are called

All callbacks are called as follows:

```
func(option, opt_str, value, parser, *args, **kwargs)
```

where

option

is the Option instance that's calling the callback

opt_str

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, `opt_str` will be the full, canonical option string--e.g. if the user puts "-foo" on the command-line as an abbreviation for "-foobar", then `opt_str` will be "-foobar".)

value

is the argument to this option seen on the command-line. `optparse` will only expect an argument if `type` is set; the type of `value` will be the type implied by the option's type. If `type` for this option is `None` (no argument expected), then `value` will be `None`. If `nargs > 1`, `value` will be a tuple of values of the appropriate type.

parser

is the `OptionParser` instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

parser.largs

the current list of leftover arguments, ie. arguments that have been consumed but are neither options nor option arguments. Feel free to modify `parser.largs`, e.g. by adding more arguments to it. (This list will become `args`, the second return value of `parse_args()`.)

parser.rargs

the current list of remaining arguments, ie. with `opt_str` and `value` (if applicable) removed, and only the arguments following them still there. Feel free to modify `parser.rargs`, e.g. by consuming more arguments.

parser.values

the object where option values are by default stored (an instance of `optparse.OptionValues`). This lets callbacks use the same mechanism as the rest of `optparse` for storing option values; you don't need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

args

is a tuple of arbitrary positional arguments supplied via the `callback_args` option attribute.

kwargs

is a dictionary of arbitrary keyword arguments supplied via `callback_kwargs`.

[6.21.4.4 Callback example 1:](#)

6.21.4.3 Raising errors in a callback

The callback function should raise `OptionValueError` if there are any problems with the option or its argument(s). `optparse` catches this and terminates the program, printing the error message you supply to `stderr`. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what he did wrong.

6.21.4.4 Callback example 1: trivial callback

Here's an example of a callback option that takes no arguments, and simply records that the option was seen:

```
def record_foo_seen(option, opt_str, value, parser):
    parser.saw_foo = True

parser.add_option("--foo", action="callback", callback=record_foo_se
```

Of course, you could do that with the `store_true` action.

[6.21.4.8 Callback example 5](#):

6.21.4.7 Callback example 4: check arbitrary condition

Of course, you could put any condition in there--you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when moon is full"
                                % opt_str)
    setattr(parser.values, option.dest, 1)
[...]
```

```
parser.add_option("--foo",
                  action="callback", callback=check_moon, dest="foo")
```

(The definition of `is_moon_full()` is left as an exercise for the reader.)

6.21.4.8 Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a `store` or `append` option: if you define `type`, then the option takes one argument that must be convertible to that type; if you further define `nargs`, then the option takes `nargs` arguments.

Here's an example that just emulates the standard `store` action:

```
def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)
[...]
```

```
parser.add_option("--foo",
                  action="callback", callback=store_value,
                  type="int", nargs=3, dest="foo")
```

Note that `optparse` takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don't need a callback for this example.)

Previous: [6.21.4.7 Callback example 4](#): Up: [6.21.4 Option Callbacks](#) Next:
[6.21.4.9 Callback example 6](#):

6.21.4.9 Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as `optparse` doesn't provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional UNIX command-line parsing that `optparse` normally handles for you. In particular, callbacks should implement the conventional rules for bare `" - "` and `" - "` arguments:

- either `" - "` or `" - "` can be option arguments
- bare `" - "` (if not the argument to some option): halt command-line processing and discard the `" - "`
- bare `" - "` (if not the argument to some option): halt command-line processing but keep the `" - "` (append it to `parser.largs`)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact implementation you choose will be based on which trade-offs you're willing to make for your application (which is why `optparse` doesn't support this sort of thing directly).

Nevertheless, here's a stab at a callback for an option with variable arguments:

```
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    done = 0
    value = []
    rargs = parser.rargs
    while rargs:
        arg = rargs[0]

        # Stop if we hit an arg like "--foo", "-a", "-fx", "--file=f
        # etc. Note that this also stops on "-3" or "-3.0", so if
        # your option takes numeric values, you will need to handle
        # this.
        if ((arg[:2] == "--" and len(arg) > 2) or
            (arg[:1] == "-" and len(arg) > 1 and arg[1] != "-")):
            break
```

```
    else:
        value.append(arg)
        del rargs[0]

    setattr(parser.values, option.dest, value)

[...]
```

```
parser.add_option("-c", "--callback",
                  action="callback", callback=varargs)
```

The main weakness with this particular implementation is that negative numbers in the arguments following "-c" will be interpreted as further options (probably causing an error), rather than as arguments to "-c". Fixing this is left as an exercise for the reader.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.5.1 Adding new types

To add new types, you need to define your own subclass of `optparse`'s `Option` class. This class has a couple of attributes that define `optparse`'s types: `TYPES` and `TYPE_CHECKER`.

`TYPES` is a tuple of type names; in your subclass, simply define a new tuple `TYPES` that builds on the standard one.

`TYPE_CHECKER` is a dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```
def check_mytype(option, opt, value)
```

where `option` is an `Option` instance, `opt` is an option string (e.g., `"-f"`), and `value` is the string from the command line that must be checked and converted to your desired type. `check_mytype()` should return an object of the hypothetical type `mytype`. The value returned by a type-checking function will wind up in the `OptionValues` instance returned by `OptionParser.parse_args()`, or be passed to a callback as the `value` parameter.

Your type-checking function should raise `OptionValueError` if it encounters any problems. `OptionValueError` takes a single string argument, which is passed as-is to `OptionParser.error()` method, which in turn prepends the program name and the string `"error: "` and prints everything to `stderr` before terminating the process.

Here's a silly example that demonstrates adding a `complex` option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because `optparse` 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```
from copy import copy
```

```
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the `TYPE_CHECKER` class attribute of your `Option` subclass):

```
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError(
            "option %s: invalid complex value: %r" % (opt, value))
```

Finally, the `Option` subclass:

```
class MyOption (Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```

(If we didn't make a `copy()` of `Option.TYPE_CHECKER`, we would end up modifying the `TYPE_CHECKER` attribute of `optparse`'s `Option` class. This being Python, nothing stops you from doing that except good manners and common sense.)

That's it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to instruct your `OptionParser` to use `MyOption` instead of `Option`:

```
parser = OptionParser(option_class=MyOption)
parser.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to `OptionParser`; if you don't use `add_option()` in the above way, you don't need to tell `OptionParser` which option class to use:

```
option_list = [MyOption("-c", action="store", type="complex", dest="")
parser = OptionParser(option_list=option_list)
```

See [About this document..](#) for information on suggesting changes.

6.21.5.2 Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

```store``` actions

actions that result in `optparse` storing a value to an attribute of the current `OptionValues` instance; these options require a `dest` attribute to be supplied to the `Option` constructor

```typed``` actions

actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the `Option` constructor.

These are overlapping sets: some default ```store``` actions are `store`, `store_const`, `append`, and `count`, while the default ```typed``` actions are `store`, `append`, and `callback`.

When you add an action, you need to decide if it's a ```store``` action, a ```typed``` action, neither, or both. Three class attributes of `Option` (or your `Option` subclass) control this:

ACTIONS

all actions must be listed in `ACTIONS`

STORE_ACTIONS

```store``` actions are additionally listed here

### **TYPED\_ACTIONS**

```typed``` actions are additionally listed here

In order to actually implement your new action, you must override `Option`'s `take_action()` method and add a case that recognizes your action.

For example, let's add an `extend` action. This is similar to the standard `append` action, but instead of taking a single value from the command-line and appending it to an existing list, `extend` will take multiple values in a single

comma-delimited string, and extend an existing list with them. That is, if "-names" is an extend option of type string, the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```
class MyOption (Option):  
  
    ACTIONS = Option.ACTIONS + ("extend",)  
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend",)  
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend",)  
  
    def take_action(self, action, dest, opt, value, values, parser):  
        if action == "extend":  
            lvalue = value.split(",")  
            values.ensure_value(dest, []).extend(lvalue)  
        else:  
            Option.take_action(  
                self, action, dest, opt, value, values, parser)
```

Features of note:

- `extend` both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`
- `MyOption.take_action()` implements just this one new action, and passes control back to `Option.take_action()` for the standard `optparse` actions
- `values` is an instance of the `optparse.Values` class, which provides the very useful `ensure_value()` method. `ensure_value()` is essentially `getattr()` with a safety valve; it is called as

```
values.ensure_value(attr, value)
```

If the `attr` attribute of `values` doesn't exist or is `None`, then `ensure_value()` first sets it to `value`, and then returns 'value'. This is very handy for actions like `extend`, `append`, and `count`, all of which accumulate data in a variable and expect that variable to be of a certain type

(a list for the first two, an integer for the latter). Using `ensure_value()` means that scripts using your action don't have to worry about setting a default value for the option destinations in question; they can just leave the default as `None` and `ensure_value()` will take care of getting it right when it's needed.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.21.5.3 Other reasons to extend optparse

Adding new types and new actions are the big, obvious reasons why you might want to extend `optparse`. I can think of at least two other areas to play with.

First, the simple one: `OptionParser` tries to be helpful by calling `sys.exit()` when appropriate, i.e. when there's an error on the command line or when the user requests help. In the former case, the traditional course of letting the script crash with a traceback is unacceptable; it will make users think there's a bug in your script when they make a command-line error. In the latter case, there's generally not much point in carrying on after printing a help message.

If this behaviour bothers you, it shouldn't be too hard to "fix" it. You'll have to

- 1) subclass `OptionParser` and override `error()`
- 2) subclass `Option` and override `take_action()`--you'll need to provide your own handling of the `help` action that doesn't call `sys.exit()`

The second, much more complex, possibility is to override the command-line syntax implemented by `optparse`. In this case, you'd leave the whole machinery of option actions and types alone, but rewrite the code that processes `sys.argv`. You'll need to subclass `OptionParser` in any case; depending on how radical a rewrite you want, you'll probably need to override one or all of `parse_args()`, `_process_long_opt()`, and `_process_short_opts()`.

Both of these are left as an exercise for the reader. I have not tried to implement either myself, since I'm quite happy with `optparse`'s default behaviour (naturally).

Happy hacking, and don't forget: Use the Source, Luke.

6.28.2.1 The `NullTranslations` class

Translation classes are what actually implement the translation of original source file message strings to translated message strings. The base class used by all translation classes is `NullTranslations`; this provides the basic interface you can use to write your own specialized translation classes. Here are the methods of `NullTranslations`:

`__init__`([*fp*])

Takes an optional file object *fp*, which is ignored by the base class. Initializes ``protected" instance variables `_info` and `_charset` which are set by derived classes, as well as `_fallback`, which is set through `add_fallback`. It then calls `self._parse(fp)` if *fp* is not `None`.

`_parse`(*fp*)

No-op'd in the base class, this method takes file object *fp*, and reads the data from the file, initializing its message catalog. If you have an unsupported message catalog file format, you should override this method to parse your format.

`add_fallback`(*fallback*)

Add *fallback* as the fallback object for the current translation object. A translation object should consult the fallback if it cannot provide a translation for a given message.

`gettext`(*message*)

If a fallback has been set, forward `gettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

`lgettext`(*message*)

If a fallback has been set, forward `lgettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

New in version 2.4.

ugettext(*message*)

If a fallback has been set, forward `ugettext ()` to the fallback.
Otherwise, return the translated message as a Unicode string. Overridden in derived classes.

ngettext(*singular, plural, n*)

If a fallback has been set, forward `ngettext ()` to the fallback.
Otherwise, return the translated message. Overridden in derived classes.

New in version 2.3.

lgettext(*singular, plural, n*)

If a fallback has been set, forward `lgettext ()` to the fallback.
Otherwise, return the translated message. Overridden in derived classes.

New in version 2.4.

ungettext(*singular, plural, n*)

If a fallback has been set, forward `ungettext ()` to the fallback.
Otherwise, return the translated message as a Unicode string. Overridden in derived classes.

New in version 2.3.

info()

Return the ``protected" `_info` variable.

charset()

Return the ``protected" `_charset` variable.

output_charset()

Return the ``protected" `_output_charset` variable, which defines the encoding used to return translated messages.

New in version 2.4.

set_output_charset(*charset*)

Change the ``protected" `_output_charset` variable, which defines the encoding used to return translated messages.

New in version 2.4.

install([*unicode*])

If the *unicode* flag is false, this method installs `self.gettext()` into the built-in namespace, binding it to `"_"`. If *unicode* is true, it binds `self.ugettext()` instead. By default, *unicode* is false.

Note that this is only one way, albeit the most convenient way, to make the `_` function available to your application. Because it affects the entire application globally, and specifically the built-in namespace, localized modules should never install `_`. Instead, they should use this code to make `_` available to their module:

```
import gettext
t = gettext.translation('mymodule', ...)
_ = t.gettext
```

This puts `_` only in the module's global namespace and so only affects calls within this module.

Previous: [6.28.2.1 The NullTranslations class](#) Up: [6.28.2 Class-based API](#)
Next: [6.28.2.3 Solaris message catalog](#)

6.28.2.2 The GNUTranslations class

The `gettext` module provides one additional class derived from `NullTranslations`: `GNUTranslations`. This class overrides `_parse()` to enable reading GNU `gettext` format `.mo` files in both big-endian and little-endian format. It also coerces both message ids and message strings to Unicode.

`GNUTranslations` parses optional meta-data out of the translation catalog. It is convention with GNU `gettext` to include meta-data as the translation for the empty string. This meta-data is in [RFC 822](#)-style `key: value` pairs, and should contain the `Project-Id-Version` key. If the key `Content-Type` is found, then the `charset` property is used to initialize the ``protected" `_charset` instance variable, defaulting to `NONE` if not found. If the charset encoding is specified, then all message ids and message strings read from the catalog are converted to Unicode using this encoding. The `ugettext()` method always returns a Unicode, while the `gettext()` returns an encoded 8-bit string. For the message id arguments of both methods, either Unicode strings or 8-bit strings containing only US-ASCII characters are acceptable. Note that the Unicode version of the methods (i.e. `ugettext()` and `ungettext()`) are the recommended interface to use for internationalized Python programs.

The entire set of key/value pairs are placed into a dictionary and set as the ``protected" `_info` instance variable.

If the `.mo` file's magic number is invalid, or if other problems occur while reading the file, instantiating a `GNUTranslations` class can raise `IOError`.

The following methods are overridden from the base class implementation:

gettext(*message*)

Look up the *message* id in the catalog and return the corresponding message string, as an 8-bit string encoded with the catalog's charset encoding, if known. If there is no entry in the catalog for the *message* id, and a fallback has been set, the look up is forwarded to the fallback's

`gettext()` method. Otherwise, the *message* id is returned.

lgettext(*message*)

Equivalent to `gettext()`, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with `set_output_charset()`.

New in version 2.4.

ugettext(*message*)

Look up the *message* id in the catalog and return the corresponding message string, as a Unicode string. If there is no entry in the catalog for the *message* id, and a fallback has been set, the look up is forwarded to the fallback's `ugettext()` method. Otherwise, the *message* id is returned.

ngettext(*singular*, *plural*, *n*)

Do a plural-forms lookup of a message id. *singular* is used as the message id for purposes of lookup in the catalog, while *n* is used to determine which plural form to use. The returned message string is an 8-bit string encoded with the catalog's charset encoding, if known.

If the message id is not found in the catalog, and a fallback is specified, the request is forwarded to the fallback's `ngettext()` method. Otherwise, when *n* is 1 *singular* is returned, and *plural* is returned in all other cases.

New in version 2.3.

Ingettext(*singular*, *plural*, *n*)

Equivalent to `gettext()`, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with `set_output_charset()`.

New in version 2.4.

ungettext(*singular*, *plural*, *n*)

Do a plural-forms lookup of a message id. *singular* is used as the message id for purposes of lookup in the catalog, while *n* is used to determine which plural form to use. The returned message string is a Unicode string.

If the message id is not found in the catalog, and a fallback is specified, the request is forwarded to the fallback's `ungettext()` method. Otherwise, when *n* is 1 *singular* is returned, and *plural* is returned in all other cases.

Here is an example:

```
n = len(os.listdir('.'))
cat = GNUTranslations(somefile)
message = cat.ungettext(
    'There is %(num)d file in this directory',
    'There are %(num)d files in this directory',
    n) % {'num': n}
```

New in version 2.3.

6.28.2.4 The Catalog constructor

GNOME uses a version of the `gettext` module by James Henstridge, but this version has a slightly different API. Its documented usage was:

```
import gettext
cat = gettext.Catalog(domain, locale_dir)
_ = cat.gettext
print _('hello world')
```

For compatibility with this older module, the function `Catalog()` is an alias for the `translation()` function described above.

One difference between this module and Henstridge's: his catalog objects supported access through a mapping API, but this appears to be unused and so is not currently supported.

Previous: [6.28.3 Internationalizing your programs](#) Up: [6.28.3 Internationalizing your programs](#) Next: [6.28.3.2 Localizing your application](#)

6.28.3.1 Localizing your module

If you are localizing your module, you must take care not to make global changes, e.g. to the built-in namespace. You should not use the GNU `gettext` API but instead the class-based API.

Let's say your module is called `spam` and the module's various natural language translation `.mo` files reside in `/usr/share/locale` in GNU `gettext` format. Here's what you would put at the top of your module:

```
import gettext
t = gettext.translation('spam', '/usr/share/locale')
_ = t.lgettext
```

If your translators were providing you with Unicode strings in their `.po` files, you'd instead do:

```
import gettext
t = gettext.translation('spam', '/usr/share/locale')
_ = t.ugettext
```

Previous: [6.28.3 Internationalizing your programs](#) Up: [6.28.3 Internationalizing your programs](#) Next: [6.28.3.2 Localizing your application](#)

Previous: [6.28.3.1 Localizing your module](#) Up: [6.28.3 Internationalizing your programs](#) Next: [6.28.3.3 Changing languages on](#)

6.28.3.2 Localizing your application

If you are localizing your application, you can install the `_()` function globally into the built-in namespace, usually in the main driver file of your application. This will let all your application-specific files just use `_(' . . . ')` without having to explicitly install it in each file.

In the simple case then, you need only add the following bit of code to the main driver file of your application:

```
import gettext
gettext.install('myapplication')
```

If you need to set the locale directory or the *unicode* flag, you can pass these into the `install()` function:

```
import gettext
gettext.install('myapplication', '/usr/share/locale', unicode=1)
```

6.28.3.3 Changing languages on the fly

If your program needs to support many languages at the same time, you may want to create multiple translation instances and then switch between them explicitly, like so:

```
import gettext

lang1 = gettext.translation('myapplication', languages=['en'])
lang2 = gettext.translation('myapplication', languages=['fr'])
lang3 = gettext.translation('myapplication', languages=['de'])

# start by using language1
lang1.install()

# ... time goes by, user selects language 2
lang2.install()

# ... more time goes by, user selects language 3
lang3.install()
```

Previous: [6.28.3.2 Localizing your application](#) Up: [6.28.3 Internationalizing your programs](#) Next: [6.28.3.4 Deferred translations](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.28.3.4 Deferred translations

In most coding situations, strings are translated where they are coded. Occasionally however, you need to mark strings for translation, but defer actual translation until later. A classic example is:

```
animals = ['mollusk',
           'albatross',
           'rat',
           'penguin',
           'python',
           ]
# ...
for a in animals:
    print a
```

Here, you want to mark the strings in the `animals` list as being translatable, but you don't actually want to translate them until they are printed.

Here is one way you can handle this situation:

```
def _(message): return message

animals = [_('mollusk'),
           _('albatross'),
           _('rat'),
           _('penguin'),
           _('python'),
           ]

del _

# ...
for a in animals:
    print _(a)
```

This works because the dummy definition of `_()` simply returns the string unchanged. And this dummy definition will temporarily override any definition of `_()` in the built-in namespace (until the `del` command). Take care, though if you have a previous definition of `_` in the local namespace.

Note that the second use of `_()` will not identify ``a"` as being translatable to the `pygettext` program, since it is not a string.

Another way to handle this is with the following example:

```
def N_(message): return message

animals = [N_('mollusk'),
           N_('albatross'),
           N_('rat'),
           N_('penguin'),
           N_('python'),
           ]

# ...
for a in animals:
    print _(a)
```

In this case, you are marking translatable strings with the function `N_()`, [6.6](#) which won't conflict with any definition of `_()`. However, you will need to teach your message extraction program to look for translatable strings marked with `N_()`. `pygettext` and `xpot` both support this through the use of command line switches.

Footnotes

...`N_()`, [6.6](#)

The choice of `N_()` here is totally arbitrary; it could have just as easily been `MarkThisStringForTranslation()`.

6.28.3.5 `gettext()` vs. `lgettext()`

In Python 2.4 the `lgettext()` family of functions were introduced. The intention of these functions is to provide an alternative which is more compliant with the current implementation of GNU `gettext`. Unlike `gettext()`, which returns strings encoded with the same codeset used in the translation file, `lgettext()` will return strings encoded with the preferred system encoding, as returned by `locale.getpreferredencoding()`. Also notice that Python 2.4 introduces new functions to explicitly choose the codeset used in translated strings. If a codeset is explicitly set, even `lgettext()` will return translated strings in the requested codeset, as would be expected in the GNU `gettext` implementation.

6.29.5.1 StreamHandler

The `StreamHandler` class sends logging output to streams such as `sys.stdout`, `sys.stderr` or any file-like object (or, more precisely, any object which supports `write()` and `flush()` methods).

class `StreamHandler`([*strm*])

Returns a new instance of the `StreamHandler` class. If *strm* is specified, the instance will use it for logging output; otherwise, `sys.stderr` will be used.

emit(*record*)

If a formatter is specified, it is used to format the record. The record is then written to the stream with a trailing newline. If exception information is present, it is formatted using `traceback.print_exception()` and appended to the stream.

flush()

Flushes the stream by calling its `flush()` method. Note that the `close()` method is inherited from `Handler` and so does nothing, so an explicit `flush()` call may be needed at times.

6.29.5.2 FileHandler

The `FileHandler` class sends logging output to a disk file. It inherits the output functionality from `StreamHandler`.

class `FileHandler`(*filename*[, *mode*])

Returns a new instance of the `FileHandler` class. The specified file is opened and used as the stream for logging. If *mode* is not specified, 'a' is used. By default, the file grows indefinitely.

`close`()

Closes the file.

`emit`(*record*)

Outputs the record to the file.

6.29.5.3 RotatingFileHandler

The `RotatingFileHandler` class supports rotation of disk log files.

```
class RotatingFileHandler(filename[, mode[, maxBytes[,  
                           backupCount]]])
```

Returns a new instance of the `RotatingFileHandler` class. The specified file is opened and used as the stream for logging. If *mode* is not specified, 'a' is used. By default, the file grows indefinitely.

You can use the *maxBytes* and *backupCount* values to allow the file to *rollover* at a predetermined size. When the size is about to be exceeded, the file is closed and a new file is silently opened for output. Rollover occurs whenever the current log file is nearly *maxBytes* in length; if *maxBytes* is zero, rollover never occurs. If *backupCount* is non-zero, the system will save old log files by appending the extensions ".1", ".2" etc., to the filename. For example, with a *backupCount* of 5 and a base file name of `app.log`, you would get `app.log`, `app.log.1`, `app.log.2`, up to `app.log.5`. The file being written to is always `app.log`. When this file is filled, it is closed and renamed to `app.log.1`, and if files `app.log.1`, `app.log.2`, etc. exist, then they are renamed to `app.log.2`, `app.log.3` etc. respectively.

doRollover()

Does a rollover, as described above.

emit(*record*)

Outputs the record to the file, catering for rollover as described previously.

See [About this document..](#) for information on suggesting changes.

6.29.5.4 TimedRotatingFileHandler

The `TimedRotatingFileHandler` class supports rotation of disk log files at certain timed intervals.

```
class TimedRotatingFileHandler(filename [,when [,interval
                               [,backupCount]]])
```

Returns a new instance of the `TimedRotatingFileHandler` class. The specified file is opened and used as the stream for logging. On rotating it also sets the filename suffix. Rotating happens based on the product of *when* and *interval*.

You can use the *when* to specify the type of *interval*. The list of possible values is, note that they are not case sensitive:

Value	Type of interval
S	Seconds
M	Minutes
H	Hours
D	Days
W	Week day (0=Monday)
midnight	Roll over at midnight

If *backupCount* is non-zero, the system will save old log files by appending the extensions ".1", ".2" etc., to the filename. For example, with a *backupCount* of 5 and a base file name of `app.log`, you would get `app.log`, `app.log.1`, `app.log.2`, up to `app.log.5`. The file being written to is always `app.log`. When this file is filled, it is closed and renamed to `app.log.1`, and if files `app.log.1`, `app.log.2`, etc. exist, then they are renamed to `app.log.2`, `app.log.3` etc. respectively.

doRollover()

Does a rollover, as described above.

emit(*record*)

Outputs the record to the file, catering for rollover as described above.

Previous: [6.29.5.3 RotatingFileHandler](#) Up: [6.29.5 Handler Objects](#) Next:
[6.29.5.5 SocketHandler](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.29.5.5 SocketHandler

The `SocketHandler` class sends logging output to a network socket. The base class uses a TCP socket.

class SocketHandler(*host*, *port*)

Returns a new instance of the `SocketHandler` class intended to communicate with a remote machine whose address is given by *host* and *port*.

close()

Closes the socket.

handleError()

emit()

Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. If the connection was previously lost, re-establishes the connection. To unpickle the record at the receiving end into a `LogRecord`, use the `makeLogRecord()` function.

handleError()

Handles an error which has occurred during `emit()`. The most likely cause is a lost connection. Closes the socket so that we can retry on the next event.

makeSocket()

This is a factory method which allows subclasses to define the precise type of socket they want. The default implementation creates a TCP socket (`socket.SOCK_STREAM`).

makePickle(*record*)

Pickles the record's attribute dictionary in binary format with a length prefix, and returns it ready for transmission across the socket.

send(*packet*)

Send a pickled string *packet* to the socket. This function allows for partial sends which can happen when the network is busy.

Previous: [6.29.5.4 TimedRotatingFileHandler](#) **Up:** [6.29.5 Handler Objects](#)

Next: [6.29.5.6 DatagramHandler](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

6.29.5.6 DatagramHandler

The `DatagramHandler` class inherits from `SocketHandler` to support sending logging messages over UDP sockets.

class `DatagramHandler`(*host*, *port*)

Returns a new instance of the `DatagramHandler` class intended to communicate with a remote machine whose address is given by *host* and *port*.

emit()

Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. To unpickle the record at the receiving end into a `LogRecord`, use the `makeLogRecord()` function.

makeSocket()

The factory method of `SocketHandler` is here overridden to create a UDP socket (`socket.SOCK_DGRAM`).

send(*s*)

Send a pickled string to a socket.

6.29.5.7 SysLogHandler

The `SysLogHandler` class supports sending logging messages to a remote or local UNIX syslog.

class `SysLogHandler`([*address*[, *facility*]])

Returns a new instance of the `SysLogHandler` class intended to communicate with a remote UNIX machine whose address is given by *address* in the form of a (*host*, *port*) tuple. If *address* is not specified, ('localhost', 514) is used. The address is used to open a UDP socket. If *facility* is not specified, LOG_USER is used.

close()

Closes the socket to the remote host.

emit(*record*)

The record is formatted, and then sent to the syslog server. If exception information is present, it is *not* sent to the server.

encodePriority(*facility*, *priority*)

Encodes the facility and priority into an integer. You can pass in strings or integers - if strings are passed, internal mapping dictionaries are used to convert them to integers.

6.29.5.8 NTEventLogHandler

The `NTEventLogHandler` class supports sending logging messages to a local Windows NT, Windows 2000 or Windows XP event log. Before you can use it, you need Mark Hammond's Win32 extensions for Python installed.

class NTEventLogHandler(*appname*[, *dllname*[, *logtype*]])

Returns a new instance of the `NTEventLogHandler` class. The *appname* is used to define the application name as it appears in the event log. An appropriate registry entry is created using this name. The *dllname* should give the fully qualified pathname of a .dll or .exe which contains message definitions to hold in the log (if not specified, 'win32service.pyd' is used - this is installed with the Win32 extensions and contains some basic placeholder message definitions. Note that use of these placeholders will make your event logs big, as the entire message source is held in the log. If you want slimmer logs, you have to pass in the name of your own .dll or .exe which contains the message definitions you want to use in the event log). The *logtype* is one of 'Application', 'System' or 'Security', and defaults to 'Application'.

close()

At this point, you can remove the application name from the registry as a source of event log entries. However, if you do this, you will not be able to see the events as you intended in the Event Log Viewer - it needs to be able to access the registry to get the .dll name. The current version does not do this (in fact it doesn't do anything).

emit(*record*)

Determines the message ID, event category and event type, and then logs the message in the NT event log.

getEventCategory(*record*)

Returns the event category for the record. Override this if you want to specify your own categories. This version returns 0.

getEventType(*record*)

Returns the event type for the record. Override this if you want to specify your own types. This version does a mapping using the handler's `typemap` attribute, which is set up in `__init__()` to a dictionary which contains mappings for `DEBUG`, `INFO`, `WARNING`, `ERROR` and `CRITICAL`. If you are using your own levels, you will either need to override this method or place a suitable dictionary in the handler's `typemap` attribute.

getMessageID(*record*)

Returns the message ID for the record. If you are using your own messages, you could do this by having the `msg` passed to the logger being an ID rather than a format string. Then, in here, you could use a dictionary lookup to get the message ID. This version returns 1, which is the base message ID in `win32service.pyd`.

Previous: [6.29.5.7 SysLogHandler](#) Up: [6.29.5 Handler Objects](#) Next: [6.29.5.9 SMTPHandler](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.29.5.9 SMTPHandler

The `SMTPHandler` class supports sending logging messages to an email address via SMTP.

class SMTPHandler(*mailhost, fromaddr, toaddrs, subject*)

Returns a new instance of the `SMTPHandler` class. The instance is initialized with the from and to addresses and subject line of the email. The *toaddrs* should be a list of strings. To specify a non-standard SMTP port, use the (host, port) tuple format for the *mailhost* argument. If you use a string, the standard SMTP port is used.

emit(*record*)

Formats the record and sends it to the specified addressees.

getSubject(*record*)

If you want to specify a subject line which is record-dependent, override this method.

6.29.5.10 MemoryHandler

The `MemoryHandler` supports buffering of logging records in memory, periodically flushing them to a *target* handler. Flushing occurs whenever the buffer is full, or when an event of a certain severity or greater is seen.

`MemoryHandler` is a subclass of the more general `BufferingHandler`, which is an abstract class. This buffers logging records in memory. Whenever each record is added to the buffer, a check is made by calling `shouldFlush()` to see if the buffer should be flushed. If it should, then `flush()` is expected to do the needful.

class `BufferingHandler`(*capacity*)

Initializes the handler with a buffer of the specified capacity.

emit(*record*)

Appends the record to the buffer. If `shouldFlush()` returns true, calls `flush()` to process the buffer.

flush()

You can override this to implement custom flushing behavior. This version just zaps the buffer to empty.

shouldFlush(*record*)

Returns true if the buffer is up to capacity. This method can be overridden to implement custom flushing strategies.

class `MemoryHandler`(*capacity*[, *flushLevel* [, *target*]])

Returns a new instance of the `MemoryHandler` class. The instance is initialized with a buffer size of *capacity*. If *flushLevel* is not specified, `ERROR` is used. If no *target* is specified, the target will need to be set using `setTarget()` before this handler does anything useful.

close()

Calls `flush()`, sets the target to `None` and clears the buffer.

flush()

For a `MemoryHandler`, flushing means just sending the buffered records to the target, if there is one. Override if you want different behavior.

setTarget(*target*)

Sets the target handler for this handler.

shouldFlush(*record*)

Checks for buffer full or a record at the *flushLevel* or higher.

Previous: [6.29.5.10 MemoryHandler](#) Up: [6.29.5 Handler Objects](#) Next: [6.29.6 Formatter Objects](#)

6.29.5.11 HTTPHandler

The `HTTPHandler` class supports sending logging messages to a Web server, using either "GET" or "POST" semantics.

class `HTTPHandler`(*host*, *url*[, *method*])

Returns a new instance of the `HTTPHandler` class. The instance is initialized with a host address, url and HTTP method. If no *method* is specified, "GET" is used.

emit(*record*)

Sends the record to the Web server as an URL-encoded dictionary.

Previous: [6.29.5.10 MemoryHandler](#) Up: [6.29.5 Handler Objects](#) Next: [6.29.6 Formatter Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

6.29.10.1 Configuration functions

The following functions allow the logging module to be configured. Before they can be used, you must import `logging.config`. Their use is optional -- you can configure the logging module entirely by making calls to the main API (defined in `logging` itself) and defining handlers which are declared either in `logging` or `logging.handlers`.

fileConfig(*fname*[, *defaults*])

Reads the logging configuration from a ConfigParser-format file named *fname*. This function can be called several times from an application, allowing an end user the ability to select from various pre-canned configurations (if the developer provides a mechanism to present the choices and load the chosen configuration). Defaults to be passed to ConfigParser can be specified in the *defaults* argument.

listen([*port*])

Starts up a socket server on the specified port, and listens for new configurations. If no port is specified, the module's default `DEFAULT_LOGGING_CONFIG_PORT` is used. Logging configurations will be sent as a file suitable for processing by `fileConfig()`. Returns a `Thread` instance on which you can call `start()` to start the server, and which you can `join()` when appropriate. To stop the server, call `stopListening()`. To send a configuration to the socket, read in the configuration file and send it to the socket as a string of bytes preceded by a four-byte length packed in binary using `struct.pack(">L", n)`.

stopListening()

Stops the listening server which was created with a call to `listen()`. This is typically called before calling `join()` on the return value from `listen()`.

Previous: [6.29.10 Configuration](#) **Up:** [6.29.10 Configuration](#) **Next:** [6.29.10.2 Configuration file format](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

6.29.10.2 Configuration file format

The configuration file format understood by `fileConfig()` is based on `ConfigParser` functionality. The file must contain sections called `[loggers]`, `[handlers]` and `[formatters]` which identify by name the entities of each type which are defined in the file. For each such entity, there is a separate section which identified how that entity is configured. Thus, for a logger named `log01` in the `[loggers]` section, the relevant configuration details are held in a section `[logger_log01]`. Similarly, a handler called `hand01` in the `[handlers]` section will have its configuration held in a section called `[handler_hand01]`, while a formatter called `form01` in the `[formatters]` section will have its configuration specified in a section called `[formatter_form01]`. The root logger configuration must be specified in a section called `[logger_root]`.

Examples of these sections in the file are given below.

```
[loggers]
keys=root,log02,log03,log04,log05,log06,log07

[handlers]
keys=hand01,hand02,hand03,hand04,hand05,hand06,hand07,hand08,hand09

[formatters]
keys=form01,form02,form03,form04,form05,form06,form07,form08,form09
```

The root logger must specify a level and a list of handlers. An example of a root logger section is given below.

```
[logger_root]
level=NOTSET
handlers=hand01
```

The `level` entry can be one of `DEBUG`, `INFO`, `WARNING`, `ERROR`, `CRITICAL` or `NOTSET`. For the root logger only, `NOTSET` means that all messages will be logged. Level values are `eval()`uated in the context of the logging package's namespace.

The `handlers` entry is a comma-separated list of handler names, which must appear in the `[handlers]` section. These names must appear in the `[handlers]` section and have corresponding sections in the configuration file.

For loggers other than the root logger, some additional information is required. This is illustrated by the following example.

```
[logger_parser]
level=DEBUG
handlers=hand01
propagate=1
qualname=compiler.parser
```

The `level` and `handlers` entries are interpreted as for the root logger, except that if a non-root logger's level is specified as `NOTSET`, the system consults loggers higher up the hierarchy to determine the effective level of the logger. The `propagate` entry is set to 1 to indicate that messages must propagate to handlers higher up the logger hierarchy from this logger, or 0 to indicate that messages are **not** propagated to handlers up the hierarchy. The `qualname` entry is the hierarchical channel name of the logger, that is to say the name used by the application to get the logger.

Sections which specify handler configuration are exemplified by the following.

```
[handler_hand01]
class=StreamHandler
level=NOTSET
formatter=form01
args=(sys.stdout,)
```

The `class` entry indicates the handler's class (as determined by `eval()` in the `logging` package's namespace). The `level` is interpreted as for loggers, and `NOTSET` is taken to mean "log everything".

The `formatter` entry indicates the key name of the formatter for this handler. If blank, a default formatter (`logging._defaultFormatter`) is used. If a name is specified, it must appear in the `[formatters]` section and have a corresponding section in the configuration file.

The `args` entry, when `eval()`uated in the context of the `logging` package's namespace, is the list of arguments to the constructor for the handler class. Refer to the constructors for the relevant handlers, or to the examples below, to see

how typical entries are constructed.

```
[handler_hand02]
class=FileHandler
level=DEBUG
formatter=form02
args=('python.log', 'w')
```

```
[handler_hand03]
class=handlers.SocketHandler
level=INFO
formatter=form03
args=('localhost', handlers.DEFAULT_TCP_LOGGING_PORT)
```

```
[handler_hand04]
class=handlers.DatagramHandler
level=WARN
formatter=form04
args=('localhost', handlers.DEFAULT_UDP_LOGGING_PORT)
```

```
[handler_hand05]
class=handlers.SysLogHandler
level=ERROR
formatter=form05
args=(('localhost', handlers.SYSLOG_UDP_PORT), handlers.SysLogHandle
```

```
[handler_hand06]
class=handlers.NTEventLogHandler
level=CRITICAL
formatter=form06
args=('Python Application', '', 'Application')
```

```
[handler_hand07]
class=handlers.SMTPHandler
level=WARN
formatter=form07
args=('localhost', 'from@abc', ['user1@abc', 'user2@xyz'], 'Logger S
```

```
[handler_hand08]
class=handlers.MemoryHandler
level=NOTSET
formatter=form08
target=
args=(10, ERROR)
```

```
[handler_hand09]
class=handlers.HTTPHandler
level=NOTSET
formatter=form09
args=('localhost:9022', '/log', 'GET')
```

Sections which specify formatter configuration are typified by the following.

```
[formatter_form01]
format=F1 %(asctime)s %(levelname)s %(message)s
datefmt=
```

The `format` entry is the overall format string, and the `datefmt` entry is the `strftime()`-compatible date/time format string. If empty, the package substitutes ISO8601 format date/times, which is almost equivalent to specifying the date format string "The ISO8601 format also specifies milliseconds, which are appended to the result of using the above format string, with a comma separator. An example time in ISO8601 format is 2003-01-23 00:29:50,411.

7.5.4.1 Semaphore Example

Semaphores are often used to guard resources with limited capacity, for example, a database server. In any situation where the size of the resource size is fixed, you should use a bounded semaphore. Before spawning any worker threads, your main thread would initialize the semaphore:

```
maxconnections = 5
...
pool_sema = BoundedSemaphore(value=maxconnections)
```

Once spawned, worker threads call the semaphore's acquire and release methods when they need to connect to the server:

```
pool_sema.acquire()
conn = connectdb()
... use connection ...
conn.close()
pool_sema.release()
```

The use of a bounded semaphore reduces the chance that a programming error which causes the semaphore to be released more than it's acquired will go undetected.

12.2.1.1 Deprecated methods

Changed in version 2.4: The `add_payload()` method was removed; use the `attach()` method instead.

The following methods are deprecated. They are documented here for completeness.

`get_type([failobj])`

Return the message's content type, as a string of the form `maintype/subtype` as taken from the `Content-Type:` header. The returned string is coerced to lowercase.

If there is no `Content-Type:` header in the message, `failobj` is returned (defaults to `None`).

Deprecated since release 2.2.2. Use the `get_content_type()` method instead.

`get_main_type([failobj])`

Return the message's *main* content type. This essentially returns the *maintype* part of the string returned by `get_type()`, with the same semantics for `failobj`.

Deprecated since release 2.2.2. Use the `get_content_maintype()` method instead.

`get_subtype([failobj])`

Return the message's sub-content type. This essentially returns the *subtype* part of the string returned by `get_type()`, with the same semantics for `failobj`.

Deprecated since release 2.2.2. Use the `get_content_subtype()` method instead.

Previous: [12.2.2 Parsing email messages](#) Up: [12.2.2 Parsing email messages](#) Next: [12.2.2.2 Parser class API](#)

12.2.2.1 FeedParser API

New in version 2.4.

The `FeedParser` provides an API that is conducive to incremental parsing of email messages, such as would be necessary when reading the text of an email message from a source that can block (e.g. a socket). The `FeedParser` can of course be used to parse an email message fully contained in a string or a file, but the classic `Parser` API may be more convenient for such use cases. The semantics and results of the two parser APIs are identical.

The `FeedParser`'s API is simple; you create an instance, feed it a bunch of text until there's no more to feed it, then close the parser to retrieve the root message object. The `FeedParser` is extremely accurate when parsing standards-compliant messages, and it does a very good job of parsing non-compliant messages, providing information about how a message was deemed broken. It will populate a message object's `defects` attribute with a list of any problems it found in a message. See the [email.Errors](#) module for the list of defects that it can find.

Here is the API for the `FeedParser`:

class `FeedParser`([*_factory*])

Create a `FeedParser` instance. Optional *_factory* is a no-argument callable that will be called whenever a new message object is needed. It defaults to the `email.Message.Message` class.

feed(*data*)

Feed the `FeedParser` some more data. *data* should be a string containing one or more lines. The lines can be partial and the `FeedParser` will stitch such partial lines together properly. The lines in the string can have any of the common three line endings, carriage return, newline, or carriage return and newline (they can even be mixed).

close()

Closing a `FeedParser` completes the parsing of all previously fed data, and returns the root message object. It is undefined what happens if you feed more data to a closed `FeedParser`.

Previous: [12.2.2 Parsing email messages](#) **Up:** [12.2.2 Parsing email messages](#) **Next:** [12.2.2.2 Parser class API](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

12.2.2.2 Parser class API

The `Parser` provides an API that can be used to parse a message when the complete contents of the message are available in a string or file. The `email.Parser` module also provides a second class, called `HeaderParser` which can be used if you're only interested in the headers of the message. `HeaderParser` can be much faster in these situations, since it does not attempt to parse the message body, instead setting the payload to the raw body as a string. `HeaderParser` has the same API as the `Parser` class.

`class Parser([_class[, strict]])`

The constructor for the `Parser` class takes an optional argument `_class`. This must be a callable factory (such as a function or a class), and it is used whenever a sub-message object needs to be created. It defaults to `Message` (see [`email.Message`](#)). The factory will be called without arguments.

The optional `strict` flag is ignored.

Deprecated since release 2.4. Because the `Parser` class is a backward compatible API wrapper around the new-in-Python 2.4 `FeedParser`, *all* parsing is effectively non-strict. You should simply stop passing a `strict` flag to the `Parser` constructor.

Changed in version 2.2.2: The `strict` flag was added. Changed in version 2.4: The `strict` flag was deprecated.

The other public `Parser` methods are:

`parse(fp[, headersonly])`

Read all the data from the file-like object `fp`, parse the resulting text, and return the root message object. `fp` must support both the `readline()` and the `read()` methods on file-like objects.

The text contained in *fp* must be formatted as a block of [RFC 2822](#) style headers and header continuation lines, optionally preceded by an envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts).

Optional *headersonly* is as with the `parse()` method.

Changed in version 2.2.2: The *headersonly* flag was added.

parsestr(*text*[, *headersonly*])

Similar to the `parse()` method, except it takes a string object instead of a file-like object. Calling this method on a string is exactly equivalent to wrapping *text* in a `StringIO` instance first and calling `parse()`.

Optional *headersonly* is a flag specifying whether to stop parsing after reading the headers or not. The default is `False`, meaning it parses the entire contents of the file.

Changed in version 2.2.2: The *headersonly* flag was added.

Since creating a message object structure from a string or a file object is such a common task, two functions are provided as a convenience. They are available in the top-level `email` package namespace.

message_from_string(*s*[, *_class*[, *strict*]])

Return a message object structure from a string. This is exactly equivalent to `Parser().parsestr(s)`. Optional *_class* and *strict* are interpreted as with the `Parser` class constructor.

Changed in version 2.2.2: The *strict* flag was added.

message_from_file(*fp*[, *_class*[, *strict*]])

Return a message object structure tree from an open file object. This is exactly equivalent to `Parser().parse(fp)`. Optional *_class* and *strict* are interpreted as with the `Parser` class constructor.

Changed in version 2.2.2: The *strict* flag was added.

Here's an example of how you might use this at an interactive Python prompt:

```
>>> import email
>>> msg = email.message_from_string(myString)
```

Previous: [12.2.2.1 FeedParser API](#) **Up:** [12.2.2 Parsing email messages](#) **Next:** [12.2.2.3 Additional notes](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

12.2.2.3 Additional notes

Here are some notes on the parsing semantics:

- Most non-multipart type messages are parsed as a single message object with a string payload. These objects will return `False` for `is_multipart()`. Their `get_payload()` method will return a string object.
- All multipart type messages will be parsed as a container message object with a list of sub-message objects for their payload. The outer container message will return `True` for `is_multipart()` and their `get_payload()` method will return the list of `Message` subparts.
- Most messages with a content type of `message/*` (e.g. `message/delivery-status` and `message/rfc822`) will also be parsed as container object containing a list payload of length 1. Their `is_multipart()` method will return `True`. The single element in the list payload will be a sub-message object.
- Some non-standards compliant messages may not be internally consistent about their multipart-ness. Such messages may have a `Content-Type:` header of type `multipart`, but their `is_multipart()` method may return `False`. If such messages were parsed with the `FeedParser`, they will have an instance of the `MultipartInvariantViolationDefect` class in their `defects` attribute list. See [email.Errors](#) for details.

Previous: [12.2.3 Generating MIME documents](#) Up: [12.2.3 Generating MIME documents](#) Next: [12.2.4 Creating email and](#)

12.2.3.1 Deprecated methods

The following methods are deprecated in `email` version 2. They are documented here for completeness.

`__call__`(`msg`[, `unixfrom`])

This method is identical to the `flatten()` method.

Deprecated since release 2.2.2. Use the `flatten()` method instead.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

13.6.2.1 DOMImplementation Objects

The `DOMImplementation` interface provides a way for applications to determine the availability of particular features in the DOM they are using. DOM Level 2 added the ability to create new `Document` and `DocumentType` objects using the `DOMImplementation` as well.

hasFeature(*feature*, *version*)

Return true if the feature identified by the pair of strings *feature* and *version* is implemented.

createDocument(*namespaceUri*, *qualifiedName*, *doctype*)

Return a new `Document` object (the root of the DOM), with a child `Element` object having the given *namespaceUri* and *qualifiedName*. The *doctype* must be a `DocumentType` object created by `createDocumentType` (), or `None`. In the Python DOM API, the first two arguments can also be `None` in order to indicate that no `Element` child is to be created.

createDocumentType(*qualifiedName*, *publicId*, *systemId*)

Return a new `DocumentType` object that encapsulates the given *qualifiedName*, *publicId*, and *systemId* strings, representing the information contained in an XML document type declaration.

13.6.2.2 Node Objects

All of the components of an XML document are subclasses of `Node`.

nodeType

An integer representing the node type. Symbolic constants for the types are on the `Node` object: `ELEMENT_NODE`, `ATTRIBUTE_NODE`, `TEXT_NODE`, `CDATA_SECTION_NODE`, `ENTITY_NODE`, `PROCESSING_INSTRUCTION_NODE`, `COMMENT_NODE`, `DOCUMENT_NODE`, `DOCUMENT_TYPE_NODE`, `NOTATION_NODE`. This is a read-only attribute.

parentNode

The parent of the current node, or `None` for the document node. The value is always a `Node` object or `None`. For `Element` nodes, this will be the parent element, except for the root element, in which case it will be the `Document` object. For `Attr` nodes, this is always `None`. This is a read-only attribute.

attributes

A `NamedNodeMap` of attribute objects. Only elements have actual values for this; others provide `None` for this attribute. This is a read-only attribute.

previousSibling

The node that immediately precedes this one with the same parent. For instance the element with an end-tag that comes just before the *self* element's start-tag. Of course, XML documents are made up of more than just elements so the previous sibling could be text, a comment, or something else. If this node is the first child of the parent, this attribute will be `None`. This is a read-only attribute.

nextSibling

The node that immediately follows this one with the same parent. See also `previousSibling`. If this is the last child of the parent, this attribute will be `None`. This is a read-only attribute.

childNodes

A list of nodes contained within this node. This is a read-only attribute.

firstChild

The first child of the node, if there are any, or `None`. This is a read-only attribute.

lastChild

The last child of the node, if there are any, or `None`. This is a read-only attribute.

localName

The part of the `tagName` following the colon if there is one, else the entire `tagName`. The value is a string.

prefix

The part of the `tagName` preceding the colon if there is one, else the empty string. The value is a string, or `None`

namespaceURI

The namespace associated with the element name. This will be a string or `None`. This is a read-only attribute.

nodeName

This has a different meaning for each node type; see the DOM specification for details. You can always get the information you would get here from another property such as the `tagName` property for elements or the `name` property for attributes. For all node types, the value of this attribute will be either a string or `None`. This is a read-only attribute.

nodeValue

This has a different meaning for each node type; see the DOM specification for details. The situation is similar to that with `nodeName`. The value is a string or `None`.

hasAttributes()

Returns true if the node has any attributes.

hasChildNodes()

Returns true if the node has any child nodes.

isSameNode(*other*)

Returns true if *other* refers to the same node as this node. This is especially useful for DOM implementations which use any sort of proxy architecture (because more than one object can refer to the same node).

Note: This is based on a proposed DOM Level 3 API which is still in the "working draft" stage, but this particular interface appears uncontroversial. Changes from the W3C will not necessarily affect this method in the Python DOM interface (though any new W3C API for this would also be supported).

appendChild(*newChild*)

Add a new child node to this node at the end of the list of children, returning *newChild*.

insertBefore(*newChild*, *refChild*)

Insert a new child node before an existing child. It must be the case that *refChild* is a child of this node; if not, `ValueError` is raised. *newChild* is returned. If *refChild* is `NONE`, it inserts *newChild* at the end of the children's list.

removeChild(*oldChild*)

Remove a child node. *oldChild* must be a child of this node; if not, `ValueError` is raised. *oldChild* is returned on success. If *oldChild* will not be used further, its `unlink()` method should be called.

replaceChild(*newChild*, *oldChild*)

Replace an existing node with a new node. It must be the case that *oldChild* is a child of this node; if not, `ValueError` is raised.

normalize()

Join adjacent text nodes so that all stretches of text are stored as single `Text` instances. This simplifies processing text from a DOM tree for many

applications. New in version 2.1.

cloneNode(*deep*)

Clone this node. Setting *deep* means to clone all child nodes as well. This returns the clone.

Previous: [13.6.2.1 DOMImplementation Objects](#) **Up:** [13.6.2 Objects in the](#)

Next: [13.6.2.3 NodeList Objects](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document...](#) for information on suggesting changes.

13.6.2.3 NodeList Objects

A `NodeList` represents a sequence of nodes. These objects are used in two ways in the DOM Core recommendation: the `Element` objects provides one as its list of child nodes, and the `getElementsByTagName()` and `getElementsByTagNameNS()` methods of `Node` return objects with this interface to represent query results.

The DOM Level 2 recommendation defines one method and one attribute for these objects:

`item(i)`

Return the *i*'th item from the sequence, if there is one, or `None`. The index *i* is not allowed to be less than zero or greater than or equal to the length of the sequence.

`length`

The number of nodes in the sequence.

In addition, the Python DOM interface requires that some additional support is provided to allow `NodeList` objects to be used as Python sequences. All `NodeList` implementations must include support for `__len__()` and `__getitem__()`; this allows iteration over the `NodeList` in `for` statements and proper support for the `len()` built-in function.

If a DOM implementation supports modification of the document, the `NodeList` implementation must also support the `__setitem__()` and `__delitem__()` methods.

See [About this document..](#) for information on suggesting changes.

13.6.2.4 DocumentType Objects

Information about the notations and entities declared by a document (including the external subset if the parser uses it and can provide the information) is available from a `DocumentType` object. The `DocumentType` for a document is available from the `Document` object's `doctype` attribute; if there is no `DOCTYPE` declaration for the document, the document's `doctype` attribute will be set to `NONE` instead of an instance of this interface.

`DocumentType` is a specialization of `Node`, and adds the following attributes:

publicId

The public identifier for the external subset of the document type definition. This will be a string or `None`.

systemId

The system identifier for the external subset of the document type definition. This will be a URI as a string, or `None`.

internalSubset

A string giving the complete internal subset from the document. This does not include the brackets which enclose the subset. If the document has no internal subset, this should be `None`.

name

The name of the root element as given in the `DOCTYPE` declaration, if present.

entities

This is a `NamedNodeMap` giving the definitions of external entities. For entity names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be `None` if the information is not provided by the parser, or if no entities are defined.

notations

This is a `NamedNodeMap` giving the definitions of notations. For notation names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be `None` if the information is not provided by the parser, or if no notations are defined.

13.6.2.5 Document Objects

A `Document` represents an entire XML document, including its constituent elements, attributes, processing instructions, comments etc. Remember that it inherits properties from `Node`.

`documentElement`

The one and only root element of the document.

`createElement(tagName)`

Create and return a new element node. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as `insertBefore()` or `appendChild()`.

`createElementNS(namespaceURI, tagName)`

Create and return a new element with a namespace. The *tagName* may have a prefix. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as `insertBefore()` or `appendChild()`.

`createTextNode(data)`

Create and return a text node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

`createComment(data)`

Create and return a comment node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

`createProcessingInstruction(target, data)`

Create and return a processing instruction node containing the *target* and *data* passed as parameters. As with the other creation methods, this one does not insert the node into the tree.

createAttribute(*name*)

Create and return an attribute node. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate `Element` object to use the newly created attribute instance.

createAttributeNS(*namespaceURI*, *qualifiedName*)

Create and return an attribute node with a namespace. The *tagName* may have a prefix. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate `Element` object to use the newly created attribute instance.

getElementsByName(*tagName*)

Search for all descendants (direct children, children's children, etc.) with a particular element type name.

getElementsByNameNS(*namespaceURI*, *localName*)

Search for all descendants (direct children, children's children, etc.) with a particular namespace URI and localname. The localname is the part of the namespace after the prefix.

13.6.2.6 Element Objects

Element is a subclass of Node, so inherits all the attributes of that class.

tagName

The element type name. In a namespace-using document it may have colons in it. The value is a string.

getElementsByTagName(tagName)

Same as equivalent method in the Document class.

getElementsByTagNameNS(tagName)

Same as equivalent method in the Document class.

hasAttribute(name)

Returns true if the element has an attribute named by *name*.

hasAttributeNS(namespaceURI, localName)

Returns true if the element has an attribute named by *namespaceURI* and *localName*.

getAttribute(name)

Return the value of the attribute named by *name* as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

getAttributeNode(attrname)

Return the Attr node for the attribute named by *attrname*.

getAttributeNS(namespaceURI, localName)

Return the value of the attribute named by *namespaceURI* and *localName* as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

getAttributeNodeNS(namespaceURI, localName)

Return an attribute value as a node, given a *namespaceURI* and *localName*.

removeAttribute(*name*)

Remove an attribute by name. No exception is raised if there is no matching attribute.

removeAttributeNode(*oldAttr*)

Remove and return *oldAttr* from the attribute list, if present. If *oldAttr* is not present, `NotFoundErr` is raised.

removeAttributeNS(*namespaceURI*, *localName*)

Remove an attribute by name. Note that it uses a *localName*, not a *qname*. No exception is raised if there is no matching attribute.

setAttribute(*name*, *value*)

Set an attribute value from a string.

setAttributeNode(*newAttr*)

Add a new attribute node to the element, replacing an existing attribute if necessary if the `name` attribute matches. If a replacement occurs, the old attribute node will be returned. If *newAttr* is already in use, `InuseAttributeErr` will be raised.

setAttributeNodeNS(*newAttr*)

Add a new attribute node to the element, replacing an existing attribute if necessary if the `namespaceURI` and `localName` attributes match. If a replacement occurs, the old attribute node will be returned. If *newAttr* is already in use, `InuseAttributeErr` will be raised.

setAttributeNS(*namespaceURI*, *qname*, *value*)

Set an attribute value from a string, given a *namespaceURI* and a *qname*. Note that a *qname* is the whole attribute name. This is different than above.

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

13.6.2.7 Attr Objects

`Attr` inherits from `Node`, so inherits all its attributes.

name

The attribute name. In a namespace-using document it may have colons in it.

localName

The part of the name following the colon if there is one, else the entire name. This is a read-only attribute.

prefix

The part of the name preceding the colon if there is one, else the empty string.

13.6.2.8 NamedNodeMap Objects

NamedNodeMap does *not* inherit from Node.

length

The length of the attribute list.

item(*index*)

Return an attribute with a particular index. The order you get the attributes in is arbitrary but will be consistent for the life of a DOM. Each item is an attribute node. Get its value with the `value` attribute.

There are also experimental methods that give this class more mapping behavior. You can use them or you can use the standardized `getAttribute*()` family of methods on the `Element` objects.

[13.6.2.10 Text and CDATASection](#)

13.6.2.9 Comment Objects

Comment represents a comment in the XML document. It is a subclass of Node, but cannot have child nodes.

data

The content of the comment as a string. The attribute contains all characters between the leading `<! - -` and trailing `- ->`, but does not include them.

Python Library Reference

[toc](#) [m](#) [i](#)
CONTENTS MODULES INDEX

Previous: [13.6.2.8 NamedNodeMap Objects](#) Up: [13.6.2 Objects in the](#) Next:
[13.6.2.10 Text and CDATASection](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

13.6.2.10 Text and CDATASection Objects

The `Text` interface represents text in the XML document. If the parser and DOM implementation support the DOM's XML extension, portions of the text enclosed in CDATA marked sections are stored in `CDATASection` objects. These two interfaces are identical, but provide different values for the `nodeType` attribute.

These interfaces extend the `Node` interface. They cannot have child nodes.

data

The content of the text node as a string.

Note: The use of a `CDATASection` node does not indicate that the node represents a complete CDATA marked section, only that the content of the node was part of a CDATA section. A single CDATA section may be represented by more than one node in the document tree. There is no way to determine whether two adjacent `CDATASection` nodes represent different CDATA marked sections.

Previous: [13.6.2.10 Text and CDATASection](#) Up: [13.6.2 Objects in the](#) Next:
[13.6.2.12 Exceptions](#)

13.6.2.11 ProcessingInstruction Objects

Represents a processing instruction in the XML document; this inherits from the Node interface and cannot have child nodes.

target

The content of the processing instruction up to the first whitespace character. This is a read-only attribute.

data

The content of the processing instruction following the first whitespace character.

Previous: [13.6.2.10 Text and CDATASection](#) Up: [13.6.2 Objects in the](#) Next:
[13.6.2.12 Exceptions](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

13.6.2.12 Exceptions

New in version 2.1.

The DOM Level 2 recommendation defines a single exception, `DOMException`, and a number of constants that allow applications to determine what sort of error occurred. `DOMException` instances carry a `code` attribute that provides the appropriate value for the specific exception.

The Python DOM interface provides the constants, but also expands the set of exceptions so that a specific exception exists for each of the exception codes defined by the DOM. The implementations must raise the appropriate specific exception, each of which carries the appropriate value for the `code` attribute.

exception `DOMException`

Base exception class used for all specific DOM exceptions. This exception class cannot be directly instantiated.

exception `DomstringSizeErr`

Raised when a specified range of text does not fit into a string. This is not known to be used in the Python DOM implementations, but may be received from DOM implementations not written in Python.

exception `HierarchyRequestErr`

Raised when an attempt is made to insert a node where the node type is not allowed.

exception `IndexSizeErr`

Raised when an index or size parameter to a method is negative or exceeds the allowed values.

exception `InuseAttributeErr`

Raised when an attempt is made to insert an `Attr` node that is already present elsewhere in the document.

exception `InvalidAccessErr`

Raised if a parameter or an operation is not supported on the underlying object.

exception InvalidCharacterErr

This exception is raised when a string parameter contains a character that is not permitted in the context it's being used in by the XML 1.0 recommendation. For example, attempting to create an `Element` node with a space in the element type name will cause this error to be raised.

exception InvalidModificationErr

Raised when an attempt is made to modify the type of a node.

exception InvalidStateErr

Raised when an attempt is made to use an object that is not defined or is no longer usable.

exception NamespaceErr

If an attempt is made to change any object in a way that is not permitted with regard to the [Namespaces in XML](#) recommendation, this exception is raised.

exception NotFoundErr

Exception when a node does not exist in the referenced context. For example, `NamedNodeMap.removeNamedItem()` will raise this if the node passed in does not exist in the map.

exception NotSupportedErr

Raised when the implementation does not support the requested type of object or operation.

exception NoDataAllowedErr

This is raised if data is specified for a node which does not support data.

exception NoModificationAllowedErr

Raised on attempts to modify an object where modifications are not allowed (such as for read-only nodes).

exception SyntaxErr

Raised when an invalid or illegal string is specified.

exception WrongDocumentErr

Raised when a node is inserted in a different document than it currently belongs to, and the implementation does not support migrating the node from one document to the other.

The exception codes defined in the DOM recommendation map to the exceptions described above according to this table:

Constant	Exception
DOMSTRING_SIZE_ERR	DomstringSizeErr
HIERARCHY_REQUEST_ERR	HierarchyRequestErr
INDEX_SIZE_ERR	IndexSizeErr
INUSE_ATTRIBUTE_ERR	InuseAttributeErr
INVALID_ACCESS_ERR	InvalidAccessErr
INVALID_CHARACTER_ERR	InvalidCharacterErr
INVALID_MODIFICATION_ERR	InvalidModificationErr
INVALID_STATE_ERR	InvalidStateErr
NAMESPACE_ERR	NamespaceErr
NOT_FOUND_ERR	NotFoundErr
NOT_SUPPORTED_ERR	NotSupportedErr
NO_DATA_ALLOWED_ERR	NoDataAllowedErr
NO_MODIFICATION_ALLOWED_ERR	NoModificationAllowedErr
SYNTAX_ERR	SyntaxErr
WRONG_DOCUMENT_ERR	WrongDocumentErr

13.6.3.1 Type Mapping

The primitive IDL types used in the DOM specification are mapped to Python types according to the following table.

IDL Type	Python Type
boolean	IntegerType (with a value of 0 or 1)
int	IntegerType
long int	IntegerType
unsigned int	IntegerType

Additionally, the `DOMString` defined in the recommendation is mapped to a Python string or Unicode string. Applications should be able to handle Unicode whenever a string is returned from the DOM.

The IDL `null` value is mapped to `None`, which may be accepted or provided by the implementation whenever `null` is allowed by the API.

13.6.3.2 Accessor Methods

The mapping from OMG IDL to Python defines accessor functions for IDL `attribute` declarations in much the way the Java mapping does. Mapping the IDL declarations

```
readonly attribute string someValue;  
attribute string anotherValue;
```

yields three accessor functions: a `get` method for `someValue` (`_get_someValue()`), and `get` and `set` methods for `anotherValue` (`_get_anotherValue()` and `_set_anotherValue()`). The mapping, in particular, does not require that the IDL attributes are accessible as normal Python attributes: `object.someValue` is *not* required to work, and may raise an `AttributeError`.

The Python DOM API, however, *does* require that normal attribute access work. This means that the typical surrogates generated by Python IDL compilers are not likely to work, and wrapper objects may be needed on the client if the DOM objects are accessed via CORBA. While this does require some additional consideration for CORBA DOM clients, the implementers with experience using DOM over CORBA from Python do not consider this a problem. Attributes that are declared `readonly` may not restrict write access in all DOM implementations.

In the Python DOM API, accessor functions are not required. If provided, they should take the form defined by the Python IDL mapping, but these methods are considered unnecessary since the attributes are accessible directly from Python. `Set` accessors should never be provided for `readonly` attributes.

The IDL definitions do not fully embody the requirements of the W3C DOM API, such as the notion of certain objects, such as the return value of `getElementsByTagName()`, being `live`. The Python DOM API does not require implementations to enforce such requirements.

16.1.2.1 How To Use This Section

This section is designed in two parts: the first half (roughly) covers background material, while the second half can be taken to the keyboard as a handy reference.

When trying to answer questions of the form "how do I do blah", it is often best to find out how to do "blah" in straight Tk, and then convert this back into the corresponding [Tkinter](#) call. Python programmers can often guess at the correct Python command by looking at the Tk documentation. This means that in order to use Tkinter, you will have to know a little bit about Tk. This document can't fulfill that role, so the best we can do is point you to the best documentation that exists. Here are some hints:

- The authors strongly suggest getting a copy of the Tk man pages. Specifically, the man pages in the `mann` directory are most useful. The `man3` man pages describe the C interface to the Tk library and thus are not especially helpful for script writers.
- Addison-Wesley publishes a book called *Tcl and the Tk Toolkit* by John Ousterhout (ISBN 0-201-63337-X) which is a good introduction to Tcl and Tk for the novice. The book is not exhaustive, and for many details it defers to the man pages.
- `Tkinter.py` is a last resort for most, but can be a good place to go when nothing else makes sense.

    def say_hi(self):
        print "hi there, everyone!"

    def createWidgets(self):
        self.QUIT = Button(self)
        self.QUIT["text"] = "QUIT"
        self.QUIT["fg"]   = "red"
        self.QUIT["command"] = self.quit

        self.QUIT.pack({"side": "left"})

        self.hi_there = Button(self)
        self.hi_there["text"] = "Hello",
        self.hi_there["command"] = self.say_hi

        self.hi_there.pack({"side": "left"})

    def __init__(self, master=None):
        Frame.__init__(self, master)
        self.pack()
        self.createWidgets()

root = Tk()
app = Application(master=root)
app.mainloop()
root.destroy()
```

16.1.6.1 Setting Options

Options control things like the color and border width of a widget. Options can be set in three ways:

At object creation time, using keyword arguments

:

```
fred = Button(self, fg = "red", bg = "blue")
```

After object creation, treating the option name like a dictionary index

:

```
fred["fg"] = "red"  
fred["bg"] = "blue"
```

Use the `config()` method to update multiple attrs subsequent to object creation

:

```
fred.config(fg = "red", bg = "blue")
```

For a complete explanation of a given option and its behavior, see the Tk man pages for the widget in question.

Note that the man pages list "STANDARD OPTIONS" and "WIDGET SPECIFIC OPTIONS" for each widget. The former is a list of options that are common to many widgets, the latter are the options that are idiosyncratic to that particular widget. The Standard Options are documented on the *options(3)* man page.

No distinction between standard and widget-specific options is made in this document. Some options don't apply to some kinds of widgets. Whether a given widget responds to a particular option depends on the class of the widget; buttons have a `command` option, labels do not.

The options supported by a given widget are listed in that widget's man page, or can be queried at runtime by calling the `config()` method without arguments,

or by calling the `keys()` method on that widget. The return value of these calls is a dictionary whose key is the name of the option as a string (for example, `'relief'`) and whose values are 5-tuples.

Some options, like `bg` are synonyms for common options with long names (`bg` is shorthand for "background"). Passing the `config()` method the name of a shorthand option will return a 2-tuple, not 5-tuple. The 2-tuple passed back will contain the name of the synonym and the "real" option (such as (`'bg'`, `'background'`)).

Index	Meaning	Example
0	option name	'relief'
1	option name for database lookup	'relief'
2	option class for database lookup	'Relief'
3	default value	'raised'
4	current value	'groove'

Example:

```
>>> print fred.config()
{'relief' : ('relief', 'relief', 'Relief', 'raised', 'groove')}
```

Of course, the dictionary printed will include all the options available and their values. This is meant only as an example.

16.1.6.2 The Packer

The packer is one of Tk's geometry-management mechanisms.

Geometry managers are used to specify the relative positioning of the positioning of widgets within their container - their mutual *master*. In contrast to the more cumbersome *placer* (which is used less commonly, and we do not cover here), the packer takes qualitative relationship specification - *above*, *to the left of*, *filling*, etc - and works everything out to determine the exact placement coordinates for you.

The size of any *master* widget is determined by the size of the "slave widgets" inside. The packer is used to control where slave widgets appear inside the master into which they are packed. You can pack widgets into frames, and frames into other frames, in order to achieve the kind of layout you desire. Additionally, the arrangement is dynamically adjusted to accommodate incremental changes to the configuration, once it is packed.

Note that widgets do not appear until they have had their geometry specified with a geometry manager. It's a common early mistake to leave out the geometry specification, and then be surprised when the widget is created but nothing appears. A widget will appear only after it has had, for example, the packer's `pack()` method applied to it.

The `pack()` method can be called with keyword-option/value pairs that control where the widget is to appear within its container, and how it is to behave when the main application window is resized. Here are some examples:

```
fred.pack()                # defaults to side = "top"
fred.pack(side = "left")
fred.pack(expand = 1)
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

16.1.6.3 Packer Options

For more extensive information on the packer and the options that it can take, see the man pages and page 183 of John Ousterhout's book.

anchor

Anchor type. Denotes where the packer is to place each slave in its parcel.

expand

Boolean, 0 or 1.

fill

Legal values: 'x', 'y', 'both', 'none'.

ipadx and ipady

A distance - designating internal padding on each side of the slave widget.

padx and pady

A distance - designating external padding on each side of the slave widget.

side

Legal values are: 'left', 'right', 'top', 'bottom'.

16.1.6.4 Coupling Widget Variables

The current-value setting of some widgets (like text entry widgets) can be connected directly to application variables by using special options. These options are `variable`, `textvariable`, `onvalue`, `offvalue`, and `value`. This connection works both ways: if the variable changes for any reason, the widget it's connected to will be updated to reflect the new value.

Unfortunately, in the current implementation of [Tkinter](#) it is not possible to hand over an arbitrary Python variable to a widget through a `variable` or `textvariable` option. The only kinds of variables for which this works are variables that are subclassed from a class called `Variable`, defined in the [Tkinter](#) module.

There are many useful subclasses of `Variable` already defined: `StringVar`, `IntVar`, `DoubleVar`, and `BooleanVar`. To read the current value of such a variable, call the `get()` method on it, and to change its value you call the `set()` method. If you follow this protocol, the widget will always track the value of the variable, with no further intervention on your part.

For example:

```
class App(Frame):
    def __init__(self, master=None):
        Frame.__init__(self, master)
        self.pack()

        self.entrythingy = Entry()
        self.entrythingy.pack()

        # here is the application variable
        self.contents = StringVar()
        # set it to some value
        self.contents.set("this is a variable")
        # tell the entry widget to watch this variable
        self.entrythingy["textvariable"] = self.contents

        # and here we get a callback when the user hits return.
        # we will have the program print out the value of the
        # application variable when the user hits return
```

```
self.entrythingy.bind('<Key-Return>',
                      self.print_contents)

def print_contents(self, event):
    print "hi. contents of entry is now ---->", \
          self.contents.get()
```

Python Library Reference

Previous: [16.1.6.3 Packer Options](#) **Up:** [16.1.6 Handy Reference](#) **Next:** [16.1.6.5 The Window Manager](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

16.1.6.5 The Window Manager

In Tk, there is a utility command, `wm`, for interacting with the window manager. Options to the `wm` command allow you to control things like titles, placement, icon bitmaps, and the like. In [Tkinter](#), these commands have been implemented as methods on the `Wm` class. Toplevel widgets are subclassed from the `Wm` class, and so can call the `Wm` methods directly.

To get at the toplevel window that contains a given widget, you can often just refer to the widget's master. Of course if the widget has been packed inside of a frame, the master won't represent a toplevel window. To get at the toplevel window that contains an arbitrary widget, you can call the `_root()` method. This method begins with an underscore to denote the fact that this function is part of the implementation, and not an interface to Tk functionality.

Here are some examples of typical usage:

```
from Tkinter import *
class App(Frame):
    def __init__(self, master=None):
        Frame.__init__(self, master)
        self.pack()

# create the application
myapp = App()

#
# here are method calls to the window manager class
#
myapp.master.title("My Do-Nothing Application")
myapp.master.maxsize(1000, 400)

# start the program
myapp.mainloop()
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

16.1.6.6 Tk Option Data Types

anchor

Legal values are points of the compass: "n", "ne", "e", "se", "s", "sw", "w", "nw", and also "center".

bitmap

There are eight built-in, named bitmaps: 'error', 'gray25', 'gray50', 'hourglass', 'info', 'questhead', 'question', 'warning'. To specify an X bitmap filename, give the full path to the file, preceded with an @, as in "@/usr/contrib/bitmap/gumby.bit".

boolean

You can pass integers 0 or 1 or the strings "yes" or "no".

callback

This is any Python function that takes no arguments. For example:

```
def print_it():
    print "hi there"
fred["command"] = print_it
```

color

Colors can be given as the names of X colors in the rgb.txt file, or as strings representing RGB values in 4 bit: "#RGB", 8 bit: "#RRGGBB", 12 bit "#RRRGGGBBB", or 16 bit "#RRRRGGGGBBBB" ranges, where R,G,B here represent any legal hex digit. See page 160 of Ousterhout's book for details.

cursor

The standard X cursor names from cursorfont.h can be used, without the XC_ prefix. For example to get a hand cursor (XC_hand2), use the string "hand2". You can also specify a bitmap and mask file of your own. See page 179 of Ousterhout's book.

distance

Screen distances can be specified in either pixels or absolute distances. Pixels are given as numbers and absolute distances as strings, with the trailing character denoting units: `c` for centimetres, `i` for inches, `m` for millimetres, `p` for printer's points. For example, 3.5 inches is expressed as `"3.5i"`.

font

Tk uses a list font name format, such as `{courier 10 bold}`. Font sizes with positive numbers are measured in points; sizes with negative numbers are measured in pixels.

geometry

This is a string of the form `"widthxheight"`, where width and height are measured in pixels for most widgets (in characters for widgets displaying text). For example: `fred["geometry"] = "200x100"`.

justify

Legal values are the strings: `"left"`, `"center"`, `"right"`, and `"fill"`.

region

This is a string with four space-delimited elements, each of which is a legal distance (see above). For example: `"2 3 4 5"` and `"3i 2i 4.5i 2i"` and `"3c 2c 4c 10.43c"` are all legal regions.

relief

Determines what the border style of a widget will be. Legal values are: `"raised"`, `"sunken"`, `"flat"`, `"groove"`, and `"ridge"`.

scrollcommand

This is almost always the `set()` method of some scrollbar widget, but can be any widget method that takes a single argument. Refer to the file `Demo/tkinter/matt/canvas-with-scrollbars.py` in the Python source distribution for an example.

wrap:

Must be one of: `"none"`, `"char"`, or `"word"`.

Python Library Reference

CONTENTS MODULES INDEX

Previous: [16.1.6.5 The Window Manager](#) Up: [16.1.6 Handy Reference](#) Next:
[16.1.6.7 Bindings and Events](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

16.1.6.7 Bindings and Events

The `bind` method from the widget command allows you to watch for certain events and to have a callback function trigger when that event type occurs. The form of the `bind` method is:

```
def bind(self, sequence, func, add='');
```

where:

sequence

is a string that denotes the target kind of event. (See the `bind` man page and page 201 of John Ousterhout's book for details).

func

is a Python function, taking one argument, to be invoked when the event occurs. An `Event` instance will be passed as the argument. (Functions deployed this way are commonly known as *callbacks*.)

add

is optional, either `""` or `"+"`. Passing an empty string denotes that this binding is to replace any other bindings that this event is associated with. Preceding with a `"+"` means that this function is to be added to the list of functions bound to this event type.

For example:

```
def turnRed(self, event):
    event.widget["activeforeground"] = "red"

self.button.bind("<Enter>", self.turnRed)
```

Notice how the widget field of the event is being accessed in the `turnRed()` callback. This field contains the widget that caught the X event. The following table lists the other event fields you can access, and how they are denoted in Tk, which can be useful when referring to the Tk man pages.

Tk Tkinter Event Field

Tk Tkinter Event Field

--	-----	--	-----
%f	focus	%A	char
%h	height	%E	send_event
%k	keycode	%K	keysym
%s	state	%N	keysym_num
%t	time	%T	type
%w	width	%W	widget
%X	x	%X	x_root
%y	y	%Y	y_root

Python Library Reference

Previous: [16.1.6.6 Tk Option Data](#) Up: [16.1.6 Handy Reference](#) Next: [16.1.6.8 The index Parameter](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
 See [About this document...](#) for information on suggesting changes.

16.1.6.8 The index Parameter

A number of widgets require ``index" parameters to be passed. These are used to point at a specific place in a Text widget, or to particular characters in an Entry widget, or to particular menu items in a Menu widget.

Entry widget indexes (index, view index, etc.)

Entry widgets have options that refer to character positions in the text being displayed. You can use these [Tkinter](#) functions to access these special points in text widgets:

AtEnd()

refers to the last position in the text

AtInsert()

refers to the point where the text cursor is

AtSelFirst()

indicates the beginning point of the selected text

AtSelLast()

denotes the last point of the selected text and finally

At(x[, y])

refers to the character at pixel location x, y (with y not used in the case of a text entry widget, which contains a single line of text).

Text widget indexes

The index notation for Text widgets is very rich and is best described in the Tk man pages.

Menu indexes (menu.invoke(), menu.entryconfig(), etc.)

Some options and methods for menus manipulate specific menu entries. Anytime a menu index is needed for an option or a parameter, you may pass in:

- an integer which refers to the numeric position of the entry in the widget, counted from the top, starting with 0;
- the string 'active', which refers to the menu position that is currently under the cursor;
- the string "last" which refers to the last menu item;
- An integer preceded by @, as in @6, where the integer is interpreted as a y pixel coordinate in the menu's coordinate system;
- the string "none", which indicates no menu entry at all, most often used with menu.activate() to deactivate all entries, and finally,
- a text string that is pattern matched against the label of the menu entry, as scanned from the top of the menu to the bottom. Note that this index type is considered after all the others, which means that matches for menu items labelled last, active, or none may be interpreted as the above literals, instead.

Previous: [16.1.6.7 Bindings and Events](#) Up: [16.1.6 Handy Reference](#) Next: [16.1.6.9 Images](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

16.1.6.9 Images

Bitmap/Pixmap images can be created through the subclasses of `Tkinter .Image`:

- `BitmapImage` can be used for X11 bitmap data.
- `PhotoImage` can be used for GIF and PPM/PGM color bitmaps.

Either type of image is created through either the `file` or the `data` option (other options are available as well).

The image object can then be used wherever an `image` option is supported by some widget (e.g. labels, buttons, menus). In these cases, Tk will not keep a reference to the image. When the last Python reference to the image object is deleted, the image data is deleted as well, and Tk will display an empty box wherever the image was used.

16.2.2.1 Basic Widgets

class `Balloon()`

A `Balloon` that pops up over a widget to provide help. When the user moves the cursor inside a widget to which a `Balloon` widget has been bound, a small pop-up window with a descriptive message will be shown on the screen.

class `ButtonBox()`

The `ButtonBox` widget creates a box of buttons, such as is commonly used for Ok Cancel.

class `ComboBox()`

The `ComboBox` widget is similar to the combo box control in MS Windows. The user can select a choice by either typing in the entry subwidget or selecting from the listbox subwidget.

class `Control()`

The `Control` widget is also known as the `SpinBox` widget. The user can adjust the value by pressing the two arrow buttons or by entering the value directly into the entry. The new value will be checked against the user-defined upper and lower limits.

class `LabelEntry()`

The `LabelEntry` widget packages an entry widget and a label into one mega widget. It can be used to simplify the creation of "entry-form" type of interface.

class `LabelFrame()`

The `LabelFrame` widget packages a frame widget and a label into one mega widget. To create widgets inside a `LabelFrame` widget, one creates the new widgets relative to the `frame` subwidget and manage them inside the `frame` subwidget.

class Meter()

The [Meter](#) widget can be used to show the progress of a background job which may take a long time to execute.

class OptionMenu()

The [OptionMenu](#) creates a menu button of options.

class PopupMenu()

The [PopupMenu](#) widget can be used as a replacement of the `tk_popup` command. The advantage of the [Tix](#) `PopupMenu` widget is it requires less application code to manipulate.

class Select()

The [Select](#) widget is a container of button subwidgets. It can be used to provide radio-box or check-box style of selection options for the user.

class StdButtonBox()

The [StdButtonBox](#) widget is a group of standard buttons for Motif-like dialog boxes.

16.2.2.2 File Selectors

class DirList()

The [DirList](#) widget displays a list view of a directory, its previous directories and its sub-directories. The user can choose one of the directories displayed in the list or change to another directory.

class DirTree()

The [DirTree](#) widget displays a tree view of a directory, its previous directories and its sub-directories. The user can choose one of the directories displayed in the list or change to another directory.

class DirSelectDialog()

The [DirSelectDialog](#) widget presents the directories in the file system in a dialog window. The user can use this dialog window to navigate through the file system to select the desired directory.

class DirSelectBox()

The `DirSelectBox` is similar to the standard Motif(TM) directory-selection box. It is generally used for the user to choose a directory. `DirSelectBox` stores the directories mostly recently selected into a `ComboBox` widget so that they can be quickly selected again.

class ExFileSelectBox()

The [ExFileSelectBox](#) widget is usually embedded in a `tixExFileSelectDialog` widget. It provides a convenient method for the user to select files. The style of the `ExFileSelectBox` widget is very similar to the standard file dialog on MS Windows 3.1.

class FileSelectBox()

The [FileSelectBox](#) is similar to the standard Motif(TM) file-selection box. It is generally used for the user to choose a file. `FileSelectBox` stores the files mostly recently selected into a `COMBOBOX` widget so that they can be quickly selected again.

class `FileEntry()`

The [FileEntry](#) widget can be used to input a filename. The user can type in the filename manually. Alternatively, the user can press the button widget that sits next to the entry, which will bring up a file selection dialog.

Previous: [16.2.2.1 Basic Widgets](#) Up: [16.2.2 Tix Widgets](#) Next: [16.2.2.3 Hierarchical ListBox](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

16.2.2.3 Hierarchical ListBox

class HList()

The [HList](#) widget can be used to display any data that have a hierarchical structure, for example, file system directory trees. The list entries are indented and connected by branch lines according to their places in the hierarchy.

class CheckList()

The [CheckList](#) widget displays a list of items to be selected by the user. CheckList acts similarly to the Tk checkbutton or radiobutton widgets, except it is capable of handling many more items than checkbuttons or radiobuttons.

class Tree()

The [Tree](#) widget can be used to display hierarchical data in a tree form. The user can adjust the view of the tree by opening or closing parts of the tree.

Previous: [16.2.2.3 Hierarchical ListBox](#) Up: [16.2.2 Tix Widgets](#) Next: [16.2.2.5 Manager Widgets](#)

16.2.2.4 Tabular ListBox

class TList()

The [TList](#) widget can be used to display data in a tabular format. The list entries of a `TList` widget are similar to the entries in the Tk listbox widget. The main differences are (1) the `TList` widget can display the list entries in a two dimensional format and (2) you can use graphical images as well as multiple colors and fonts for the list entries.

Previous: [16.2.2.3 Hierarchical ListBox](#) Up: [16.2.2 Tix Widgets](#) Next: [16.2.2.5 Manager Widgets](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

16.2.2.5 Manager Widgets

class `PanedWindow()`

The `PanedWindow` widget allows the user to interactively manipulate the sizes of several panes. The panes can be arranged either vertically or horizontally. The user changes the sizes of the panes by dragging the resize handle between two panes.

class `ListNoteBook()`

The `ListNoteBook` widget is very similar to the `TixNoteBook` widget: it can be used to display many windows in a limited space using a notebook metaphor. The notebook is divided into a stack of pages (windows). At one time only one of these pages can be shown. The user can navigate through these pages by choosing the name of the desired page in the `hlist` subwidget.

class `NoteBook()`

The `NoteBook` widget can be used to display many windows in a limited space using a notebook metaphor. The notebook is divided into a stack of pages. At one time only one of these pages can be shown. The user can navigate through these pages by choosing the visual "tabs" at the top of the `NoteBook` widget.

Previous: [16.2.2.5 Manager Widgets](#) Up: [16.2.2 Tix Widgets](#) Next: [16.2.2.7 Miscellaneous Widgets](#)

16.2.2.6 Image Types

The [Tix](#) module adds:

- [pixmap](#) capabilities to all [Tix](#) and [Tkinter](#) widgets to create color images from XPM files.
- [Compound](#) image types can be used to create images that consists of multiple horizontal lines; each line is composed of a series of items (texts, bitmaps, images or spaces) arranged from left to right. For example, a compound image can be used to display a bitmap and a text string simultaneously in a Tk `Button` widget.

Previous: [16.2.2.5 Manager Widgets](#) Up: [16.2.2 Tix Widgets](#) Next: [16.2.2.7 Miscellaneous Widgets](#)

Release 2.4.4c1, documentation updated on 11 October 2006.

16.5.1.1 File menu

New window

create a new editing window

Open...

open an existing file

Open module...

open an existing module (searches sys.path)

Class browser

show classes and methods in current file

Path browser

show sys.path directories, modules, classes and methods

Save

save current window to the associated file (unsaved windows have a * before and after the window title)

Save As...

save current window to new file, which becomes the associated file

Save Copy As...

save current window to different file without changing the associated file

Close

close current window (asks to save if unsaved)

Exit

close all windows and quit IDLE (asks to save if unsaved)

16.5.1.2 Edit menu

Undo

Undo last change to current window (max 1000 changes)

Redo

Redo last undone change to current window

Cut

Copy selection into system-wide clipboard; then delete selection

Copy

Copy selection into system-wide clipboard

Paste

Insert system-wide clipboard into window

Select All

Select the entire contents of the edit buffer

Find...

Open a search dialog box with many options

Find again

Repeat last search

Find selection

Search for the string in the selection

Find in Files...

Open a search dialog box for searching files

Replace...

Open a search-and-replace dialog box

Go to line

Ask for a line number and show that line

Indent region

Shift selected lines right 4 spaces

Dedent region

Shift selected lines left 4 spaces

Comment out region

Insert ## in front of selected lines

Uncomment region

Remove leading # or ## from selected lines

Tabify region

Turns *leading* stretches of spaces into tabs

Untabify region

Turn *all* tabs into the right number of spaces

Expand word

Expand the word you have typed to match another word in the same buffer; repeat to get a different expansion

Format Paragraph

Reformat the current blank-line-separated paragraph

Import module

Import or reload the current module

Run script

Execute the current file in the `__main__` namespace

16.5.2.1 Automatic indentation

After a block-opening statement, the next line is indented by 4 spaces (in the Python Shell window by one tab). After certain keywords (break, return etc.) the next line is dedented. In leading indentation, Backspace deletes up to 4 spaces if they are there. Tab inserts 1-4 spaces (in the Python Shell window one tab). See also the indent/dedent region commands in the edit menu.

16.5.2.2 Python Shell window

- C-C interrupts executing command
 - C-D sends end-of-file; closes window if typed at a "»> " prompt
 - Alt-p retrieves previous command matching what you have typed
 - Alt-n retrieves next
 - Return while on any previous command retrieves that command
 - Alt-/ (Expand word) is also useful here
-

16.5.3.1 Command line usage

```
idle.py [-c command] [-d] [-e] [-s] [-t title] [arg] ...

-c command  run this command
-d          enable debugger
-e          edit mode; arguments are files to be edited
-s          run $IDLESTARTUP or $PYTHONSTARTUP first
-t title    set title of shell window
```

If there are arguments:

1. If **-e** is used, arguments are files opened for editing and `sys.argv` reflects the arguments passed to IDLE itself.
2. Otherwise, if **-c** is used, all arguments are placed in `sys.argv[1: ...]`, with `sys.argv[0]` set to `'-c'`.
3. Otherwise, if neither **-e** nor **-c** is used, the first argument is a script which is executed with the remaining arguments in `sys.argv[1: ...]` and `sys.argv[0]` set to the script name. If the script name is `'-'`, no script is executed but an interactive Python session is started; the arguments are still available in `sys.argv`.

18.1.6.1 Emulation of `compile()`

While many useful operations may take place between parsing and bytecode generation, the simplest operation is to do nothing. For this purpose, using the `parser` module to produce an intermediate data structure is equivalent to the code

```
>>> code = compile('a + 5', 'file.py', 'eval')
>>> a = 5
>>> eval(code)
10
```

The equivalent operation using the `parser` module is somewhat longer, and allows the intermediate internal parse tree to be retained as an AST object:

```
>>> import parser
>>> ast = parser.expr('a + 5')
>>> code = ast.compile('file.py')
>>> a = 5
>>> eval(code)
10
```

An application which needs both AST and code objects can package this code into readily available functions:

```
import parser

def load_suite(source_string):
    ast = parser.suite(source_string)
    return ast, ast.compile()

def load_expression(source_string):
    ast = parser.expr(source_string)
    return ast, ast.compile()
```

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document..](#) for information on suggesting changes.

18.1.6.2 Information Discovery

Some applications benefit from direct access to the parse tree. The remainder of this section demonstrates how the parse tree provides access to module documentation defined in docstrings without requiring that the code being examined be loaded into a running interpreter via `import`. This can be very useful for performing analyses of untrusted code.

Generally, the example will demonstrate how the parse tree may be traversed to distill interesting information. Two functions and a set of classes are developed which provide programmatic access to high level function and class definitions provided by a module. The classes extract information from the parse tree and provide access to the information at a useful semantic level, one function provides a simple low-level pattern matching capability, and the other function defines a high-level interface to the classes by handling file operations on behalf of the caller. All source files mentioned here which are not part of the Python installation are located in the `Demo/parser/` directory of the distribution.

The dynamic nature of Python allows the programmer a great deal of flexibility, but most modules need only a limited measure of this when defining classes, functions, and methods. In this example, the only definitions that will be considered are those which are defined in the top level of their context, e.g., a function defined by a `def` statement at column zero of a module, but not a function defined within a branch of an `if ... else` construct, though there are some good reasons for doing so in some situations. Nesting of definitions will be handled by the code developed in the example.

To construct the upper-level extraction methods, we need to know what the parse tree structure looks like and how much of it we actually need to be concerned about. Python uses a moderately deep parse tree so there are a large number of intermediate nodes. It is important to read and understand the formal grammar used by Python. This is specified in the file `Grammar/Grammar` in the distribution. Consider the simplest case of interest when searching for docstrings: a module consisting of a docstring and nothing else. (See file `docstring.py`.)

```
"""Some documentation.
"""
```

Using the interpreter to take a look at the parse tree, we find a bewildering mass of numbers and parentheses, with the documentation buried deep in nested tuples.

```
>>> import parser
>>> import pprint
>>> ast = parser.suite(open('docstring.py').read())
>>> tup = ast.totuple()
>>> pprint.pprint(tup)
(257,
 (264,
  (265,
   (266,
    (267,
     (307,
      (287,
       (288,
        (289,
         (290,
          (292,
           (293,
            (294,
             (295,
              (296,
               (297,
                (298,
                 (299,
                  (300, (3, '""Some documentation.\n""'))))))))))))
      (4, ' ')),
     (4, ' ')),
    (0, ' '))
```

The numbers at the first element of each node in the tree are the node types; they map directly to terminal and non-terminal symbols in the grammar. Unfortunately, they are represented as integers in the internal representation, and the Python structures generated do not change that. However, the [symbol](#) and [token](#) modules provide symbolic names for the node types and dictionaries which map from the integers to the symbolic names for the node types.

In the output presented above, the outermost tuple contains four elements: the integer 257 and three additional tuples. Node type 257 has the symbolic name `file_input`. Each of these inner tuples contains an integer as the first element; these integers, 264, 4, and 0, represent the node types `stmt`,

NEWLINE, and ENDMARKER, respectively. Note that these values may change depending on the version of Python you are using; consult `symbol.py` and `token.py` for details of the mapping. It should be fairly clear that the outermost node is related primarily to the input source rather than the contents of the file, and may be disregarded for the moment. The `stmt` node is much more interesting. In particular, all docstrings are found in subtrees which are formed exactly as this node is formed, with the only difference being the string itself. The association between the docstring in a similar tree and the defined entity (class, function, or module) which it describes is given by the position of the docstring subtree within the tree defining the described structure.

By replacing the actual docstring with something to signify a variable component of the tree, we allow a simple pattern matching approach to check any given subtree for equivalence to the general pattern for docstrings. Since the example demonstrates information extraction, we can safely require that the tree be in tuple form rather than list form, allowing a simple variable representation to be `['variable_name']`. A simple recursive function can implement the pattern matching, returning a Boolean and a dictionary of variable name to value mappings. (See file `example.py`.)

```
from types import ListType, TupleType

def match(pattern, data, vars=None):
    if vars is None:
        vars = {}
    if type(pattern) is ListType:
        vars[pattern[0]] = data
        return 1, vars
    if type(pattern) is not TupleType:
        return (pattern == data), vars
    if len(data) != len(pattern):
        return 0, vars
    for pattern, data in map(None, pattern, data):
        same, vars = match(pattern, data, vars)
        if not same:
            break
    return same, vars
```

Using this simple representation for syntactic variables and the symbolic node types, the pattern for the candidate docstring subtrees becomes fairly readable. (See file `example.py`.)

```
import symbol
import token
```

```

DOCSTRING_STMT_PATTERN = (
    symbol.stmt,
    (symbol.simple_stmt,
     (symbol.small_stmt,
      (symbol.expr_stmt,
       (symbol.testlist,
        (symbol.test,
         (symbol.and_test,
          (symbol.not_test,
           (symbol.comparison,
            (symbol.expr,
             (symbol.xor_expr,
              (symbol.and_expr,
               (symbol.shift_expr,
                (symbol.arith_expr,
                 (symbol.term,
                  (symbol.factor,
                   (symbol.power,
                    (symbol.atom,
                     (token.STRING, ['docstring'])
                    ))))))))))))))),
            (token.NEWLINE, ''))
    ))

```

Using the `match()` function with this pattern, extracting the module docstring from the parse tree created previously is easy:

```

>>> found, vars = match(DOCSTRING_STMT_PATTERN, tup[1])
>>> found
1
>>> vars
{'docstring': '""Some documentation.\n""'}

```

Once specific data can be extracted from a location where it is expected, the question of where information can be expected needs to be answered. When dealing with docstrings, the answer is fairly simple: the docstring is the first `stmt` node in a code block (`file_input` or `suite` node types). A module consists of a single `file_input` node, and class and function definitions each contain exactly one `suite` node. Classes and functions are readily identified as subtrees of code block nodes which start with `(stmt, (compound_stmt, (classdef, ... or (stmt, (compound_stmt, (funcdef,` Note that these subtrees cannot be matched by `match()` since it does not support multiple sibling nodes to match without regard to number. A more elaborate matching function could be used to overcome this limitation, but this is sufficient for the example.

Given the ability to determine whether a statement might be a docstring and extract the actual string from the statement, some work needs to be performed to walk the parse tree for an entire module and extract information about the names defined in each context of the module and associate any docstrings with the names. The code to perform this work is not complicated, but bears some explanation.

The public interface to the classes is straightforward and should probably be somewhat more flexible. Each "major" block of the module is described by an object providing several methods for inquiry and a constructor which accepts at least the subtree of the complete parse tree which it represents. The `ModuleInfo` constructor accepts an optional *name* parameter since it cannot otherwise determine the name of the module.

The public classes include `ClassInfo`, `FunctionInfo`, and `ModuleInfo`. All objects provide the methods `get_name()`, `get_docstring()`, `get_class_names()`, and `get_class_info()`. The `ClassInfo` objects support `get_method_names()` and `get_method_info()` while the other classes provide `get_function_names()` and `get_function_info()`.

Within each of the forms of code block that the public classes represent, most of the required information is in the same form and is accessed in the same way, with classes having the distinction that functions defined at the top level are referred to as "methods." Since the difference in nomenclature reflects a real semantic distinction from functions defined outside of a class, the implementation needs to maintain the distinction. Hence, most of the functionality of the public classes can be implemented in a common base class, `SuiteInfoBase`, with the accessors for function and method information provided elsewhere. Note that there is only one class which represents function and method information; this parallels the use of the `def` statement to define both types of elements.

Most of the accessor functions are declared in `SuiteInfoBase` and do not need to be overridden by subclasses. More importantly, the extraction of most information from a parse tree is handled through a method called by the `SuiteInfoBase` constructor. The example code for most of the classes is clear when read alongside the formal grammar, but the method which recursively creates new information objects requires further examination. Here is the

relevant part of the `SuiteInfoBase` definition from `example.py`:

```
class SuiteInfoBase:
    _docstring = ''
    _name = ''

    def __init__(self, tree = None):
        self._class_info = {}
        self._function_info = {}
        if tree:
            self._extract_info(tree)

    def _extract_info(self, tree):
        # extract docstring
        if len(tree) == 2:
            found, vars = match(DOCSTRING_STMT_PATTERN[1], tree[1])
        else:
            found, vars = match(DOCSTRING_STMT_PATTERN, tree[3])
        if found:
            self._docstring = eval(vars['docstring'])
        # discover inner definitions
        for node in tree[1:]:
            found, vars = match(COMPOUND_STMT_PATTERN, node)
            if found:
                cstmt = vars['compound']
                if cstmt[0] == symbol.funcdef:
                    name = cstmt[2][1]
                    self._function_info[name] = FunctionInfo(cstmt)
                elif cstmt[0] == symbol.classdef:
                    name = cstmt[2][1]
                    self._class_info[name] = ClassInfo(cstmt)
```

After initializing some internal state, the constructor calls the `_extract_info()` method. This method performs the bulk of the information extraction which takes place in the entire example. The extraction has two distinct phases: the location of the docstring for the parse tree passed in, and the discovery of additional definitions within the code block represented by the parse tree.

The initial `if` test determines whether the nested suite is of the "short form" or the "long form." The short form is used when the code block is on the same line as the definition of the code block, as in

```
def square(x): "Square an argument."; return x ** 2
```

while the long form uses an indented block and allows nested definitions:

```

def make_power(exp):
    "Make a function that raises an argument to the exponent `exp'."
    def raiser(x, y=exp):
        return x ** y
    return raiser

```

When the short form is used, the code block may contain a docstring as the first, and possibly only, `small_stmt` element. The extraction of such a docstring is slightly different and requires only a portion of the complete pattern used in the more common case. As implemented, the docstring will only be found if there is only one `small_stmt` node in the `simple_stmt` node. Since most functions and methods which use the short form do not provide a docstring, this may be considered sufficient. The extraction of the docstring proceeds using the `match()` function as described above, and the value of the docstring is stored as an attribute of the `SuiteInfoBase` object.

After docstring extraction, a simple definition discovery algorithm operates on the `stmt` nodes of the `suite` node. The special case of the short form is not tested; since there are no `stmt` nodes in the short form, the algorithm will silently skip the single `simple_stmt` node and correctly not discover any nested definitions.

Each statement in the code block is categorized as a class definition, function or method definition, or something else. For the definition statements, the name of the element defined is extracted and a representation object appropriate to the definition is created with the defining subtree passed as an argument to the constructor. The representation objects are stored in instance variables and may be retrieved by name using the appropriate accessor methods.

The public classes provide any accessors required which are more specific than those provided by the `SuiteInfoBase` class, but the real extraction algorithm remains common to all forms of code blocks. A high-level function can be used to extract the complete set of information from a source file. (See file `example.py`.)

```

def get_docs(fileName):
    import os
    import parser

    source = open(fileName).read()
    basename = os.path.basename(os.path.splitext(fileName)[0])
    ast = parser.suite(source)

```

```
return ModuleInfo(ast.totuple(), basename)
```

This provides an easy-to-use interface to the documentation of a module. If information is required which is not extracted by the code of this example, the code may be extended at clearly defined points to provide additional capabilities.

Abstract:

Python is an interpreted, object-oriented, high-level programming language with dynamic semantics. Its high-level built in data structures, combined with dynamic typing and dynamic binding, make it very attractive for rapid application development, as well as for use as a scripting or glue language to connect existing components together. Python's simple, easy to learn syntax emphasizes readability and therefore reduces the cost of program maintenance. Python supports modules and packages, which encourages program modularity and code reuse. The Python interpreter and the extensive standard library are available in source or binary form without charge for all major platforms, and can be freely distributed.

This reference manual describes the syntax and "core semantics" of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in the [Python Library Reference](#). For an informal introduction to the language, see the [Python Tutorial](#). For C or C++ programmers, two additional manuals exist: [Extending and Embedding the Python Interpreter](#) describes the high-level picture of how to write a Python extension module, and the [Python/C API Reference Manual](#) describes the interfaces available to C/C++ programmers in detail.

Previous: [3.3.2 Customizing attribute access](#) Up: [3.3.2 Customizing attribute access](#)
Next: [3.3.2.2 Implementing Descriptors](#)

3.3.2.1 More attribute access for new-style classes

The following methods only apply to new-style classes.

`__getattr__`(*self*, *name*)

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines `__getattr__`(), the latter will not be called unless `__getattr__`() either calls it explicitly or raises an `AttributeError`. This method should return the (computed) attribute value or raise an `AttributeError` exception. In order to avoid infinite recursion in this method, its implementation should always call the base class method with the same name to access any attributes it needs, for example, "object.`__getattr__`(self, name)".

Previous: [3.3.2 Customizing attribute access](#) Up: [3.3.2 Customizing attribute access](#)
Next: [3.3.2.2 Implementing Descriptors](#)

Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.

3.3.2.2 Implementing Descriptors

The following methods only apply when an instance of the class containing the method (a so-called *descriptor* class) appears in the class dictionary of another new-style class, known as the *owner* class. In the examples below, "the attribute" refers to the attribute whose name is the key of the property in the owner class' `__dict__`. Descriptors can only be implemented as new-style classes themselves.

`__get__(self, instance, owner)`

Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). *owner* is always the owner class, while *instance* is the instance that the attribute was accessed through, or `None` when the attribute is accessed through the *owner*. This method should return the (computed) attribute value or raise an `AttributeError` exception.

`__set__(self, instance, value)`

Called to set the attribute on an instance *instance* of the owner class to a new value, *value*.

`__delete__(self, instance)`

Called to delete the attribute on an instance *instance* of the owner class.

3.3.2.3 Invoking Descriptors

In general, a descriptor is an object attribute with "binding behavior", one whose attribute access has been overridden by methods in the descriptor protocol: `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined and how they were called. Note that descriptors are only invoked for new style objects or classes (ones that subclass `object()` or `type()`).

The starting point for descriptor invocation is a binding, `a.x`. How the arguments are assembled depends on `a`:

Direct Call

The simplest and least common call is when user code directly invokes a descriptor method: `x.__get__(a)`.

Instance Binding

If binding to a new-style object instance, `a.x` is transformed into the call: `type(a).__dict__['x'].__get__(a, type(a))`.

Class Binding

If binding to a new-style class, `A.x` is transformed into the call: `A.__dict__['x'].__get__(None, A)`.

Super Binding

If `a` is an instance of `super`, then the binding `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately preceding `B` and then invokes the descriptor with the call:
`A.__dict__['m'].__get__(obj, A)`.

For instance bindings, the precedence of descriptor invocation depends on the which descriptor methods are defined. Data descriptors define both `__get__()` and `__set__()`. Non-data descriptors have just the `__get__()` method. Data descriptors always override a redefinition in an instance dictionary. In contrast, non-data descriptors can be overridden by instances.

Python methods (including `staticmethod()` and `classmethod()`) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to acquire behaviors that differ from other instances of the same class.

The `property()` function is implemented as a data descriptor. Accordingly, instances cannot override the behavior of a property.

			Python Reference Manual		
Previous:	3.3.2.2 Implementing Descriptors	Up:	3.3.2 Customizing attribute access	Next:	3.3.2.4 __slots__

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

3.3.2.4 `__slots__`

By default, instances of both old and new-style classes have a dictionary for attribute storage. This wastes space for objects having very few instance variables. The space consumption can become acute when creating large numbers of instances.

The default can be overridden by defining `__slots__` in a new-style class definition. The `__slots__` declaration takes a sequence of instance variables and reserves just enough space in each instance to hold a value for each variable. Space is saved because `__dict__` is not created for each instance.

`__slots__`

This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. If defined in a new-style class, `__slots__` reserves space for the declared variables and prevents the automatic creation of `__dict__` and `__weakref__` for each instance. New in version 2.2.

Notes on using `__slots__`

- Without a `__dict__` variable, instances cannot be assigned new variables not listed in the `__slots__` definition. Attempts to assign to an unlisted variable name raises `AttributeError`. If dynamic assignment of new variables is desired, then add `'__dict__'` to the sequence of strings in the `__slots__` declaration. Changed in version 2.3: Previously, adding `'__dict__'` to the `__slots__` declaration would not enable the assignment of new attributes not specifically listed in the sequence of instance variable names.
- Without a `__weakref__` variable for each instance, classes defining `__slots__` do not support weak references to its instances. If weak reference support is needed, then add `'__weakref__'` to the sequence of strings in the `__slots__` declaration. Changed in version 2.3: Previously, adding `'__weakref__'` to the `__slots__` declaration would not enable support

for weak references.

- `__slots__` are implemented at the class level by creating descriptors ([3.3.2](#)) for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by `__slots__`; otherwise, the class attribute would overwrite the descriptor assignment.
- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.
- The action of a `__slots__` declaration is limited to the class where it is defined. As a result, subclasses will have a `__dict__` unless they also define `__slots__`.
- `__slots__` do not work for classes derived from "variable-length" built-in types such as `long`, `str` and `tuple`.
- Any non-string iterable may be assigned to `__slots__`. Mappings may also be used; however, in the future, special meaning may be assigned to the values corresponding to each key.

Abstract:

This library reference manual documents Python's extensions for the Macintosh. It should be used in conjunction with the [Python Library Reference](#), which documents the standard library and built-in types.

This manual assumes basic knowledge about the Python language. For an informal introduction to Python, see the [Python Tutorial](#); the [Python Reference Manual](#) remains the highest authority on syntactic and semantic questions. Finally, the manual entitled [Extending and Embedding the Python Interpreter](#) describes how to add new extensions to Python and how to embed it in other applications.

Abstract:

Python is an interpreted, object-oriented programming language. This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see the [Python Tutorial](#). The [Python Reference Manual](#) gives a more formal definition of the language. The [Python Library Reference](#) documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate [Python/C API Reference Manual](#).

2.2.3.1 Generic Attribute Management

New in version 2.2.

Most extension types only use *simple* attributes. So, what makes the attributes simple? There are only a couple of conditions that must be met:

1. The name of the attributes must be known when `PyType_Ready()` is called.
2. No special processing is needed to record that an attribute was looked up or set, nor do actions need to be taken based on the value.

Note that this list does not place any restrictions on the values of the attributes, when the values are computed, or how relevant data is stored.

When `PyType_Ready()` is called, it uses three tables referenced by the type object to create *descriptors* which are placed in the dictionary of the type object. Each descriptor controls access to one attribute of the instance object. Each of the tables is optional; if all three are `NULL`, instances of the type will only have attributes that are inherited from their base type, and should leave the `tp_getattro` and `tp_setattro` fields `NULL` as well, allowing the base type to handle attributes.

The tables are declared as three fields of the type object:

```
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
```

If `tp_methods` is not `NULL`, it must refer to an array of `PyMethodDef` structures. Each entry in the table is an instance of this structure:

```
typedef struct PyMethodDef {
    char        *ml_name;           /* method name */
    PyCFunction ml_meth;           /* implementation function */
    int         ml_flags;          /* flags */
    char        *ml_doc;           /* docstring */
};
```

```
} PyMethodDef;
```

One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The `ml_name` field of the sentinel must be `NULL`.

XXX Need to refer to some unified discussion of the structure fields, shared with the next section.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```
typedef struct PyMemberDef {  
    char *name;  
    int type;  
    int offset;  
    int flags;  
    char *doc;  
} PyMemberDef;
```

For each entry in the table, a descriptor will be constructed and added to the type which will be able to extract a value from the instance structure. The `type` field should contain one of the type codes defined in the `structmember.h` header; the value will be used to determine how to convert Python values to and from C values. The `flags` field is used to store flags which control how the attribute can be accessed.

XXX Need to move some of this to a shared section!

The following flag constants are defined in `structmember.h`; they may be combined using bitwise-OR.

Constant	Meaning
<code>READONLY</code>	Never writable.
<code>RO</code>	Shorthand for <code>READONLY</code> .
<code>READ_RESTRICTED</code>	Not readable in restricted mode.
<code>WRITE_RESTRICTED</code>	Not writable in restricted mode.
<code>RESTRICTED</code>	Not readable or writable in restricted mode.

An interesting advantage of using the `tp_members` table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its `__doc__` attribute.

As with the `tp_methods` table, a sentinel entry with a name value of `NULL` is required.

Previous: [2.2.3 Attribute Management](#) **Up:** [2.2.3 Attribute Management](#) **Next:** [2.2.3.2 Type-specific Attribute Management](#)

*Release 2.4.4c1, documentation updated on 11 October 2006.
See [About this document...](#) for information on suggesting changes.*

2.2.3.2 Type-specific Attribute Management

For simplicity, only the `char *` version will be demonstrated here; the type of the name parameter is the only difference between the `char *` and `PyObject *` flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. The value in showing this is two-fold: it demonstrates how basic attribute management can be done in a way that is portable to older versions of Python, and explains how the handler functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The `tp_getattr` handler is called when the object requires an attribute lookup. It is called in the same situations where the `__getattr__()` method of a class would be called.

A likely way to handle this is (1) to implement a set of functions (such as `newdatatype_getSize()` and `newdatatype_setSize()` in the example below), (2) provide a method table listing these functions, and (3) provide a `getattr` function that returns the result of a lookup in that table. The method table uses the same structure as the `tp_methods` field of the type object.

Here is an example:

```
static PyMethodDef newdatatype_methods[] = {
    {"getSize", (PyCFunction)newdatatype_getSize, METH_VARARGS,
     "Return the current size."},
    {"setSize", (PyCFunction)newdatatype_setSize, METH_VARARGS,
     "Set the size."},
    {NULL, NULL, 0, NULL}          /* sentinel */
};

static PyObject *
newdatatype_getattr(newdatatypeobject *obj, char *name)
{
    return Py_FindMethod(newdatatype_methods, (PyObject *)obj, name)
}
```

The `tp_setattr` handler is called when the `__setattr__()` or

`__delattr__()` method of a class instance would be called. When an attribute should be deleted, the third parameter will be `NULL`. Here is an example that simply raises an exception; if this were really all you wanted, the `tp_setattr` handler should be set to `NULL`.

```
static int
newdatatype_setattr(newdatatypeobject *obj, char *name, PyObject *v)
{
    (void)PyErr_Format(PyExc_RuntimeError, "Read-only attribute: %s", name);
    return -1;
}
```

Abstract:

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to [Extending and Embedding the Python Interpreter](#), which describes the general principles of extension writing but does not document the API functions in detail.

Warning: The current version of this document is incomplete. I hope that it is nevertheless useful. I will continue to work on it, and release new versions from time to time, independent from Python source code releases.

The application of [LaTeX2HTML](#) to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.

Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the [Python Bug Tracker](#) at [SourceForge](#). If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, [comp.lang.python](#), or the [Python mailing list](#) (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.

See [About this document...](#) for information on suggesting changes.*

1.2.1.1 Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of *ownership of references*. Ownership pertains to references, never to objects (objects are not owned: they are always shared). "Owning a reference" means being responsible for calling `Py_DECREF` on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually decref'ing it by calling `Py_DECREF ()` or `Py_XDECREF ()` when it's no longer needed--or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the caller is said to receive a *new* reference. When no ownership is transferred, the caller is said to *borrow* the reference. Nothing needs to be done for a borrowed reference.

Conversely, when a calling function passes it a reference to an object, there are two possibilities: the function *steals* a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are `PyList_SetItem ()` and `PyTuple_SetItem ()`, which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple `(1, 2, "three")` could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```
PyObject *t;

t = PyTuple_New(3);
PyTuple_SetItem(t, 0, PyInt_FromLong(1L));
PyTuple_SetItem(t, 1, PyInt_FromLong(2L));
PyTuple_SetItem(t, 2, PyString_FromString("three"));
```

Here, `PyInt_FromLong ()` returns a new reference which is immediately stolen by `PyTuple_SetItem ()`. When you want to keep using an object

although the reference to it will be stolen, use `Py_INCREF()` to grab another reference before calling the reference-stealing function.

Incidentally, `PyTuple_SetItem()` is the *only* way to set tuple items; `PySequence_SetItem()` and `PyObject_SetItem()` refuse to do this since tuples are an immutable data type. You should only use `PyTuple_SetItem()` for tuples that you are creating yourself.

Equivalent code for populating a list can be written using `PyList_New()` and `PyList_SetItem()`.

However, in practice, you will rarely use these ways of creating and populating a tuple or list. There's a generic function, `Py_BuildValue()`, that can create most common objects from C values, directed by a *format string*. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use `PyObject_SetItem()` and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding reference counts is much saner, since you don't have to increment a reference count so you can give a reference away ("have it be stolen"). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```
int
set_all(PyObject *target, PyObject *item)
{
    int i, n;

    n = PyObject_Length(target);
    if (n < 0)
        return -1;
    for (i = 0; i < n; i++) {
        PyObject *index = PyInt_FromLong(i);
        if (!index)
            return -1;
        if (PyObject_SetItem(target, index, item) < 0)
            return -1;
        Py_DECREF(index);
    }
}
```

```

    }
    return 0;
}

```

The situation is slightly different for function return values. While passing a reference to most functions does not change your ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like `PyObject_GetItem()` and `PySequence_GetItem()`, always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only -- *the plumage* (the type of the object passed as an argument to the function) *doesn't enter into it!* Thus, if you extract an item from a list using `PyList_GetItem()`, you don't own the reference -- but if you obtain the same item from the same list using `PySequence_GetItem()` (which happens to take exactly the same arguments), you do own a reference to the returned object.

Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using `PyList_GetItem()`, and once using `PySequence_GetItem()`.

```

long
sum_list(PyObject *list)
{
    int i, n;
    long total = 0;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail */
        if (!PyInt_Check(item)) continue; /* Skip non-integers */
        total += PyInt_AsLong(item);
    }
    return total;
}

long
sum_sequence(PyObject *sequence)

```

```
{
    int i, n;
    long total = 0;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)
        return -1; /* Has no length */
    for (i = 0; i < n; i++) {
        item = PySequence_GetItem(sequence, i);
        if (item == NULL)
            return -1; /* Not a sequence, or other failure */
        if (PyInt_Check(item))
            total += PyInt_AsLong(item);
        Py_DECREF(item); /* Discard reference ownership */
    }
    return total;
}
```

7.2.5.1 Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so *by value* rather than dereferencing them through pointers. This is consistent throughout the API.

Py_complex

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```
typedef struct {
    double real;
    double imag;
} Py_complex;
```

`Py_complex` **_Py_c_sum**(`Py_complex` *left*, `Py_complex` *right*)

Return the sum of two complex numbers, using the C `Py_complex` representation.

`Py_complex` **_Py_c_diff**(`Py_complex` *left*, `Py_complex` *right*)

Return the difference between two complex numbers, using the C `Py_complex` representation.

`Py_complex` **_Py_c_neg**(`Py_complex` *complex*)

Return the negation of the complex number *complex*, using the C `Py_complex` representation.

`Py_complex` **_Py_c_prod**(`Py_complex` *left*, `Py_complex` *right*)

Return the product of two complex numbers, using the C `Py_complex` representation.

`Py_complex` **_Py_c_quot**(`Py_complex` *dividend*, `Py_complex` *divisor*)

Return the quotient of two complex numbers, using the C `Py_complex`

representation.

`Py_complex _Py_c_pow(Py_complex num, Py_complex exp)`

Return the exponentiation of *num* by *exp*, using the C `Py_complex` representation.

7.2.5.2 Complex Numbers as Python Objects

PyComplexObject

This subtype of `PyObject` represents a Python complex number object.

PyTypeObject **PyComplex_Type**

This instance of `PyTypeObject` represents the Python complex number type.

int **PyComplex_Check**(PyObject *p)

Return true if its argument is a `PyComplexObject` or a subtype of `PyComplexObject`. Changed in version 2.2: Allowed subtypes to be accepted.

int **PyComplex_CheckExact**(PyObject *p)

Return true if its argument is a `PyComplexObject`, but not a subtype of `PyComplexObject`. New in version 2.2.

PyObject* **PyComplex_FromCComplex**(Py_complex v)

Return value: **New reference.**

Create a new Python complex number object from a C `Py_complex` value.

PyObject* **PyComplex_FromDoubles**(double *real*, double *imag*)

Return value: **New reference.**

Return a new `PyComplexObject` object from *real* and *imag*.

double **PyComplex_RealAsDouble**(PyObject *op)

Return the real part of *op* as a C `double`.

double **PyComplex_ImagAsDouble**(PyObject *op)

Return the imaginary part of *op* as a C `double`.

PyObject *op)

Py_complex **PyComplex_AsCComplex**(

Return the Py_complex value of the complex number *op*.

Release 2.4.4c1, documentation updated on 11 October 2006.

See [About this document..](#) for information on suggesting changes.

7.3.2.1 Built-in Codecs

Python provides a set of builtin codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors. These parameters encoding and errors have the same semantics as the ones of the builtin `unicode()` Unicode object constructor.

Setting encoding to `NULL` causes the default encoding to be used which is ASCII. The file system calls should use `Py_FileSystemDefaultEncoding` as the encoding for file names. This variable should be treated as read-only: On some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes `setlocale`).

Error handling is set by errors which may also be set to `NULL` meaning to use the default handling defined for the codec. Default error handling for all builtin codecs is `strict` (`ValueError` is raised).

The codecs all use a similar interface. Only deviation from the following generic ones are documented for simplicity.

These are the generic codec APIs:

`PyObject*` **PyUnicode_Decode**(`const char *s`, `int size`, `const char *encoding`, `const char *errors`)

Return value: **New reference.**

Create a Unicode object by decoding `size` bytes of the encoded string `s`. `encoding` and `errors` have the same meaning as the parameters of the same name in the `unicode()` builtin function. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

`const Py_UNICODE *s`, `int size`, `const char`

PyObject* **PyUnicode_Encode**(**encoding*, const char **errors*)

Return value: New reference.

Encode the Py_UNICODE buffer of the given size and return a Python string object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsEncodedString**(PyObject **unicode*, const char **encoding*, const char **errors*)

Return value: New reference.

Encode a Unicode object and return the result as Python string object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

These are the UTF-8 codec APIs:

PyObject* **PyUnicode_DecodeUTF8**(const char **s*, int *size*, const char **errors*)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the UTF-8 encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_DecodeUTF8Stateful**(const char **s*, int *size*, const char **errors*, int **consumed*)

Return value: New reference.

If *consumed* is NULL, behave like `PyUnicode_DecodeUTF8()`. If *consumed* is not NULL, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*. New in version 2.4.

const Py_UNICODE **s*, int *size*,

PyObject* **PyUnicode_EncodeUTF8**(const char *errors)

*Return value: **New reference.***

Encode the Py_UNICODE buffer of the given size using UTF-8 and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsUTF8String**(PyObject *unicode)

*Return value: **New reference.***

Encode a Unicode objects using UTF-8 and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the UTF-16 codec APIs:

PyObject* **PyUnicode_DecompileUTF16**(const char *s, int size, const char *errors, int *byteorder)

*Return value: **New reference.***

Decode *length* bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. *errors* (if non-NULL) defines the error handling. It defaults to ``strict``.

If *byteorder* is non-NULL, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

and then switches according to all byte order marks (BOM) it finds in the input data. BOMs are not copied into the resulting Unicode string. After completion, **byteorder* is set to the current byte order at the end of input data.

If *byteorder* is NULL, the codec starts in native order mode.

Return NULL if an exception was raised by the codec.

const char *s, int size,
const char *errors, int

PyObject* **PyUnicode_DecodeUTF16Stateful**(*byteorder, int
*consumed)

*Return value: **New reference.***

If *consumed* is NULL, behave like `PyUnicode_DecodeUTF16()`. If *consumed* is not NULL, `PyUnicode_DecodeUTF16Stateful()` will not treat trailing incomplete UTF-16 byte sequences (i.e. an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.
New in version 2.4.

PyObject* **PyUnicode_EncodeUTF16**(const Py_UNICODE *s, int size,
const char *errors, int byteorder)

*Return value: **New reference.***

Return a Python string object holding the UTF-16 encoded value of the Unicode data in *s*. If *byteorder* is not 0, output is written according to the following byte order:

```
byteorder == -1: little endian  
byteorder == 0: native byte order (writes a BOM mark)  
byteorder == 1: big endian
```

If *byteorder* is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If `Py_UNICODE_WIDE` is defined, a single `Py_UNICODE` value may get represented as a surrogate pair. If it is not defined, each `Py_UNICODE` value is interpreted as an UCS-2 character.

Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsUTF16String**(PyObject *unicode)

*Return value: **New reference.***

Return a Python string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is "strict". Return NULL if an exception was raised by the codec.

These are the "Unicode Escape" codec APIs:

const char *s, int size,

PyObject* **PyUnicode_DecodeUnicodeEscape**(const char *errors)

*Return value: **New reference.***

Create a Unicode object by decoding *size* bytes of the Unicode-Escape encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeUnicodeEscape**(const Py_UNICODE *s, int size, const char *errors)

*Return value: **New reference.***

Encode the Py_UNICODE buffer of the given size using Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsUnicodeEscapeString**(PyObject *unicode)

*Return value: **New reference.***

Encode a Unicode objects using Unicode-Escape and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the ``Raw Unicode Escape`` codec APIs:

PyObject* **PyUnicode_DecodeRawUnicodeEscape**(const char *s, int size, const char *errors)

*Return value: **New reference.***

Create a Unicode object by decoding *size* bytes of the Raw-Unicode-Escape encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeRawUnicodeEscape**(const Py_UNICODE *s, int size, const char *errors)

*Return value: **New reference.***

Encode the Py_UNICODE buffer of the given size using Raw-Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsRawUnicodeEscapeString**(PyObject
*unicode)

*Return value: **New reference.***

Encode a Unicode objects using Raw-Unicode-Escape and return the result as Python string object. Error handling is ``strict". Return NULL if an exception was raised by the codec.

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

PyObject* **PyUnicode_DecodeLatin1**(const char *s, int size, const char
*errors)

*Return value: **New reference.***

Create a Unicode object by decoding *size* bytes of the Latin-1 encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeLatin1**(const Py_UNICODE *s, int size,
const char *errors)

*Return value: **New reference.***

Encode the Py_UNICODE buffer of the given size using Latin-1 and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsLatin1String**(PyObject *unicode)

*Return value: **New reference.***

Encode a Unicode objects using Latin-1 and return the result as Python string object. Error handling is ``strict". Return NULL if an exception was raised by the codec.

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

PyObject* **PyUnicode_DecodeASCII**(const char *s, int size, const char
*errors)

*Return value: **New reference.***

Create a Unicode object by decoding *size* bytes of the ASCII encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeASCII**(const Py_UNICODE *s, int size,
const char *errors)

*Return value: **New reference.***

Encode the Py_UNICODE buffer of the given size using ASCII and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsASCIIString**(PyObject *unicode)

*Return value: **New reference.***

Encode a Unicode objects using ASCII and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the mapping codec APIs:

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the `encodings` package). The codec uses mapping to encode and decode characters.

Decoding mappings must map single string characters to single Unicode characters, integers (which are then interpreted as Unicode ordinals) or None (meaning "undefined mapping" and causing an error).

Encoding mappings must map single Unicode characters to single string characters, integers (which are then interpreted as Latin-1 ordinals) or None (meaning "undefined mapping" and causing an error).

The mapping objects provided must only support the `__getitem__` mapping interface.

If a character lookup fails with a `LookupError`, the character is copied as-is meaning that its ordinal value will be interpreted as Unicode or Latin-1 ordinal resp. Because of this, mappings only need to contain those mappings which map characters to different code points.

PyObject* **PyUnicode_DecodeCharmap**(const char *s, int size, PyObject
*mapping, const char *errors)

*Return value: **New reference.***

Create a Unicode object by decoding *size* bytes of the encoded string *s* using the given *mapping* object. Return NULL if an exception was raised by the codec.

```
PyObject* PyUnicode_EncodeCharmap( const Py_UNICODE *s, int size,  
                                     PyObject *mapping, const char  
                                     *errors)
```

Return value: **New reference.**

Encode the Py_UNICODE buffer of the given size using the given *mapping* object and return a Python string object. Return NULL if an exception was raised by the codec.

```
PyObject* PyUnicode_AsCharmapString( PyObject *unicode, PyObject  
                                     *mapping)
```

Return value: **New reference.**

Encode a Unicode objects using the given *mapping* object and return the result as Python string object. Error handling is ``strict". Return NULL if an exception was raised by the codec.

The following codec API is special in that maps Unicode to Unicode.

```
PyObject* PyUnicode_TranslateCharmap( const Py_UNICODE *s, int  
                                     size, PyObject *table, const  
                                     char *errors)
```

Return value: **New reference.**

Translate a Py_UNICODE buffer of the given length by applying a character mapping *table* to it and return the resulting Unicode object. Return NULL when an exception was raised by the codec.

The *mapping* table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the `__getitem__()` interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that

MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

PyObject* **PyUnicode_DecodeMBCS**(const char *s, int size, const char *errors)

*Return value: **New reference.***

Create a Unicode object by decoding *size* bytes of the MBCS encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeMBCS**(const Py_UNICODE *s, int size, const char *errors)

*Return value: **New reference.***

Encode the Py_UNICODE buffer of the given size using MBCS and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsMBCSString**(PyObject *unicode)

*Return value: **New reference.***

Encode a Unicode objects using MBCS and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

7.3.2.2 Methods and Slot Functions

The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return NULL or -1 if an exception occurs.

PyObject* **PyUnicode_Concat**(PyObject **left*, PyObject **right*)

Return value: **New reference.**

Concat two strings giving a new Unicode string.

PyObject* **PyUnicode_Split**(PyObject **s*, PyObject **sep*, int *maxsplit*)

Return value: **New reference.**

Split a string giving a list of Unicode strings. If *sep* is NULL, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most *maxsplit* splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

PyObject* **PyUnicode_Splitlines**(PyObject **s*, int *keepend*)

Return value: **New reference.**

Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If *keepend* is 0, the Line break characters are not included in the resulting strings.

PyObject* **PyUnicode_Translate**(PyObject **str*, PyObject **table*, const char **errors*)

Return value: **New reference.**

Translate a string by applying a character mapping table to it and return the resulting Unicode object.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the `__getitem__()` interface;

dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

`errors` has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

`PyObject*` **PyUnicode_Join**(`PyObject *separator`, `PyObject *seq`)

Return value: **New reference.**

Join a sequence of strings using the given separator and return the resulting Unicode string.

`int` **PyUnicode_Tailmatch**(`PyObject *str`, `PyObject *substr`, `int start`, `int end`, `int direction`)

Return value: **New reference.**

Return 1 if `substr` matches `str[start:end]` at the given tail end (`direction == -1` means to do a prefix match, `direction == 1` a suffix match), 0 otherwise. Return -1 if an error occurred.

`int` **PyUnicode_Find**(`PyObject *str`, `PyObject *substr`, `int start`, `int end`, `int direction`)

Return the first position of `substr` in `str[start:end]` using the given `direction` (`direction == 1` means to do a forward search, `direction == -1` a backward search). The return value is the index of the first match; a value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.

`int` **PyUnicode_Count**(`PyObject *str`, `PyObject *substr`, `int start`, `int end`)

Return the number of non-overlapping occurrences of `substr` in `str[start:end]`. Return -1 if an error occurred.

`PyObject*` **PyUnicode_Replace**(`PyObject *str`, `PyObject *substr`, `PyObject *replstr`, `int maxcount`)

Return value: **New reference.**

Replace at most `maxcount` occurrences of `substr` in `str` with `replstr` and return the resulting Unicode object. `maxcount == -1` means replace all occurrences.

`int` **PyUnicode_Compare**(`PyObject *left`, `PyObject *right`)

Compare two strings and return -1, 0, 1 for less than, equal, and greater than, respectively.

PyObject* **PyUnicode_Format**(PyObject **format*, PyObject **args*)

Return value: *New reference.*

Return a new string object from *format* and *args*; this is analogous to *format % args*. The *args* argument must be a tuple.

int **PyUnicode_Contains**(PyObject **container*, PyObject **element*)

Check whether *element* is contained in *container* and return true or false accordingly.

element has to coerce to a one element Unicode string. -1 is returned if there was an error.

About this document ...

Documenting Python, 11 October 2006, Release 2.4.4c1

This document was generated using the [LaTeX2HTML](#) translator.

[LaTeX2HTML](#) is Copyright © 1993, 1994, 1995, 1996, 1997, [Nikos Drakos](#), Computer Based Learning Unit, University of Leeds, and Copyright © 1997, 1998, [Ross Moore](#), Mathematics Department, Macquarie University, Sydney.

The application of [LaTeX2HTML](#) to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.

Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the [Python Bug Tracker](#) at [SourceForge](#). If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, [comp.lang.python](#), or the [Python mailing list](#) (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
